Infectious Colitides

Frederick R. Lane and Dipen C. Maun

Key Concepts

- Common bacterial colitides are often the result of food-borne pathogens from undercooked meat or contaminated vegetables.
- Parasites are an important pathogen in the differential diagnosis of diarrhea and colitis, especially in patients who have traveled abroad.
- Cytomegalovirus can cause a life-threatening colitis usually in the setting of decreased immune status such as HIV or inflammatory bowel disease.
- Travelers to low-income parts of the world frequently have the misfortune of developing acute diarrhea, caused by various forms of *Escherichia coli* in over 50 % of cases.
- Diarrhea in the setting of HIV or immunosuppression for transplantation requires an extensive workup for bacteria, viruses, and protozoa.

Infectious colitis is a worldwide cause of morbidity and mortality. Estimates suggest that 2–4 billion episodes of infectious diarrhea occur in developing countries annually [1], and around 48 million Americans were afflicted with food-borne illness in 2012 [2]. Bacteria, parasites, viruses, or fungi may cause infectious colitides.

Pseudomembranous colitis, caused by the *Clostridium difficile* toxin, has become an increasingly more common cause of infectious colitis and should be included in the differential diagnosis for any patient presenting with an acute diarrheal illness. This entity is fully discussed in Chap. 53.

Bacterial Colitides

Campylobacter

Campylobacter typically produces diarrhea and fever. The stool may be bloody, and infection may be accompanied by abdominal pain. *Campylobacter* results in up to 14 % of cases worldwide, with *Campylobacter jejuni* the usual culprit. Transmission is commonly through contaminated poultry, but many animals can be infected. A recent report described an outbreak of campylobacter enteritis following a mud bike race, thought to be from ingestion of contaminated mud [3].

Infection of the terminal ileum and cecum can mimic acute appendicitis. Most illnesses last less than 7 days, but up to 16 % of patients may harbor the organism for 2–10 weeks. Complications of infection can include hemorrhage, toxic megacolon, pancreatitis, Reiter syndrome, and Guillain–Barre' syndrome [4].

Stool samples with fecal leucocytes and blood support the diagnosis of infectious colitis, but diagnosis of *Campylobacter* is made by culture of the bacteria. Colonoscopy may demonstrate segmental edema, loss of vascular pattern, and patchy erythema of the mucosa. These findings are nonspecific and may be difficult to differentiate from that of other colonic mucosal diseases [5].

The majority of patients do not require treatment, as the disease is self-limiting. Fluoroquinolone antibiotics, which are also active against *Shigella* and other common enteric organisms, can be used empirically. However, resistance to fluoroquinolones is becoming a major problem, with Smith et al. [6] showing an increase in resistance from 1.3 to 10.2 % between 1992 and 1998. In some countries, resistance has been found in up to 80 % of isolates [7]. Azithromycin has been shown to be effective when fluoroquinolone resistance is an issue, while Erythromycin is a third-line choice.

Salmonella

Salmonella can cause both typhoid and non-typhoid illnesses. The non-typhoid version causes self-limited diarrhea. *Salmonella typhi* and *Salmonella paratyphi* cause typhoid fever, while *Salmonella enteritidis* and *Salmonella typhimurium* are the most common serotypes in the United States.

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_52

The major route of transmission is by the "5 Fs": flies, food, fingers, feces, and fomites [4]. Contaminated meat and poultry are the main sources of infection, but imported jalapeno, peanut butter, mangoes, live animals (turtles), smoked salmon, and sesame paste have all been implicated in major outbreaks [8].

Infections with non-typhoidal *Salmonella* present with nausea, vomiting, abdominal cramps, and diarrhea. Symptoms may occur between 8 and 48 h after ingestion of contaminated food. Illness can last up to 3 weeks and bacteremia may occur in up to 10 % of patients. Typhoid fever can manifest with high fever, delirium, abdominal pain, splenomegaly, and skin rash. Typhoid fever occurs when organisms penetrate the small bowel wall and enter the lymphatics and ultimately the bloodstream [4].

Diagnosis is established by identification of the organism with blood culture or cultures from the stool. Endoscopic findings in non-typhoidal *Salmonella* infection may include hyperemia, mucosal friability, aphthous erosions, or deep ulcers with segmental involvement. Typhoid disease may show punched-out ulcers with slightly raised margins, with the most commonly affected areas being the terminal ileum and right colon. In Lee's report of seven patients, the left colon was spared in all cases [9].

Antibiotics are traditionally reserved for patients where bacteremic disease is suspected or would place the patient at marked risk. These are patients who are febrile or toxic, young (3 or less) or elderly (65 or older). Patients with sickle cell disease, inflammatory bowel disease, or acquired immune deficiency syndrome (AIDS) or patients on steroids or hemodialysis should be considered for antibiotic treatment. When indicated, fluoroquinolones are the treatment of choice [10]. For patients with typhoid fever, azithromycin should be used both in developing countries and in travelers returning to industrialized countries [11].

Shigella

Shigellosis is most commonly a disease of children under 5 years of age but can affect all age groups. It is the third most common enteric infection in the United States, but is uncommon in Europe [8]. *Shigella sonnei* accounts for more the two-thirds of cases in the United States and is typically spread through contaminated food or water, or person-to-person contact. In developed countries, *Shigella* is seen most frequently in day care centers, in nursery schools, and in male homosexuals [8].

Diarrhea is initially watery without blood, but tenesmus and bloody stools develop 3–5 days after onset. Bacteremia is uncommon, but perforation, megacolon, hemolytic-uremic syndrome, and severe dehydration may occur. Children typically have mild infections, which may last up to 3 days. Adults have more prolonged courses, with severe cases lasting 3–4 weeks.

Symptoms include lower abdominal pain, rectal pain, and diarrhea. Stool cultures are needed for diagnosis, and stool typically contains red and white blood cells. Colonoscopy shows nonspecific erythema, edema, and loss of vascular pattern. In a study of 33 patients with shigellosis, Speelman [12] found continuous inflammation, more prominent distally, mimicking that of inflammatory bowel disease. Luminal exudate and star-shaped ulcerations may also be seen [13].

Antibiotic treatment is always indicated for *Shigella* infections. Resistance to tetracyclines, co-trimoxazole, and ampicillin was 45 % or higher in a study of 191 isolates by Pons et al. in 2010. Resistance to ciprofloxacin and azithromycin remained well under 5 % [14]. Although fluoroquinolone resistance is slowly becoming an issue, treatment may be with either ciprofloxacin 750 mg daily for 3 days or azithromycin 500 mg daily for 3 days [10].

Escherichia coli

Escherichia coli is one of the most populous of the normal intestinal flora. Five groups of *E. coli* cause enteric infections: enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enteroadherent *E. coli* (EAEC), enteroinvasive *E. coli* (EIEC), and enterohemorrhagic *E. coli* (EHEC) [4].

EPEC is associated with diarrhea in infants and nursery outbreaks, while EAEC can cause persistent childhood diarrhea. ETEC and EAEC (mainly children) are two of the leading causes of traveler's diarrhea, especially in Latin America and the Caribbean [15], while EIEC is an endemic cause of dysentery in South America and Eastern Europe and has been a rare cause of food-borne outbreaks in the United States [8].

EHEC causes hemorrhagic colitis with bloody or mucoid diarrhea and is a common cause of infectious colitis in Western countries, including the United States. *E. coli* O157:H7, a subtype of EHEC, was first identified in 1982, from outbreaks in Michigan and Oregon. It is an important cause of acute bacterial colitis, especially from undercooked ground beef [16]. Although less common than *Salmonella* or *Campylobacter*, *E. coli* O157:H7 shows a higher hospitalization and fatality rate [17]. Most cases start with non-bloody diarrhea and resolve spontaneously. Some patients will progress to bloody diarrhea, and 5–10 % of these can progress to the life-threatening hemorrhagic-uremic syndrome or thrombocytopenic purpura [18].

Non-O157 strains have recently emerged as an important cause of infection worldwide. Outbreaks in the United States between 2011 and 2013 from frozen food products and sprouts have been associated with serotypes O121, O145, and O26. One of the largest outbreaks occurred in Germany in the summer of 2011. Investigations implicated an organic sprout farm near Hamburg. Over 20 % of affected patients developed hemolytic uremic syndrome from the toxin-producing serotype O104:H4 [19].

Many hospital laboratories are routinely testing for *E. coli* O157:H7 on stool culture, but it should be requested in any patient with bloody diarrhea. PCR assays are in various degrees of development [20]. Colonoscopy findings show shallow ulcerations, marked edema, and longitudinal ulcer-like lesions throughout the colon. Inflammation tends to predominate on the right side of the colon [21].

Clinical data do not support the use of antibiotics for hemorrhagic *E. coli* infection. In fact, some studies show that antibiotics and anti-motility agents may cause increased production of toxin and increase the risk of hemolytic uremic syndrome. Rifaximin 200 mg three times a day for 3 days may be used for EAEC, as well as fluoroquinolones or azithromycin [10]. Attempts to develop a vaccine against *Escherichia coli* for traveler's diarrhea have not proven successful [22].

Yersinia

Yersinia can occur from handling of contaminated animals or animal products, or ingestion of contaminated food or water (most commonly undercooked pork or contaminated milk). Typical symptoms are fever, diarrhea, and abdominal pain, lasting up to 3 weeks. The infection may cause mesenteric adenitis or ileitis, mimicking Crohn's disease. Extraintestinal symptoms, such as migratory arthritis, Reiter's syndrome, and erythema nodosum, may occur.

Radiographic and endoscopic findings also may be indistinguishable from Crohn's disease with erosions and ulcerations on the right side of the colon [23]. Laboratory isolation is difficult, while hemagglutination is an indirect test with titers in the 1:128 range suggestive of infection. The disease is usually self-limited, but in prolonged cases or patients with extraintestinal manifestations, aminoglycosides, trimethoprim-sulfamethoxazole (TMP-SMX), doxycycline, and fluoroquinolones have all been used successfully [4].

Vibrio

Vibrio can cause either a cholera or noncholera illness. Infections are usually associated with consumption of raw or undercooked shellfish. The Cholera and Other Vibrio Illness Surveillance (COVIS) system reported 7700 cases in the United States over a 15-year period ending in 2010, with the highest incidence in the gulf coast states of Alabama, Florida, Louisiana, and Texas [24]. Most patients with gastroenteritis reported having eaten raw oysters in the week before their illness.

Patients with *Vibrio parahaemolyticus* infection typically present with diarrhea and abdominal cramps. About half have fever and vomiting. Stool testing does not typically test for *Vibrio* species, but may be specially requested, especially when illness develops within 48 h of ingesting raw or undercooked shellfish. Most patients don't require treatment, but tetracycline, fluoroquinolones, aminoglycosides, and third-generation cephalosporins are usually effective [25].

Vibrio cholera and invasive *Vibrio* infections can cause profuse watery diarrhea, vomiting, and muscle cramps. Stool volumes may reach a liter per hour, and this can lead to shock and death within hours without treatment. *Vibrio cholerae* O1 and *Vibrio cholerae* O139 are major sources of cholera outbreaks. An estimated 2.8 million cases occur annually in endemic countries (mostly Asia and Africa) with 87,000 cases in non-endemic countries [26].

Raw or undercooked shellfish again is the most common cause, and most cases in the United States come from foreign travel or Gulf Coast shellfish. Treatment of cholera includes aggressive fluid replacement. Ciprofloxacin (1 g orally for one dose) or doxycycline (300 mg orally for one dose) is the antibiotic of choice. Vaccines for overseas travelers have not proven to be effective and are not available in the United States [27, 28]. Vaccines for endemic populations have demonstrated some potential, but fail to meet all the requirements of the World Health Organization [29].

Other Bacterial Colitides

Tuberculosis is prevalent in the developing world. Mycobacterium tuberculosis is primary to the lungs and may be carried to the intestinal tract from swallowed sputum. Patients may present with abdominal pain, weight loss, anorexia, and fever. Because of its predilection for the ileocecal regions, findings frequently mimic Crohn's disease or appendicitis. Cultures are difficult, and a positive skin test is not diagnostic [4]. Endoscopic biopsies of ulcers may be helpful [30].

Classic radiologic signs include a contracted terminal ileum with a wide ileocecal valve (Fleischner sign) and a narrow ileum opening into a contracted cecum (Sterlin's sign) [31]. Medical management is complicated and is beyond the scope of this discussion. Surgery is indicated for complications, most commonly obstruction or perforation.

Aeromonas causes diarrhea, most commonly in the tropics. Persistent diarrhea, usually lasting longer than 2 weeks, is common. The bacteria may be cultured, but a specific request to the lab may be needed. The disease is usually self-limited. Treatment, in prolonged cases or immunocompromised hosts, is typically with a fluoroquinolone or azithromycin [32].

Bacteroides fragilis is part of the normal colonic flora, but a subclass that secretes a toxin has been recognized as a cause of acute diarrhea in endemic regions. *Arcobacter* is considered an emerging food-borne pathogen. A study of isolates from patients with acute diarrhea acquired in Mexico, Guatemala, and India showed 8 % of specimens with *Arcobacter* and 7 % with *Bacteroides* [33].

Listeria monocytogenes is a rare cause of gastroenteritis, most commonly presenting as diarrhea in an immunocompromised patient. The largest listeriosis outbreak in the

Table 52-1. Treatment of bacterial colitides

Campylobacter	Azithromycin 500 mg daily for 3 days or erythromycin 500 mg four times daily for 3–5 days
Salmonella	Mild illness—none. Possible bacteremic disease—levofloxacin 500 mg (or other fluoroquinolone) daily for seven (immunocompetent) or 14 days (immunocompromised)
Shigella	Ciprofloxacin 750 mg (or other fluoroquinolone) daily for 3 days or azithromycin 500 mg daily for 3 days
EHEC (*E. coli*)	None
EAEC (*E. coli*)	Rifaximin 200 mg three times daily for 3 days
Other *E. coli*	Same as *Shigella*
Yersinia	Same as *Shigella*
Vibrio	Same as *Shigella*
Tuberculosis	Usual TB treatment
Aeromonas	Same as *Shigella*
Traveler's diarrhea	Same as *Shigella*

With permission from DuPont HL. Approach to the patient with infectious colitis. Curr Opin Gastroenterol. 2012;28:39–46 [10]

United States occurred in 2011 from contaminated cantaloupes, causing 147 illnesses and 33 deaths [34]. Symptoms include diarrhea, nausea, and vomiting, often with fever. Listeria should be considered a cause of food-borne outbreaks of febrile diarrhea when routine cultures fail to identify a source [35]. Disease is usually self-limited, and antibiotic treatment is not indicated, but ampicillin or TMP-SMX may be used in higher risk patients [36].

Chlamydia trachomatis is a common cause of proctitis in homosexual males or women practicing anoreceptive intercourse. It may present with bloody diarrhea, mucopurulent anal discharge, tenesmus, and anal pain. Rectal examination may show extreme tenderness, and sigmoidoscopy may show typical findings of proctitis. The bowel may become fibrotic with progressive disease.

Culture for chlamydia can be obtained from stool or rectal swab. Nucleic acid amplification tests (NAAT) are currently considered the gold standard for testing. Azithromycin (1.0 g orally single dose) and doxycycline (100 mg orally twice daily for 7 days) are highly effective for treatment, with treatment of all sex partners indicated, as well [37].

Neisseria gonorrhoeae is a common sexually transmitted disease that can cause proctitis, especially in homosexual males. Symptoms start about a week after exposure and may include mucus discharge, rectal bleeding, and diarrhea. Diagnosis is made by rectal swab on chocolate agar (Thayer-Martin). Single-dose ceftriaxone 125 mg IM cures nearly 100 % of uncomplicated disease, while fluoroquinolones are an acceptable alternative [38].

See Table 52-1 for a summary of treatment for bacterial colitides [10].

Parasitic Colitides

Entamoeba

Amebiasis is caused by the protozoan parasite *Entamoeba histolytica*. It is prevalent in the tropical areas of Central and South America, Africa, and India. Most cases of amebiasis in the United States are from immigrants or travelers returning from an endemic area. 2970 cases of amebiasis in the United States were reported to the Centers for Disease Control and Prevention (CDC) in 1993 [39]. Infection occurs from ingestion of fecally contaminated food or water or by oral/anal sexual contact.

Disease presentation can include asymptomatic colonization, diarrhea and dysentery, or liver or brain abscess. The majority of patients who ingest cysts from *E. histolytica* remain asymptomatic. A typical incubation period is 2–4 weeks followed by gradual onset of abdominal pain and bloody diarrhea. In rare cases (<0.5 %), this can lead to fulminant colitis, toxic megacolon, or extraintestinal abscess.

Diagnosis can be made by stool microscopy, antigen detection, PCR, serology, and endoscopy. Colonoscopy is preferred over sigmoidoscopy because colitis can be limited to the right side. Bowel preparation should be avoided because it will decrease the detection of the parasites. The mucosa of the colon may have friability, may show classic flask-shaped ulcerations, and may be indistinguishable from inflammatory bowel disease. Microscopic analysis of aspirate from the base of the ulcers or biopsy of the ulcer edges can show the cysts and prove to be diagnostic for amebiasis.

Treatment of intestinal amebiasis is metronidazole 750 mg PO tid for 10 days [40, 41] (Table 52-2). Intravenous antibiotics are reserved for severe cases or those resistant to oral therapy. Surgery can be necessary in cases of perforation, peritonitis, and abdominal catastrophe.

Anisakis

Anisakidosis is primarily caused by *Anisakis simplex* and *Pseudoterranova decipiens*. The majority of the cases in the world (>90 %) occur in Japan [42]. The first case in North America was described in 1975 and involved the cecum [43]. Infection typically results from the consumption of raw or undercooked fish during which larvae can attach themselves to mucosa of the stomach (most common), small bowel, or colon. Incidence has been increasing as foods like sushi, sashimi, ceviche, and anchovies gain popularity [44, 45].

TABLE 52-2. Summary of parasitic colitis treatment

Diagnosis	Pathogen	Treatment
Amebiasis	*Entamoeba histolytica*	Metronidazole 750 mg three times daily for 10 days
Anisakidosis	*Anisakis simplex Pseudoterranova decipiens*	Albendazole 400–800 mg for 6–21 days
Ascariasis	*Ascaris lumbricoides*	Mebendazole 100 mg twice daily for 3 days Albendazole 400 mg single dose
Strongyloidiasis	*Strongyloides stercoralis*	Ivermectin at 200 μg/kg/day for 2 days Albendazole 400 mg twice a day for 7 days[a] Thiabendazole at 50 mg/kg daily for 2 days[a]
Trichuriasis	*Trichuris trichiura*	Mebendazole 100 mg twice daily for 3 days Albendazole 400 mg daily for 3 days
Enterobiasis	*Enterobius vermicularis*	Mebendazole 100 mg single dose or Albendazole 400 mg single dose
Cryptosporidiosis	Cryptosporidium	Nitazoxanide
Balantidiasis	*Balantidium coli*	Tetracycline 500 mg four times a day
Giardiasis	*Giardia lamblia*	Metronidazole 250 mg three times a day for 7 days Tinidazole 2 g as a single dose
Schistosomiasis	*S. haematobium* *S. Mansoni* *S. Japonicum*	Praziquantel 40 mg/kg single dose
Tapeworm	*Taenia solium* (pork) *Taenia saginata* (beef) *Diphyllobothrium latum* *Hymenolepis nana* *Dipylidium caninum*	Praziquantel 5–10 mg/kg single dose Niclosamide 2 g single dose
Chagas	*Trypanasoma cruzi*	Benznidazole Nifurtimox

[a]Denotes second-line treatment

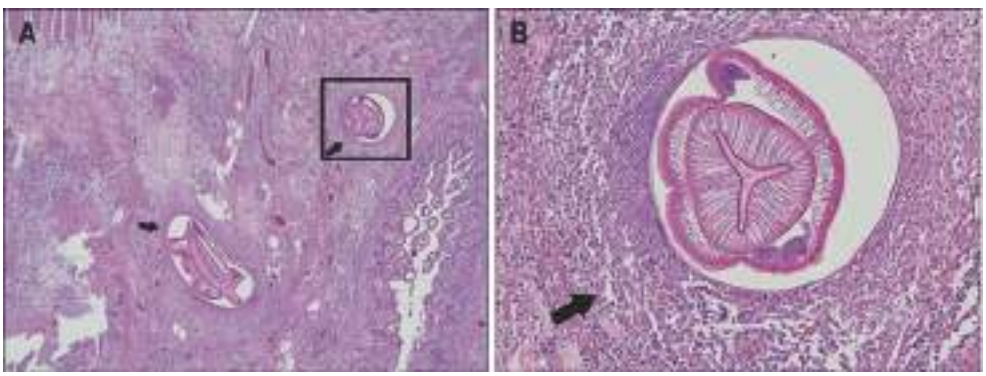

FIGURE 52-1. Histopathologic findings show the severe infiltration of inflammation and edema in all layers of the intestinal wall with a submucosal eosinophilic granuloma around larvae (*arrows*), which were findings of anisakiasis (**a**) (H&E X40), and magnification view of square showed eosinophilic granuloma around anisakiasis larva (**b**) (H&E X200). Kang DB, Oh JT, Park WC, Lee JK. Small bowel obstruction caused by acute invasive enteric anisakiasis. Korean J Gastroenterol. 2010;56:192–5 [114].

The majority of patients with anisakidosis present with gastric involvement; only about 4 % of cases present in either the small bowel or colon. Intestinal anisakidosis presents with vague complaints such as lower abdominal pain, fever, diarrhea, nausea, and vomiting [46]. After consumption, the larvae burrow into the intestinal mucosa and cause an intense hypersensitivity reaction with formation of granulomas and infiltration of eosinophils (Figure 52-1). Symptoms can mimic appendicitis, Crohn's ileitis, diverticulitis, gastroenteritis, or other causes of an acute abdomen. In rare cases, the infection can require surgery due to perforation, intussusception, small bowel obstruction, or pneumoperitoneum.

Diagnosis of intestinal anisakidosis is very challenging and almost never made preoperatively. A history of ingestion of raw fish can be a useful clue. If the diagnosis is made prior to any surgical intervention, then albendazole 400–800 mg orally for 6–21 days is effective (Table 52-2) [47].

Ascaris

Ascariasis is caused by the intestinal nematode *Ascaris lumbricoides*. It is prevalent in areas of the world with warm and humid climates such as China, India, southeast Asia, Africa, Latin America, and the Caribbean [48]. There are more than one billion people infected with the parasite worldwide.

The life cycle begins with ingestion of eggs. The larvae then hatch in the small intestine and migrate into the venous circulation where they break into the lung spaces. From there they ascend into the trachea and are swallowed back into the intestine, where they can grow into adults and create more eggs. As adults, the nematodes can live in the intestine for 1–2 years and produce up to 200,000 eggs per day. The eggs can live in the environment for years, which contributes to the high infection rate.

Most patients with ascariasis are asymptomatic. As the larvae migrate through the lungs, patients may complain of pneumonia-like symptoms. The larvae can also produce an allergic reaction with an urticarial rash. Most patients with intestinal ascariasis are children, because the lumen of the bowel is narrower, allowing for easier obstruction. A common site of obstruction is at the ileocecal valve. Large quantities of the worms can lead to formation of a mass that can intertwine and cause obstruction, volvulus, intussusception, or perforation [49].

The diagnosis of ascariasis is made by stool microscopy. The eggs have a characteristic appearance and are easily identifiable. During the larval pulmonary stage, eosinophilia in the bloodstream can be seen. Retrograde contrast studies may show obstruction or curvilinear densities as the parasite may ingest some of the barium. Treatment is very effective with cure rates as high as 90 % [50]. Mebendazole 100 mg twice daily for 3 days or albendazole 400 mg as a single dose are common therapeutic regimens (Table 52-2). Obstructed patients with no peritoneal signs can be managed conservatively with hydration and nasogastric tube decompression. Surgery is reserved for complicated cases of obstruction and perforation. During laparotomy, the ball of worms can be simply milked into the colon provided there is no perforation or bowel ischemia.

Strongyloides

Strongyloidiasis is caused by *Strongyloides stercoralis*, another intestinal nematode. The disease is most prevalent in the tropical climates of the world, as well as the Appalachian region of the United States. Larvae of *Strongyloides* are shed in the feces and then penetrate another host through the skin. Like the *Ascaris*, they travel to the lungs and then are swallowed into the intestine. They lodge in the intestinal wall and produce offspring. *S. stercoralis* is unique in that its entire life cycle can occur within the host and result in autoinfection.

Hyperinfection can also occur in conditions of immune suppression and results in large numbers of worms traveling through the lungs and intestines. Disease usually presents in two phases: acute and chronic. The acute phase is hallmarked by skin abnormalities from larvae penetration otherwise known as larva currens. Vague pulmonary and abdominal complaints may infrequently be seen as the worms migrate through. Chronic infection is a result of autoinfection, which can lead to epigastric abdominal pain and diarrhea [51, 52].

Strongyloidiasis can sometimes present with a pancolitis and can be confused with ulcerative colitis. Endoscopic features may include yellowish-white nodules, erythema, and loss of vascular pattern [53]. Detecting larvae in the stool makes the diagnosis of strongyloidiasis; however, multiple tests may be necessary. Other options include duodenal biopsy, enzyme-linked immunosorbent assay (ELISA) testing, or bronchial washings.

All patients with *S. stercoralis* should be treated because of the risk of autoinfection. The first-line option for treatment is ivermectin at 200 μg/kg/day for 2 days. Other options are albendazole 400 mg twice a day for 7 days and thiabendazole at 50 mg/kg daily for 2 days [54] (Table 52-2).

Trichuris

Trichuriasis is caused by *Trichuris trichiura*, also known as the whipworm. There are an estimated 600–800 million infected individuals worldwide, primarily in humid and tropical regions of the world [55]. Infection occurs by ingestion of contaminated soil/food. The larvae live in the cecum and colon and can shed up to 20,000 eggs per day. Like the roundworm, most infected with the whipworm are asymptomatic. As the wormload in the cecum and colon increases, symptoms such as diarrhea, tenesmus, and hematochezia can occur. Stools can be watery and will have a characteristic odor.

Trichuriasis can cause rectal prolapse and the worms can be visualized on the rectal mucosa (Figure 52-2). Blood loss can lead to anemia and, for unclear reasons, growth retardation. Diagnosis is made by identifying the barrel-shaped eggs in the stool or by visualizing the worms on the colonic or rectal wall during endoscopy. Treatment is either mebendazole 100 mg twice daily for three days or albendazole 400 mg daily for three days [56] (Table 52-2). Surgery is reserved for cases of rectal prolapse.

Enterobius

Enterobiasis is caused by the pinworm *Enterobius vermicularis*. Unlike other nematodes where infections occur primarily in tropical regions with poor sanitation, enterobiasis is prevalent in all parts of the world including urban areas of the United States and Europe. Children are the most commonly affected group [57].

Infection occurs by ingestion of eggs. Adult pinworms live in the cecum for as long as 13 weeks. About four weeks after ingestion, female pinworms migrate to the perianal skin and

FIGURE 52-2. Whipworm and rectal prolapse. Prolapsed rectum from whipworms [114]. Available from http://phil.cdc.gov/Phil/details.asp.

FIGURE 52-3. Eggs of *Enterobius vermicularis* on wet mount [115]. Available from http://www.cdc.gov/dpdx/enterobiasis/gallery.html#eggs.

can lay up to 11,000 eggs. The larvae quickly mature and can cause an intense pruritis ani. The intense scratching facilitates fecal–oral transmission to classmates and family members.

Enterobiasis rarely causes significant abdominal or intestinal complaints. The most common clinical feature is perianal irritation. In young girls it is a well-known cause of vulvovaginitis. Other symptoms can include teeth grinding, enuresis, urinary tract infection, and insomnia. Diagnosis is typically made by the scotch tape test. This entails taking a strip of clear tape and pressing it against the buttocks. The tape is then transferred to a slide where the eggs can be seen under a microscope. The eggs have a characteristic appearance (Figure 52-3).

Treatment can be with either mebendazole or albendazole. Mebendazole can be given as a single 100 mg dose and is often repeated 2–4 weeks later. Albendazole is given as a single 400 mg dose for adults and 100 mg for children less than two, which is then repeated seven days later (Table 52-2). Usually the entire family is treated empirically.

Cryptosporidium

Cryptosporidiosis is caused by *Cryptosporidium*, an intracellular protozoan. The first human case was described in 1976 [58]. In the 1980s, it became a common cause of debilitating diarrhea in AIDS patients. The diarrhea caused by *Cryptosporidium* is usually seen in one of the four settings: childhood diarrhea in developing areas, travelers' diarrhea, debilitating diarrhea in immunocompromised patients, or waterborne outbreaks in developed areas in the immunocompetent host.

The parasite is ingested in contaminated food or water. The oocysts then excyst within the small bowel lumen, where they can multiply, and then shed via the stool. *Cryptosporidium* oocysts are highly infectious and require only a few to cause infection. They are also extremely small, which allows them to avoid being filtered by conventional water filters. They are resistant to chlorination and can spread with person-to-person contact [59]. Only heating, freezing, or ozonation can destroy the oocysts.

Disease presentation is hallmarked by explosive watery diarrhea and may be associated with abdominal pain, fever, nausea, and vomiting. In immunocompetent hosts, the disease is usually self-limited. Immunocompromised patients have a more protracted course which can be debilitating and sometimes life-threatening. In this patient population, the most common site of extraintestinal infection is the biliary tree, which can cause acalculous cholecystitis or sclerosing cholangitis.

Diagnosis is made by identifying oocysts in stool or in bodily fluids via microscopy, PCR, ELISA, or loop-mediated isothermal amplification (LAMP) [60]. The test may need to be repeated three times to detect the infection. Treatment in immunocompetent patients is primarily supportive (hydration, nutrition, and anti-motility agents), as the disease is self-limited. There is no drug or antimicrobial that has been shown to be effective in controlling cryptosporidiosis. Nitazoxanide is the only Food and Drug Administration [5]-approved medication and may shorten the clinical course of the disease (Table 52-2). In AIDS patients, the most effective form of therapy is the institution of highly active antiretroviral therapy (HAART) [61, 62].

Cholecystectomy may be useful in cases of acalculous cholecystitis and endoscopic retrograde cholangiopancreatography (ERCP) may help in cases of sclerosing cholangitis. Prevention is key with strict handwashing and treatment of affected water and food supplies. Research is currently under way in the development of a vaccine against *Cryptosporidium* [63].

Balantidium

Balantidiasis is caused by *Balantidium coli*, the largest and only ciliated protozoan that infects humans. Pigs serve as the main reservoir for human infection and transmission occurs through ingestion of contaminated food or water. Balantidiasis is endemic in Southeast Asia, South America, and the Western Pacific islands.

Once the parasite is ingested, the cysts embed in the colon causing ulceration and inflammation. This can result in asymptomatic infection, non-bloody diarrhea, or severe bloody diarrhea. Severe diarrhea can result in large volume loss, peritonitis, and even death. Visualizing trophozoites in a stool sample can make the diagnosis. The parasite can also be seen on biopsy specimens of ulcers taken during endoscopy. Treatment with tetracycline 500 mg four times a day is usually effective (Table 52-2). Metronidazole and doxycycline are also effective. Surgery is rarely necessary.

Giardia

Giardiasis is caused by *Giardia lamblia* and is one of the most common parasitic infections in the United States. It can occur in almost any country and most climates. There are three methods of transmission: waterborne, food-borne, and direct fecal–oral. Waterborne transmission occurs when feces contaminate water sources. Infection can occur from drinking from mountain lakes or streams, or when fecal matter from children contaminates recreational water, like swimming pools. Uncooked foods such as salads and cold meat are the most common food sources [64].

Direct fecal–oral is common amongst children at day care centers as well as anal–oral encounters in males who have sex with males. After ingestion, *Giardia* excysts in the stomach to produce trophozoites (Figure 52-4). These attach to the small bowel mucosa and can cause villous blunting and crypt hypertrophy. Diarrhea usually begins 1–2 weeks after infection. Patients tend to have greasy stools with a foul odor and often have other accompanying symptoms such as abdominal cramps, nausea, anorexia, weight loss, vomiting, and fever. Many patients are either asymptomatic or have a benign course. Chronic cases especially in children can lead to malabsorption and growth retardation.

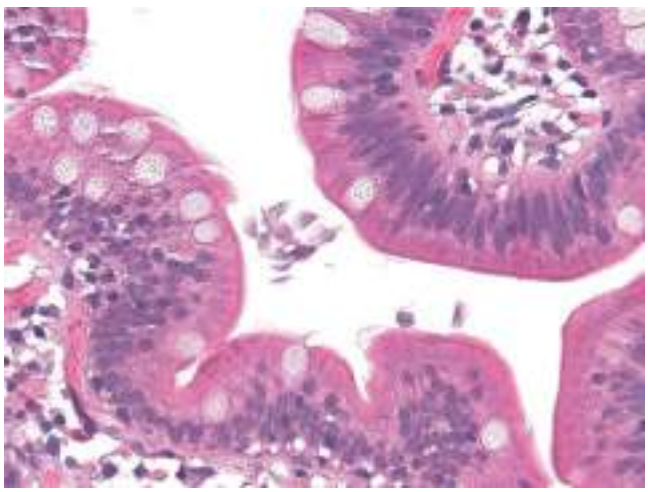

FIGURE 52-4. Duodenal giardiasis. Pale pink organisms are identified in the lumen. No architectural distortion or inflammation is seen. (Courtesy of Jeanette R. Burgess, MD).

Stool ova and parasite examination can easily make the diagnosis. There are a variety of commercial tests available that employ ELISA or immunofluorescence. Endoscopy to obtain small bowel or duodenal biopsy is sometimes used when stool assays are inconclusive. The mainstay of treatment is the nitroimidazole class of drugs. Metronidazole 250 mg three times a day for seven days is the most common regimen, though not FDA approved [65] (Table 52-2). Tinidazole 2 g as a single dose is better tolerated. Alternative medicines include albendazole, nitazoxanide, paromomycin, quinacrine, and furazolidone.

Schistosomiasis

Schistosomiasis is primarily caused by three species of trematodes: *S. haematobium*, *S. mansoni*, and *S. japonicum*. It is one of the most prevalent helminthic infections worldwide. Most infections occur in the tropics, such as South America, Africa, Middle East, Asia, and the Philippines [66, 67].

Eggs of this parasite are shed in the urine and stool of humans. Snails then serve as the intermediate host, where they metamorphose into mobile cercariae in the water. These cercariae attach and penetrate the skin, which can lead to cercarial dermatitis. They migrate to heart and lungs over the next week, travel to the liver, continue to mature, and travel to their final destination. *S. haematobium* settles in and around the bladder; *S. mansoni* and *S. japanocium* settle in the mesenteric vasculature of the small and large bowel. Eggs that are deposited in the body cause a tremendous immune response, which leads to destruction of that host organ.

Depending on the organ that is damaged, schistosomiasis can lead to dermatitis, Katayama fever, obstructive uropathy, bladder cancer, intestinal fistulas and strictures, hepatosplenic disease, pulmonary hypertension, glomerulonephritis, and neural and spinal cord pathology. Intestinal schistosomiasis can cause abdominal symptoms like pain and diarrhea and can lead to more complicated issues such as fistulas, ulcers, and polyposis. In rare cases, perforation or obstruction can occur, necessitating the need for surgical intervention.

Diagnosis is typically made by identification of eggs in the stool by microscopy. Serologic assays, radiographs, and endoscopy can also assist in making the diagnosis. Colonoscopy may show erosions and petechial and superficial ulcerations, and tissue biopsy can identify the eggs in the colonic mucosa. The mainstay of treatment is a praziquantel given as a single dose of 40 mg/kg (Table 52-2). Cure rates in excess of 85 % have been described.

Tapeworms

Tapeworms are cestodes or parasitic flatworms. They all have different life histories but typically live in the intestines of the species they infect. The most common tapeworms to infect humans are *Taenia solium* (pork), *Taenia saginata* (beef), *Diphyllobothrium latum*, *Hymenolepis nana*, and *Dipylidium caninum*. Most carriers of taenia are asymptomatic.

Patients with *T. saginata* may feel the motile proglottids passing through the anus. Remarkably, they can grow as long as 55 ft (Figure 52-5). Symptomatic patients complain of vague abdominal pain and cramps, nausea, vomiting, anorexia, and weight loss. Ingesting the eggs of *T. solium* can result in cysticercosis and cause a variety of neurological issues. Diagnosis is made by analyzing the parasite using microscopy or by using ELISA or PCR technology.

Infection with *D. latum* results from eating raw fish. Chronic infection can lead to megaloblastic anemia because the broad tapeworm attaches in the ileum. The worms can sometimes obstruct small ducts and cause cholangitis, pancreatitis, or appendicitis. H. nana has no intermediate host and usually infects humans by ingestion of eggs in areas of poor hygiene. Infection with *D. caninum* occurs when children ingest fleas or lice of pets.

The treatment for all the tapeworms is a single dose of praziquantel 5–10 mg/kg or niclosamide 2 g [68] (Table 52-2). A bowel preparation may be recommended a few hours after treatment to help purge remaining proglottids.

Trypanosoma

Trypanosomiasis (Chagas disease) is caused by *Trypanosoma cruzi*, a flagellate protozoan parasite. It is endemic in Mexico, Latin America, and South America. A triatomine vector known as the reduviid bug infects humans.

There are two clinical manifestations of Chagas disease: acute and chronic. The acute stage follows parasite entry through the skin. Many patients are asymptomatic, but some may show vague signs like malaise, fever, peripheral edema, periorbital edema, hepatosplenomegaly, and lymphadenopathy. After the acute stage, the body enters an indeterminate stage where many stay asymptomatic for life. 10–30 % of patients develop symptomatic chronic Chagas disease, which can lead to cardiomyopathy and megadisease, namely megaesophagus and megacolon [69, 70].

For unclear reasons, the parasite causes destruction of neurons in the lining of the gastrointestinal tract, which leads to dilatation and dysfunction. The sigmoid colon is the most affected segment. Patients usually complain of constipation and abdominal pain from distention. Volvulus and bowel ischemia necessitating surgery can occur in severe cases. Treatment for megacolon is primarily conservative with high fiber diet, laxative, and enemas. Fecalomas requiring disimpaction can be common. All patients with acute and chronic Chagas should be treated medically. The two drugs available are benznidazole and nifurtimox (Table 52-2). Both have significant side effect profiles with gastrointestinal and central nervous system (CNS) toxicities.

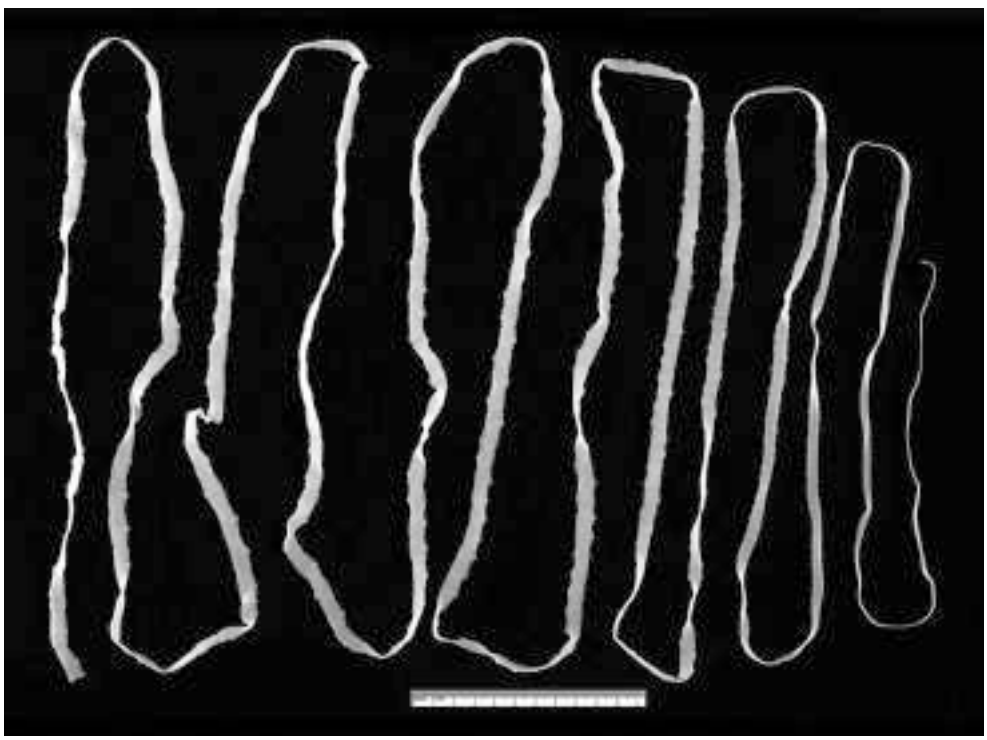

FIGURE 52-5. *Taenia saginata* adult worm measures approximately 4 m in length. These worms may grow to over 50 ft [116]. Available from http://phil.cdc.gov/Phil/details.asp.

Viral Colitides

Cytomegalovirus

Cytomegalovirus (CMV) is a DNA virus and member of the herpes virus family. Prevalence of the virus is quite high with rates approaching 60–70 % in US cities and close to 100 % in various parts of Africa [71]. Most immunocompetent patients with CMV are asymptomatic, whereas immunodeficient hosts can suffer from life-threatening illness.

Similar to other viruses in the herpes family, once primary infection occurs the virus will enter a latent/dormant state. It can be challenging to differentiate between reactivation of latent infection versus primary infection. In immunocompromised patients, CMV can cause devastating illness to organ systems such as the lungs, liver, brain, gastrointestinal (GI) tract, heart, and even skin. Colitis related to CMV is most common in patients with AIDS or inflammatory bowel disease.

Patients can present with ulcers and inflammation in the esophagus and throughout the colon, which can lead to pain, diarrhea, and fever. Severe CMV colitis can cause perforation and gangrene requiring urgent surgical intervention. Diagnosis of CMV is typically made by biopsy of infected tissue. Cells with CMV have "owl's eye" inclusion bodies, which are pathognomonic (Figure 52-6).

Flexible endoscopy is also very useful and can show friability, erythema, and heaped-up tissue resembling a mass (Figure 52-7). PCR assays are available to assist with diagnosis. CMV plays a special role in the ulcerative colitis (UC) patient. Cytomegalovirus reactivation is common in patients with severe colitis, with a reported prevalence of 4.5–16.6 %, and as high as 25 % in patients requiring colectomy for severe colitis [72]. CMV is also a cause of treatment failure in patients with UC. There are four main drugs used in the treatment of CMV: ganciclovir, foscarnet, valacyclovir, and cidofovir.

Other Viruses

Herpes simplex virus (HSV) is also a DNA virus and member of the herpes virus family. There are two main strains, HSV-1 and HSV-2. The prevalence of HSV-2 may be as high as 20 % in the United States and can approach nearly 50 % in countries in South America and Africa.

HSV-2 is the main cause of recurrent genital infections and proctitis. Patients with proctitis can present with anal pain, bloody discharge, tenesmus, bleeding, sacral paresthesias, and difficulty urinating. The majority of the cases of proctitis are in patients who have rectal intercourse [73]. The disease is usually limited to the distal 10 cm of the rectum. Endoscopic features include ulceration and necrosis. Culturing open sores or rectal aspirate can typically make the diagnosis. PCR tests and serum testing for antibodies can also aid in identifying HSV.

There is no cure for herpes, but outbreaks can be controlled with acyclovir 400 mg three times a day for 7–10 days.

Other viruses can cause colitis, but they are usually found in immunocompromised or AIDS patients. Adenovirus can cause a colitis that closely resembles CMV colitis [74]. Other colitis-forming viral pathogens in AIDS patients include human herpesvirus type 6, astrovirus, picobirnavirus, calicivirus, Norwalk, and rotavirus [75].

The 2014 West African outbreak of Ebola has led to a few Americans contracting the disease. Ebola virus is spread by contact with infected bodily fluids from other humans or primates. Within a few days to a few weeks, patients will develop fever, sore throat, muscle aches, and headaches, which is then followed by rash, vomiting, and severe diarrhea. The diarrhea is often voluminous and can lead to hypotension and shock. It is unclear as to whether bacterial toxins or invasion of mucosa causes the diarrhea. Treatment of Ebola is primarily supportive. Antidiarrheal agents may be

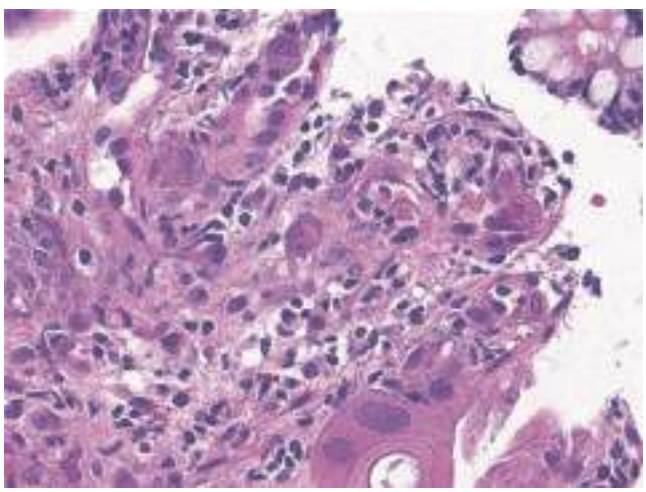

FIGURE 52-6. Cytomegalovirus colitis. Infected cells are enlarged with eosinophilic intranuclear and intracytoplasmic inclusions. (Courtesy of Jeanette R. Burgess, MD).

FIGURE 52-7. Endoscopic appearance of CMV colitis in the descending colon.

used, especially in cases with massive GI loss, but close monitoring for distention and other adverse events is mandatory [76].

Fungal Colitides

Histoplasma

Histoplasmosis, caused by *Histoplasma capsulatum*, is endemic in the Ohio and Mississippi river valleys. Though it is most commonly known for causing a pulmonary infection, *Histoplasma* can lead to progressive disseminated histoplasmosis (PDH) causing life-threatening illness in many organ systems, especially in immunocompromised hosts. Gastrointestinal involvement is most common in subacute PDH. Ulcerations of the small and large bowel are present in many cases with the terminal ileum and cecum being the most frequently involved areas. Severe cases may have deep ulcerations with pseudopolyps, which may appear similar to adenocarcinoma or inflammatory bowel disease [77, 78].

Diagnosis is made by tissue culture or tissue histology showing granulomas and yeast within the mucosa. Surgery is reserved for cases of perforation, obstruction, or failure to respond to medical therapy. In many occasions, the diagnosis is not even known preoperatively. The mainstay of medical treatment is intravenous amphotericin B. Itraconazole may be used in mild cases or when amphotericin is not tolerated.

Candida

The *Candida* species are thin-walled yeasts that grow by budding. They are found worldwide and have become a significant cost burden to hospitals and patients. The yeast typically is not pathogenic in patients unless immune systems are diminished. Nearly every organ system in the body can be affected by candidiasis. Candidal infections of the colon are uncommon as only a handful of case series and case reports have been published in the literature [79]. *Candida albicans* is the most common organism. Patients are often very ill with diffuse abdominal pain and diarrhea. Flexible endoscopy may show white curd-like plaques on the mucosa. Visualizing the budding yeast and hyphae with culture or biopsy makes the diagnosis. Treatment depends on the severity of the disease. Fluconazole at varying doses and varying lengths is commonly used. Surgery is reserved in cases of perforation or peritonitis. Mortality is high in this patient population because of the concomitant immunosuppression.

Other Fungi

Aspergillosis, caused by the mold *Aspergillus*, is another fungal infection primarily in the immunocompromised patient [80]. Though the most common clinical manifestation is pulmonary, gastrointestinal-invasive aspergillosis is possible in disseminated cases. These patients present with fever, abdominal pain, tenderness, and bleeding. Bowel resection is required in cases of ischemia and bowel perforation. Demonstration of characteristic hyphae from biopsy specimens or from culture makes the diagnosis. Treatment is with voriconazole and a second-line agent is amphotericin B.

Cryptococcosis, caused by *Cryptococcus neoformans* and *Cryptococcus gattii*, primarily affects the lung and the central nervous system. Risk factors for infection are disease states that cause immunosuppression, such as AIDS, transplantation, steroid use, cancer, and sarcoidosis. Cryptococcus can however affect any organ system in the body. Within the gastrointestinal tract, it can cause colitis and occasional spontaneous perforation. Nodules and ulcers in the stomach and small intestine, which can resemble Crohn's disease, are other manifestations of disseminated Cryptococcus [81]. Diagnosis is made by microscopy of biopsy specimens or culture of bodily fluids. Treatment in severe cases is intravenous amphotericin B.

Special Situations

Traveler's Diarrhea

Travelers to low-income parts of the world frequently have the misfortune of developing acute diarrhea. Disease is characterized by three or more unformed stools in 24 h associated with other gastrointestinal issues, such as abdominal cramping, tenesmus, nausea, vomiting, fever, or urgency of bowel movement.

Incidence of diarrhea has been shown to inversely correlate to the income level of the country visited [82]. Overall rates have declined in the last two decades, but rates remain over 20 % in parts of South Asia and West/Central Africa [83]. Cruise ship passengers and staff are at risk for outbreaks of norovirus, which may be difficult to contain once started.

The average duration of untreated traveler's diarrhea is 4–5 days, with average incapacitation of less than a day. Most travelers are able to continue their activity unaltered [84]. More than 10 % will present with diarrhea after returning home [85]. Traveler's diarrhea is caused by various forms of *Escherichia coli* in more than 50 % of cases. *Campylobacter*, *Shigella*, and *Salmonella* are the other frequent bacterial etiologies [15] (Table 52-3). Parasites tend to cause more prolonged diarrhea, with *Giardia lamblia* and *Entamoeba histolytica* the most common [86].

Campylobacter or *Salmonella* infection may increase the risk of developing inflammatory bowel disease [87], while a number of infectious agents have also been implicated in the development of postinfectious irritable bowel syndrome [88]. Many organisms can cause diarrhea, but bloody diarrhea is typically the result of *Shigella*, *Salmonella*, *E. coli* 0157, *Campylobacter*, and *Entamoeba histolytica* [86].

Table 52-3. Regional differences in etiology of Traveler's diarrhea

Organism	Latin America and Caribbean (%)	Africa (%)	South Asia (%)	Southeast Asia (%)
ETEC	35–70	25–35	15–25	5–15
EAEC	25–35	0–35	15–25	n/a
Campylobacter	1–7	5–25	15–25	25–35
Salmonella	0–15	5–15	<5	5–15
Shigella	5–30	5–15	5–15	<5
Norovirus	15–25	15–25	5–15	<5
Rotavirus	15–25	5–15	5–15	<5
Giardia	<5	<5	5–15	5–15

Data compiled from compilation from: Steffen R, Hill DR, DuPont HL. Traveler's diarrhea a clinical review. JAMA. 2015;313(1):71–80 [83] and Montes M, DuPont HL. Infectious diseases. 2nd ed. Philadelphia: Mosby Elsevier; 2004. Chapter 43, Enteritis, enterocolitis and infectious diarrhea syndromes; p. 477–90 [110]

Laboratory investigation is indicated when the diarrhea is severe, bloody, or prolonged. This should include stool culture and microscopy looking for parasites. Antigen testing is indicated if *Giardia*, *Cryptosporidium*, or *Entamoeba* are suspected. Blood cultures may be useful in the septicemic patient [89].

Prophylactic bismuth subsalicylate has been shown to reduce diarrhea rate by 65 % when given four times daily but due to its salicylate component should be used with caution in patients at risk for bleeding [90]. Rifaximin, which is an antibiotic that is poorly absorbed from the intestinal tract, significantly reduced the incidence of traveler's diarrhea in a meta-analysis of over 500 patients [91]. The use of probiotics has not been shown to be beneficial [83].

Systemic antibiotics reduce the incidence of traveler's diarrhea by more than 90 %, with fluoroquinolones most frequently used. Concerns about adverse reactions and bacterial resistance make antibiotic prophylaxis controversial, and prophylaxis is not currently recommended for most travelers. High-risk patients may benefit from prophylaxis and include patients with a history of stroke, insulin-dependent diabetes mellitus, chronic renal failure, and inflammatory bowel disease as well as patients with ileostomies or colostomies [83].

Self-treatment in the event of illness should include oral hydration, treatment with loperamide, and a 1–3 day course of a fluoroquinolone. In countries with known antibiotic resistance, azithromycin may be substituted [92].

Infections in Inflammatory Bowel Disease

Infectious complications are a major concern in patients with inflammatory bowel disease (IBD). Numerous pathogens can play a role in enteric infections, including *Clostridium difficile*, *Salmonella*, *Shigella*, *Campylobacter*, *Escherichia coli*, cytomegalovirus, and *Entamoeba histolytica*.

Mylonaki et al. found that about 10 % of relapses were caused by infections, with more than half of those attributed to *Clostridium difficile* [93]. Another report found that up to 20 % of patients with IBD flare-ups had positive stool ELISA testing for *Clostridium difficile* [94]. This mirrors the increased incidence found in numerous studies of overall *Clostridium difficile* infection (CDI). These infections increase risk of hospitalization as well as colectomy in patients with inflammatory bowel disease [95].

Clostridium difficile in IBD may be atypical, with bloody stools and younger patient age. CDI should be considered in the absence of diarrhea in patients with constitutional symptoms and leukocytosis. Small bowel disease (CDI) may occur after colectomy in IBD patients [96].

Medications used to treat inflammatory bowel disease are all associated with infections. Purine antimetabolites predispose to infections by some of the herpes viruses, with cytomegalovirus a major cause of colitis. Immunosuppression with corticosteroids increases the risk of Candidal infections, which can affect the bowels. TNF antagonists increase risk of granulomatous infections, such as extrapulmonary tuberculosis [97].

CMV infection is very prevalent in patients with inflammatory disease, with numbers as high as 33 %. Many of these patients are "innocent bystanders," and the diagnosis of active CMV disease can be challenging. CMV colitis can clearly complicate IBD colitis and should strongly be considered in steroid-resistant cases [98].

Several bacterial agents have also been postulated as infectious causes of inflammatory bowel disease. These include *Mycobacterium avium paratuberculosis*, non-pylori Helicobacter, *Escherichia coli* (EIEC), and *Campylobacter concisus* [99].

Diarrhea and HIV

The human immunodeficiency virus (HIV) targets CD4+ T-lymphocytes, a major player in the immune defense system in the human body. A large concentration of CD4+ cells are found on the gut mucosal lining, so it is no surprise that infection with HIV can cause a plethora of gastrointestinal complaints [100].

Nearly all patients infected with HIV develop some sort of gastrointestinal complication [101]. Colitis can produce symptoms such as abdominal pain, tenesmus, and urgency.

The list of pathogens that can cause colitis is extensive and includes bacteria, viruses, and parasites (Table 52-4). Though opportunistic infections are the most common cause of diarrhea, many noninfectious etiologies exist as well.

Workup of diarrhea in an HIV-infected patient begins with assessment of the disease itself: i.e., CD4 count and HIV viral load. Other tests include stool microscopy for ova, cysts, and parasites, bacterial culture, *Clostridium difficile* toxin, and PCR testing for parasites and viruses. Colonoscopy allows for visualization and biopsy of the colonic and terminal ileum mucosa for histologic analysis and CMV PCR. Not all cases require flexible endoscopy, but in culture-negative patients, endoscopy can help make the diagnosis in 50 % of cases [102, 103].

Cross-sectional imaging, such as CT scan, antegrade barium studies, and tuberculosis testing are other options when no diagnosis has been made. An algorithm for evaluating patients with HIV-associated diarrhea is shown in Figure 52-8.

Like diarrhea from other causes, treatment is initially geared at resuscitation and rehydration. Pathogen-specific treatment should be initiated as soon as identification is made. Antiretroviral therapy (ART) will drastically reduce viral load allowing for CD4 count to rise. ART assists in the resolution of opportunistic infections and decreases future chance of infection [104]. Anti-motility agents such as loperamide and diphenoxylate can help curtail symptoms in cases where workup has been negative and ART has been unsuccessful. Octreotide may be used in refractory cases of HIV enteropathy with limited benefit [105].

Diarrhea and Solid Organ Transplantation

Due to the high levels of immunosuppression needed to prevent graft rejection, solid organ transplantation patients are also at higher risk for infectious gastrointestinal complications. Estimates of diarrhea in this population range from 22 to 52 % [106, 107]. Infectious etiologies are the most common cause of diarrhea in solid organ transplant patients, whereas graft versus host disease (GVHD) is the most common cause of diarrhea in stem cell transplant patients.

Cytomegalovirus (CMV) and *Clostridium difficile* are the two most common culprits [108]. Workup typically starts with stool culture, *Clostridium difficile* toxin assay, and blood CMV viral load. Colonoscopy can be useful as a second-line test. Other tests include fecal leukocytes, ova and parasites, isospora and cyclospora assays, *Cryptosporidium* antigen screen, and norovirus PCR.

Echenique et al. reported their experience of 422 admissions for diarrhea over an 18-month period. The majority of the cases had no identifiable etiology and were self-limited. *Clostridium difficile*, norovirus, and cytomegalovirus were the most common identified agents. Other bacterial and parasitic causes were very rare [109]. Treatment of the diarrhea is geared to the identified agent. Modifications of immunosuppression dosages and regimens may be required.

Evaluation of Patient with Infectious Diarrhea

Evaluation of the patient with acute diarrhea should include a careful history of possible exposures (family members, foods) and travel history. Stool culture is probably not indicated in patients who are not hospitalized and who have mild to moderate diarrhea. Patients with severe diarrhea, persistent diarrhea, weight loss, extremes of age, or immunodeficiency issues should have more thorough testing.

Microscopic evaluation of fecal smears can be easily accomplished. Polymorphonuclear leukocytes may suggest an invasive or inflammatory pathogen, while mononuclear leukocytes may be seen with typhoid fever or amebic dysentery. Many organisms produce fecal leukocytes, so a positive test is an indication for stool cultures and empiric antibiotic treatment.

Parasitic evaluation is indicated for patients with diarrhea lasting longer than 2 weeks, as well as patients in a day care setting, male homosexuals, or HIV-infected patients (Figure 52-8). Special stains are indicated in immunocompromised patients, looking for cryptosporidia or microsporidia. ELISA evaluation can directly detect *Isospora*, *Giardia*, *Cryptosporidium*, and *Entamoeba* [110].

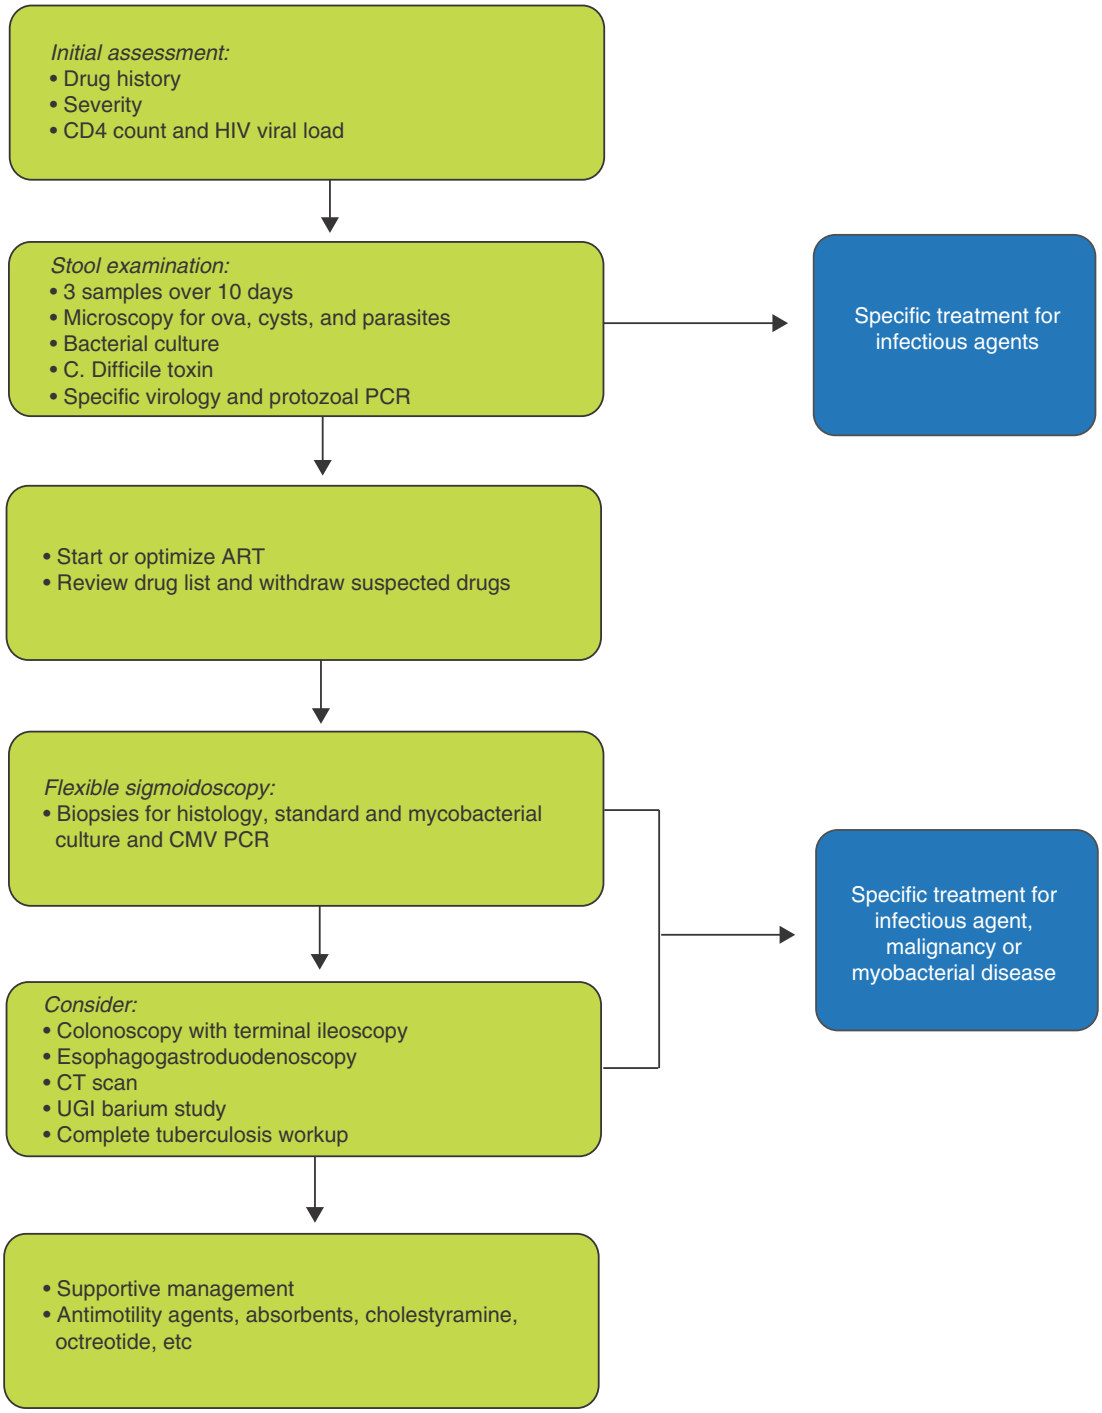

FIGURE 52-8. Algorithm showing the management approach to the HIV patient with diarrhea. With permission from Feasey NA, Healey P, Gordon MA. Review article: the aetiology, investigation and management of diarrhoea in the HIV-positive patient. Alimt Pharm There. 2011; 34(6): 587–603 [100]. © John Wiley and Sons.

Salmonella, *Shigella*, and *Campylobacter* are the most frequently discovered pathogens on stool culture, especially in patients with bloody diarrhea [111]. *Vibrio* testing should be done with a history of travel to coastal areas or a history of seafood ingestion. Special agars may be needed to isolate *E. coli* O157:H7. The laboratory may need to be notified to culture if unusual agents, such as *Yersinia* or *Aeromonas*, should be considered. *Clostridium difficile* testing should be done in patients with a history of prior antibiotic use.

Proctosigmoidoscopy is useful in patients with bloody diarrhea, prior antibiotic use, history of anal manipulation, or an immunocompromised status. Higher risk patients may also benefit from colonoscopy or gastroduodenoscopy with biopsies, looking for CMV inclusions, fungi, or acid-fast bacilli. Viral cultures may also be useful in these patients. Endoscopy can help to exclude other causes of noninfectious diarrhea, such as inflammatory bowel disease or ischemic colitis [112].

Clostridium difficile Infection

David B. Stewart Sr.

Key Concepts

- The incidence and severity of *C. difficile* infection is increasing worldwide.
- Testing for *C. difficile* infection has transitioned to the more sensitive nucleic acid amplification tests (NAATs).
- Exposure to healthcare facilities, prior antibiotic therapy, and proton pump inhibitor use are common risk factors for infection.
- The preponderance of studies suggests that infection with ribotype 027 is associated with worse disease outcomes.
- The mainstay of CDI therapy is resuscitation and treatment with metronidazole and/or vancomycin.
- Fecal microbiota transplant is a promising emerging therapy.
- Surgery can be avoided in most patients but should be considered in cases of continued clinical deterioration despite maximal medical therapy.

Introduction

During the previous 20 years, *Clostridium difficile* infection (CDI) has transitioned from being a relatively uncommon diarrheal illness principally limited to patients rendered immunocompromised from cancer treatment or HIV to a billion dollar per year hospital-acquired infection with a diverse at-risk patient spectrum. Since this epidemiological shift has placed every inpatient at higher relative risk for developing CDI, and considering the potential for this infection to reach a severity requiring surgical intervention as a last resort, a knowledge of *Clostridium difficile* is important for the general and colorectal surgeon. This chapter reviews the epidemiological changes that have surrounded CDI during the previous two decades, as well as touching upon the key microbiological features of this bacterium that promote CDI and which account for its symptoms. A review of the clinical science directing the proper use of antibiotics against *C. difficile* is provided, as is a discussion of surgical treatment options as well as fecal microbiota transplantats (FMT) as an emerging alternative to conventional medical and surgical therapies.

Epidemiology

Rising Incidence and Increasing Severity

During the previous two decades, and particularly within the previous 15 years, there has been a population level increase in the incidence of CDI both in the United States and in Western Europe [1–3]. Due to greater government funding in European countries, a larger volume of epidemiologic studies and those with the greatest detail related to prevalent strains (ribotypes) of *C. difficile* [4] have come from Europe. The trends observed in those regions, however, mirror changes in CDI observed in the United States, and this parity between these regional studies provides a similar conclusion when the data is summarized. *C. difficile* is the predominant form of antibiotic-associated diarrheal illnesses in acute care facilities, and it is reliably estimated to be the causal microbe in at least 15–25 % of such cases [5]. During the previous century, a precipitous increase in the incidence of CDI has been documented; in a study from Quebec evaluating patients from 1991 to 2003, Pepin and colleagues [6] documented a population-level increase of CDI approaching fivefold, while those defined as elderly (≥65 years of age) experienced an approximately eightfold increase in CDI incidence. In the United States, the most recent data from the Agency for Healthcare Research and Quality reported [7] that in 2009 there were 336,600 hospitalizations which involved CDI either as a primary or a secondary diagnosis, a number comprising 1 % of all hospitalizations in the United States during that year. Likewise, the Centers for Disease Control (CDC) reported that between 1993 and 2009, hospital stays effected by CDI increased fourfold, while rates for persons ≥65 years of age increased by 200 % [8, 9]. Similar trends of increasing

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_53

incidence have been reported [10] in European countries such as France and Belgium, especially during periods of so-called outbreaks, with patients of advanced age being disproportionately affected. The impact of this rising incidence on healthcare costs translates into an over 3 billion dollar annual burden to the US healthcare system, when costs from inpatient and outpatient treatments are both included. [11] While there is a consensus that studies such as these have documented a veridical shift in disease prevalence, recent data from the CDC has documented stability in the incidence of CDI in the United States from 2010 to 2011 [9, 12]. Though this data encompasses a very short time period in epidemiological terms, it is useful in so far as it allows for standardization of disease incidence on the basis of the type of *C. difficile* testing being used. This is a subtle but important factor, since many hospitals transitioned their method of CDI testing from enzyme immunoassay (EIA) platforms to the more sensitive nucleic acid amplification tests (NAATs). This change in testing protocol could, arguably, have artificially increased the reported incidence of CDI apart from an actual change in disease incidence. The effect exerted by the type of CDI testing on reported incidences has been described elsewhere [13], though as more hospitals in the US have adopted NAAT testing protocols, the effect of testing platforms on future reports of CDI incidence will likely be lessened.

Of even greater concern than a rising incidence of CDI, however, were reports from multiple regions of an increase in severity associated with this infection. In 2005, there were several published reports of epidemical outbreaks of *Clostridium difficile* associated with two previously underreported observations: higher mortality rates overall, and higher mortality among patients not previously considered to be at risk for CDI, let alone fulminant forms of this disease. Loo and colleagues [14] described the results of a prospective study conducted at 12 hospitals in Quebec in an effort to accurately describe the incidence and risk factors for CDI. After reviewing the care of 1703 CDI patients, the incidence of CDI was estimated to be 22.5 per 1000 hospital admissions. The 30-day mortality attributable to CDI was calculated to be a robust 6.9 %, and the use of quinolone and cephalosporin antibiotics was associated with development of the infection. This study provided details on specific isolates using pulsed field gel electrophoresis (PFGE) and other molecular techniques in order to identify the presence or absence of toxin genes as well as toxin regulatory genes. Warny *et al*. extended these findings, [15] with an analysis of *C. difficile* isolates from 124 separate patients from Quebec and other Canadian regions, the United States, and the United Kingdom. Using standard PFGE and restriction fragment length polymorphism fingerprinting, the predominant strain in the Warny study was confirmed to be what is now referred to as ribotype 027. Both the Warny and Loo studies demonstrated *C. difficile* ribotype 027 was not only associated with the production of both toxins A and B, as well as a third toxin now referred to as binary toxin, but that it was also associated with >15 times the volume of toxin A and B production than the other ribotypes evaluated. In the Loo study, identification of one of several forms of gene deletions occurring at a putative toxin inhibitory gene was also described as a potential causal factor for increased toxin production. These two studies produced some of the first data that provided clinically relevant information regarding the incidence of CDI at the institutional and regional level, helping to establish a relationship between antibiotic use and CDI, and providing a plausible explanation for outbreaks based upon genetic characteristics clustered within one potentially epidemical ribotype of *C. difficile*.

Two additional studies from the same time period further emphasized the relationship between CDI and fluoroquinolone antibiotics. In a retrospective case–control study from Pittsburgh, Muto *et al*. [16] described the results of an institutional outbreak where, during a 2-year period, there were 253 cases of CDI associated with admission to a healthcare facility, of which 26 required emergent colectomy and 18 died of disease-related complications. Odds of CDI were associated with clindamycin (OR = 4.8), ceftriaxone (OR = 5.4), and levofloxacin (OR = 2.0), with each of these agents serving as independent risk factors. There was a particularly strong association between the use of fluoroquinolones and outbreaks of CDI, and one of the two clonal lines associated with such outbreaks was suspicious for ribotype 027. Similarly, McDonald and colleagues [17] reviewed 187 clinical *C. difficile* isolates obtained from eight US healthcare facilities located in the Northeast, the Southeast, and the West, performing PFGE, toxinotyping, and restriction endonuclease analysis (REA), as well as using PCR to evaluate the presence of toxin genes and their regulatory genes, all in an effort to characterize the predominant clonal line of *C. difficile*. When comparing newer isolates to a historical tissue bank of earlier *C. difficile* isolates, a significant increase in the incidence of ribotype 027 was observed, as was a more frequent occurrence of resistance to certain quinolone antibiotics. Further, the frequent presence of the genes for toxins A and B and binary toxin, and a predilection for large deletions in genes (such as *tcdC*) whose function may include suppression of toxin production, provided evidence of the emergence of a type of *C. difficile* with molecular characteristics which would explain its frequent associations with epidemical forms of severe CDI.

To summarize, there is evidence from North America and Western Europe that the incidence of CDI has increased during the previous century and that this increase in incidence accelerated during the previous two decades. Though simultaneous improvements in the rapidity and sensitivity of *C. difficile* testing contributed to changes in incidence due to greater detection rates, this alone does not discount descriptions of a legitimate increase in disease frequency. The emergence of at least one ribotype of *C. difficile* (ribotype 027) during outbreaks of severe disease provides further evidence of a change in CDI in healthcare facilities, and certain genetic

characteristics of this ribotype suggest that this strain of bacterium may have certain selective advantages toward epidemical forms of the infection.

Clinical Risk Factors for CDI

The literature is replete with long lists of clinical factors identified as being frequently associated with the development of CDI. In many cases, these risk factors are not causally related to CDI in an independent manner, and in most cases the one commonality which they share is frequent contact with acute or chronic healthcare facilities.

A distinction must first be made between healthcare facility-acquired CDI, and the rarer form of the disease, community-acquired CDI (CA-CDI). A generally accepted definition for CA-CDI centers on an onset of disease at least 12 weeks after any personal contact with a healthcare facility [18]. While this is a reasonable definition, it does leave open the possibility that a patient labeled as having CA-CDI may have contracted *C. difficile* while in contact with a facility, and for various reasons, they developed symptoms of the illness in a latent fashion. Therefore, what should be called a case of truly community-acquired CDI would be a distinct entity, and a rarer one, compared to the more common healthcare facility acquired, community-onset CDI. Since CA-CDI is an uncommon manifestation of CDI, and since CDI is not a reportable disease in the United States and other countries, the limited surveillance and incidence data obscure an accurate measurement of the incidence of CA-CDI. The CDC [19] published data in 2005 suggesting that in the United States the incidence of CA-CDI was 7.7 cases per 100,000 persons annually. In this report, approximately 35 % of patients had not received antibiotics within 40 days of developing symptoms of CDI. In a more recent study from 2014, Collins *et al.* [20] reviewed a 5 % random sample of Medicare beneficiaries, totaling more than 860,000 subjects. This study estimated that the incidence of CA-CDI was only 0.18 % of the study population, with approximately 57 % of the CA-CDI cohort having received oral antibiotics within 90 days of the onset of symptoms. In this study, 14 % of CA-CDI patients required an ICU admission, while only 1 % required surgery due to CDI. In-hospital mortality was surprisingly high at 9 %. While it is possible that an at-risk person could contract *C. difficile* from the environment (soil, water, food or animals) [21–23], a study by Chitnis and colleagues [24] reported that of 984 patients with CA-CDI, only 35.9 % did not receive antecedent antibiotics and only 18 % had no contact with healthcare facilities. Those patients with no preceding contact with healthcare facilities who developed CA-CDI had exposure either to infants younger than 1 year of age (thus, children who had been in previous contact with a healthcare facility) or exposure to household members with CDI. The data currently available suggests that CA-CDI is probably not a disease with a distinct pathophysiology as compared to healthcare-acquired, healthcare-onset CDI. This is an important point considering that many of the described community-acquired cases developed in persons with some direct contact with healthcare centers, with contact with patients who themselves had recently used antibiotics, and in scenarios involving contact with individuals who harbored these two risk factors. The development of CDI in a person without recent contact with a facility, a hospital patient or a CDI patient, and all without antecedent antibiotic use, is likely a very uncommon phenomenon.

For the remainder of the chapter, unless otherwise specified, CDI will refer to healthcare facility-acquired, healthcare facility-onset CDI.

Advanced Age

Advanced age is one of the most frequently cited risk factors for CDI [25–27]. While it is possible that elderly individuals may have changes to their gut microbiome, or to their gut immunity, that predispose them to develop CDI, the current evidence indicates that age primarily serves as a risk factor by its association with many other risk factors which themselves are more directly responsible for the development of CDI.

Contact with a Healthcare Facility

Both acute care and long-term care settings pose a risk for CDI due to higher populations of at-risk persons, with the convergence of other additional risk factors. The risk posed by residence in a care facility may increase in magnitude [28] with longer durations of stay in such settings. Since the primary mode of disease transmission in care settings is person to person through a fecal–oral transmission route, it is not surprising that with increased potential exposure to the organism, the estimated prevalence of asymptomatic colonization of adult patients admitted to an acute care setting ranges from 7 to 26 % [29] and may be as high as 5–7 % among elderly subjects in subacute or long-term care facilities [30]. Considering that these studies are older, it is likely that these percentages would be higher if these studies were repeated in the present day, especially if such studies included patients cared for during outbreaks of selectively advantaged types of *C. difficile*.

Use of Antibiotics and Their Effect on the Microbiome

The most important, and the most modifiable, of all risk factors for CDI revolve around the use of antibiotics. The manner in which antibiotics effect the development of CDI, however, is much more complex than previously recognized.

There is ample evidence that antibiotics, of any class, increase the risk of CDI and that this risk increases with the number of agents and with their length of use. In one of the best studies to date to describe the risk relationship between non-*difficile* directed antibiotics and CDI, Stevens and colleagues [31] performed a 1-year retrospective study of 7792 patients, of whom 241 developed CDI. There were both dose-dependent relationships, as well as cumulative dose associations, between the use of antibiotics and the development of CDI; the number of antibiotics, and the number of days of their use, also increased the risk of CDI. When using the cohort with one non-*difficile* directed antibiotic as a reference group, the use of five such agents was associated with a hazards ratio for the development of CDI of 9.6. The use of fluoroquinolones was noted to be an independent risk factor for CDI in this study, an observation which has been described elsewhere [32].

Particular antibiotics may increase the risk of CDI to a greater degree than other agents. Whether this is due more to the effect of the antibiotics on commensal flora, or the effect of these antibiotics on *C. difficile* itself, or perhaps a combination of the two, is uncertain. In a recent systematic review, Slimings and Riley [33] reviewed 13 case–control studies as well as one cohort study. Of the antibiotic classes analyzed, second-, third-, and fourth-generation cephalosporins (OR = 2.23–3.2), clindamycin (OR = 2.8), and fluoroquinolones (OR = 1.6) were associated with higher odds of developing CDI. Though this review was limited due to the heterogeneity of the individual studies meta-analyzed, it provides an updated estimate of the relative risk accrued by classes of antibiotic agents.

One of the emerging concepts in digestive disease states is that the human gut contains myriad host-associated microbial communities which vary not only between different regions of the alimentary tract, but which vary depending on the health and disease states of their human host. Though the causal mechanisms are not well understood, in part due to the high degree of statistical "noise" inherent to most microbiome studies, changes in gut microbial communities may not only reflect a host disease state, but rather, these gut microbial changes may actually *direct* host disease states. Host-associated microbial communities maintain a degree of integrity within the larger environment of the microbiome, and they are able through unknown means to influence, or "communicate with," other microbial communities within the same human host. These microbial communities include more than simply bacteria, although it is the bacterial component of the microbiome that has received the most attention, and it may be this component, more than any other, which in a normal state confers resistance to bacterial pathogens such as *C. difficile* [34]. Specifically how the microbiome confers resistance to CDI is not understood at the individual bacterial level, because the current data is largely descriptive and inferential rather than establishing causal relationships. However, several broad concepts have been repeatedly observed and are worth noting. The primary difference between healthy and unhealthy gut environments is a matter of microbial population density and diversity. Based upon 16S rRNA sequencing, high microbial counts (greater than 10^{12} bacteria/gram of feces) with a high degree of bacterial species diversity, and with the possible predominance of two or more particular phyla (such as those including *Firmicutes*, *Bacteroides*, and *Acinetobacter*) are factors associated with a relative resistance to CDI [35–37]. Rather than there being one or only several combinations of bacteria which help to prevent CDI, most studies have identified *Bacteroides* spp., *Bifidobacteriae*, and *Lachnospiraceae* with other combinations of microbes as being the most effective at preventing colonization with *C. difficile* [35, 38]. This suggests that the issue of maintaining gut health is one of bacterial diversity in great enough numbers, with a lesser emphasis on particular combinations of taxa. While antibiotics do, in fact, reduce microbiota diversity and density through their indiscriminate killing of bacteria, their effect on the development of CDI may be even more important through the mediatory effect of bile salts in the gut. For example, in vitro studies have demonstrated differential effects on *C. difficile* spores by conjugated and deconjugated forms of cholate and chenodeoxycholate, with the latter inhibiting spore germination at ten-fold lower concentrations than the former [39, 40]. Under healthy conditions, therefore, chenodeoxycholate suppresses *C. difficile* growth arising from vegetative forms of the bacterium. It is also known that cholate and chenodeoxycholate are metabolized into the secondary bile acids deoxycholate and lithocholate, respectively. Deoxycholate stimulates *C. difficile* germination, while lithocholate inhibits this process; interestingly, deoxycholate is also lethal to vegetative forms of *C. difficile*. Studies in rodents have demonstrated that antibiotics change the proportion of bile salts present in the colon, increasing cholate concentrations, which may result in greater germination of *C. difficile* spores, with a concomitant decrease in deoxycholate and its inhibition on *C. difficile* growth. This effect from antibiotics may be more important than the provincial concepts that these drugs decrease competition for nutrients and quorum-based inhibitions in colony growth, though no doubt these are also mechanisms by which antibiotics promote CDI.

Perioperative Prophylactic Antibiotics and Mechanical Bowel Preparations

In keeping with the previous discussion regarding alterations in background bacterial populations and the development of CDI, questions have been raised regarding whether perioperative prophylactic antibiotics and/or a mechanical bowel preparation increase the risk of CDI. Since these two measures are often used together, if each were to represent an

independent risk for CDI, then their combination may pose even greater odds of developing the infection. Despite the controversy among surgeons regarding the need for bowel preparations prior to elective colorectal surgery, there is fairly convincing evidence that mechanical bowel preparations do not significantly elevate the risk of CDI. In a retrospective review of data from multiple hospitals in the state of Michigan, Morris and colleagues [41] reviewed the care of 2263 colectomy patients, of whom 1685 received a mechanical bowel preparation. A mere 54 patients within the study population developed CDI, and neither the use of a bowel preparation nor the use of preoperative oral antibiotics were associated with CDI. In a more recent study, Kim *et al*. [42] reviewed the same statewide database as Morris and colleagues, using propensity score matching to compare 957 paired cases of patients undergoing colectomy who either did or did not receive an oral laxative with oral preoperative antibiotics. Those who received a bowel preparation were actually found to have a lower incidence of CDI, though the absolute magnitude of this difference was small (0.5 % versus 1.8 %; $p=0.01$).

The effect that prophylactic parenteral antibiotics have on the incidence of CDI is much more difficult to study precisely, in large part due to the admixture of patients who are undergoing their first surgery and who have had limited preoperative contact with healthcare facilities, who are then compared alongside those patients with previous surgeries and relatively recent hospitalizations. It is this latter group of patients who are more at risk for developing CDI even after a single dose of prophylactic antibiotics due to their status as an asymptomatic carrier. The incidence of asymptomatic carriage decreases during the life of healthy subjects from 40 to 60 % in the neonatal period to as low as 2–4 % in healthy adults who are not frequently in contact with hospitals [43]. The rates of asymptomatic carriage are also higher in particular disease groups, such as those with inflammatory bowel disease (see below). No studies to date have properly segregated patients by disease category and history of exposure to healthcare facilities in order to provide a credible estimate of risk. In a study from 2002 which analyzed 157 CDI patients, Morris [44] and colleagues noted that 9.5 % of all CDI patients received prophylactic perioperative antibiotics as the only discernible risk factor; this study was small, with relatively few CDI patients for the 6-year time frame encompassing patient inclusion, and therefore further studies would be required to gauge the scope of the problem. What is clear is that, though infrequent, a single dose of antibiotics can potentially lead to CDI, and even more rarely, to life-threatening forms [45] of CDI. While this is not sufficient grounds alone to forego prophylactic antibiotics prior to abdominal surgery, given the clear benefit they provide in other areas of surgical outcomes, these observations underscore the need to de-escalate and discontinue antibiotics as soon as possible.

Immunocompromised States

There is a clear association between a compromise to the immune system, whether from HIV or from cancer, and the development of CDI. Studies have not precisely distinguished the association between immunosuppression causing CDI directly and immunosuppression requiring hospital care and thus leading to the convergence of other risk factors, such that immunosuppression is only circumstantially associated with CDI. The actual state of affairs probably incorporates both of these aspects. In a recent study by Gebo, [46] the relative risk for HIV patients developing CDI was twice that previously described, with an estimated 8.3 cases per 1000 patient years. Based on a multivariate analysis, a CD4 count of ≤50 cells/μL was an independent risk factor for developing CDI, with an adjusted odds ratio of 27.6. The absence of normal cellular immunity is also a likely role in patients with cancer who develop CDI, being especially common among those with hematologic malignancies [47] who require bone marrow transplantation.

Inflammatory Bowel Disease (IBD)

CDI is associated with both ulcerative colitis (UC) and Crohn's disease (CD); [48] there is no consensus as to whether one phenotype of IBD is more likely to promote CDI. Though the current data on IBD patients is heavily skewed toward those patients seeking medical care due to an exacerbation of their disease, the most recent population level and institutional studies estimate that the incidence of CDI in this group of IBD subjects ranges [48, 49] from 6 to 20 %. IBD populations may harbor an innate immune dysregulation, [50] which may lead to a chronic dysbiosis; [51] this, in concert with their more frequent need for hospitalizations and antibiotics, as well as the frequent use of immunosuppressive medications as medical therapy for IBD, produces a merging of host and environmental factors promoting CDI in IBD patients. With respect to IBD medical therapy, the data demonstrating risk for CDI is somewhat limited. At least one study [52] from 2009 reviewed 10,662 IBD patients, estimating that the use of infliximab was not associated with higher odds of CDI; corticosteroids, however, were associated with a threefold increased relative risk of CDI. There is also limited evidence [53] that the combination of *difficile*-directed antibiotics in the setting of ongoing immunomodulator therapy is associated with poorer outcomes (such as higher odds of death or colectomy within 3 months of admission) though the risk for developing CDI imposed by immunomodulators is unclear.

The development of CDI in the setting of a flare of IBD symptoms is associated with a higher rate of surgery, with one study estimating a sixfold [54] higher increase toward needing intestinal surgery. The incidence of recurrent CDI

is also higher in IBD patients, [55] and mortality rates for CDI in IBD patients may be higher than for CDI patients alone [56].

Proton Pump Inhibitors

The use of proton pump inhibitors (PPIs) is extremely common among hospitalized patients; their actual need probably falls far below their actual use, and it may be the case that these drugs are ordered almost by habit, especially since they are mistakenly viewed as being relatively harmless. The release [57] of a statement by the Food and Drug Administration warning of the association between PPIs and CDI has promoted a reevaluation of the proper role of acid-suppressing medications among inpatients, especially among those patients who are not experiencing reflux symptoms, and for those patients who are not critically ill but who are being given PPI therapy for "prophylaxis" or other more questionable indications. The means by which PPIs promote CDI is usually suggested to involve a fecal–oral route of transmission, with the concept being that an alkalinized stomach might allow for a greater number of ingested *C. difficile* (both active and spore forms) to survive the gastric environment, reaching the colon in a viable state to then go on to create an infection if other factors are also present. It should be noted that while this model has a certain conceptual appeal, it is far from established beyond reasonable doubt, especially when considering that gastric acid does not reliably eradicate *C. difficile* spores. PPIs (and H2 blockers) may have other mechanisms by which they promote CDI. One recent in vitro study [58] by Stewart and colleagues demonstrated that omeprazole actually stimulated the expression of *C. difficile* toxin genes and that this effect was present in both basic and acidic ambient conditions. In addition to a direct effect on *C. difficile*, PPIs may affect the other bacterial members [59] of the microbial community by decreasing diversity, with one recent study suggesting that these drugs reversibly decrease operational taxonomic unit counts for up to 1 month after exposure. There may also be off-target effects of PPIs on colonocytes themselves; Hegarty and colleagues [60] performed in vitro testing using PPIs and T84 cells (a human colon cancer line); PPIs resulted in alterations to gene expression in colonocytes associated with changes involving cell-to-cell junctions, toxin susceptibility and bile acid transport.

Though the majority of individual studies show an association between PPIs and CDI, the number of meta-analyses is far smaller, and these systematic reviews have provided contradictory evidence in favor of [61], as well as against [62], such an association. The weight of the current evidence lies in favor of PPIs placing patients at risk for CDI, though the issue is far from settled, and the degree of influence independently exerted by PPIs may be small.

Hospital Environmental Factors

Hand hygiene is effective at preventing the transmission of *C. difficile* (both spores and active bacteria) in acute and subacute care settings; [63, 64] there is a preponderance of evidence that soap and water is better at removing spores from hands than alcohol-based cleansers [65]. Isolation techniques for patients with CDI, [66] including dedicated toilets and terminal cleaning programs, [67] can decrease institutional CDI rates.

Microbiological Considerations for *Clostridium difficile*

Pathogenicity Locus Genes

Clostridium difficile is a variably motile, Gram-positive, obligate anaerobe which derives its latter name from "difficulties" isolating this organism in culture in previous eras. With modern anaerobic techniques, culturing *C. difficile* is no longer a significant challenge. That portion of *C. difficile*'s genome most responsible for human disease is referred to as the Pathogenicity locus (PaLoc) [68], which is most commonly a 19.6 kb island of genes (Figure 53-1) that encodes for toxins A (*tcdA*) and B (*tcdB*). Some ribotypes of *C. difficile* also produce another toxin referred to as binary toxin, whose genes (*CDT*) and their regulators are located outside the PaLoc.

The three most commonly discussed regulatory genes within the PaLoc are *tcdR*, *tcdC*, and *tcdD*. *tcdC* is important for the clinician to be familiar with since it is occasionally cited as a risk factor for severe forms of disease, being frequently found in a variant form in *C. difficile* associated with outbreaks. The *tcdR* gene produces proteins which are structurally and functionally similar to bacterial sigma factors, [69] a large family of RNA polymerase transcriptional factors which are vital both for transcription of *tcdA* and *tcdB* as well as for promoting the transcription of *tcdR* itself [68–71]. Ambient factors are known to increase the expression of *tcdR*, such as antibiotics, nutrient and carbon sources, pH and temperature changes, [71] and *tcdR* in turn increases the transcription of the entire PaLoc except for *tcdC*. This inverse pattern of gene transcription was one of the first suggestions that perhaps *tcdC* had a putative negative regulatory function [71]. It is now known that the protein produced by *tcdC* is a membrane-bound acidic protein [72] which in its active form exists as a homodimer. In vitro studies have demonstrated that the product of *tcdC* prevents the product of *tcdR* from directing RNA polymerase to the promoter for *tcdA*, sequestering *tcdR* products in a manner similar to anti-sigma factors studied in other bacteria.

Reports of outbreaks associated with *tcdC* variants have been published, with the suggestion that a truncated *tcdC* protein product may not effectively inhibit *tcdA* transcrip-

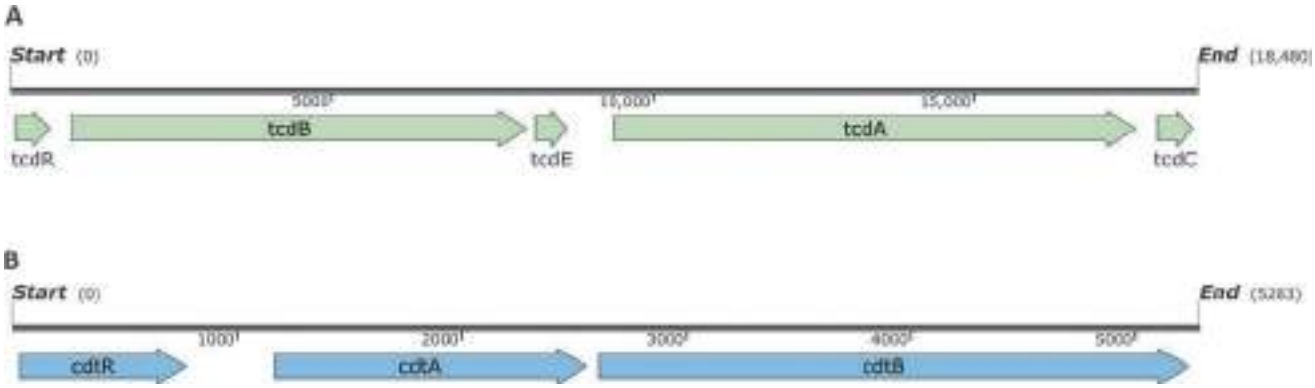

FIGURE 53-1. Schematic demonstrating the regulatory and toxin genes of the Pathogenicity locus (*upper portion*) and the binary toxin genes (*lower portion*).

tion, potentially leading to a larger volume [15] of toxin production. Studies collecting clinical isolates of patients with CDI for the purpose of studying this issue are few. In an analysis of 69 CDI patients whose dominant *C. difficile* was genetically characterized, Stewart *et al*. [74] determined that the presence of binary toxin and a *tcdC* truncation (18 or 36 base pair deletion) was associated with a higher incidence of recurrent CDI (OR = 5.3). In a follow-up study also focused on recurrent CDI, the same group observed [75] that two particular single nucleotide polymorphisms of the *tcdC* gene strongly predicted recurrent CDI. While *tcdC* variants may potentiate the risk of recurrence, there are other studies which have questioned whether *tcdC* has any clinical impact on CDI, especially with respect to severity of disease. Goldenberg and colleagues [76] failed to observe an association between binary toxin and *tcdC*, and disease severity, by reviewing over 200 *C. difficile* isolates. It should be noted that only 8 % of these isolates were ribotype 027, despite a high prevalence of *tcdC* truncations. Additional data calling into question the clinical relevance of *tcdC* for disease severity comes from Nigel Minton, [77] whose lab used an eloquent allele exchange system to introduce the loss of, and the subsequent restoration of, *tcdC* function in CD630, a well-characterized reference strain. This study was particularly valuable in that it demonstrated that the presence of a functional *tcdC* product did not affect volume of toxin production.

Toxin Nomenclature and Physiology

Toxins A and B are considered part of the Large Clostridial Toxin (LCT) family. These toxins are 308 kDa and 269 kDa, respectively, hence their designation as "large." Though there are studies which have attempted to weigh the relative contribution of these two toxins toward injury of colonocytes, especially given the rare occurrence of tcdA(−)/tcdB(+) ribotypes, [78] studies using isogenic strains [79] producing either toxin A or B were shown to be capable of causing life-threateningly severe CDI in rodents, while simultaneously using a gene knockout approach to demonstrate cytopathy in vitro and symptoms of disease in vivo. As described in an excellent review, toxins A and B have a multi-modular domain structure (ABCD model), [80] where A represents the biologically active N-terminus, B represents the C-terminal binding domain, C represents a cysteine protease domain, and D is a hydrophobic domain. The mechanism by which LCTs are taken up by cellular targets includes a receptor specific binding of the B domain which facilitates receptor-mediated endocytosis; a decrease in the pH of the resultant endosome promotes pore formation with translocation of a portion of the toxin across the endosomal membrane and into the cytoplasm of the cell. The D domain, being hydrophobic, is instrumental in forming these endosomal pores and in promoting membrane translocation of the toxin. The C domain then promotes autoproteolysis which allows the A domain to be released into the cytosol. The end effect of toxins A and B is mediated through targeted Rho GTPases (Rho, Ras, and CDC42), which are involved in cytoskeletal organization. These toxins perform monoglucosylation of these GTPases, resulting in cytoskeletal disruption and eventual cell death [81, 82].

The binary toxin (*CDT*) is not as prevalent as toxins A and B. *CDT* is part of a different family of toxins, having an ADP-ribosyltransferase function (the ADPRT family) [83]. The prevalence of this toxin is estimated to be 15 %, [84] although there is clearly a higher incidence of this toxin among ribotype 027 isolates. *CDT* is made up of two independently transcribed components, *CDTa*, which is the enzymatic component, and *CDTb*, the transporter element [78, 85]. In vitro studies using Caco-2 cells have demonstrated that *CDT* has a unique characteristic in promoting its adherence to, and entry into, target cells. The target cell is induced by *CDT* to produce multiple microtubular protrusions which

increase the apical membrane surface area five-fold, which helps with both toxin and bacterial adherence [86]. The downstream effect of the toxin on cellular targets is similar to that observed with toxins A and B; ADP-ribosylation blocks polymerization of G-actin to F-actin, leading to a disruption of actin equilibrium, with resultant cytoskeletal disruption leading to cell death.

While the binary toxin may not be present in the majority of clinically encountered ribotypes, the vast majority of clinically relevant types of *C. difficile* will produce toxins A and B. Deletions of *tcdA* are more common than *tcdB*, though both of these variants are uncommon in clinical practice [87, 88].

Association Between Bacterial "Type" and Disease Severity

Some of the earliest reports [15–17] of outbreaks of severe CDI which also included data on molecular typing pointed to a particular strain of *C. difficile* as the culprit of these severe instances of disease. This strain has been variably referred to as NAP-1, REA BI, and toxinotype III, though more recently these competing monikers have been replaced with reference to this organism as ribotype 027. The preponderance of studies suggest that this ribotype is associated with worse disease outcomes, though ribotype 027 designation does not appear to be an independent, stand-alone factor which is sufficient or necessary for severe disease, as there are examples of ribotype 027 not associated with adverse outcomes, [75] and since there are other ribotypes which can also be associated with severe disease [97]. This point is important to remember in reviewing the literature, as many clinical studies which have implicated ribotype 027 as an "epidemical strain" may not have adequately controlled for other factors which could account for adverse disease outcomes in the form of elevated recurrence rates, need for ICU care, need for colectomy or death. In a study focusing on patients with severe forms of CDI, Walk and colleagues [98] reviewed 34 cases of severe disease identified from a larger cohort of 310 CDI cases. Based on an initial and unadjusted univariate analysis, multiple covariates, including ribotype, were associated with severe CDI. However, after controlling for other potentially confounding factors, only a subject's white blood cell count and albumin were associated with the development of severe CDI; ribotype 027, as well as ribotype 078 (discussed below), was not associated with disease severity.

There are plausible molecular mechanisms which might, in the right clinical setting, account for greater odds of severe or recurrent disease associated with ribotype 027, which speaks to the evolutionary fitness of this strain of *C. difficile* but which does not require that ribotype designation be a principal determinant of disease outcome. First, there is evidence that 027 may be selectively advantaged to become the predominant type of *C. difficile* in health care facilities. In a small study [99] comparing patients being admitted to a single US hospital either from home or from a long-term care facility, ribotype 027 was found to be much more prevalent in long term care facility residents than were other strains of the bacteria. Patients with 027 were found to have higher six month mortality rates, though the ability for the authors to control for confounding factors was limited due to the small study sample size and due to population heterogeneity. In a review of a Canadian provincial database on patients in an acute care setting, Labbe [100] and colleagues analyzed both ribotype and clinical outcomes in both epidemical and non-epidemical periods of CDI. Ribotype 027 was associated with higher CDI-related mortality in this study, and the data suggested that antibiotic use for non-*difficile* infections was strongly associated with a shift toward a predominance of ribotype 027 within the CDI population, a change which frequently preceded outbreaks and which suggested a causal relationship between 027 and those outbreaks.

Secondly, 027 may be advantaged in terms of its efficiency in forming spores. *C. difficile* is an obligate anaerobe, and primarily in an effort to survive the aerobic environment outside the gut, the organism is capable of developing endospores, which are physiologically dormant and non-reproductive bacterial structures. Due to their metabolic quiescence, spores are resistant to antibiotics, and in the case of *C. difficile*, these spores are resistant to alcohol based hand sanitizers as well [65]. There are several genes which regulate sporulation in *C. difficile*, though a key regulator, and the most frequently studied, is *Spo0A* (Stage 0, sporulation protein A). This gene product may have a role in activating spore formation during periods of limited nutritional resources [101]. There are studies which have suggested that 027 is more transmissible due to a greater frequency of sporulation, and that perhaps the spores produced by 027 are more resistant to adverse environmental factors [102]. However, as pointed out in a review by Smits, [103] there are a number of studies calling this observation into question [104].

It has been proposed that ribotype 027 may have an advantage in toxin production compared to other ribotypes. This difference has been described both in terms of volume of toxin production [105] as well as in harboring genes not only for toxins A and B but also for binary toxin [106]. Other studies have suggested increased resistance of 027 toward *difficile*-directed antibiotics. [107] As with the other potential virulence features for 027, these observations have not been unanimously reported.

A judicious summary of the literature on 027 would be as follows. The bulk of research on *C. difficile* is *in vitro*, which while potentially valuable, does introduce a degree of artificiality to those research findings. *C. difficile* is a living organism which responds to its environment in the same manner that any other organism does. *In vitro* study or manipulation of *C. difficile* usually involves creating an ideal environment for bacterial growth and survival, and usually in complete

isolation to other bacteria, not to mention to the exclusion of other important components of the gut microbiome such as viruses. Described another way, the ambient environment of *C. difficile* research is a nested and synthetic one, frequently far removed from anything analogous to the human gut in either a healthy or a diseased state. It would be unreasonable to expect that observations of bacterial behavior in a lab environment would be directly reproducible to the situation in the human gut without important qualifications. In fact, the rationale behind the study of a gut microbiome lends to the opposite framework to that of an atomistic study of microorganisms one at a time, the latter being much more akin to the majority of *in vitro* research today. It is this difference between a laboratory culture and a living microbial community which may help to account for the disparity between those studies which found ribotype, toxin genes or some other bacterial factor as being predictive of bacterial behavior, and those studies which could not repeat these observations. Ribotype 027 definitely carries the genetic machinery which one would think is necessary for virulence, in the form of a well-preserved PaLoc, and with a higher prevalence of the binary toxin gene. What may be more important, however, than well-conserved toxin genes is the propensity of 027, like many other bacteria, to be lysogenous, which is to harbor bacteriophage genetic material in the form of a prophage. This viral genetic material is incorporated into the bacterial genome and carried along as a (largely) silent passenger. The prophage genetic material is replicated in a linear fashion with the *C. difficile* genome, which is a significant metabolic demand on the bacterium to maintain replication fidelity in the process of copying viral genetic material in addition to its own. This situation creates a strong deletional bias among bacteria to shed unnecessary physiological debts, which includes pressure in favor of losing any components of prophage DNA which do not offer some advantage to *C. difficile*. There are studies which have described a diverse number of phages which have contributed to lysogeny in *C. difficile*, [108] and studies have demonstrated that lysogeny can result in a greater volume of toxin production in 027 strains [109]. The process of lysogeny may account for recent comparative genomic studies [110] which have noted that epidemical forms of 027 have, on average, 234 additional genes compared to reference strain CD630, and that up to five ribotype-unique genetic regions were noted, including a previously unreported phage island. From all of this, a circumstantial case can be made that 027 is itself a heterogeneous subset of *C. difficile*, containing variants some of which are more, and some of which are less, selectively advantaged to produce outbreaks and severe forms of disease. This heterogeneity cannot be explained by the PaLoc, but rather it is related to the horizontal transmission of mobile genetic elements (such as phages, and transposons, the latter of which will not be discussed in this chapter due to space limitations). Those forms of "epidemical 027" have collected a critical mass of integrative genetic elements to create outbreaks of disease, and it is the interaction between *C. difficile* and its gut environment that can allow for outbreaks to develop through lateral gene flow, leading to the subsequent transmission of these epidemical, genetically enhanced *C. difficile* strains between human hosts in the hospital setting.

There are also other ribotypes which like 027 demonstrate facility at causing outbreaks. Briefly, one such ribotype is 078, which may represent an important zoonotic [111] link for CDI in humans. Ribotype 078 harbors *CDT* in addition to *tcdA* and *tcdB*, and it has been associated with greater severity of disease than other non-027 ribotypes [75, 97]. Interestingly, 078 is also capable of lysogeny, [112] though comparative genomics studies for this ribotype are currently lacking.

Diagnosis of *C. difficile* Infection

Clinical Presentation

CDI is a toxin-mediated disease whose hallmark is diarrhea. There are instances of asymptomatic carriage as referenced earlier in this chapter, though this is not generally a feature of a healthy subject, and in virtually every case described in the literature, carriage occurs among patients and healthcare workers, those who have frequent and prolonged exposure to areas where *C. difficile* is endemic. Patients who maintain a carriage state without symptoms of CDI are those who have the ability to develop an antibody to toxins A and B [113]. Studies on carriage status have demonstrated that an asymptomatic colonized state is more likely to develop in patients with greater concentrations of antibodies to toxin A compared to those who have symptoms of CDI; [114] higher titers of this antibody have also been associated with lower rates of recurrent CDI, [115] as have antibodies to toxin B [116].

For the majority of patients, if there is no diarrhea, there is no CDI. The one notable, albeit rare, exception would be those patients who have such life-threatening colitis from CDI that they have a paralytic colon, though in these instances the totality of clinical findings would strongly suggest a diagnosis of CDI such that the absence of diarrhea would not mislead the astute clinician. Other signs and symptoms (such as tachycardia, abdominal distention, abdominal pain/peritonitis, and hypotension) are variably associated with CDI depending on its severity. CT scan findings can include bowel wall thickening, pericolic fat stranding, megacolon, and ascites as the most common radiographic markers of severe infection (Figures. 53-2 and 53-3). Though segmental colitis with CDI is possible, in most cases, either a left-sided colitis with or without proctitis, or in more severe cases a pan-colitis, will be observed. Pneumoperitoneum and portal venous gas are uncommon radiographic features. Plain films and ultrasounds have little, if any, utility in diagnosing or managing this infection.

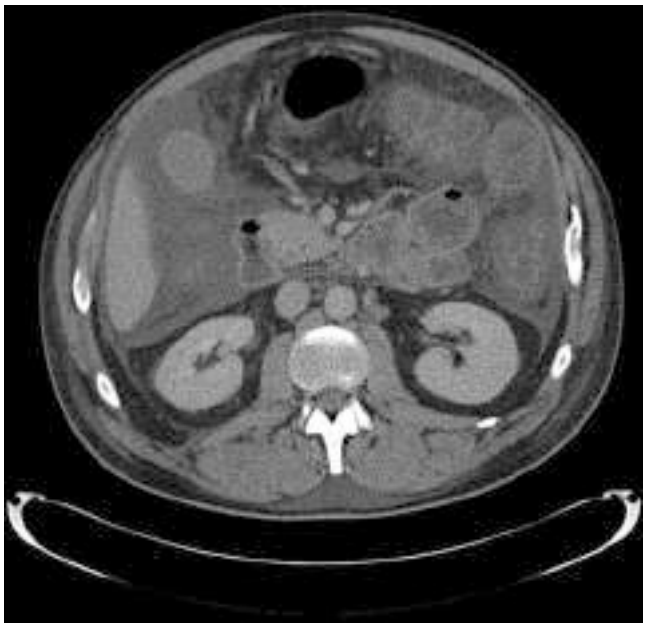

FIGURE 53-2. CT findings in a patient with severe, complicated CDI. Note the presence of ascites and the mural thickening of the left colon.

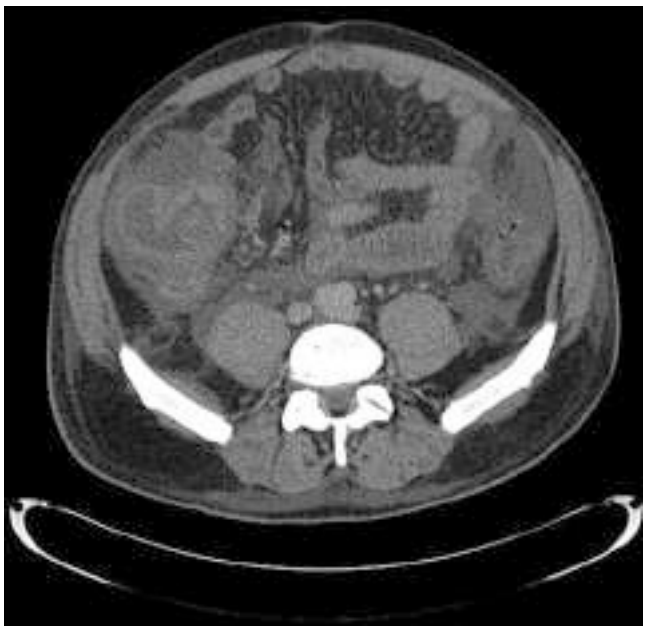

FIGURE 53-3. Severe, complicated CDI with characteristic cecal thickening. Colonic wall thickening to this degree is typical of fulminant CDI.

Laboratory Diagnosis

Historically, the diagnostic tests of choice for CDI involved either a tissue culture cytotoxicity neutralization assay (CNA) or toxigenic culture [117]. CNA involves stool cultures incubated with normal serum while a second sample of stool is incubated with antitoxin. With these aliquots exposed to cellular cultures, morphological changes consistent with the effects of toxins A and B are searched for during a 48-h period. The absence of cytopathy with both aliquots was considered a negative study, while cytopathy only observed in the sample without antitoxin was considered positive for CDI. These tests were often repeated with dilution for confirmation. Clearly, this form of testing is slow and labor intensive, and though it is a test with high specificity, its sensitivity was less than toxigenic culture, which itself is laborious [118].

With the later development of antibodies to toxins A and B, immunologic centered tests were developed. These initial tests were plagued by inaccuracies induced by the presence of antibodies to glutamate dehydrogenase (GDH), a cell wall antigen [118, 119]. A more specific form of immunologic testing was made available by the subsequent development of enzyme immunoassay tests, (EIA) and development of EIA testing against toxins A and B produced testing with >80 % sensitivity and >90 % specificity [120]. Further advances demonstrated that GDH provided a >98 % negative predictive value, while positive tests required confirmation through some other method [118].

At the present time, many hospitals have transitioned to one of several forms of nucleic acid amplification testing (NAATs). This group of tests use real-time PCR, loop-mediated amplification (LMAP), or helicase-dependent amplification techniques [118] to detect highly conserved sequences of the toxin A or B gene. NAATs are more sensitive than toxigenic culture and GDH-based approaches, and NAATs have increasingly become a standard, and stand-alone, test for CDI [11]. Although there are recommendations by some to use GDH as an initial screening test, with either EIA or NAAT for confirmation as part of a two-step process toward diagnosis, PCR-based NAATs are sufficiently sensitive and specific to serve as an adequate single step toward diagnosing toxigenic *C. difficile*. Routine retesting with NAATs to confirm eradication of the infection is not recommended as part of routine clinical practice, since NAATs are quite sensitive, and since *C. difficile* DNA may linger within stool for as long as 30 days after resolution of infection, leading to a false-positive test [121].

Clinical Severity Scores

There are several clinical severity guidelines which have been published, with the 2010 Infectious Disease Society of America/Society for Hospital Epidemiology in America (IDSA/SHEA) [18] and the 2013 American College of Gastroenterology [11] guidelines being those most commonly used in the United States. The IDSA guidelines define mild or moderate CDI as being associated with a white blood cell count (WBC) <15,000 cells/μL and a serum creatinine <1.5 times the patient's premorbid level. Severe CDI is then

defined as disease exceeding these two indices, while "severe, complicated" disease is CDI accompanied by such factors as hypotension, ileus, or megacolon. The ACG guidelines share certain similarities with the IDSA/SHEA schema, defining mild CDI as diarrhea without other abnormalities, and with severe CDI including those patients with either a WBC ≥ 15,000 cells/μL or a serum albumin of <3 g/dL. Moderate CDI then would range between mild and severe disease, while complicated CDI is defined in this system as anyone requiring ICU admission, a temperature ≥ 38.5°C, ileus, significant abdominal distention, altered mental status, a WBC either >35,000 or <2000 cells/μL, a serum lactate >2.2 mmol/L, or any evidence of organ dysfunction. An excellent comparison of these different systems as well as others used more frequently in Europe is provided by Katzman [122].

Two of the potential advantages of using a severity scale such as these are avoiding ambiguity in describing the severity of a patient's CDI between healthcare providers, while providing a consistent and empirical basis for choosing antibiotic therapy by reference to a scoring system that standardizes both disease definitions and their treatment. These systems, however, are quite limited for use by the surgeon, since most CDI patients treated by surgeons will be approached in consultation, and these patients are a selected subgroup of CDI patients who are not the principal focus of these scoring systems, systems largely devised by non-surgeons who primarily treat a different CDI cohort. Virtually all of the patients treated by surgeons will fall into the severe or severe, complicated categories of disease, yet most of these patients will not require surgery, which limits the discriminatory power of these systems in terms of choosing between medical and surgical therapy. The antibiotics recommended on the basis of these systems in many cases do not make sense given the proposed severity of the infection (i.e., the option of providing oral vancomycin for patients in the severe, complicated category who may be in septic shock or who may have an ileus). Further, the clinical markers of severity may be sensitive, insofar as those who are severely ill will be captured by these systems, though they are hardly helpful in guiding the decision to perform a colectomy, and this represents a significant knowledge gap in clinical research on CDI. Serum creatinine elevations as a marker of CDI severity, for example, may not be discriminatory, especially with respect to choosing surgical intervention, as in the case of a patient who is under-resuscitated but able to be resuscitated with appropriate medical care. Yet clinical indices such as serum creatinine are often referred to as indicators for surgery, without qualification, in the literature. Extreme values of WBCs should also be interpreted with caution by the surgeon. Neutropenic patients, especially those being treated for hematologic malignancies, may be at increased risk for CDI while simultaneously being protected from the most severe forms of the infection, both being a result of their neutropenia since functional leukocytes may be required for *C. difficile* toxins to exert their full and deleterious effect on colonocytes [123]. The more common aberrant WBC finding in CDI is an extreme leukocytosis, with counts of 50,000 cells/μL or higher being fairly common. However, there are aspects of this infection which make it unique compared to other diseases surgeons encounter. An exaggerated leukocytosis may be driven by both toxigenic [78] and non-toxigenic factors, [124] and these phenomena may not be directly related to the severity of colitis. An excellent description of bacteria–host interactions apart from the effect of toxins (an understudied aspect of CDI) was recently published by Jafari and colleagues, [124] who used human gastrointestinal mucosa studied in an ex vivo model to demonstrate increases in pro-inflammatory cytokines, such as IL-8, in response to the bacteria. This development may promote neutrophil migration to the gut, enhancing the cytopathy induced by toxins. Of even greater interest was the observation of bone marrow-derived dendritic cell activation which occurred apart from *C. difficile* toxins. IL-1β was also increased in a toxin-independent manner, and there were other cytokine changes which were felt to have a significant effect on T-cell responses to the infection. Though the purpose of this paper was not to investigate peripheral WBC counts in CDI, the information provided may help to partially explain the clinical observation that this infection can promote very elevated WBC counts, counts which are sometimes far more abnormal than the overall status of the patient. Though treatment will be discussed below, serum creatinine and lactate levels may indeed reflect disease severity, assuming there has been no delay in diagnosis and institution of treatment for the patient to otherwise account for these findings. However, without confirmation of maximal medical therapy having been delivered, these indices should probably not serve as justification for surgery, at least not as standalone indices. Neutropenia and significant leukocytosis require further study in terms of how they both reflect severity of CDI and the need for surgery, and this will probably be influenced both by characteristics of the predominant *C. difficile* type causing the infection and the genetics of the human host with respect to their cytokine response to infection. Therefore, the surgeon's interpretation of the significance of a WBC of 70,000 cells/μL, for example, should probably be adjusted from how this would be interpreted in other diseases such as diverticulitis or colitis from inflammatory bowel disease where, unlike CDI, such a finding would virtually always mandate emergent surgery.

Antibiotic Therapy for CDI

Metronidazole and Vancomycin

Excellent reviews of antibiotics either previously used for CDI or which lack enough scientific data to support their routine recommendation can be found by Venugopal [125]

and Wilcox [126]. In clinical practice, there are primarily two agents used for treating CDI, those being metronidazole and vancomycin.

Oral metronidazole preceded oral vancomycin as first-line treatment beginning in the mid-1990s due to concerns that overuse of vancomycin may select for resistant strains of bacteria such as *Enterococcus* [127]. Not only is metronidazole able to be provided in a parenteral route for CDI, but its cost is far lower than oral vancomycin. The data comparing metronidazole to vancomycin has evolved since initial studies on this topic, allowing for greater certainty regarding the proper use of these two agents. Prior to 2007, there were several [128, 129] small and underpowered studies which were not placebo controlled, and some of which did not adequately stratify patients based on severity of disease. These earlier studies suggested that metronidazole had similar rates of efficacy and recurrence compared to vancomycin, not to mention a significant cost savings in favor of metronidazole. In 2007, Zar and colleagues [130] published the first prospective, randomized, double-blinded, placebo-controlled trial comparing metronidazole and vancomycin, while also stratifying for CDI severity. In this study, patients were grouped into mild and severe disease categories, and although the severity scale used for this study was somewhat *ad hoc*, it was nonetheless based on factors known to be associated with disease severity. This study demonstrated that for mild CDI, rates of clinical cure were not significantly different between metronidazole and vancomycin, though for severe CDI, vancomycin was associated with higher rates of cure (97 % vs. 76 %; $p=0.02$). Though there have been abstracts and presentations of data at meetings, which have provided further support to these observations, the Zar study was very important for guiding current recommendations that metronidazole is the appropriate first-line agent for non-recurrent, mild-to-moderate CDI, a decision which balances efficacy, cost, and the potential risks of emerging resistant bacterial strains. Unlike vancomycin, metronidazole is effective by a parenteral route. The dosage should be 500 mg three times daily for 10–14 days. Longer lengths of treatment are not supported by evidence. Failure to demonstrate a response to metronidazole therapy within the first 5–7 days of treating mild-to-moderate CDI, or a deterioration to severe CDI, should prompt a change to vancomycin [11]. There is no evidence to support oral vancomycin combined with oral metronidazole, especially for milder forms of CDI.

For severe CDI, as defined by IDSA/SHEA criteria, [18] ideal treatment would involve oral vancomycin dosed at 125 mg four times daily for 10–14 days. There is a tendency for clinicians to increase this dosage, though there is little evidence to support such a practice given very high fecal concentrations [125, 131] of vancomycin at 125 mg dosing. For severe, complicated CDI, recommendations are for oral vancomycin (if tolerated) at 500 mg four times daily, though the clinician will often be required to instead use vancomycin enemas due to factors such as an ileus. The addition of parenteral metronidazole at 500 mg every 8 h is also recommended by IDSA/SHEA; though it provides little drawback, the evidence of "double therapy" in patients with CDI of this severity has been understudied, and so this recommendation does not carry the weight of evidence to support it as dogma. The use of vancomycin enemas has lower level support in its favor for fulminant cases of CDI; this evidence is from small and underpowered studies, [132] and the available data certainly would not support the use of intracolonic vancomycin for CDI of lesser severities. With the use of vancomycin, the clinician should remember that the use of cholestyramine is contraindicated due to its ability to bind to vancomycin.

For recurrent CDI, recommendations are to repeat a course of treatment using the same agent from the preceding course. Second recurrences are generally approached with vancomycin given in pulsed or tapered forms, for which there are several approaches aimed at eradicating vegetative forms of the bacterium. It should be mentioned that more recent data suggests that vancomycin should be used both for first recurrences [133] and potentially for all first CDI episodes in patients with inflammatory bowel disease, [134] given reports of higher success rates in both circumstances.

Fidaxomicin

Fidaxomicin is a macrocyclic compound [135] which exhibits its antibacterial activity through inhibition of bacterial sigma subunits which serve as transcription factors, thus preventing the expression of key bacterial genes. This agent has a more limited spectrum of activity than many other antimicrobials, with in vitro studies demonstrating resistance to fidaxomicin in certain *Bacteroides*, *Enterococcus*, and *Staphylococcus* species [136]. In 2011, the first Phase III study was published, [137] evaluating 629 patients, the majority of whom were treated per protocol. In this study, clinical rates of cure were non-inferior in the fidaxomicin group compared to the vancomycin treatment arm (92.1 % versus 89.8 %, respectively), while a significantly lower recurrence rate was observed in those treated with fidaxomicin in both the intention to treat and the per protocol groups. The group with lower recurrence rates was those *without* the potentially epidemical NAP1 strain. The results of this important study were limited by its inclusion of patients who received metronidazole, vancomycin or both as soon as 24 h prior to enrollment, which could clearly have affected the study results. The study also excluded patients with hypotension, fever or a leukocytosis greater than 30,000 cells/μL, and the study's approach to defining severity of disease was somewhat at variance with established guidelines in the literature, all of which makes the application of these results to the typical "surgical CDI" patient of less relevance. Further, this study did not provide evidence of equal efficacy with

vancomycin with potentially more virulent strains, such as ribotype 027.

There are a number of in vitro and in vivo observations suggesting a potential advantage to the use of fidaxomicin compared to vancomycin. There may be a longer post-antibiotic effect [138] compared to vancomycin, both in terms of the parent compound (10 h vs. 5.5 h) and also when comparing a metabolite of fidaxomicin to vancomycin. In a manuscript by Mullane and colleagues, [139] one of the first descriptions of the worsened cure rates in CDI patients receiving concomitant antibiotics for non-*difficile* infections was provided. The use of concomitant antibiotics was associated with lower cure rates (84 % vs. 92 %; $p<0.001$) and a significantly longer time to resolution of diarrhea (97 h versus 54 h; $p<0.001$). In this study, the use of fidaxomicin in the setting of concomitant antibiotics was associated with a higher cure rate than in those patients treated with vancomycin (90 % versus 74 %; $p=0.04$), with a lower rate of recurrent CDI (16.9 % versus 12.2 %; $p=0.04$). There is limited though intriguing in vitro evidence that fidaxomicin and its principal metabolite, OP-1118, reduce the expression of key *PaLoc* genes involved with toxin production (*tcdR*, *tcdA*, *tcdB*) in reference strains as well as in 027 isolates [140]. Though a considerable degree of further study would be needed on this topic, this observation, if confirmed, would indicate that fidaxomicin may not only target *C. difficile*, but may induce a change to its transcriptome favoring a reduction in the toxins that mediate the infection. A recent meta-analysis [141] of the limited body of literature on fidaxomicin concluded that while clinical cure rates were quite similar between fidaxomicin and vancomycin (OR = 1.17), relapse rates and sustained cure rates were improved in those treated with fidaxomicin. Interestingly, these results were sustained in both severe and non-severe CDI. There is also emerging evidence [142] that given fewer relapse rates, the use of fidaxomicin is cost-effective in severe cases of CDI and in those who have experienced their first relapse, as compared to costs associated with vancomycin. Additional studies will be needed to define the role of fidaxomicin among inpatients with CDI, especially those with severe disease and among those who develop CDI in the setting of hospital outbreaks. Fidaxomicin is dosed at 200 mg twice daily for 10 days for mild-to-moderate CDI, and this route would obviously be unavailable to those with fulminant colitis. Whether this drug can be delivered by retention enemas, in the manner of vancomycin, is also unknown. Currently, due to the higher cost of the drug, and considering reports of emerging *C. difficile* strains with a variant form of RNA polymerase B who have elevated MICs to this drug, [11] fidaxomicin should not be prescribed cavalierly as the third routine option for inpatients with CDI alongside metronidazole and vancomycin. Its role among the CDI patients that surgeons typically treat is unclear, as most of the studies on this drug are aimed at a different CDI population.

Surgery for CDI

The incidence of patients with CDI who require surgery is estimated to be as high as 10 % [143–145] although this would certainly be the upper limit, with the actual number likely being closer to 5 % or fewer (Figures. 53-4, 53-5, and 53-6). There are numerous papers, all with a retrospective methodology, which have documented the high mortality rates associated with severe, complicated CDI, and which have attempted to identify clinical indices associated with mortality. Several of these works have extrapolated from this data several possible markers for the need

FIGURE 53-4. Patient with fulminant CDI with a dilated and thickened colon, with telangiectasias and serositis indicative of severe, transmural inflammation mediated by *C. difficile* toxins.

FIGURE 53-5. Non-confluent regions of transmural ischemia observed in a patient with fulminant CDI. The combination of bacterial toxins as well as septic shock can produce nonviable large intestine.

FIGURE 53-6. Gross findings of mucosal thickening, inflammation, and pseudopolyps, consistent with severe CDI.

for colectomy. In 2001, Dallal and colleagues [144] reviewed an approximately 11-year experience at a single referral center. The incidence of CDI for the final year included for analysis was 1.2 %; the highest incidence of "life-threatening" CDI reached a zenith of 3.2 %. Out of 2334 hospitalized patients, 44 required a colectomy with a postoperative mortality rate of 57 %; 20 others were reported as dying as a direct result of CDI. An antecedent and recent surgery and previous lung transplantation were associated with development of CDI, while lung transplantation was associated with severe CDI. In 2008, Byrn *et al.* [146] reviewed the medical records of 73 CDI colectomy patients at a single hospital spanning an 11-year period. This surgical subgroup comprised only 1.3 % of the institution's CDI population, with an inpatient mortality rate of 34 %. Findings of organ dysfunction such as the need for intubation, the need for vasopressors, and mental status changes were identified as predictors of mortality, as was an elevated and/or prolonged elevation of arterial lactate levels. Similar findings were also reported by Hall and colleagues [147] who described the outcomes of 36 colectomy patients identified from 3237 consecutive CDI patients. A total of 64 % of the colectomy patients survived to be discharged; the need for intubation prior to surgery and the need for vasopressors were identified as significantly increasing odds of inpatient mortality.

There are two systematic reviews evaluating the survival benefit of total colectomy for fulminant forms of CDI, though they approach the issue from slightly different perspectives. Bhangu and colleagues [148] meta-analyzed 31 studies in order to compare survivors and non-survivors following colectomy for CDI; this review included patients who underwent partial colectomy in addition to those who underwent total colectomy. Among the study population, total colectomy comprised 89 % of the surgeries performed. In addition to a strong association between postoperative mortality and preoperative findings of septic shock as well as other manifestations of organ failure such as acute renal failure and the need for intubation, partial colectomies were associated with an approximately 16 % need for reoperation to resect additional colon. The conclusion of this study was that total colectomy with an end ileostomy, as opposed to lesser colon resections, is the preferred surgery for fulminant CDI failing medical therapy. The authors provided the caveat that perhaps, in highly selected patients, partial colectomies may have a role. In a second review by Stewart and colleagues, [149] a meta-analysis of 510 patients was performed in order to evaluate whether total colectomy performed in the setting of failing medical therapy provided any measurable survival benefit. Pooled odds ratios of mortality were lower in the total colectomy cohort (OR = 0.70); those undergoing partial colectomy were not included in this review.

More recently, an alternative surgical intervention was proposed by Neal and colleagues, [143] where instead of performing a partial or total colectomy with an end ileostomy, patients deemed to need surgery for fulminant CDI underwent the construction of a loop ileostomy, with intraoperative lavage of the colon with eight liters of PEG via the stoma, followed by postoperative lavage of the colon via the ileostomy using intraluminal vancomycin, and with the addition of parenteral metronidazole, both for 10 days following surgery. These patients ($n = 42$) were compared to a historical control group of CDI patients who had undergone colectomy with an end ileostomy. The two surgical groups were similar in terms of their preoperative APACHE scores and their preoperative clinical indices such as WBC, serum albumin, need for vasopressors or mechanical ventilation, and immunosuppression. The treatment group experienced a significantly lower mortality rate (19 % versus 50 %), and, as an added benefit, in 83 % of patients the ileostomy was able to be constructed laparoscopically. Interestingly, one patient underwent a laparoscopic total colectomy (based on the wording of the manuscript, it would appear during the same anesthetic as the ileostomy construction), while two patients required a return to the operating room for a total colectomy (one due to recurrent vasopressor requirements, and the other due to abdominal compartment syndrome).

Based on the totality of clinical data currently available, the proportion of patients requiring surgical intervention for fulminant forms of CDI appears far smaller than the proportion of patients who develop fulminant forms of this infection. Given this, surgery should be viewed as an intervention which, while potentially life-saving, will be required in only a small minority of patients. It is also important to remember that the majority of publications studying the issue of surgery for CDI approach the subject through a retrospective analysis of outcomes among patients who were selected for

surgery; these studies attempted to identify clinical indices associated with mortality or the need for surgery, though the study methods are limitations in this effort given the bias introduced by a primarily, or in some cases exclusively, surgical cohort. What is perhaps most important to recognize, however, is that surgery should be reserved for patients who have failed maximal medical therapy, and defining when adequate medical therapy has been reached is a topic which has not been systematically studied. Certainly, adequate medical therapy would include goal-directed resuscitation achieved in a timely fashion, the de-escalation of non-*difficile* directed antibiotics, and the appropriate use of *difficile*-directed antibiotics, even if the latter are instituted prior to the results of confirmatory stool tests being available. In clinical practice, it is clear that this is not frequently the scenario which unfolds and that the surgeon is often consulted on a critically ill CDI patient who may not have received timely and/or appropriately directed care. Surgery may then be required to salvage such patients, though it is not always clear if the need for surgery in this scenario was inevitable, being due to a virulent strain of bacteria, or whether the patient's complicated sepsis is a sequela of an undertreated infection.

Additional studies are needed in several areas. The current severity scales discussed earlier will be unhelpful for the majority of patients surgeons are asked to evaluate, since virtually all of these patients will have severe or severe, complicated CDI, and yet the published literature suggests that only a small fraction of such patients will truly require exigent surgery. Identifying those indices which best predict the unavoidable need for surgery, if such clinical markers exist, will be important, and a careful reevaluating of the currently cited markers for surgery (such as WBC—see above discussion [124]) will be necessary to avoid overly aggressive surgical intervention. This will be especially important in the case of ileostomy and colonic lavage, which is admittedly less invasive and better tolerated than colectomy, but which might result in surgeons inappropriately lowering the threshold to perform surgery, in an effort to prevent an adverse disease outcome which would not have occurred had appropriate medical therapy been continued. It seems prudent to recommend that surgeons be involved early in the course of severe or severe, complicated CDI, at least as consultants, and perhaps as the primary caregivers if aggressive resuscitation is not being provided to patients with fulminant forms of disease. While stand-alone factors such as leukocytosis may serve as general indicators of disease severity, the decision to surgically intervene in the disease will more reliably be made by an evaluation of the trend of the patient's state in the setting of goal-directed resuscitation (which will often significantly lower WBC and improve renal function) with appropriate antibiotics. At this time, the decision to use ileostomy and colonic lavage should be part of a research protocol, since it is not at all clear which ribotypes of *C. difficile* will respond to diversion and lavage, and since the sickest CDI patients may not tolerate the use of PEG and intracolonic lavage in a compromised hemodynamic state.

Fecal Microbiota Transplant

Fecal microbiota transplant (FMT) involves the use of donor stool which has been screened for a litany of infectious agents and is then applied to patients with CDI either via a nasogastric/nasoduodenal tube or, more commonly, by lower endoscopy. Its mechanism of action involves increasing the bacterial population diversity and density, reestablishing healthy microbial communities which were eradicated through the use of antibiotics. Studies have shown that FMT creates a population shift in 16S rRNA surveys, shifts which closely approximate the taxa present in the stool of the FMT donor [150]. These changes in host-associated microbial communities have been observed, in the absence of antibiotics, to persist for up to 1 year after FMT [151, 152]. FMT is known to help break the cycle of multiple recurrences of CDI which have been treated with straight and pulsed/tapered regimens of vancomycin, but what is an emerging concept is the use of FMT for fulminant CDI (both case reports [153–155] and unpublished personally communicated case series). Surgeons should be involved with the on-protocol use of FMT for patients traditionally evaluated as potentially requiring surgery.

Conclusion

C. difficile infection has evolved to be a potential threat for virtually any inpatient, acting as an opportunistic pathogen in response to microbiota changes induced by the use of antibiotics. Though the antibiotics available to treat CDI are still limited, newer agents such as fidaxomicin show a measure of promise. Surgeons have a key role in treating this infection, as it is a potentially life-threatening form of colitis which in a minority of cases requires surgery. Timely and aggressive medical care including fluid resuscitation and proper antibiotic stewardship are the cornerstones of good practice, and surgeons can be helpful in ensuring that CDI patients receive this, even in their role as a consultant. The proper role of surgery requires refinement, beginning with additional studies in less biased study populations to further identify which clinical markers indicate the irreversible failure of medical therapy and the need for surgery. Which surgery should be used (total colectomy versus ileostomy and colonic lavage) is unclear and will require correlating surgical outcomes with often neglected microbiological data in a prospective and multicenter fashion, as different ribotypes may respond differently to these surgeries. Lastly, there is seminal data that FMT may provide a salvage therapy for fulminant forms of CDI, and surgeons should be involved in studying this issue as an alternative to both antibiotics and surgery.

Radiation, Microscopic, Ischemic Colitis

Isabelle Raîche and Husein Moloo

Key Concepts

- Microscopic colitis is likely an underappreciated diagnosis. Although there is no "cure," the quality of life for a patient can be improved significantly with treatment which is typically medical and rarely surgical.
- Budesonide is the only evidence-based treatment for microscopic colitis
- Radiation colitis and proctitis spans a time course that ranges from acute to chronic which require different management strategies. Patients can present with problems even after 30 years of being asymptomatic.
- Colorectal cancer risk is increased with pelvic radiation and patients should be screened 5 years after completion of therapy.
- Surgical treatment for radiation proctitis/colitis should be individualized and based on the clinical context of the patient as morbidity and mortality rates are high postoperatively.
- Ischemic colitis represents the most common cause of gastrointestinal ischemia. The clinical picture has a wide spectrum ranging from mild cases with minimal mucosal ischemia to severe cases associated with transmural necrosis. Management and investigations need to be tailored depending on the clinical scenario encountered and patients require close vigilance by the surgeon.

Radiation Colitis

Introduction

An understanding of radiation injury to the colon and anorectal area is important for a coloproctologist. It is estimated that approximately 50 % of treatment protocols for cancer involve the use of radiation [1]. With malignancies such as anal cancer increasing, and a higher number of cancer survivors, the colorectal surgeon will continue to encounter post-radiation problems. The areas covered in this section consist of (1) pathogenesis, (2) prevention, (3) presentation, and (4) treatment. An important aspect to keep in mind while reading this section is the lack of high-quality evidence; an attempt has been made to provide the reader with recommendations based on the best evidence available.

Pathogenesis of Radiation Injury

The two main forms of radiation delivery are external beam radiation therapy (EBRT) and brachytherapy [2]. External beam is what we encounter most and is delivered via linear accelerators which produce high-energy X-rays. The planning is typically done in three dimensions with CT (computed tomography) images. Gray (Gy) is the standard unit to indicate the amount of absorbed radiation. Fractionation refers to giving the total dose over multiple sessions—for example, 50 Gray of radiation could be given over 25 sessions with 2 Gy per session. Fractionation is done to minimize collateral tissue damage while maximizing tumor destruction. Conformal radiation refers to the use of metal plates (multileaf collimators) to bend the X-rays in order to target the tumor and minimize radiation to normal tissue.

Brachytherapy refers to placement of the radiation source inside the body—i.e., beads or pellets.

Radiation damage has been described through the "target cell" theory. This theory focused on the epithelium of the bowel and explained acute effects through the damage done to this layer which is rapidly proliferating. The delayed effects were explained by damage of other target cells such as endothelial cells or fibroblasts as their turnover is slower compared to intestinal epithelium. The main addition to this thinking is that other tissues/cells are part of the injury process [3]. Therefore, alterations to the gut microflora, immune system, microvasculature, and immune system are all thought to play a role in the symptoms induced by radiation [3].

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_54

When radiation is used in the treatment of abdominal or pelvic malignancies, the colon and rectum are sometimes included in the field of radiation. As a result, injury can occur. As with other treatments, there are patient and "radiation" factors that can influence outcomes.

Patient factors include Body Mass Index (BMI) with a higher BMI being protective. Smoking is a significant factor for worsening radiation-associated bowel complications [4], yet another reason to offer these patients a smoking cessation program. Additionally, previous surgery (fixing pieces of bowel in place—likely more relevant for small bowel injury), inflammatory bowel disease, diabetes, vascular and collagen vascular disease [3, 5, 6], and genetic predisposition are all predisposing factors [2].

The most important radiation factor is the dose. Other factors that play a role are the length of bowel radiated, fractionation, and use of chemotherapy [3].

Radiation effects can be considered acute or chronic. Acute symptomatology refers to those that occur during the actual treatment to 6 months after treatment is completed. Chronic radiation symptoms can continue on from the acute phase or after an asymptomatic period. Radiation symptoms can occur for up to 30 years after being latent; most patients will typically present with chronic changes 8–12 months after finishing their treatment [3, 7].

Prevention

The first question then is can anything be done to prevent acute changes especially because there appears to be a higher rate of chronic problems in patients who experience severe acute proctitis. The absence of acute symptoms does not preclude chronic changes and symptoms from occurring [7–9]. This process of severe acute injury leading to chronic changes is termed the "consequential" late effect [9, 10]. Prevention can be divided into those related to radiation delivery and those that are not.

The main goal with radiation delivery is to minimize damage to normal tissues surrounding the tumor. Conformal radiation therapy is one of the main methods of doing this. The 3D planning performed using CT and computer technology results in a higher dose of radiation delivery with less normal tissue being affected. Intensity-modulated radiation therapy (IMRT) is a technology whereby different intensities of radiation can be given (high and low) within the planned field. The neoplastic tissue is clearly identified as well as the normal tissue around it [11]. This modality has led to significant decrease in radiation toxicity and reduction in intestinal radiation during prostate cancer treatment even when compared to 3D planning/simulation [12]. In prostate cancer patients, acute and late radiation toxicity has also been reduced with the use of IMRT [13, 14]. In a study in prostate cancer, stereotactic radiation therapy has been found to cause lower rates of acute toxicity [14].

Brachytherapy, as mentioned previously, is when the source of radiation is implanted into the neoplasm (interstitial brachytherapy) or in a cavity which is close to the neoplasm (intracavitary brachytherapy). It can be used alone or with external beam radiation therapy and the goal again is to reduce normal tissue injury and is sometimes a good option for patients with inflammatory bowel disease [15, 16].

Proton beam radiation is an area where more research with respect to gastrointestinal toxicity is needed, but theoretically and with other tumors such as hepatocellular cancer the data looks promising [17]. The theory behind photon beams is that it "stops" in the target tissue and therefore collateral damage should be less.

With respect to non-radiation delivery factors, patient positioning has been found to be an effective way of reducing radiation to rectal wall, small bowel, and bladder—i.e., prone, Trendelenburg [18]. Other strategies employ bladder distension, abdominal wall compression, and determining position based on pretreatment contrast studies [11, 19].

The Multinational association of Supportive Care for Cancer and International Society of Oral Oncology has recently written a good paper to guide clinical practice with respect to Gastrointestinal Mucositis secondary to radiation injury [20]. Intravenous amifostine and sulfasalazine orally have been recommended as preventative measures for radiation proctitis and enteropathy. The panel also "suggested" that probiotics containing Lactobacillus could be used to prevent diarrhea in patients being treated with radiation for a pelvic malignancy. It was also specifically recommended based on the best available evidence that 5-ASA and related agents such as mesalazine not be used to prevent diarrhea in patients receiving radiation for a pelvic neoplasm. They also recommended against using misoprostol suppositories to prevent acute proctitis from radiation.

There are also operative maneuvers such as omental slings and tissue expanders that can be used to avoid radiation damage if it is planned post-resection.

Acute Radiation Colitis and Proctitis

Radiation damages the mitotic activity that is occurring at the base of crypts, where stem cells. Reside therefore the cells that migrate to line the bowel are damaged leading to a suboptimal mucosal surface and mucosal inflammation [21]. This can lead to diarrhea because of the impaired absorption. The barrier to bacteria is also affected because of this process and bacteremia can result [8]. Motility is also affected through the creation of Giant Migrating Complexes and this goes back to normal after treatment is complete; during treatment it is thought this alteration contributes to the diarrhea and cramping experienced by patients; diarrhea is the most common acute symptoms experienced by patients [22]. Other acute symptoms include nausea, tenesmus, fatigue, and abdominal pain [3]. Nearly all patients (50–75 %) expe-

rience symptoms in the acute period, but luckily these symptoms are usually self-limited. Consequently, treatment is usually supportive. Diarrhea, for example, can usually be controlled by antidiarrheal medications such as loperamide. Dietary modifications can sometimes help such as a lactose-free diet or one low in fat. Diarrhea that is severe can sometimes necessitate admission to hospital for intravenous hydration or parenteral nutrition. If first-line antidiarrheals such as loperamide are not effective, octreotide can be used to slow diarrhea [23]. Suppositories with steroids can also be used. Butyrate enemas have been shown to help in the acute proctitis setting with the thought that supplying colonocytes with this short chain fatty acid nutrition will help resolve damage that has occurred [24]. With respect to nausea, antiemetics are usually effective. Nausea is usually an earlier symptom seen in the first week of radiation treatment versus diarrhea and abdominal pain are typically seen 2–3 weeks into treatment [3].

Chronic Radiation Colitis and Proctitis

Chronic symptoms and complications from radiation can range in severity but can be debilitating and significantly affect the quality of life of an individual. The Radiation Therapy Oncology Group (RTOG) and the European Organization for Treatment and Research of Cancer (EORTC) have devised a grading for late effects of radiation with grades of 0–5. Zero represents the effect of radiation that created no change compared to baseline and five is the effects that led to death (Table 54-1) [25].

There is not a lot written specifically about radiation colitis. There are articles written regarding non-rectal radiation-induced injury. Based on these reports some predictions can be made regarding colitis. The most common symptom is likely diarrhea. Patients can also present with more severe symptoms such as obstruction or perforation. Determining specific complication rates regarding radiation colitis specifically is difficult because studies that describe theses usually include small intestine pathology as well [26].

The symptoms of chronic radiation proctitis are outlined well in Table 54-1. The pathophysiology of these complications is related to ischemic injury. The main pathology relates to fibrosis, atrophy, and vascular damage. Fibrosis which plays a prominent role in radiation injury is thought to occur because of the reaction of fibroblasts to cytokines, growth factors, and chemokines [2]. Atrophy results from the killing of cells and in concert with the other changes lead to malabsorption and strictures. The vascular damage from radiation can lead to dilation of small blood vessels—this is manifested as telangiectasias[2]. There can also be constriction of arterioles which leads to ischemia and in more severe cases necrosis; the fibrosis that occurs and which can progress over time can worsen the resultant ischemic injury [2, 3, 8]. The small vessel disease described is what distinguishes chronic from acute radiation changes.

Diagnosis

With an understanding of pathology, it is easier to understand chronic complications. Bleeding for example can be seen because of telangiectasias or ulcerations from ischemia. Malabsorption leading to diarrhea can be seen because of the atrophy of the mucosal lining or strictures leading to bacterial overgrowth. As mentioned earlier, radiation can also impact the nerves associated with gastrointestinal function and therefore accelerated small and large bowel motility can result [23]. With worsening ischemic strictures can occur leading to obstruction. With full thickness necrosis of the bowel wall, fistulas or free perforation can result. Surgery is complicated by the fact that anastomotic leak rates are higher when irradiated (with poorer blood supply) bowel is used [25].

Diagnosis is usually done with endoscopy and the features seen correspond to the pathological changes—telangiectasias, atrophy, and friable tissue. Biopsies, if necessary, can rule out processes such as inflammatory bowel disease, ischemic colitis, or drug-induced injuries. One should be cautious about taking biopsies in the radiated rectum as these have been implicated in a higher rate of fistula formation [27]. Histologic features of radiation therapy vary with the interval between completion of radiation treatment and onset of symptoms. Acute radiation injury (within 2–3 days after treatment) is characterized by surface epithelial damage, nuclear atypia with bizarre mitoses, attenuation and loss of crypts epithelium, increased apoptosis, and increased eosinophils with eosinophilic crypt abscesses. In the chronic phase of radiation injury, superimposed episodes of ischemia or the presence of mucosal or submucosal fibrosis can mimic primary acute or chronic ischemic colitis. The distinctive features of chronic

Table 54-1. Late radiation effects on small/large intestine

Grade	Symptoms
0	None
1	Mild diarrhea, mild cramping, bowel movement 5 times per day; slight rectal discharge or bleeding
2	Moderate diarrhea and colic; bowel movement >5 times per day; excessive rectal mucus and intermittent rectal bleeding
3	Obstruction or bleeding, requiring surgery
4	Necrosis/Perforation, Fistula
5	Death

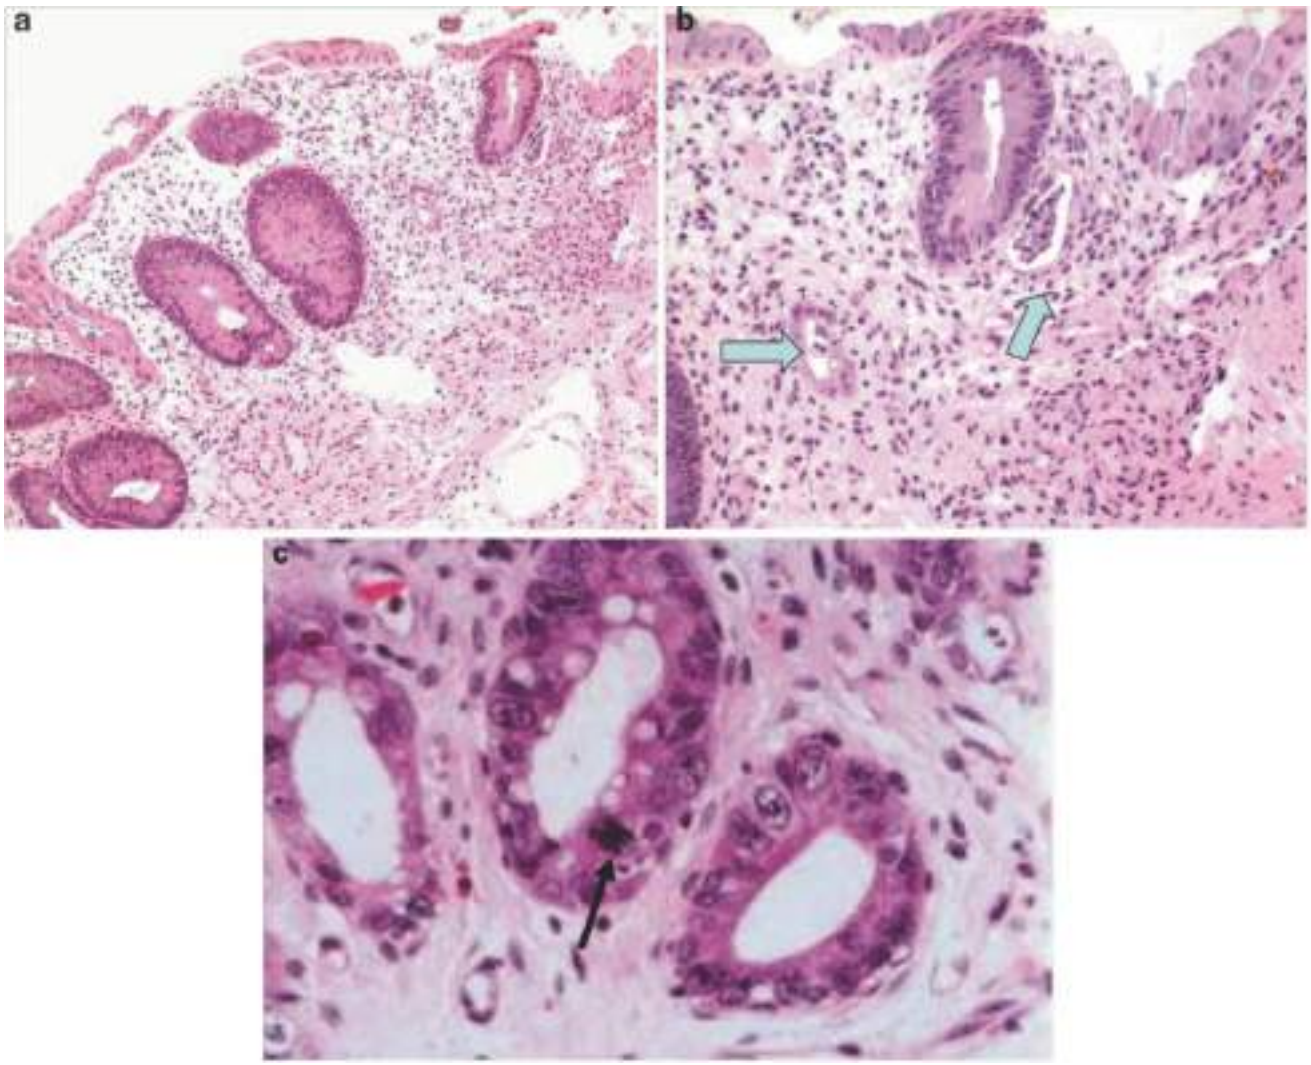

FIGURE 54-1. Radiation induced colitis. Colonic mucosa shows crypt distortion, crypt abscesses (*thick arrows*) and crypt atrophy, similar with inflammatory bowel disease. The crypt epithelium shows marked mucin depletion, regenerative nuclei and mitotic figures (*thin arrow*). Bizarre stromal fibroblasts and endothelial cells may be seen in lamina propria. Vascular injury may be also seen (not shown). Hematoxylin and eosin, ×100, ×200, ×4000. Reproduced with permission from Celia Marginean MD.

radiation injury include dilated, thickened, and hyalinized blood vessels, reactive or bizarre-shaped endothelial cells, fibroblasts and myofibroblasts, and foamy cells within the arteries (obliterative arteritis) [8] (Figure 54-1).

Management

Treatment of chronic radiation injury to the colon and rectum can be divided into medical, endoscopic, or surgical.

Medications

Medical treatment consists of topical versus systemic treatment. The main delivery method of topical treatment is via enema per rectum. Sucralfate enemas have been endorsed through the MASCC guidelines for the treatment of chronic radiation injury in patients who are having rectal bleeding [20, 28, 29]. There is one trial that showed oral sucralfate was beneficial in helping with diarrhea [30]; however, in their examination of the evidence, the MASCC recently suggested that oral sucralfate not be used [20].

5-ASA enemas have had mixed results and there is no clear evidence on whether it is beneficial for the treatment of chronic radiation proctitis or sigmoiditis and has been found to be harmful in some [31–33]. In the trial cited in the previous paragraph, it would seem that sucralfate is likely a more efficacious agent compared to 5-ASA [28]. Short chain fatty acid enemas still require further research prior to being able to recommend them as a treatment in chronic radiation proctitis [34]. Steroid enemas have also not been found to be consistently effective in the treatment of radiation proctitis [11, 23].

There is one trial that divided 60 patients into either a group that had betamethasone enemas, mesalamine orally, and metronidazole orally or a group that did not include oral metronidazole. In this trial it was found that bleeding and ulceration were lower in the group with metronidazole even up to 1 year [35]

A topical treatment that has been shown to be effective in dealing with bleeding from chronic radiation proctitis is topical formalin therapy. The theory behind this is that the formalin is used to chemically cauterize the telangiectasias and ulcers that are bleeding. The two main methods of delivery are via irrigation of formalin or direct application of a formalin soaked gauze onto the mucosa usually via a rigid proctoscope—the concentration typically used is 4 % although there are papers that have utilized 10 % solutions [8, 36, 37]. After either method it is recommended that a washout of the formaldehyde is done. It should also be noted that multiple applications may be required to achieve high efficacy rates of around 80 % (and sometimes higher); those with severe proctitis or taking an antiplatelet agent may require more applications [36–38]. For example, in one study the average number of applications of direct application with a cotton swab via a proctoscope was 3.5 with 1.5 more applications for patients taking aspirin or with severe proctitis [37]. Another important aspect of this treatment is to avoid contact with the anoderm as formalin can be irritating to this area. The irrigation or direct contact is done during an application until it can be visualized that cauterization has occurred of the affected rectal mucosa. For irrigation with formalin, it can be done in small aliquots ranging from 20–50 cc up to a total volume of 400–500 cc [38, 39]. It is important to be cognizant of the potential complications which includes anal or pelvic pain, stricture, rectal wall necrosis, and fistula formation [36, 39]. Finally, there may be a higher complication rate in patients who have received radiation for anal cancer [40].

Other medical treatments include use of vitamins—one study of 20 patients with chronic radiation proctitis looked at vitamin E and C use and whether a variety of symptoms improved. There was significant reduction in bleeding, diarrhea, and urgency, but it is important to note that the authors felt that a proper randomized controlled trial was required to see if these vitamins have actual benefit [41]. Loperamide was also examined with a small randomized controlled trial with a total of 36 patients and was found to decrease diarrhea and transit time and increase bile acid absorption [42]. Hyperbaric oxygen therapy has reasonable evidence to support its use for radiation proctitis [43, 44]; this recommendation (support for its use) is one of the changes that has been made in the most recent MASCC guidelines [20].

Endoscopy

Endoscopic therapy plays a role not only in the diagnosis of radiation injury to the bowel but can be used for treatment of it.

With respect to bleeding, argon plasma coagulation (APC) likely plays the biggest role and for many would be the treatment of choice prior to using formalin. It is a safe and effective therapy with bleeding cessation in 80–90 % of cases. Its advantage is also related to the fact that it coagulates to a reliable superficial depth. As with formalin instillation, it can require multiple treatments. Not only has there been found to be a reduction in bleeding, but bowel function has improved as well. There are no randomized controlled trials examining this particular technology, but based on multiple retrospective studies it appears to be safe and efficacious [45–47]. One has to be careful to avoid the dentate line because it can cause pain. Complications are rare and typically consist of rectal pain and cramping.

In one randomized trial comparing APC to formalin there was no difference in outcomes and both were found to be very effective in stopping bleeding (94 % APC and 100 % Formalin) [48]. In another randomized controlled trial with approximately 60 patients in each group, it was found that the addition of oral sucralfate to APC did not make a difference to the success rate of APC [49]. Historically, Nd:YAG laser therapy was used endoscopically, but with APC this is rarely used at present. In previous studies, it was found to be safe with rare complications of stricture, ulcers, fistula, and mucus discharge [50]. Another endoscopic technology that may find a wider application in the future is radiofrequency ablation as it can target a larger area and theoretically may have a lower stricture rate [51]. It is also important to remember that individuals who receive abdominopelvic radiation are at a higher risk of developing colorectal cancer. If there is not a reason to screen those patients earlier, they should definitely get surveillance done at 5 years post-completion of therapy.

Surgery

Surgical treatment is required for patients whose symptoms cannot be managed with medical or endoscopic therapy and also for complications such as perforations, fistulas, or strictures/obstruction. For both patients and surgeons, surgery is not something to be taken lightly. Individualized management plans are likely required depending on the context of the patient and discussion with at least one colleague or at a multidisciplinary setting regarding the management is recommended. Luckily, only 10 % of patients require an operative intervention for colorectal complications post-radiation [52]. In any type of bowel resection, one needs to be aware that anastomotic leak rates are high when putting two pieces of radiated bowel together and is lower if only one of the pieces is irradiated [53].

Pelvic fistulas can be one of the difficult problems that surgeons can encounter post-radiation. Similar management principles can be employed as with other types of fistulas—i.e., management of any ongoing sepsis and trying to optimize the situation for healing (knowing of course that with irradiated tissue fistulas are more difficult to repair) through measures such as nutritional optimization. With many of these patients whether it is a rectovaginal or rectourethral fistula, diversion will likely be necessary. Surgery will then

depend on factors such as how high the fistula is. Is it amenable to a perineal or abdominal approach and how will well-vascularized tissue be incorporated. The repair can therefore involve a flap reconstruction for a low rectovaginal fistula (i.e., gracilis or Martius) or a coloanal anastomosis with interposition of well-vascularized tissues such as omentum if it is a higher fistula. In the most severe cases, proctectomy or pelvic exenteration type procedures may be required.

Diversion may be helpful in non-fistula cases as well. Studies have shown that a colostomy or ileostomy may resolve symptoms of pain, tenesmus, sepsis, incontinence, and obstruction and improve quality of life to the point where further surgical intervention may not be needed [52, 54]. Because dissection can be difficult in an irradiated pelvis, transverse and descending colostomies were found to be safer than a sigmoid colostomy [52]. Diversion does not always help with bleeding, but there has been at least one retrospective study that has shown improvement in bleeding with a stoma [55].

Overall, on a 30-year retrospective review (looking at colorectal surgery for radiation injuries), the approach—resection versus diversion versus bypass—did not lead to a difference in success. It is not surprising, considering that it was a retrospective review where the surgeons picked an operative approach based on what was most reasonable [54]. The promising finding was that 70 % of patients had symptomatic relief. Of the different indications fistula repair had the lowest success rate (55 %) compared to stricture (78 %), hemorrhage (64 %), and perforation (100 %). It is sobering to note that the morbidity rate was 65 % with a mortality rate of 7 % [54]. The conclusion of this 30 years review is that treatment plans should be highly individualized and this lesson is likely the one that the surgeon should remember when dealing with these patients.

Microscopic Colitis

Introduction

First described in 1976, microscopic colitis (MC) is an inflammatory colitis and a relatively common cause of non-bloody diarrhea [56, 57]. Two main types of MC have been described: collagenous colitis and lymphocytic colitis [58]. Although considered to be a milder disorder when compared to other inflammatory bowel diseases such as ulcerative colitis and Crohn's disease [58], MC can have a significant impact on patients' quality of life [59, 60].

Epidemiology

The incidence of microscopic colitis is increasing [61–63]. In 2001, the estimate prevalence in the United States was 103 cases/100,000 persons [63]. It has been found in all age groups; however, it is more common in the older population and believed to be present in 10–30 % of patients older than 70 investigated for chronic diarrhea and presenting with a normal colonoscopy [58, 61, 62]. Collagenous colitis is more common in women, while lymphocytic colitis is equally distributed between genders [63, 64]. Relative incidence of collagenous vs. lymphocytic colitis varies between series; in a recent report, it was estimated that the prevalence of collagenous colitis was 39.3 per 100,000 persons vs. 63.7 for lymphocytic colitis [62, 63].

Etiology and Risk Factors

The cause of MC remains unknown; it is hypothesized to be multifactorial [65].

Genetics

A limited number of Familial cases of MC have been reported [62]. It is interesting to note that members of the same family can develop either collagenous or lymphocytic colitis [66]. An association has been found with HLA-DQ2 and TNF2 allele carriage and microscopic colitis suggesting a possible association with the pathogenesis of coeliac disease [67, 68]. On the other hand, NOD2/CARD15 gene, known to be linked to Crohn's disease susceptibility, was not found to be more frequent in MC patients compared to healthy controls [69]. MMP-9, another marker of inflammatory bowel disease, has been found more frequent in MC patients, but MMP 1 and 7 were not found to be associated with MC [70].

Infection

Stool cultures are negative in most patients with MC. However, onset after infection with *Yersinia enterocolitica*, *Clostridium difficile*, and *Campylobacter jejuni* has been described [58].

Smoking

In case–control study, smoking has been associated with an increased risk of MC (OR 2.12) [71]. In a retrospective review of 184 patients, smokers tended to develop symptoms earlier in their life: in one study the mean age at onset of diarrhea was 50.4 years old vs. 65.5 in the nonsmoking group. In the same study, smoking habits were not associated with increased risks of relapse [72].

Medications

Evidence regarding the association between MC and medications is equivocal. Some studies suggest a link between MC and nonsteroidal anti-inflammatory drugs (NSAIDS),

HMG-CoA reductase inhibitors (statins), proton pump inhibitors (PPI), and selective serotonin reuptake inhibitors (SSRI), while others did not find a similar association [64, 73]. Some classes of drugs potentially linked to MC such as NSAIDS and PPI are known to cause watery diarrhea as a common side effect confounding the potential causal relationship. Because they can exacerbate symptoms of a preexisting MC, further investigations may be prompted and lead to an MC diagnosis [74].

Autoimmunity

In a recent survey of 116 patients with MC, 30.4 % had an autoimmune condition [75]. Some diseases have a particularly strong association: celiac disease and thyroid disease. Other conditions that have been linked to MC include diabetes mellitus, arthritis, alopecia, psoriasis, and Sjögren's syndrome [75]. In contrast to Crohn's and ulcerative colitis, no association has been found with autoimmune liver conditions [58].

Clinical Manifestations

Clinical Presentation

Chronic, non-bloody, watery diarrhea is the hallmark of this disease [62]. It can occasionally lead to fecal incontinence, especially in the elderly. In a retrospective cohort study, fecal incontinence was present in 25 % of patients [76]. Watery diarrhea, even during flare-ups, rarely leads to dehydration [65]. Bile salt malabsorption can make diarrhea worse and therefore cholestyramine is sometimes used for treating these patients [77].

Weight loss is also common, being found in 41–46 % of patients [64, 76]. Abdominal pain is more common in MC patients compared to controls. Interestingly, patients considered to be in remission also have more abdominal pain compared to healthy control [65]. Fatigue is another frequent complaint of patients with MC, present in 50–60 % of patients; it is unclear if it is due to nocturnal diarrhea preventing rest or to the disease itself [58, 65].

Lymphocytic and collagenous colitis cannot be differentiated based on clinical presentation [62]. Interestingly, the pathologic abnormalities found in MC have been found in asymptomatic and constipated patients [65].

Complications

MC rarely leads to complications [62]. Cases of spontaneous perforation have been reported, but it is more common for perforation to occur as a result of a colonoscopy [78, 79]. "Fractured colon" associated with linear ulceration developing during colonoscopy has been described in collagenous colitis [80]. Collagenous deposition on the wall of colon is thought to render the wall less pliable and more likely to "fracture" during colonoscopy [81].

MC has not been found to be associated with an increased risk of colorectal cancer in a retrospective analysis of 547 MC cases [82]. A recent case–control study of 647 patients with MC followed for an average of 4.63 years found that MC was associated with a lower risk of colon cancer or adenomatous polyps [83].

Diagnosis

Histopathology is the mainstay of the diagnosis of MC. Because of the nonspecific clinical presentation the differential diagnosis is wide and includes inflammatory bowel disease, infectious colitis, medication-induced changes, celiac disease, bile salt malabsorption, lactose malabsorption, and irritable bowel disease [62, 84].

Colonoscopy with two or more biopsies in each of areas of the ascending, transverse, descending, and sigmoid colon respectively is the exam of choice to diagnosis MC. Biopsies should be sent separately [85]. The pathologic findings tend to be patchy involvement occurring anywhere in the colon; however, the disease is classically more severe in the right colon [84, 86]. Up to 30 % of rectal biopsies are normal in patients with MC, underscoring the need to obtain biopsies throughout the colon. MC was originally described in patients with a normal endoscopic exam and most patients with MC do have a normal exam. However, endoscopic abnormalities have been described in a small number. In a recent literature review of 42 articles (total number of patients included not mentioned), 88 patients with abnormal colonoscopy and a diagnosis of collagenous colitis were found. The most frequent findings were mucosal nodularity, alteration of the vascular pattern, and mucosal defects [87].

Pathologic findings of collagenous colitis include preserved crypt architecture and expanded lamina propria by a mixed inflammatory infiltrate, including plasma cells, eosinophils, and occasional neutrophils, mostly on the superficial portion underneath the surface epithelium. The crypt epithelium shows regenerative nuclear changes. Focally the subepithelial collagen layer is thickened, which is the main diagnosis feature, has a lacy appearance, and incorporates inflammatory cells and small capillaries. The surface epithelium shows markedly increased intraepithelial lymphocytes and focally may be detached from the mucosa. The pathologic findings of lymphocytic colitis include preserved crypt architecture and expanded lamina propria by numerous plasma cells, lymphocytes, and eosinophils. The surface and crypt epithelium are diffusely infiltrated by numerous T lymphocytes (diagnostic if >20 IELs per 100 epithelial cells), which by immunohistochemistry express CD3 and CD8 and lack CD4. The crypt epithelium shows hyperchromatic, regenerative nuclei (Figures 54-2 and 54-3).

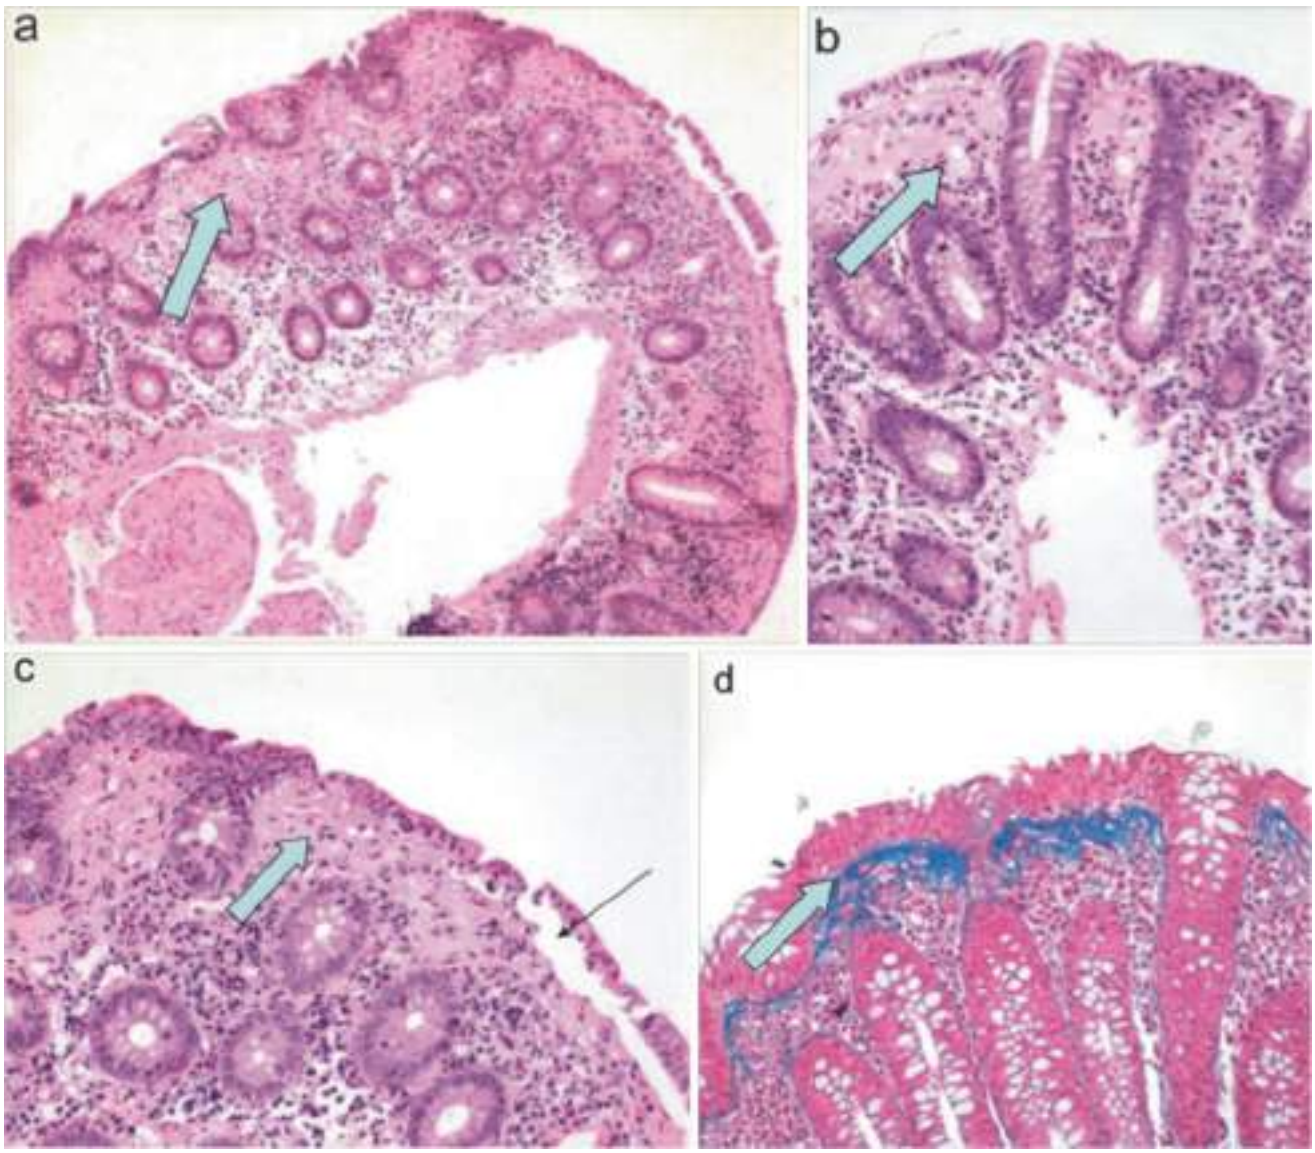

FIGURE 54-2. Collagenous colitis. (**a**) Colonic mucosa shows preserved crypt architecture. The lamina propria is expanded by a mixed inflammatory infiltrate, including abundant plasma cells admixed with eosinophils and occasional neutrophils, mostly on the superficial portion underneath the surface epithelium. The crypt epithelium shows regenerative nuclear changes. On several areas, the epithelial collagen layer is moderately thickened. Focally, the collagen band has a lacy appearance and incorporates inflammatory cells and small capillaries. The surface epithelium shows markedly increased intraepithelial lymphocytes and focally is detached (split) from the mucosa. Hematoxylin and eosin, ×100. (**b**) Thick subepithelial collagen layer, incorporating microcapillaries and inflammatory cells (*thick arrows*). Hematoxylin and eosin, ×200. (**c**) Thick subepithelial collagen layer, incorporating microcapillaries and inflammatory cells, with splitting of the surface epithelium (*thin arrow*). Hematoxylin and eosin, ×200. (**d**) Thick subepithelial collagen layer (*blue*), incorporating microcapillaries and inflammatory cells. Masson trichrome stain, ×200. Reproduced with permission from Celia Marginean MD.

Figure 54-4 presents an algorithm to illustrate pathologic diagnosis of MC. The term incomplete MC is used when a patient has pathological alterations not meeting the criteria for MC [85, 89]. A study conducted to assess observer variability in the diagnosis of MC found a high intra-observer and interobserver reliability for assessment of samples containing normal colon, inflammatory bowel disease samples, and MC samples. The reliability assessment for differentiating collagenous and lymphocytic colitis was lower but still good (κ=0.64–0.70 for types of MC vs. κ=0.84–0.86 for diagnosis of MC) [89].

Laboratory analysis usually shows nonspecific abnormalities such as mildly elevated inflammation markers. Fecal calprotectin and lactoferrin are not consistently elevated (in contrast to inflammatory bowel disease), limiting their use in the diagnosis of MC [90]. Research to identify reliable

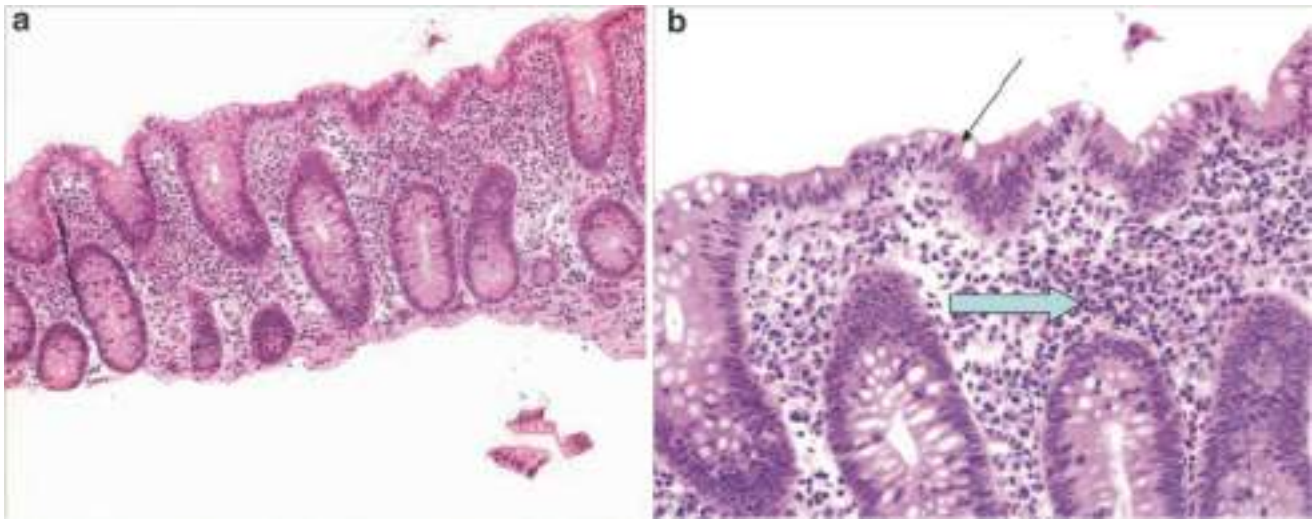

FIGURE 54-3. Lymphocytic colitis. (**a**, **b**) The colon shows preserved crypt architecture. FIGURE 54-4. Algorithm for pathological diagnosis. Adapted from Warren, Edwards & Travis, 2002 [86].

biomarkers is ongoing [58, 65]. Imaging is typically normal and does not have a role in the diagnosis of MC [58].

Management

There is no curative treatment for MC. The goal of the treatment is to control the symptoms. In 2009, after conducting multiple surveys, Hjortswang et al. published criteria to define clinical remission based on the impact of the symptoms on patient quality of life. According to their work, patient with a mean of <3 stools per day and a mean of <1 watery stool per day should be considered in remission [91]. The role of pathologic response in recurrence rate and quality of life is not known currently [62]. Patients should be advised to stop smoking and dietary factors (dairy product, alcohol, caffeine) should be controlled. Long-term remission has been documented in 63–80 % of patients depending on the series [77]. The treatment and frequency of treatment course varies and the main options will now be discussed:

Budesonide

In a meta-analysis of nine randomized controlled trials, budesonide was shown superior to placebo to induce clinical and pathological response. However, the recurrence rate with treatment cessation was high [92]. Two Cochrane reviews have been published on the treatment of collagenous colitis and lymphocytic colitis [93]. When budesonide therapy was continued for 6 months after clinical remission, it was shown to prolong the disease-free interval from 45 to 207 days with 83 % of patients maintaining response vs. 28 % in the placebo group [94]. Increased stool frequency (>5 per day) and symptom duration longer than 12 months have been identified as factors associated with shorter duration of remission [95].

Prednisolone

The role of prednisolone in the treatment of MC is limited. It is associated with more side effects than budesonide [58]. In a recent meta-analysis, it was not shown to be superior to placebo [92].

Cholestyramine and Loperamide

Antidiarrheals are often recommended as the first line of treatment. They seem to have the most benefit in patients with mild symptoms. They are unlikely to induce a pathologic response and the long-term efficacy has not been proven. Patients with MC not responding to budesonide or recurring symptoms after multiple cycles of treatment should be tested for bile salt malabsorption; affected patients could benefit from cholestyramine [58, 62, 65].

Aminosalicylates

The evidence supporting the use of aminosalicylates in MC is limited. In a three-arm randomized controlled trial comparing budesonide, placebo, and mesalamine, there was no statistically significant difference between placebo and mesalamine at 8 weeks in terms of clinical remission [96]. A previous trial comparing mesalazine alone and mesalazine with cholestyramine for 6 months reported a remission rate >85 % in both groups, with a 13 % relapse rate in the remission group at 2 years. There was no placebo arm in this study [97].

Immunosuppressive and Anti-TNF Medications

This class of medication is generally reserved for patients refractory to other types of medical management because of their potential side effects. The role of azathioprine and mercaptopurine in budesonide refractory MC was studied through a retrospective review of 46 patients. Overall, thiopurines achieved remission in 41 % of patients; side effects included elevated liver enzymes and nausea/vomiting [98]. The evidence supporting the use of methotrexate in budesonide refractory MC is conflicting with one study reporting a clinical response in 16 of 19 patients and another study showing no improvement in nine patients [99, 100, 102]. Small series (less than ten patients) refractory to standard medical management report symptom improvement with the use of anti-TNF medication [103–104]. Larger studies are needed to better define the role of immunosuppressants in MC.

Bismuth Subsalicylate

Bismuth subsalicylate has been widely used, but there is limited evidence to support its use. A recent Cochrane review found only one partially published trial on bismuth subsalicylate including nine patients [105]. It was found to induce remission in 100 % of patients at a dose of 262 mg, eight tablets divided into three doses for 8 weeks [84]. The same authors published a 13-patient series with a response rate of 85 % and a 7 months remission in 69 % of patients [106]. Interestingly, bismuth subsalicylate has been found to be useful in treating chronic intractable diarrhea in up to 74 % of patients in a 31-patient case series [107].

Other Medications

Many other medications have been used to treat MC. *Boswellia serrata* extract and probiotics were not associated with a statistically significant response to treatment [94]. Antibiotics such as metronidazole and erythromycin have been used, but their effects have not been formally studied [65].

Surgery

Surgery has a limited role in the treatment of MC. Loop ileostomy, subtotal colectomy, and proctocolectomy with J-Pouch have been described to treat severe intractable disease [108, 109]. Indications for surgery are ill defined and likely to be less frequent as our understanding of the optimal medical regimen improves [58, 62, 65].

Ischemic Colitis

Introduction

The term ischemic colitis was coined by Martson and published for the first time in 1966 [110]. Colon gangrene had been recognized since the late 1800, but the physiopathology of the disease had remained unsolved until the mid-twentieth century [113]. Ischemic colitis (IC) can be defined as "the condition that results when blood flow to the colon is reduced to a level insufficient to maintain cellular metabolic function" [111]. It is a fairly common disease usually self-limited. Affected patients are often frail which explain the relatively high rate of mortality associated with this disease [112].

Anatomy and Physiology

Branches from the superior mesenteric artery and the inferior mesenteric artery supply the colon. Splanchnic vessels are amongst the most reactive in the body, with blood flow varying from 10 to 35 % of cardiac output depending on physiologic or pathologic conditions [112]. This characteristic partially explains the high frequency of a low flow state in the colon. Two watershed regions have been described in the colon where ischemia is most likely: the splenic flexure (area of Griffith) and the recto-sigmoid junction (Sudeck's point) [113]. This is superimposed on the fact that the colon receives the least amount of blood flow in the gastrointestinal tract as measured by blood flow to 100 g of tissue [113].

Epidemiology and Risk Factors

The incidence of IC varies between 4.5 and 44 cases per 100,000 person-years. It is the most frequent site of gastrointestinal ischemia [113]. It is more common in females and in patients over the age of 65 [114]. It is recognized as a disease affecting older, comorbid patients. Chronic obstructive pulmonary disease, thrombophilia, history of irritable bowel disease, constipation, diabetes, renal failure, hypertension, extreme exercise, myocardial infarction, and history of vascular disease have been identified as risks factors [111, 114, 115]. Multiple drugs are known to increase the risks of developing colonic ischemia—a literature review published in 2007 documented drug classes having been linked with development of ischemic colitis [116] (Table 54-2).

Table 54-2. Pharmacologic agents in order of evidence strength [111, 116]

Moderate evidence (further research would like have an impact on authors' confidence in the estimate effect)	Constipation-inducing medications Immunosuppressive agents Illicit drugs
Low evidence (further research is expected to have an important impact on authors' confidence in the estimate effect)	Antibiotics Appetite suppressants Chemotherapeutic agents Decongestants Diuretics Ergot alkaloids Hormones Laxatives Psychotropic medications
Very low evidence (estimate effect is uncertain)	Digitalis Satins Nonsteroidal anti-inflammatory agents Serotonin agonists/antagonists Vasopressor

There is a classic association between ischemic colitis and AAA repair. A review of 89,967 patients undergoing AAA repair showed a global incidence of ischemia of 2.2 %. The type of repair performed correlated with the incidence of IC. Almost 9 % of ruptured AAA repair were complicated by IC in contrast to 1.9 % of open elective procedures and 0.5 % of endovascular repairs [117]. Following all types of AAA repair, IC was associated with a mortality of 37.8 % vs. 6.7 % for the patients without this complication.

With ischemic colitis being so frequent after ruptured AAA, it has been suggested by some that routine sigmoidoscopy could be beneficial in this patient population. In a prospective trial of 161 patients only one-third of patients found to have IC on routine endoscopy developed symptoms [118]. Importantly, routine use of colonoscopy has not been shown to improve patient outcomes and therefore is not recommended [111, 119].

The first manifestation of ischemia in a postoperative patient is often rectal bleeding, generally happening in the first 48 h after surgery. These patients should be investigated with endoscopy [115]. In patients requiring surgery, anastomosis should be avoided to minimize the risk of graft contamination [120].

Pathophysiology

Mechanisms of ischemic colitis can be divided into non-occlusive arterial ischemia, embolic or thrombotic arterial occlusion, and mesenteric vein thrombosis. The mucosa is the first layer of the bowel to show ischemic changes, after which if there is a progression all layers of the bowel wall can be involved. Because it is furthest from the mesentery, the antimesenteric part of the bowel is affected first [111]. Transient mucosal damage can be seen after 20 min to 1 h of insufficient blood flow with transmural changes occurring after 8–16 h [121, 122].

Non-occlusive Ischemia

Non-occlusive ischemia is responsible for 95 % of IC cases [120]. Non-occlusive ischemia can be idiopathic without identifiable cause or may be secondary to a medical or surgical condition diminishing colonic blood flow [111]. Colorectal vascular anatomy explains why IC happens on the left side of the colon in >75 % of cases but affects the rectum in only 5 % of patients [116, 117]. When the ascending colon is diseased, the cecum is the most frequently affected colonic segment [112]. Colonic injury and the systemic response to IC are due to both the hypoxic state and reperfusion injury [115]. Most of the evidence presented in the chapter is based on the management of this type of IC.

Arterial Thrombosis and Emboli Related Ischemia

An embolic source of ischemia is a less frequent cause of colonic ischemia. It is often seen with concomitant small bowel ischemia and the distribution is less likely to follow the zones of watershed area. In a case–control study on 60 patients with segmental non-transmural ischemia, patients with IC were 2.5 times more likely to have a cardiac source of embolism than control patients with similar comorbidities and medications but without IC. Thirty-two percent of patients were placed on anticoagulation and 25 % on antiarrhythmic therapy after cardiac work-up including transthoracic echocardiogram, electrocardiogram, and rhythmic Holter monitoring [112, 123].

Venous Thrombosis

Venous thrombosis is more frequently related with small bowel ischemia; and it is the rarest cause of IC [113]. It tends to affect the ascending colon more frequently than the descending. The management of this entity is usually nonoperative : systemic anticoagulation and occasional catheter-directed thrombolysis are typically used to improve the situation.

A new entity, mesenteric phlebosclerotic colitis, has been described in 2003. Its etiology is still unknown. Patients present with abdominal pain, mesenteric venostasis, and fibrotic and calcified veins. The optimal management of this condition remains to be defined, so far it has been mostly surgical for severe cases [114].

Clinical Presentation

Abdominal pain and rectal bleeding are the most frequent symptoms associated with acute IC [125]. Nine to twenty-four percent of lower GI bleeds are caused by ischemic colitis [111]. In a review of 401 IC cases, 5 % required a blood transfusion [125]. Abdominal pain is usually combined with an urgent desire to defecate [115]. Other symptoms include nausea, vomiting, abdominal distension, diarrhea, dizziness, and syncope [125]. Right-sided colitis is less likely to be associated with rectal bleeding and this diagnosis should be kept in mind in patients with isolated right-sided abdominal pain [111].

IC can evolve from an acute reversible colopathy (70 %) into different clinical patterns including gangrene (10 %), chronic colitis (18 %), and fulminant colitis (2 %) [126, 127]. Strictures form in 3.3–9.4 % of patient—they are asymptomatic in the majority of cases [111].

Diagnosis

Laboratory Studies

Results from laboratory studies are often nonspecific. Increased white blood count and acidosis are associated with infarction. There is no reliable marker of ischemia. Increased lactate, LDH, CPK, or amylase can sometimes indicate tissue damage [120].

Stool culture should be sent in patients with uncertain diagnosis. *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *E. coli* O157:H7, and parasites can cause a similar clinical picture. *C. difficile* should be considered even though it is usually not associated with bloody diarrhea [119]. *Klebsiella oxytoca* has been found in patients with right-sided hemorrhagic colitis mimicking ischemic colitis. It has been found more commonly in patients exposed to penicillin derivatives [128, 129].

Imaging

Plain films and contrast enema

In IC, plain abdominal films can be normal or show nonspecific findings of distention and ileus. Free air can be seen with perforation. Classic findings of bowel ischemia (i.e., thumbprinting and pneumatosis) are present in 21–30 % of plain films in patients with IC [111, 120]. Contrast enemas have a limited use in the acute phase as they may make ischemia worse by increasing intraluminal pressure. Contrast studies can be used after the acute process has resolved to assess stricture formation [115].

Abdominal CT scan

CT scans are frequently performed in the Emergency Room to evaluate patients with abdominal pain; CT scan with intravenous contrast is currently the imaging modality of choice to assess IC [111]. The accuracy of CT scan in determining bowel ischemia varies between 74 and 79 % depending on the study protocol and the experience of the radiologist [130]. In a recent review of CT imaging at different clinical phases during ischemia, 100 % of patients presenting in the acute phase had a radiologic abnormality, most frequently pericolonic fluid and free fluid, change in bowel wall densities, and

bowel wall thickening [131]. Pneumatosis was present in <5 % of patient in acute phase. The clinical significance of pneumatosis and portal venous gas is becoming controversial. It used to represent a definite sign of bowel wall necrosis and was associated with a dismal prognosis. However, recent reports have suggested that pneumatosis and portal venous gas can be associated with different conditions. Lassandro et al. described 25 other conditions presenting with pneumatosis [132]. In their review, pneumatosis and portal venous gas were a sign of transmural necrosis in 62–92 % [132]. When portal venous gas and pneumatosis were found in combination with bowel necrosis, the mortality rate was 71 % [132]. CT angiography has not been found to increase diagnostic accuracy in the acute setting [133]. It can be used to rule out superior mesenteric occlusion if clinically suspected; inferior mesenteric occlusion is of limited clinical significance as it is found in 10 % of asymptomatic patients older than 60 years old [111].

Endoscopy

Colonoscopy can be used to confirm the diagnosis of ischemic colitis and to exclude other etiologies for colitis. It should not be performed in patients with findings of peritonitis or known perforation. Findings indicating ischemia at the time of endoscopy include erythema (84 % of cases), edema (70 %), friability (43 %), superficial ulceration (57 %), deep ulceration (22 %), stenosis (8 %), and intraluminal blood (8 %) [117]. Disproportionate involvement of the antimesenteric side with occasional single linear antimesenteric ulcer and segmental involvement are also signs of IC. Hemorrhagic nodules can be seen if the ischemia reaches the submucosa. In severe and transmural ischemia, the bowel wall may be gray, green, or black [115]. It is difficult to evaluate the severity of the disease with endoscopy. In 2011, Beppu et al. presented a case series of 106 patients and compared their clinical course based on endoscopy findings. Patients with longitudinal and circumferential ulcers stayed in the hospital longer than patients with only redness and erosion [134]. Endoscopic findings should be integrated into the complete clinical context when making decisions regarding whether surgical or medical management should be undertaken [111]. If severe ischemia is suspected a biopsy should not be taken as the risk of perforation would be high. The endoscopy should be aborted when an ischemic segment is reached [111].

The features of acute ischemic colitis include preserved architecture of the colonic crypts, necrosis of the superficial portion of the crypts, sparing the deep portion of the crypts (with or without ghost of crypts), mucin depletion, and reactive changes in the residual crypt epithelium, which may mimic dysplasia. The lamina propria is hypocellular, with very rare or completely absent acute inflammatory cells (neutrophils), and shows hyalinization. Sloughed necrotic mucosa may produce a microscopic appearance of a pseudomembrane which is composed of fibrin admixed with numerous neutrophils and mucin. Numerous small intravascular hyaline thrombi are seen in small mucosal capillaries (Figure 54-5). Montoro et al. noted that those findings were more commonly observed in the first 48 h [124]. In more chronic presentation, mucosal atrophy and area of granulation tissue may be found as well as fibrosis in area of stricture [110].

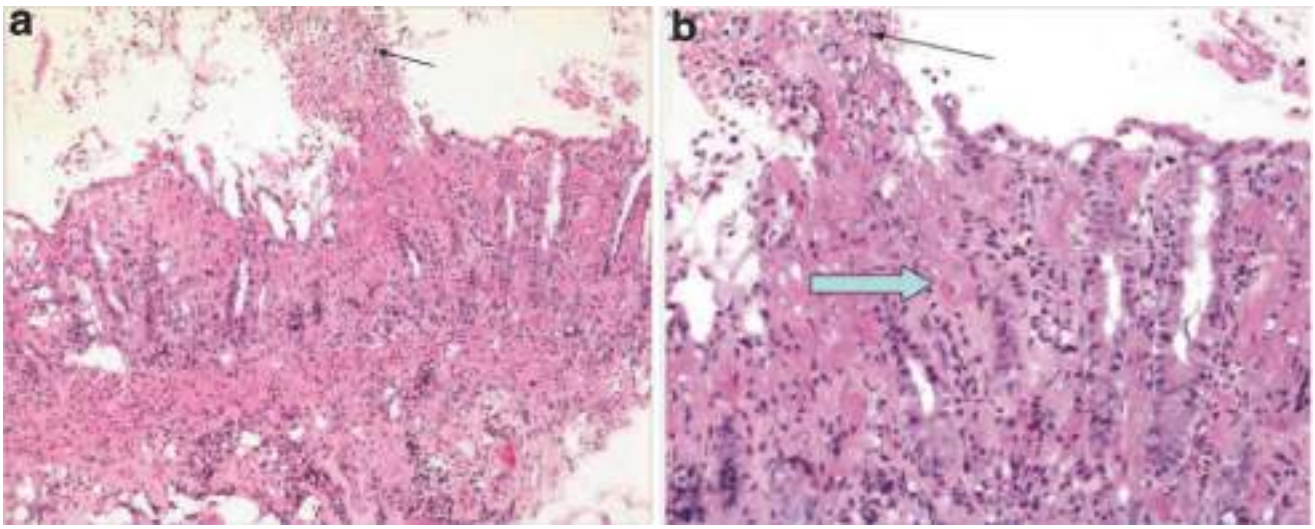

FIGURE 54-5. Ischemic colitis. (**a**) Colonic mucosa shows necrosis of the superficial portion of the crypts, sparing the deep portion of the crypts. The lamina propria is hypocellular and shows hyalinization (dense, eosinophilic color). Hematoxylin and eosin, ×100. (**b**) Sloughed necrotic mucosa may produce a microscopic appearance of a pseudomembrane erupting from a crypt, composed of fibrin admixed with numerous neutrophils and mucin (*arrows*). Numerous hyaline thrombi are seen in small vessels (*thick arrow*). Hematoxylin and eosin, ×200. Reproduced with permission from Celia Marginean MD.

Arteriography

Arteriography has a limited use in diagnosis of IC since it is usually an arteriolar disease. It can be used to exclude small bowel ischemia and large vessels occlusion. In the elderly and comorbid population usually presenting with IC, arteriography should be used cautiously, balancing the benefits of the information gained from the exam with the potential risks of a contrast load [115].

Ultrasound

Criteria suggestive of colonic ischemia include bowel wall thickening, altered pericolonic fat, and absence of Doppler flow with a thickened bowel wall. In a study of 62 patients with IC, the sensitivity of ultrasound was 93.5 %. Repeated exams showed improvement in patients successfully treated conservatively and no improvement in patients with transmural necrosis [135]. Ultrasound has its usual limitations—user dependent and limited by body habitus and the presence of bowel gas [116].

Management

There is limited empirical evidence to guide management of ischemic colitis [136]. Guidelines and recommendations are based on case series and expert consensus.

General Principles

Many patients with IC have a self-limited disease and would improve without specific intervention [111]. Treatment is usually supportive and includes the maintenance of hydration. Patients with an ileus may benefit from nasogastric tube decompression. Medications should be reviewed and those promoting splanchnic vasoconstriction should be stopped if possible and cardiac output should be optimized. Steroids should not be used to treat IC unless it is the consequence of a vasculitis [111].

Improvement should be seen in 1–2 days with complete clinical resolution in 1–2 weeks. Absence of improvement may suggest development of chronic ischemia or progression towards transmural ischemia.

If an endoscopy is performed in the acute phase, bowel preparation is contraindicated [115]. After complete resolution of the initial episode, patients should undergo a colonoscopy to ensure compete healing and assess for possible stricture [118]. Asymptomatic strictures can be observed; symptomatic strictures can be managed through surgical resection or endoscopic dilatation. Since no evidence supports the use of dilatation specifically for ischemic stricture, its use should be reserved for patients with too much comorbidity to undergo surgery [111]. The potential benefits of stent insertion in benign stricture remain to be defined [137]. In a retrospective study, balloon dilatation was associated with longer patency time than self-expandable stent and a lower rate of complications [138].

Antibiotics

Broad-spectrum antibiotics are recommended considering that the loss of mucosal integrity caused by ischemia can lead to bacterial translocation. However, there is no empirical evidence to support their use [111]. The use of antibiotics is based on older studies describing diminished bowel damage with antibiotics during an ischemic event [111]. Some studies conducted in animals documented bacterial translocation from bowel to mesentery and liver and also support the use of antimicrobials [120, 121].

The choice of antibiotic is based on expert opinions. Considering the possibility of translocation associated with bowel ischemia, the ACG guidelines recommend broad-spectrum antibiotics, and animal studies support the use of metronidazole [111].

Antithrombotic

Anticoagulation is not routinely recommended for patients with ischemic colitis secondary to microvascular pathology or low flow states. If bowel ischemia is due to venous thrombosis or arterial thromboembolic events, anticoagulation is indicated. Patients should be investigated for thrombophilia if no other risk factors are found on history. Antiplatelet agents are not generally recommended [120].

Surgical Management

Surgical indications include peritonitis, sepsis, radiologic evidence of perforation, suspicion of transmural ischemia on endoscopy, absence of improvement or deterioration under medical management (persistent sepsis or protein losing colopathy), and stricture causing obstruction [111, 115].

In the acute setting anastomosis creation is controversial especially on the left side. Huguier et al. published a series of 31 patients undergoing surgery for ischemic colitis: 17 had a primary anastomosis with a 11.7 % leak rate; the factors leading to primary anastomosis or stoma were not described [139].

Prognosis

Overall mortality rates vary from 4 to 12 % depending on the study [111]. In a recent literature review, 19.3 % required surgical intervention [140]. IC necessitating surgery is associated with higher mortality: 39 % in surgically treated patients vs. 6 % in medically managed patients [140].

The recurrence rate is difficult to compare amongst different patient cohorts because of the many factors involved in the development of the disease and its treatment. A retrospective review of 401 patients with IC found a recurrence

rate of 10 % at 5 years [125] and, not surprisingly, has been shown to increase with time [111]. Factors commonly associated with poor prognosis include right-sided colitis, male gender, peritonitis on presentation, absence of rectal bleeding, and concomitant renal dysfunction [140]. In a recent effort to establish a "prognostic scoring model" for IC, Chung et al. [141] reviewed 153 cases of IC. They identified ulceration on endoscopy, tachycardia, and shock in the first 24 h of presentation as the strongest predictor of poor outcomes defined as death, need for resection, and improvement delayed for more than 2 weeks [141].

Conclusion

There is no doubt that the term and conditions that encompass colitis span a varying spectrum of pathologies. Medical providers who care for these patients must have a thorough understanding of the medical, interventional, and surgical approaches to the diagnosis and treatment in order to optimize outcomes for this complex group of colonic pathologies.

Acknowledgments Thanks to Celia Marginean for her help with the pathology sections of this chapter.

Intestinal Stomas

Michael F. McGee and Peter A. Cataldo

Key Concepts

- Preoperative stoma site marking and patient education improve stoma-related clinical outcomes, patient quality of life, and experience, while decreasing healthcare resource utilization.
- The finished stoma should protrude from the skin which improves appliance sealing and decreases complications.
- Optimal care for patients undergoing ostomy surgery includes preoperative and postoperative care by an ostomy nurse specialist, such as a WOCN-certified nurse.
- Early stoma-related complications such as leakage, peristomal dermatitis, and dehydration can often be remedied with stoma care and education.
- Loop ileostomy is preferred over transverse loop colostomy for temporary fecal diversion in most circumstances.
- Stapled and hand-sutured techniques are both acceptable for loop ileostomy closure.
- Asymptomatic parastomal hernias do not mandate repair, while mild symptoms may benefit from appliance modifications or stomal support belt. Suitable-risk patients with significant parastomal hernia symptoms may be candidates for repair.

Introduction

Stomas are employed as temporary or permanent means of fecal diversion in the management of a variety of gastrointestinal, neurologic, and genitourinary conditions. Approximately 120,000 stomas are created annually in North America, with an estimated prevalence of 450,000–800,000 ostomates [1]. Stomas can be fashioned in an "end" or "loop" configuration depending on surgical strategy and perioperative conditions and are classified by the location of exteriorized bowel (e.g., colostomy, ileostomy, jejunostomy).

Intestinal stoma creation, often relegated as a minor component of a larger operation, will significantly impact the patient and his or her support system. Stoma-related complications are common, but even absent complications, patient dissatisfaction with stoma appearance, and body image can negatively impact quality of life. Societal stigmas, ignorance, and misunderstandings can further complicate care. Conscientious surgical stewardship and collaborative nursing care can decrease complications and improve quality of life for ostomates. As such, mastery of preparing, creating, caring for, and reversing stomas are a hallmark of the colorectal surgeon's armamentarium.

Colostomy

Configuration

Creation of an end colostomy may be indicated in several benign and malignant diseases for permanent or temporary enteric drainage (Figure 55-1a). Low rectal cancer, recurrent anal cancer, severe anorectal Crohn's disease, or severe radiation proctitis may require a permanent end colostomy. An end colostomy may be used emergently for severe sigmoid diverticulitis (i.e., Hartmann's procedure) and as a means of trauma-related damage control. An end colostomy may be required in patients who are not candidates for restorative procedures that establish continuity with the anus or rectum such as those with fecal incontinence, severe neurologic impairment, old age, prohibitive medical comorbidities, and prior resection of the anal sphincter complex. Although sphincter-preserving operations increasingly garner attention, the end colostomy remains a relevant and sometimes necessary entity.

A loop colostomy can be used to divert fecal flow proximal to a tenuous anastomosis or problematic distal bowel on a temporary or permanent basis (Figure 55-1b). The redundant, non-peritonealized nature of the sigmoid and transverse colon make each suitable for a loop colostomy, although high outputs and prolapse may hinder transverse colostomies. The dual lumen nature of the loop colostomy

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_55

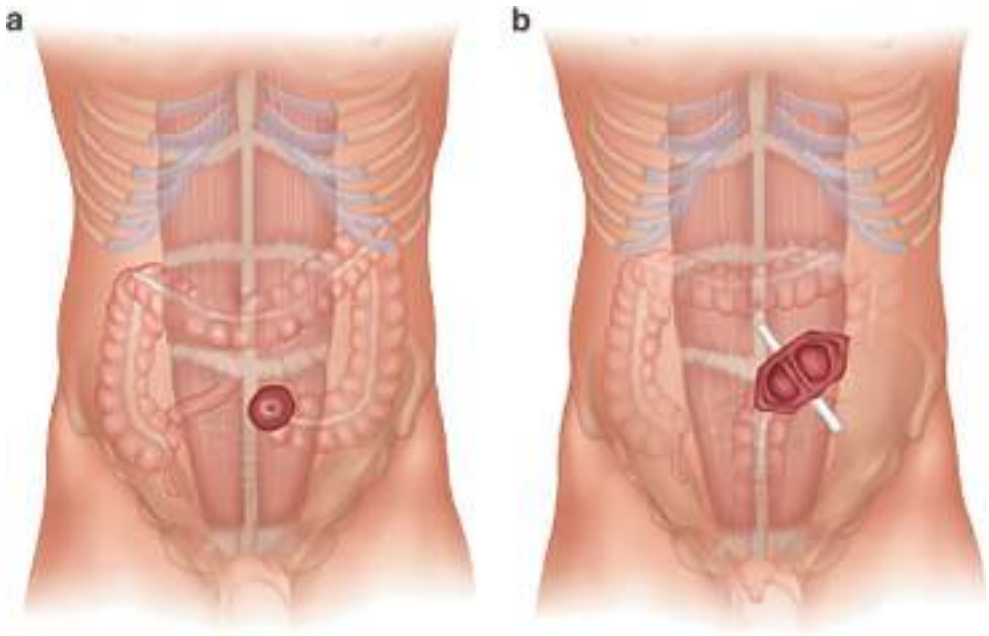

FIGURE 55-1. (**a**) End descending colostomy. (**b**) Loop sigmoid colostomy.

allows proximal diversion with retrograde venting of the distal segment, rendering the loop colostomy an excellent option for palliative diversion of obstructing lesions of the distal bowel. The loop colostomy may be used to temporarily protect colorectal or coloanal anastomoses. The loop colostomy may also be used to temporarily divert stool and facilitate staged repair for pelvic sepsis, rectal trauma, non-healing sacral decubitus ulcers, and anorectal fistulizing processes. Rarely, an iatrogenic or penetrating-trauma perforation of the colon can be mobilized and exteriorized as a loop colostomy, with the injury incorporated as the stoma orifice. Although a transverse loop colostomy is a relatively simple stoma to create, it is often poorly tolerated by patients due to its large size, cephalad location on the abdominal wall, and frequent stoma-related complications. In most instances, a loop ileostomy provides better short-term and long-term outcomes. Since both proximal and distal bowel conduits are accessed easily through the stoma trephine, loop stomas can often be closed easily through a peristomal dissection without laparotomy. Although loop stomas can usually be reversed easily, they may be employed on a permanent basis if needed and may be useful in the setting of unclear prognoses.

Physiology

Colostomy function is dependent upon the level of diversion. The colon receives approximately 1500–2000 mL of liquid stool from the small bowel daily, of which it reabsorbs approximately 90 % of water (1350 mL) and excretes 100–150 mL of water within solid waste [2, 3]. The majority of colonic fluid and electrolyte reabsorption occurs in the right colon. Distal colostomies arising from the sigmoid or left colon tend to produce more solid stool than proximal stomas fashioned from the transverse or ascending colon. Transverse colostomies may be more prone to fluid and electrolyte imbalances akin to small bowel stomas.

Similar to the wide range in bowel movement frequency and consistency seen across individuals, colostomies function variably. Since colonic transit time varies between 24 and 150 h [2], distal colostomies may function periodically as solid stool is propelled through the colon, whereas gas tends to pass more continuously. The episodic nature of stool passage through distal colostomies can lend itself to specialized colostomy irrigation techniques which may enable patients to control stool passage or occasionally avoid a stoma appliance altogether [4]. Proximal colostomies with liquid stool tend to function more continuously akin to small bowel stomas and are not well suited for stoma irrigation techniques.

Small Bowel Stomas

Configuration

Like colostomies, small bowel stomas (e.g., ileostomy, jejunostomy) can be used for permanent or temporary enteric drainage. A permanent end ileostomy (Figure 55-2a) is commonly used following a total proctocolectomy for Crohn's disease, whereas a temporary end ileostomy may be used following a total abdominal colectomy for ulcerative colitis for an eventual ileal-pouch anal anastomosis. Patients with hereditary cancer syndromes (e.g., familial adenomatous polyposis, hereditary non-polyposis colon cancer) who are poor candidates for restorative procedures may be offered a permanent end ileostomy. Repetitive bowel resections, which

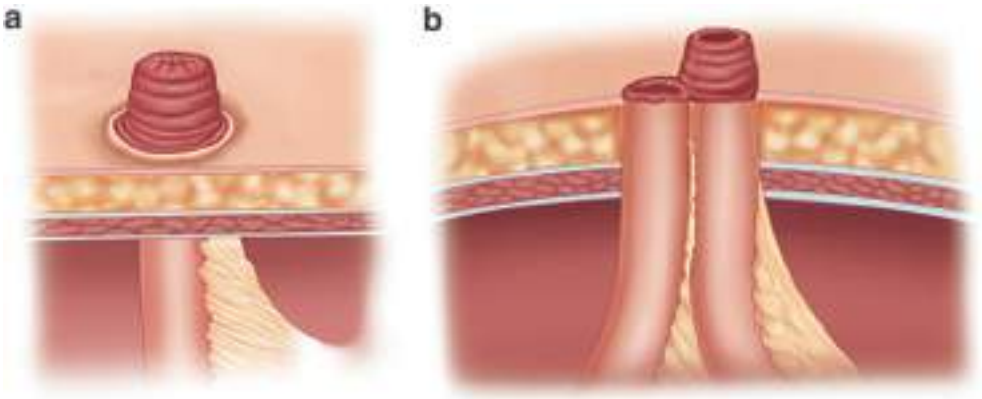

FIGURE 55-2. (**a**) End ileostomy. (**b**) Loop ileostomy.

may be seen occasionally in Crohn's disease, may require creation of a jejunostomy since no ileum may remain from prior resections. Akin to a colostomy, a temporary small bowel end stoma may be created in a damage control situation when anastomosis creation is inadvisable due to contamination, hemodynamic instability, poor tissue quality, or preoperative patient factors including nutritional status and immunosuppression.

Like a loop colostomy, a loop small bowel stoma (Figure 55-2b) is a helpful adjunct commonly utilized as temporary means of fecal diversion, although a well-constructed loop stoma can be permanent if needed. The small bowel caliber, robust vascularity, and distance from the distal colon and rectum make loop ileostomy a favorable choice for temporary diversion by many surgeons. Liquid ileostomy output can rarely lead to pouching problems, dehydration, electrolyte imbalance, and renal failure. A comparison of temporary diverting loop ileostomy and colostomy is debated later in this chapter.

Physiology

Since small bowel stomas bypass colonic sodium and water reabsorption, they may render patients with variable, but occasionally profound, fluid and electrolyte imbalances. Small bowel length is highly variable ranging from 275 to 850 cm [5] with a mean in situ length of approximately 500 cm [6] which receives from 9 to 10 L of fluid daily from proximal gastrointestinal sources. The majority of small intestinal nutritional absorption occurs within the first 150 of intestine, as nearly 6 L of fluid is reabsorbed from the jejunum while only 2.5 L is reabsorbed in the ileum [2]. Normal end ileostomy outputs can be highly variable ranging from 200 to 1200 mL daily with a composition listed in Table 55-1. As a result, stomas created more proximally in the small bowel (e.g., jejunostomy) bypass absorptive intestinal surface area and may cause nutritional, electrolyte, and fluid imbalance. Since fat-soluble nutrients are absorbed in the terminal ileum, proximal fecal diversion (greater than 100 cm proximal to the ileocecal valve) can render a patient with steatorrhea and vitamin B12 deficiency. Even creation of a new terminal end ileostomy that preserves the total length of small bowel may be transiently prone to high outputs due to diversion of the ileocecal valve and colon. Management of high ileostomy outputs is detailed later in the chapter.

TABLE 55-1. Composition of normal ileostomy effluent

	Daily excretion	Range	Concentration	Range
Wet weight	500 g	200–600 g		
Dry weight	38 g	24–48 g		
Water content			92 %	88–94 %
pH			6.3	6.1–6.5
Sodium	55 mEq	30–80 mEq	115 mEq/L	100–130 mEq/L
Potassium	4 mEq	3–6 mEq	8 mEq/L	5–11 mEq/L
Chloride	20 mEq	15–30 mEq	45 mEq/L	15–40 mEq/L
Calcium	18 mEq	15–40 mEq	25 mEq/L	10–64 mEq/L
Magnesium	8 mEq	7–9 mEq	15 mEq/L	10–28 mEq/L
Phosphorus	150 mEq	122–202 mEq		
Nitrogen	1 g	0.6–2.4 g		
Fat	2.2 g	1.5–3.8 g

Preoperative Considerations for the Ostomate

As with most aspects of surgery, conscientious preoperative preparation is essential and can profoundly impact the patient. Preoperative stoma site marking and patient education improve stoma-related clinical outcomes and patient quality of life and experience, while decreasing healthcare resource utilization. Although many medical centers provide robust complementary ancillary resources to assist the ostomate and surgeon, the surgeon is ultimately responsible for perioperative care and should be competent in preoperative stoma preparation.

Stoma Site Marking

Routine preoperative identification of potential stoma sites is a crucial skill for the colorectal surgeon and is recommended by ASCRS and the Wound, Ostomy, and Continence Nurses Society whenever stoma creation is a possibility [7, 8]. Preoperative stoma site marking decreases postoperative complications [9, 10] and improves stoma-specific quality of life, overall patient quality of life, confidence, and independence compared to non-marked patients and may decrease stoma care costs [11]. Creating any intestinal stoma, whether permanent or temporary, in a properly chosen location is the most important predictor of an ostomate's quality of life following stoma construction.

The ideal stoma site is based on individualized assessment of the patient with respect to body habitus, contours, scars, bony prominences, and the umbilicus assessed in the standing, sitting, and laying positions. Special consideration to the patient's lifestyle, occupation, impairments, and preferences should be sought in conjunction with the patient. The "stoma triangle" (Figure 55-3a) is bounded by the anterior superior iliac spine, the pubic tubercle, and the umbilicus and has

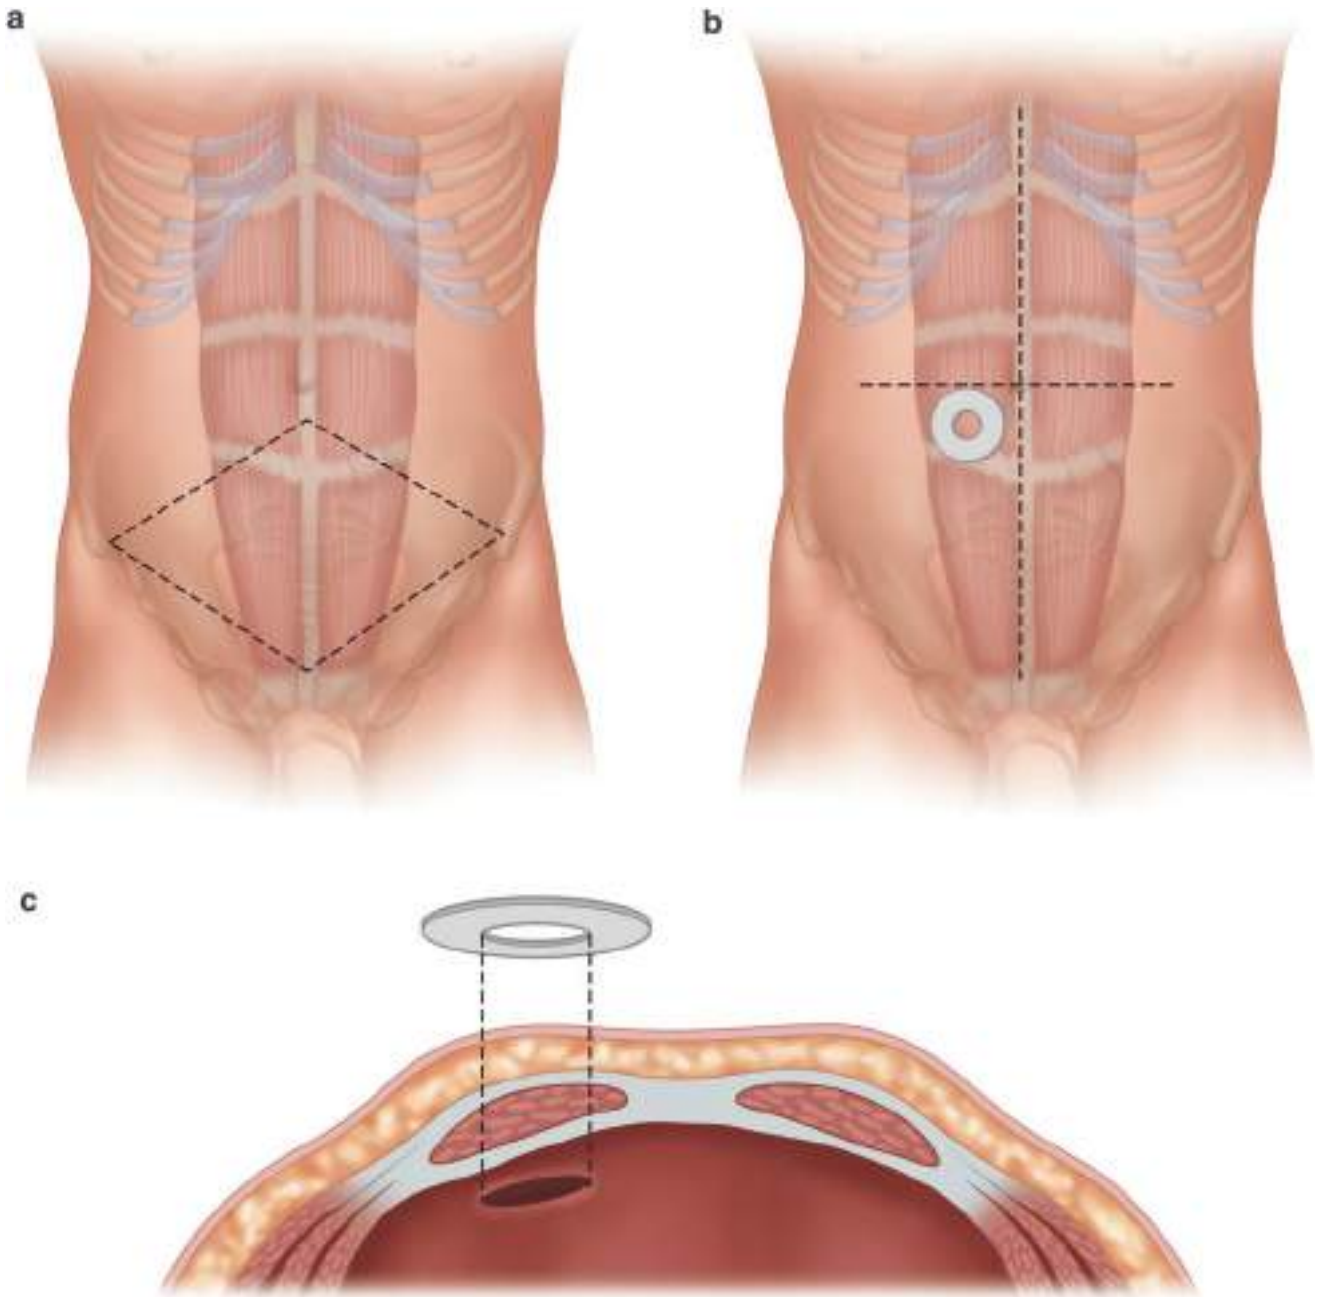

FIGURE 55-3. (**a**) The "stoma triangle." (**b**) Intersection of the infraumbilical fat pad and rectus sheath, marked by a stoma siting ring. (**c**) Cross-sectional view of the stoma trephine path and stoma siting ring, fashioned perpendicular to the abdominal wall without veering medially or laterally.

FIGURE 55-4. (**a**) A loop ileostomy created too close to an incision which interfered with stoma appliance sealing, resulting in leaks and marked skin excoriation (photo credit: Michael McGee). (**b**) A transverse loop colostomy created too close to the costal margin, causing frequent appliance dislodgement (photo credit: Michael McGee). (**c**) Stomas created in a skin fold, which may not be realized until the patient is sitting or bending over [photo credit: Wound, Ostomy, and Continence Nurses Society (http://www.wocn.org/page/ImageLibrary)].

been used by some groups to initially direct the surgeon to a preliminary area suitable for stomas [12]. The stoma site is at the geometric center of the triangle within the rectus sheath. Alternatively, the surgeon may identify the intersection of the infra-umbilical fat pat summit and the rectus sheath as a preliminary stoma site (Figure 55-3b, c) [13]. All efforts should be made to keep the stoma within the rectus sheath, as this is argued to decrease risk of parastomal herniation, although meta-analyses failed to show an effect in stoma location [14, 15].

After preliminary selection of a site, the surrounding peristomal skin must be carefully inspected ensuring the site avoids scars, folds, creases, and the umbilicus that may hinder stoma appliance application and cause leakage (Figure 55-4a). Ideally, the site should have a 2-in. perimeter of clear, intact skin to adequately seal with a stoma appliance, and a commercially available stoma-siting disk may help with siting (Figure 55-3c). The costal margin, anterior superior iliac spine, and pubic symphysis should be avoided since these bony prominences may dislodge the stoma appliance (Figure 55-4b). Skin folds and creases are not typically appreciated until the patient is sitting, so the correct site should be reconfirmed once the patient is sitting (Figure 55-4c). While the patient is sitting, it is equally important that the patient has a clear sight line to the stoma site. Patients with a large pannus may require moving the site superiorly along the rectus to a supra-umbilical sight ensuring sight lines to the intended area. Moreover, an obese pannus may be thinner superiorly compared to inferiorly, easing stoma trephine creation. Lastly, the patient should be assessed while standing to confirm that the intended site avoids the pants waistline, pendulous breasts, or hernias. While standing, attention to the patient's posture, contractures, and stoma site location while bending should be assessed. Finally, reviewing potential stoma sites with the preoperative patient confirms suitable sites for both patient and practitioner.

Stoma sites should be marked with an indelible marker or tattooed with a fine gauge needle (26 gauge) and India ink [13]. Stoma sites can be marked several days in advance and protected with an occlusive transparent dressing to protect the ink from washing away. Multiple potential stoma sites can be identified, marked, and ranked in order of preference affording the surgeon options should intra-operative findings require alternate stoma locations. Rarely, two stomas may be required for urinary and fecal drainage (e.g., for pelvic exenteration) and each stoma site should be created on opposite sides and at different levels whereby avoiding interference in case a stoma belt is needed. Since preoperative stoma site markings may wipe away with antiseptic skin preparations, the surgeon may find it helpful to etch a small epidermal scratch mark at each site with an 18-gauge needle following anesthesia induction to mark the site for the duration of the operation.

Preoperative Stoma Education

The mainstay of stoma education traditionally occurs in the postoperative period; however, emerging evidence suggests that preoperative stoma education may be equally important. Several factors may hinder postoperative stoma education. Pain, medications, and psychological stress may diminish

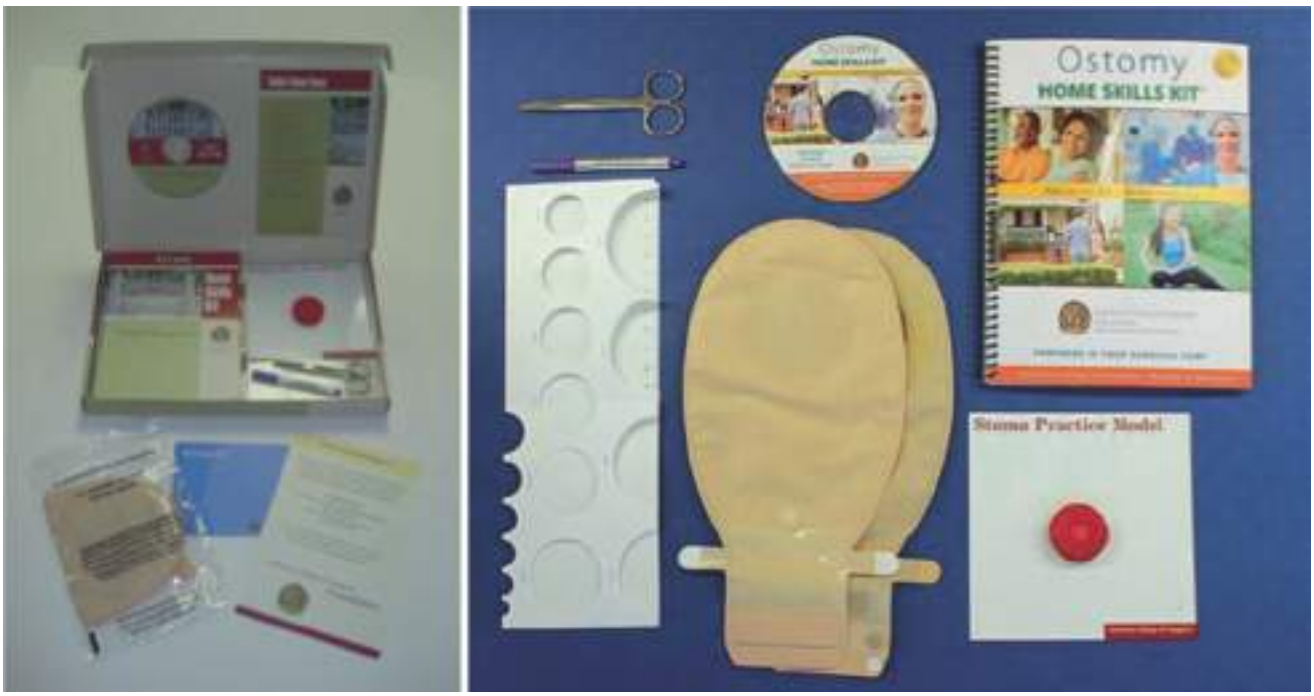

FIGURE 55-5. The American College of Surgeons Ostomy Home Skills Kit (photo credit: American College of Surgeons).

educational effectiveness in the early postoperative period where by increasing the value of preoperative education. Chaudhri et al. reported that two, 45-min pre-op visits with audiovisual aids and instruction decreased time to stoma care proficiency from 9 to 5.5 days, decreased hospital length of stay from 10 to 8 days, and decreased unplanned provider encounters with a net cost savings of $2104 per patient [16]. Similarly, Younis et al. revealed preoperative patient education sessions reviewing stoma models, sample appliances, and supplies decreased inpatient length of stay from 14 to 8 days [17]. Free and low-cost, commercially prepared, preoperative resources are available from stoma supply manufacturers and through the American College of Surgeons (ACS). The ACS Ostomy Home Skills Kit (Figure 55-5) contains an instructional DVD demonstrating stoma care techniques, sample stoma supplies, and a plastic model stoma that allows the patient to simulate preoperative stoma care. The standardized interactive program has been developed by the American College of Surgeons (ACS) in collaboration with the American Society of Colon and Rectal Surgeons (ASCRS) and other societies and organizations. Over 55,000 kits have been distributed since release in 2010. Preliminary, unpublished data from the ACS reveal that patients receiving the Ostomy Home Skills Kit preoperatively were more confident with stoma care, were less likely to have problems, required less provider help once home, and were more satisfied with their care compared to patients receiving standard postoperative stoma education.

Technical Considerations of Stoma Creation

Small Bowel End Stoma

Small bowel end stomas are typically easy to create owing to the mobility of the robustly collateralized small bowel mesentery. Laparoscopic or open approaches may be used, although the laparoscopic approach is favored, if feasible [7]. After selecting the target small bowel segment, care is taken to ensure the mesentery is fully mobilized and all adhesions are freed to allow tension-free reach beyond the abdominal wall. Division of some mesenteric vessels may be necessary to obtain adequate reach, particularly in patients with a thick abdominal wall.

During open surgery, identification of mesenteric vessels can be assisted by transillumination of the mesentery with a light source, providing guidance on which vessels to preserve or sacrifice to sustain stomal perfusion, if needed. Akin to preparing bowel for an anastomosis, careful assessment of bowel perfusion can avoid ischemia-related stomal complications such as stenosis and retraction. Obese patients or those with thickened or inflamed small bowel mesentery may require additional lengthening maneuvers detailed later in this chapter (see section “Special Considerations: The Difficult Stoma”).

Once adequate mobilization of the small bowel segment is obtained, a cylindrical stoma trephine is created at the previously marked stoma site. For an end ileostomy with normal

caliber bowel and mesentery, the authors prefer to excise an approximately 2-cm diameter skin disk and vertically divide the subcutaneous tissues down to the level of the anterior rectus sheath without "coring" or removing subcutaneous tissues. During open surgery, an assistant's two fingers firmly pushing a folded gauze sponge anteriorly at the intended point of peritoneal entry may ease trephine creation by compressing the tissue girth and ensuring the trephine cylinder remains orthogonal to the abdominal wall (Figure 55-6). The anterior rectus sheath is incised with a 3-cm vertical incision. The exposed fibers of the rectus muscle are carefully split with a large clamp to allow lateral and medial distraction of the split rectus muscle to expose the posterior rectus sheath. Special care is taken to ensure all fibers of the rectus muscle and inferior epigastric vessels are completely split and retracted to avoid pesky muscular bleeding. With the posterior rectus sheath exposed, cautery is used to make a 3-cm vertical incision directly onto the assistant's gauze sponge, whereby completing the stoma trephine. Passage of one or two fingers through the completed trephine gently dilates and confirms trephine size. If necessary, the trephine diameter can be further enlarged by making a radial skin incision at the skin level or extending either anterior or posterior rectus sheath incisions.

Laparoscopic approaches follow the same general principles as open surgery. After assuring adequate mobilization laparoscopically, an abdominal wall trephine is made. If an extraction site is present, a trephine can be made akin to open surgery with an assistant using two digits pressing upward. If no extraction site exists, careful trephine creation is needed to avoid injuring intra-abdominal contents while incising the posterior rectus sheath and peritoneum. Once the trephine is completed, pneumoperitoneum is quickly lost and it can be difficult to locate target segment of bowel through the small trephine. An extra-small plastic sleeve wound retractor placed in the stoma trephine may aid visualization. The authors suggest placing a locking atraumatic bowel grasper on the tip of target loop of bowel, left immediately under the peritoneal side of the stoma trephine so that the bowel can easily be visualized once pneumoperitoneum is lost. Once the abdomen is desufflated, the laparoscopic bowel grasper can be directed to a stoma trephine. Once the target bowel is identified through the trephine, it can then be transferred to a Babcock clamp placed through the trephine.

For both open and laparoscopic techniques, the previously mobilized bowel segment is carefully delivered through the properly sized trephine with assistance of a Babcock clamp. To avoid stoma retraction, 5–6 cm of small bowel and corresponding mesentery should be completely pulled through and be left above the level of the skin. Care should be taken to carefully coax the corresponding bowel mesentery through the trephine without injury or avulsion. A bimanual approach may be necessary to gently push and guide the bowel mesentery from the peritoneal surface while the surgeon is gently pulling the bowel at the skin. The blunt side of an Adson tissue forceps can be used as a shoehorn and assist the stoma mesentery eviscerate if it lodges at the rectus sheaths or subcutaneous tissues. Additional techniques are described to help coax the difficult stoma through the abdominal wall later in the chapter (see section "Special Considerations: The Difficult Stoma"). With an adequate length of bowel exteriorized through the abdominal wall, the stoma should be assessed for tension, viability, and mesenteric bleeding. A persistently dusky stoma may be related to mesenteric vascular injury, venous outflow occlusion from a narrow trephine, or unintentional vascular division during mesenteric mobilization and should be revised prior to closing the abdomen. Typically, the stoma is left for maturation until all other abdominal wounds are closed to minimize incisional contamination.

Once all remaining abdominal wounds are closed and protected from topical contamination, the end ileostomy is matured to ideally protrude 2–3 cm. Ileostomy maturation is necessary to cover and protect the eviscerated bowel serosa with mucosa, whereby shielding it from the caustic bowel effluent which can cause inflammatory serositis and ileostomy stricture. If the ileostomy was stapled closed, the staple line is excised and the full thickness of the bowel wall is everted. Occasionally, thick or fatty mesentery may require careful debulking to allow complete bowel wall eversion. Multiple interrupted absorbable sutures are used to suture the everted bowel wall to the skin (Figure 55-7). Classically, such "Brooke" sutures also incorporate a seromuscular purchase of the bowel at the skin level that fixes the everted structure at the skin. Sutures should carefully be placed through the dermis, but not the epidermis, to avoid mucosal cellular implants that have been reported to migrate along suture lines and colonize the epidermis with ectopic mucosal islands. Such dermal mucosal islands are thought to secrete mucus on the peristomal skin and interfere with stoma appliance adhesion [18]. The finished end small bowel stoma should ideally protrude 2–3 cm from the skin that distances the skin–appliance sealing interface from the point of stool egress that improves sealing and decreases complications [7, 10]. Flush or inadequately protruding small bowel stomas may be fraught with leakage since caustic liquid small bowel contents can easily leak underneath the stoma flange causing painful, excoriated, weeping skin wounds that are difficult to pouch. Ileostomy heights less than 2 cm are associated with problems, and the height of the stoma is inversely proportional to likelihood of complications [19]. Since a significant portion of end stomas will be permanent, the surgeon should take great care in making the perfect stoma, which may save the patient, surgeon, and family a lifetime of frustration.

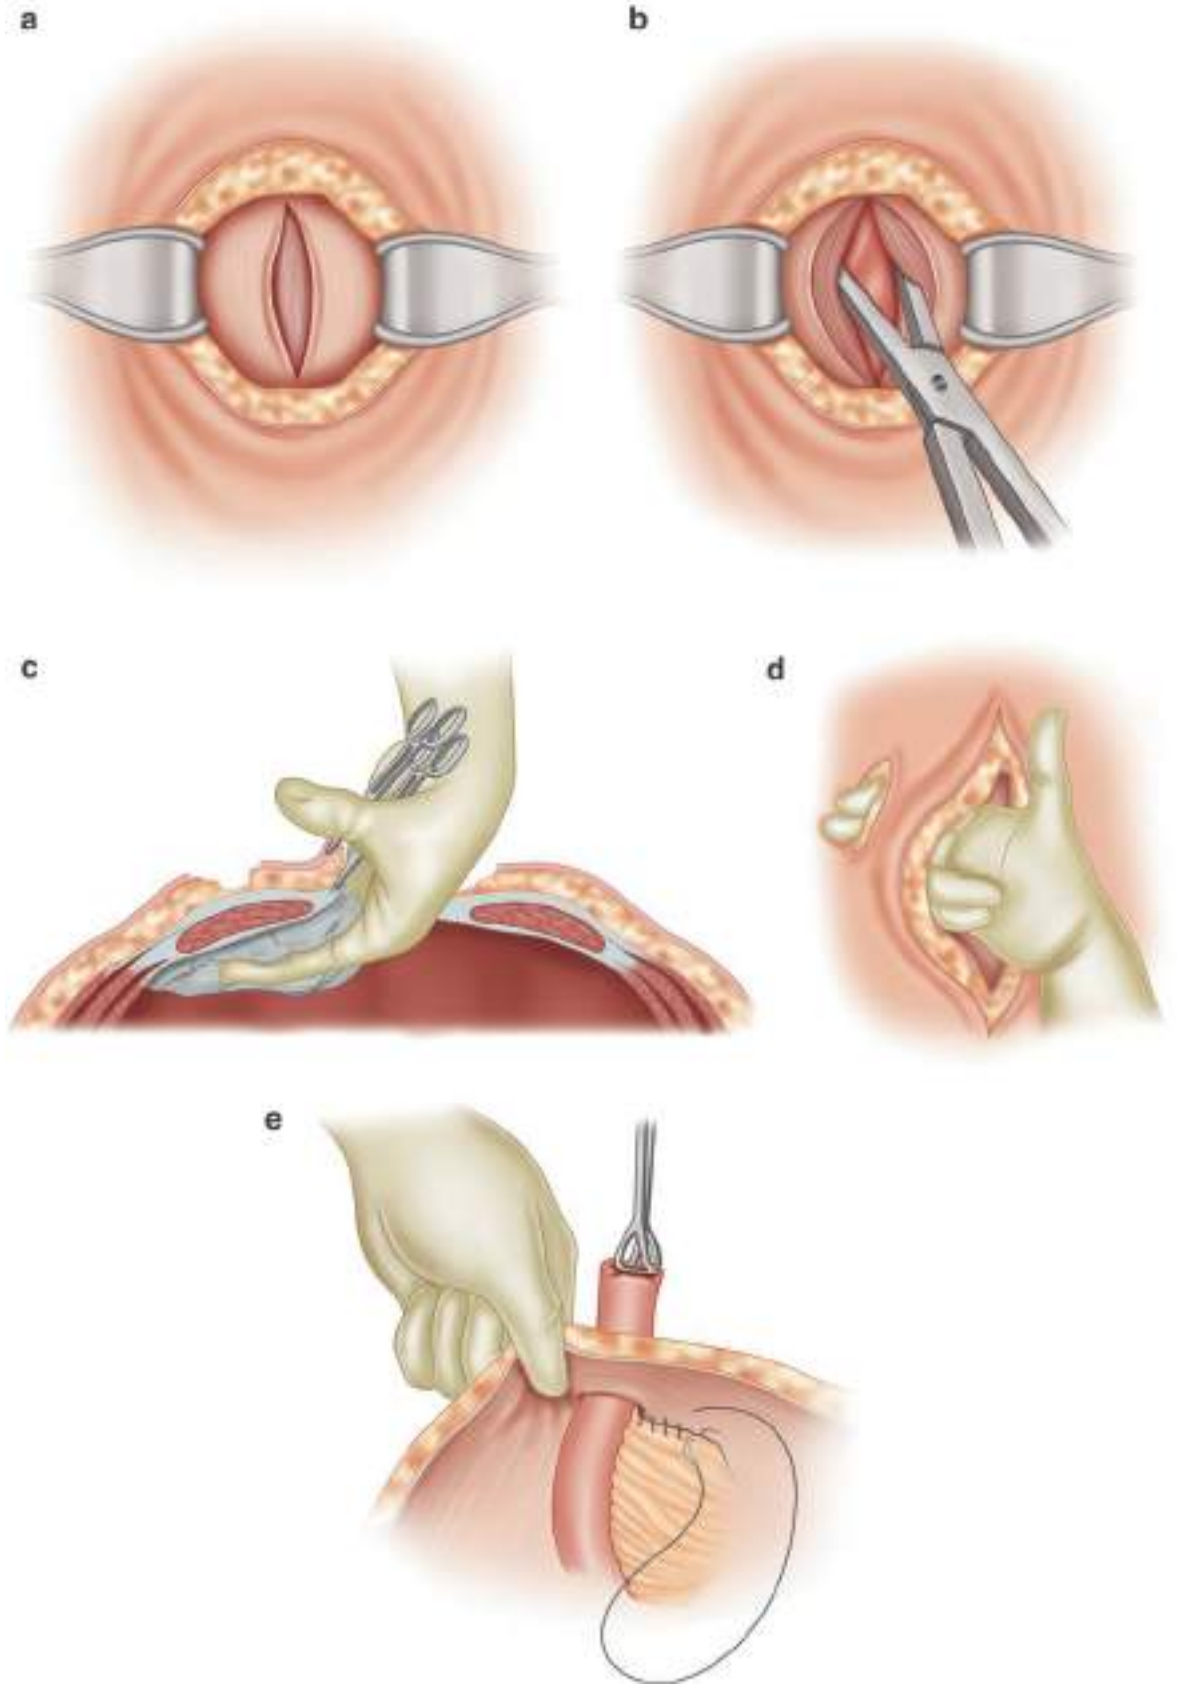

FIGURE 55-6. Creation of an end small bowel stoma. (**a**) A 2-cm skin disk is excised and the subcutaneous tissues are split to the level of the anterior rectus sheath. (**b**) The anterior and posterior rectus sheaths are incised vertically and the rectus muscle is split. (**c**) An assistant may assist in stoma creation by pushing anteriorly using a folded sponge to protect intra-abdominal contents. (**d**) Two fingers are passed through the completed stoma trephine to assure adequate sizing. (**e**) The ileostomy is eviscerated with assistance of a Babcock clamp.

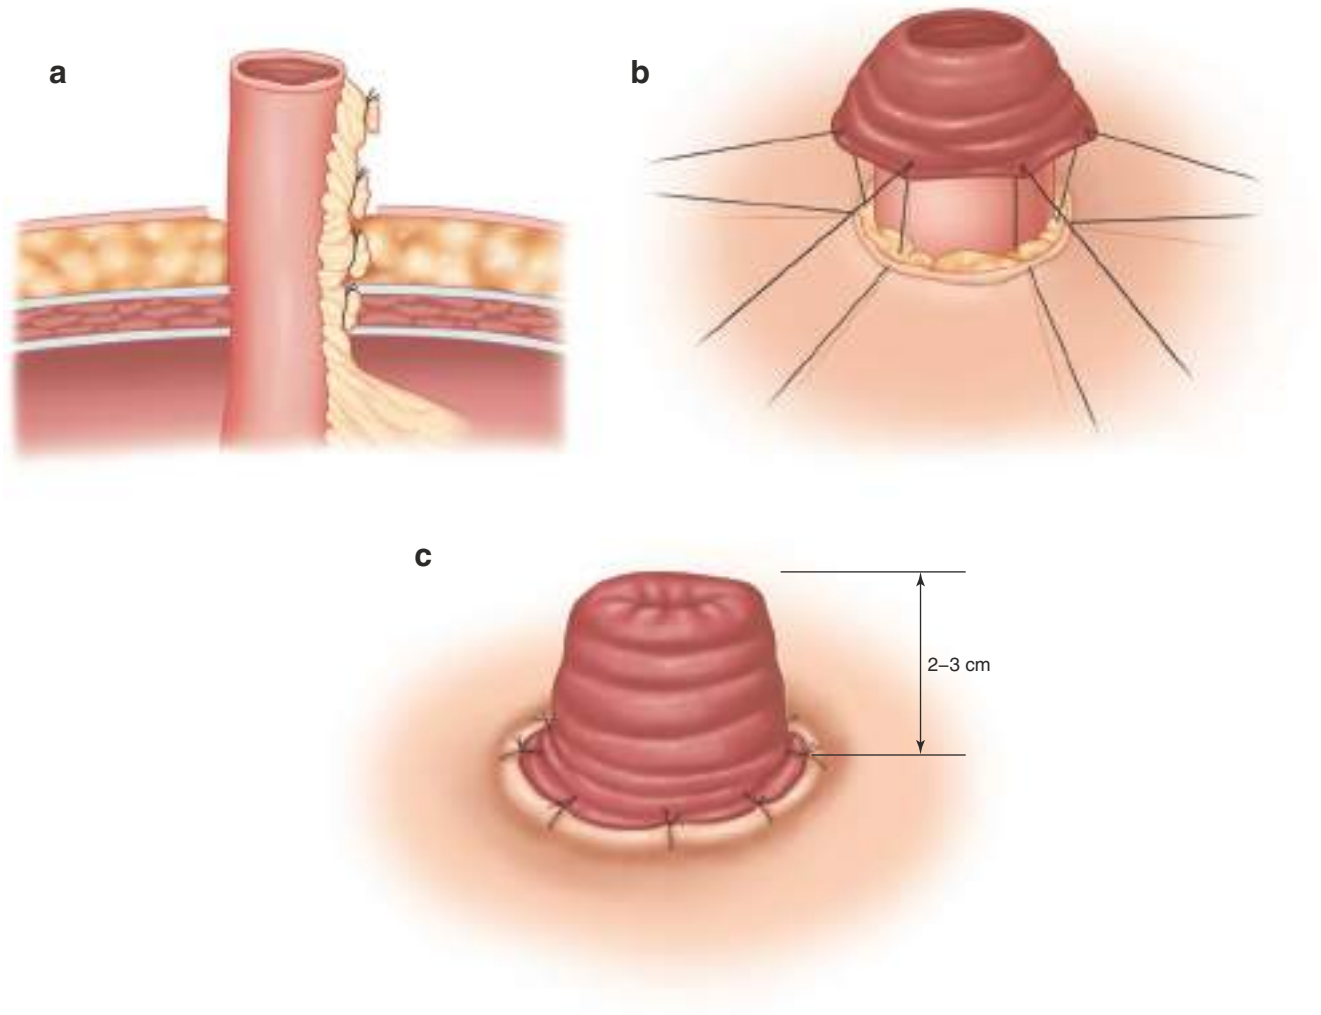

FIGURE 55-7. Maturation of an end small bowel stoma. (**a**) An adequately mobilized, tension-free, length of small bowel is eviscerated through the stoma trephine. (**b**) Multiple interrupted absorbable sutures are used to mature the stoma. (**c**) The completed small bowel stoma should ideally protrude 2–3 cm from the skin level.

Small Bowel Loop Stoma

Small bowel loop stomas are fashioned with either laparoscopic or open techniques with a segment of well-mobilized bowel free of adhesions. For open loop stomas, a fine-tipped clamp is passed to create a small defect at the bowel wall–mesentery interface and a thin Penrose drain or umbilical tape is passed underneath the bowel (Figure 55-8). Some prefer to place different colored seromuscular marking stitches to orient the bowel limbs and prevent twisting and inadvertently maturing the distal limb of the loop. Alternatively correct bowel orientation can be insured by drawing an arrow on the anti-mesenteric border of the bowel, indicating the proper direction of intestinal flow. A 2.5-cm diameter stoma trephine is made at a previously marked site using the previously described technique. Generally, the stoma trephine is made slightly larger for loop stomas than end stomas, and the final trephine typically accommodates two fingers easily. The Penrose drain is then used to safely pull the loop of bowel through the stoma trephine while minimizing trauma to the bowel. The surgeon confirms that there is no twisting of the mesentery. The blunt paddle-like back end of an Adson forceps is again helpful if the bowel is caught at the fascia or dermal level. The Penrose drain may be exchanged for a plastic stoma rod to temporarily support the bowel loop above the skin until adhesions form between the trephine and bowel wall, although the utility and type of a supporting rod is debatable [20]. If used, the rod should not be under significant posterior tension and additional bowel should be mobilized or pulled through the trephine if the rod is causing a deep indentation. Laparoscopic loop stomas are made similarly to laparoscopic end stomas as detailed above.

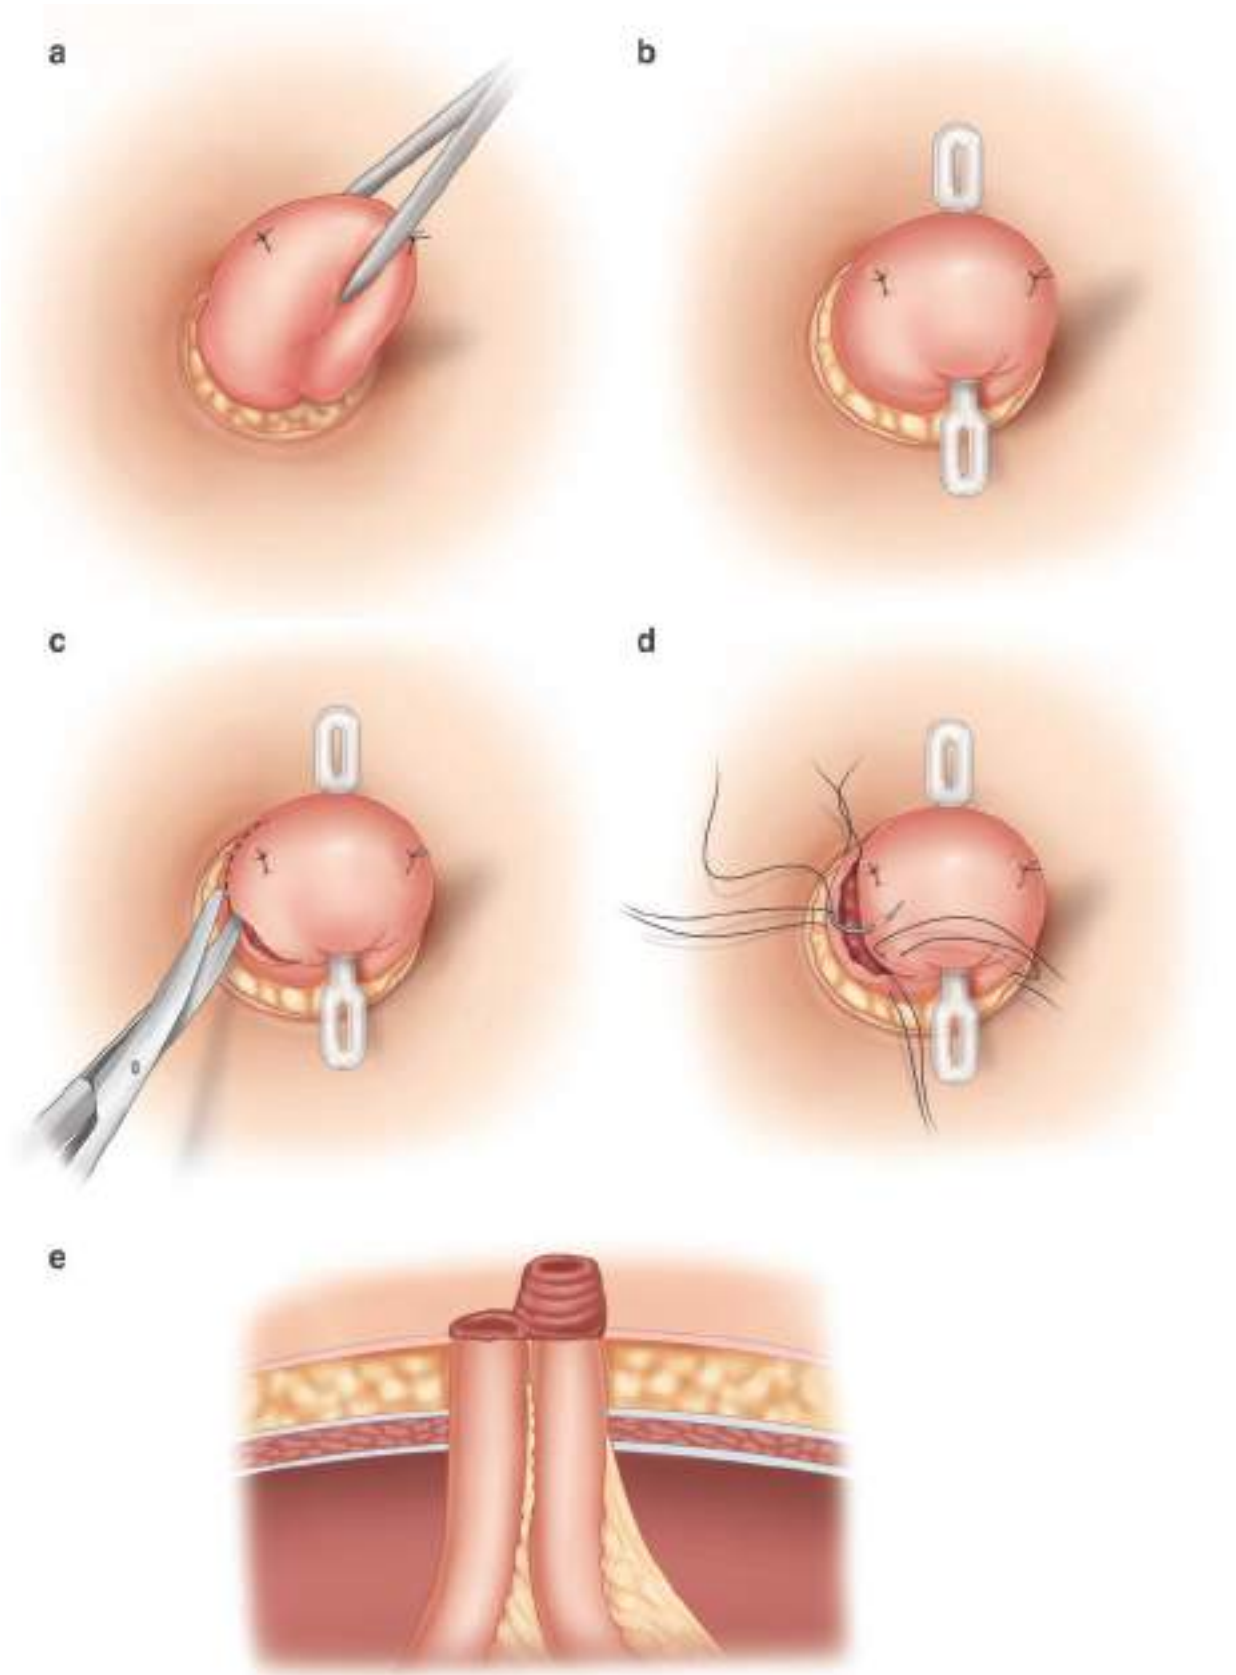

FIGURE 55-8. Creation of a loop small bowel stoma. (**a**) A narrow Penrose drain is passed through a mesenteric defect and used to gently pull the target loop through the stoma trephine. (**b**) The Penrose drain may be exchanged for a stoma rod. (**c**) The distal segment of the loop stoma is opened at the skin level. (**d**) The distal "hood" of small bowel is then everted and sutured over the proximal limb to create a spout. (**e**) The completed small bowel loop stoma.

Following closure and protection of all abdominal wounds, a near-circumferential incision is made along the distal limb bowel wall at the level of the skin. The mesenteric portion of the bowel wall is left intact and is not divided. Absorbable sutures are used to secure the defunctioned segment to the dermis. The remaining "hood" of bowel is then everted with the blunt back end of an Adson clamp and sutured to the dermis. As with end small bowel stomas, the proximal bowel limb should protrude 2–3 cm from the skin when finished allowing a watertight fit between the stoma appliance and the peristomal skin whereby decreasing postoperative stoma-related complications. When used, the stoma rod is typically removed in 3–5 days once adhesions have formed assuming there is no tension between the rod and skin. Although loop stomas are often considered temporary, they should be constructed durably in the event that distal intestinal continuity cannot be restored. The use of intra-abdominal anti-adhesion materials may be considered to decrease adhesions and possibly ease subsequent reversal at temporary ostomy sites [7, 21–23].

End Colostomy

Creation of an end colostomy follows similar techniques as described for small bowel stomas, but the tenuous colonic blood supply requires special consideration. Both laparoscopic and open approaches can be used. For either approach, great care should be taken to assuredly and completely mobilize the intended segment of colon so that several centimeters of bowel reaches above skin level in a tension-free manner. Unlike the relatively mobile small bowel mesentery, the colonic conduit and mesentery may require substantial mobilization depending upon the level of diversion. An end sigmoid colostomy may not require significant mobilization due to the redundant nature of the sigmoid loop in a thin patient; however, a proximal end descending colostomy may require full mobilization of the splenic flexure with high vascular ligation to obtain sufficient reach in an obese patient. The authors strongly suggest that the surgeon treats the colonic conduit akin to an anastomosis by eliminating tension with adequate colonic mobilization and assuring adequate perfusion. Confirming pulsatile blood flow from the marginal artery during colonic division helps to assess adequate perfusion of the colostomy. It may be helpful to excise all epiploic appendages from the anti-mesenteric bowel wall easing eventual evisceration.

For open end colostomies, once the segment of colonic conduit is chosen and prepared, a 2.5-cm diameter stoma muscle-splitting trephine is fashioned at the site of previous marking using the previously described techniques. An end colostomy may require a larger trephine depending upon the bowel caliber and mesentery thickness. Epiploic appendages may be excised to ease colon passage through the abdominal wall trephine. The colon is passed through the stoma trephine with a Babcock clamp and eviscerated. The surgeon confirms a pink, well-perfused stoma rests comfortably for 3–4 cm above the skin level without tension or retraction. Following closure and protection of abdominal wounds, the colostomy is opened everted and sutured to the skin to produce a colostomy that protrudes 1–2 cm. Typically, the solid nature of colostomy effluent is not toxic to surrounding skin, and a lengthy stoma eversion is not necessary. If necessary, a colostomy can be made flush with the skin, but the authors suggest that a small protrusion helps patients with stoma pouching and skin care. Once matured, the colostomy should be evaluated to confirm adequate perfusion with a pink glistening mucosa. Laparoscopic end colostomies utilize the same principles as detailed above.

Loop Colostomy

A loop colostomy is typically fashioned from the non-peritonealized sigmoid or transverse colon, although any segment of colon can be used in a loop configuration with adequate mobilization via open or laparoscopic techniques. After identifying the target segment of colon, an assessment of reach and mobilization is performed assuring the colon loop reaches several centimeters above the previously marked stoma site without tension. For open surgery, a narrow Penrose drain is passed through an avascular recess at the junction of the mesentery and colon wall. After creating an approximately 3-cm diameter trephine using aforementioned techniques, the colon loop is gently pulled through the trephine and delivered over a stoma rod. Following closure and protection of abdominal incisions, the loop colostomy is matured by incising along the long axis of the bowel and maturing the cut edge of bowel to the skin circumferentially (Figure 55-9). The matured loop colostomy may be quite large depending upon the bowel caliber, mesenteric thickness, and postoperative edema. As with loop small bowel stomas, loop colostomies may be temporary or permanent and should always be constructed durably if stoma reversal is inadvisable. Laparoscopic

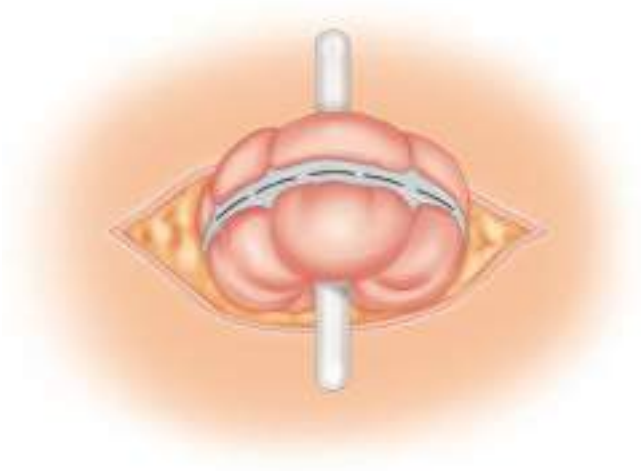

FIGURE 55-9. Creating an incision along the long axis of the colon to create a loop colostomy.

techniques follow similar principles as detailed above. As with loop small bowel stomas, use of intra-abdominal anti-adhesive products may be considered with temporary loop colostomies to potentially ease future reversal [7].

Postoperative Care for the Stoma

Early Inpatient Postoperative Care

Immediately after creation, the stoma will become edematous and swell to two to three times the original size. The stoma will shrink to normal size after approximately 4–6 weeks. The new stoma should be monitored daily and assessed for color, viability, and retraction and should remain pink and moist and protrude well. If a stoma rod was used, the rod is typically removed between 3 and 5 postoperative days or when centripetal tension decreases and the rod easily slides out. The stoma rod can be left for longer periods of time for difficult or tenuous stomas.

Both small bowel and colonic stomas do not typically function immediately. Stoma outputs initially resemble small volumes of serosanguinous or mildly bilious thin fluid without particulate matter described as "bowel sweat." Bowel function will recover with time and stoma outputs will increase. Colostomies tend to produce gas first, followed by liquid stool, and ultimately more solid waste as time proceeds—although this cadence can be variable. Small bowel stomas tend to function sooner than colostomies. Even during fasting, small bowel stomas will produce significant volumes or dark green bilious outputs. As diet is advanced, particulate materials intensify and small bowel effluent becomes increasingly thicker. As described earlier, small bowel stoma outputs can be high leading to profound dehydration and electrolyte abnormalities. As early postoperative bowel function returns, a deluge of backlogged bowel contents may rush out producing initially high stoma outputs. Small bowel stoma outputs generally taper with time, but may require dietary and medical interventions if outputs are persistently high (see section "High Output Small Bowel Stomas"). Over 30 % of new ileostomy patients may experience dehydration with early postoperative readmission rates exceeding 15 % [24]. Recent studies show that perioperative stoma care pathways focusing on patient education, standardized discharge criteria, output logs, visiting nurse care, and early follow-up may decrease postoperative readmissions related to dehydration and should be strongly considered for new ostomates [7, 25].

Patient-centered postoperative stoma education should begin as soon as the patient can participate. Since approximately half of stoma care is provided by a spouse and a quarter of stoma care is provided by an offspring, caregiving family members should participate in stoma education [11]. The ultimate goal is to train the patient and caregivers to become proficient in caring for the stoma and troubleshoot problems. Postoperative patients typically follow a graduated program that focuses on both knowledge and skills training for emptying, applying, and troubleshooting common stoma problems. Many new ostomates are only capable of emptying a stoma pouch at the time of discharge. As a result, patients are often discharged home lacking knowledge on how to manage common pouch-related issues. Unpublished data from the American College of Surgeons revealed only 53 % of home-going new ostomates were capable of applying a new pouch and only 28 % were able to fix pouch leaks. As a result, 45 % of all new home-going ostomates worried about self-care, 40 % felt sad and/or depressed, and 62 % were uncomfortable leaving home. As a result, many institutions bridge postoperative stoma care and education into the outpatient domain with home nursing.

Postoperative Outpatient Care

ASCRS believes that optimal care for patients undergoing ostomy surgery includes preoperative and postoperative care by an ostomy nurse specialist, such as a WOCN-certified nurse [7]. Periodic stoma assessment and educational reinforcement should continue following discharge from stoma surgery, particularly in the early postoperative period when stoma-related complications are most frequent. Attention should be paid to stoma outputs and the frequency that the stoma flange is changed, which is a good surrogate for peristomal skin quality and leakage. Ideally, a flange should last 3–5 days between changes. More frequent appliance changes may indicate improper technique, inappropriate appliance, peristomal skin disease, or a poorly located or constructed stoma. A recent survey indicated that a scheduled postoperative visit with a certified wound, ostomy, and continence nurse (WOCN) revealed that over 60 % of new ostomates had peristomal skin irritation that was unrecognized in nearly half of patients. Once identified and treated, stoma-specific quality of life improved [26]. Additionally, structured postoperative group sessions may prove beneficial to the ostomate even in the late postoperative period [27]. Ostomy support groups, which are organized online and in person, may provide ongoing support for novice and experienced ostomates alike [28].

Stoma Appliances

Stoma appliances come in a variety of sizes and configurations, but generally consist of an adhesive flange (wafer) that seals to the skin and a collecting bag which may come in one or two piece models (Figure 55-10). Two-piece appliances allow the collection bag to completely detach from the flange and allow inspection of the stoma without completely removing the flange and may be advantageous in the early postoperative period while the stoma is examined daily. Stoma flanges generally comprise a pectin-like adhesive wafer ring surrounded by waterproof tape-like layer. The inner diameter of the ring comes in various sizes and can often be trimmed

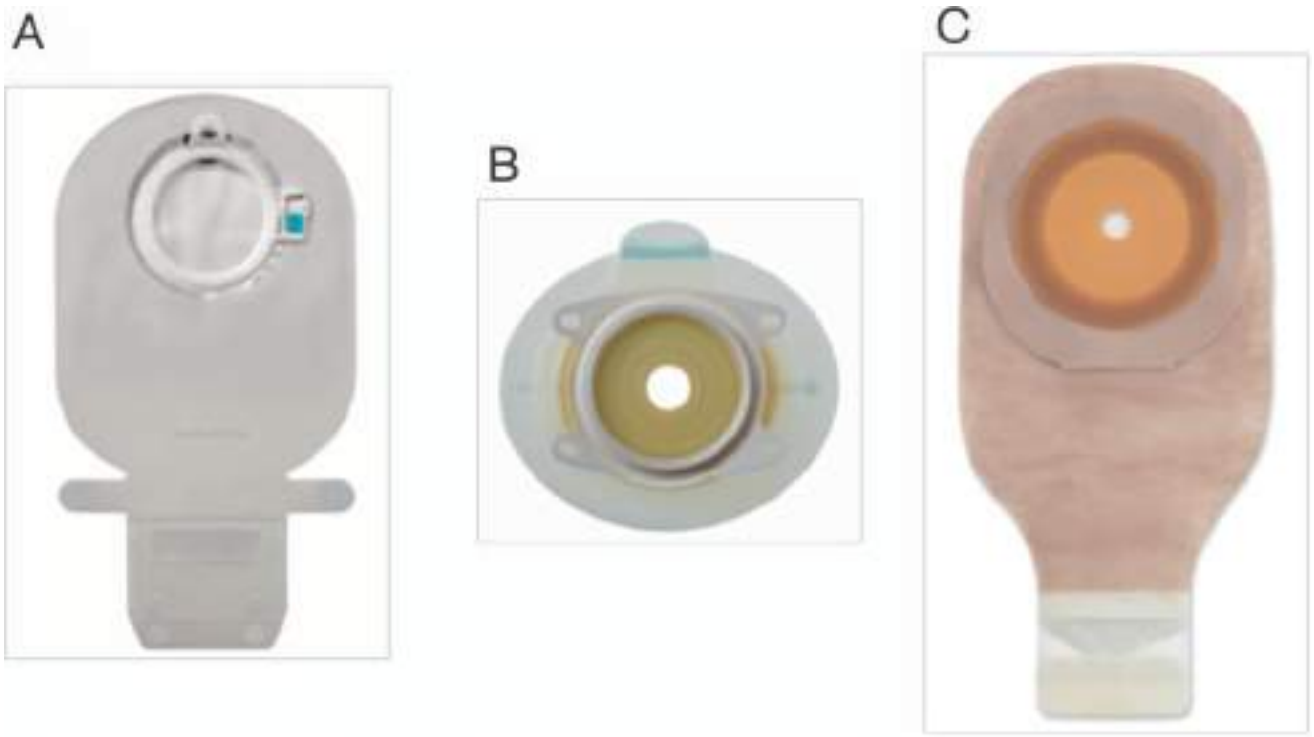

FIGURE 55-10. (**a**) Two-piece stoma appliance with flange and pouch (photo courtesy of Coloplast). (**b**) One-piece stoma appliance and belt (photo courtesy of Hollister). (**c**) One-piece stoma appliances (photo courtesy of ConvaTec).

with scissors to accommodate larger or irregularly shaped stomas. Generally speaking, the wafer should be trimmed to the exact size of the stoma leaving little to no peristomal skin exposed to bowel contents. Disposable stoma sizing templates are available from most stoma supply manufacturers. Appropriate sizing and trimming of stoma appliances is crucial—particularly during the first 6 weeks as stoma edema subsides. Survey data indicate that the average ostomate places a new flange every 4–5 days. The flange should be changed every 3–7 days depending upon peristomal skin care needs [29].

Collection bags come in a variety of sizes in both clear and opaque models based on patient preference. Venting charcoal filter bags may be used to help patients with high gaseous outputs. High output bags may be used to connect to a leg collection system akin to a Foley catheter. Bags should be emptied at the discretion of the patient. New small bowel stoma patients are encouraged to log outputs for the first several weeks and monitor for high outputs.

Specialized stoma appliances may be necessary depending upon the condition of the peristomal skin, stoma morphology, and body habitus. Convex stoma appliances feature a bowl-shaped wafer that assists sealing flush or retracted stomas. Elastic stoma belts may be used to bolster skin sealing for leak-prone stomas. Stoma paste and preformed stoma barrier rings may be used to improve sealing between the peristomal skin and wafer and may be particularly useful when skin folds or scars create an uneven peristomal skin surface. A variety of skin adhesives, protectant wipes, adhesive removers, and topical powders are available to assist with difficulties surrounding the peristomal skin.

Stoma Complications

Stoma problems are ubiquitous and profoundly impact ostomate quality of life, but can often be mitigated with proper care and education in collaboration with stoma care professionals. National Surgical Quality Improvement Program data showed a 37 % unadjusted complication rate for elective cases involving a stoma and 55 % for emergency operations [30]. Stoma-specific complication rates are even higher when considering patient-reported outcomes (Table 55-2). Early stoma-related complications such as leakage, peristomal dermatitis, and dehydration tend to arise from stoma management issues that can be remedied with stoma care and education. Prolapse, stenosis, and parastomal hernia are late-term stoma-related complications that require surgery for definitive correction. Although specialized stoma care nursing is available at many institutions, recognition, care, and management of stoma-related complications are under the purview of the colorectal surgeon.

Table 55-2. Stoma complications

Complication	Incidence rates (%)
Retraction	0–22
Parastomal hernia	0–40
Stoma prolapse	0–10
Stoma necrosis	0–7
Peristomal skin problems	10–42
Total complications	12–72

Adapted from Salvadalena G. Incidence of complications of the stoma and peristomal skin among individuals with colostomy, ileostomy, and urostomy: a systematic review. J Wound Ostomy Continence Nurs. 2008;35(6): 596–607 [31]

Stomal Ischemia: Necrosis, Retraction, and Stenosis

Poorly perfused stomas can necrose in the early postoperative period (Figure 55-11a). Arterial insufficiency is the most common cause of stoma necrosis; however, venous ischemia can rarely arise from fascial obstruction within the trephine. Loop stomas, which preserve collateralized mesenteric vasculature proximal and distal to the stoma, are more resistant to ischemia than end stomas, which require mesenteric division and typically rely upon unidirectional arterial flow. Proper stoma creation techniques can help avoid ischemia-related stoma complications by assuring adequacy of bowel perfusion. Intra-operative assessments of mesenteric pulses, pulsatile bleeding from the cut edge of the mesentery, nuisance bleeding from the cut edge of the bowel wall, and mucosal evaluation can mitigate risk of stoma ischemia and related complications.

Akin to ischemic colitis, marginally perfused stomas may demonstrate variable degrees of ischemia with regard to timing, length, and depth of the ischemic bowel segment, rendering early postoperative assessment of stoma viability crucial. Stoma ischemia typically begins with mucosal pallor and progresses to petechiae, cyanosis, and purple-black mucosal necrosis. Mild stomal ischemia may cause a limited, partial-thickness, mucosal necrosis and slough, but deeper bowel wall layers may remain viable. The most distal edge of the stoma, typically matured to the peristomal skin, is the segment most vulnerable to ischemia. As the everted bowel wall courses proximally, perfusional viability gradient may be seen where ischemia may transition to a viable bowel wall.

Identification of the proximal extent of the ischemic stoma is crucial and can often be identified with a bedside "test-tube" examination. A lubricated clear glass test tube is inserted through the stoma os while a flashlight is directed down the stomal lumen. The illuminated glass permits bedside mucosal evaluation for the length of the tube, allowing the surgeon to assess the proximal extent of mucosal ischemia along the stomal conduit. Management of early postoperative stoma ischemia varies between small bowel and colonic stomas. Any stoma with early evidence of sub-fascial ischemia (i.e., posterior to abdominal wall fascia) should be revised, since deep ischemia may progress to frank intraperitoneal necrosis and perforation. A colostomy appearing viable anterior to the fascia may be carefully observed without revision, since intraperitoneal perforation is unlikely, and solid colostomy outputs can be reasonably pouched even if distal stoma necrosis renders the stoma flush with the skin. A partially viable permanent end ileostomy with significant ischemia of the muscularis, however, should be revised in the postoperative period in suitable operative candidates since distal necrosis may result in a flush ileostomy that is difficult to pouch.

Long-term mild ischemia may result in late-term stoma stenosis and retraction (Figure 55-11b). Non-ischemic stomal retraction can be seen in patients with inadequately mobilized stoma conduits and the obese. Akin to ischemic colitis, necrosis and atrophy of the bowel conduit may cause variable degrees of stomal stricturing and/or retraction that may necessitate surgical revision depending upon symptom severity. Asymptomatic mild stoma stenosis or retraction can be carefully observed provided an adequate seal is maintained with pouching and the peristomal skin remains healthy (Figure 55-12). Skin level symptomatic colostomy stenosis can be locally revised provided the majority of the supra-fascial colon is normal. Sub-fascial stomal stenosis may require intra-abdominal approaches to mobilize a new segment of well-perfused bowel enabling creation of a new stoma. A chronically retracted colostomy can be observed absent stenosis or pouching problems; however, a difficult-to-pouch small bowel may require local revision or complete resection and creation of a new stoma.

Peristomal Skin Disorders

Peristomal skin disorders are the most commonly occurring complication for ostomates [31]. Although skin irritation can occur at any time during the course of the stoma, dermatologic conditions are most commonly seen in the early postoperative period as the ostomate learns proper stoma care techniques. Up to 70 % of new ostomates may have peristomal dermatitis, which is often unrecognized by the patient [26, 32, 33]. Fortunately, most peristomal skin complications arising from a well-constructed and properly located stoma can be successfully managed with local wound care.

Most peristomal skin irritation arises from poorly fitted or improperly sized appliances that expose vulnerable peristomal skin to potentially caustic stoma effluent (Figure 55-13). Leakage viciously begets leakage as irritated peristomal skin weeps exudative fluids that hinder stoma appliance adhesion, which further worsens leakage, excoriation, and appliance maladhesion. Leakage often requires frequent appliance changes, which inflicts additional mechanical stripping trauma to vulnerable peristomal skin. Pouch leaks and peristomal skin excoriation are treated best with a critical reappraisal of pouching apparatus and sizing. Care should be

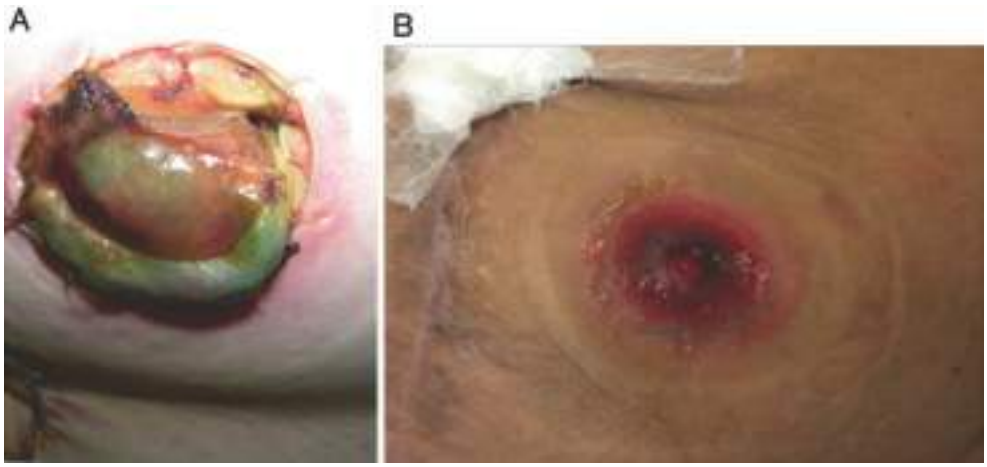

FIGURE 55-11. (**a**) Acute postoperative stoma necrosis with mucocutaneous separation [photo credit: Wound, Ostomy, and Continence Nurses Society (http://www.wocn.org/page/ImageLibrary)]. (**b**) Chronic ileostomy ischemia leading to retraction, stenosis, difficulty pouching, and peristomal erosions (photo credit: Adam Stein, MD).

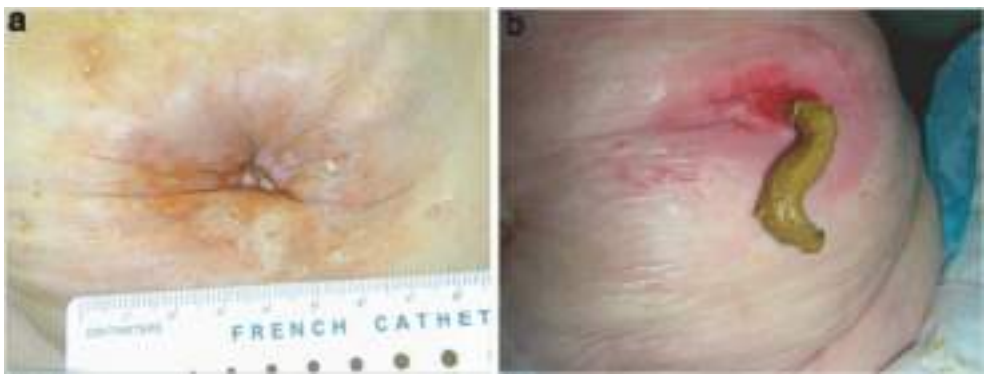

FIGURE 55-12. Chronic stoma stenosis [photo credit: Wound, Ostomy, and Continence Nurses Society (http://www.wocn.org/page/ImageLibrary)].

taken to ensure the stoma flange aperture is sized and trimmed to fit the mucocutaneous junction perfectly so that no skin is exposed to stoma effluent. Flush or poor-fitting stomas may benefit from a convex pouching system, which may improve sealing at the mucocutaneous junction. Protective skin barrier wipes can be used to create a thin polymeric layer to improve and protect skin integrity at the pouch–skin interface. Weeping superficial peristomal skin excoriation can be treated with a thin layer of topical stoma powder. Peristomal contour issues such as peristomal indentations, skin folds, and mucocutaneous separation may be filled with stoma paste to "caulk" under-the-flange leakage.

Fungal peristomal infections typically appear as reddened, shiny patches with satellite papules involving the skin underlying the stoma appliance flange [33]. *Candida albicans*, the most common skin fungus, can proliferate in the warm moist environment at the skin–appliance interface causing itching, irritation, and pain. A fungal infection is first treated by removing and assessing the pouching system for occult leaks that add to skin moisture and irritation. Topical antifungal nystatin powder is then applied and rubbed into the irritated peristomal skin. Excess powder is then brushed off and a skin sealant is typically applied over the powder to enable application of a new stoma appliance. This process is repeated with each appliance change until the rash resolves which usually occurs within 1–2 weeks. In rare cases, topical miconazole and clotrimazole may be required for treatment of resistant fungal dermatitis.

The importance of assessing the peristomal skin cannot be overstressed, particularly in the early postoperative period. High-risk patients, such as those with low health literacy, poor support systems, and emergently created stomas, should be paid special attention. Additionally, obese ileostomy patients are at a higher risk of developing peristomal skin issues owing to the liquid nature of effluent and stoma creation challenges seen in thick abdominal walls [34]. As postoperative stoma edema subsides, the first several postoperative weeks require gradual adaptations in the pouching system to accommodate a shrinking stoma. New home-going ostomates should be made aware that the stoma diameter will gradually shrink and that the flange aperture should be trimmed smaller over time. Since the majority of peristomal skin disorders can be treated with pouching adjustments, postoperative WOCN support, if available, is an immensely valuable tool for the duration of the patient's stoma. Studies indicate a majority of ostomates do not realize a treatable dermatologic condition exists [32, 34], and when treated, can expect an improvement in quality of life [26]. To that end, routine postoperative follow-up with a stoma care professional, such as a WOCN-certified nurse, is recommended [7, 29].

Peristomal Pyoderma Gangrenosum

Pyoderma gangrenosum is a rare inflammatory skin disease characterized by painful ulcers with well-defined erythematous or violaceous undermined borders (Figure 55-14) [35]. Approximately 0.5–5 % of patients with inflammatory bowel disease can develop peristomal pyoderma gangrenosum. Pyoderma gangrenosum is also associated with rheumatoid arthritis, paraproteinemia, or hematologic malignancy in half of patients, but may be idiopathic in 25–50 % of patients [35–37]. Peristomal pyoderma gangrenosum can be seen in approximately 0.6 % of ostomates; however, some postulate the actual incidence may be higher due to underdiagnosis [36]. For unclear reasons, peristomal pyoderma is associated with female gender, autoimmune disorders, and obesity in IBD patients [36–38]. Pyoderma, although poorly understood, is felt to arise from pathergy arising from local skin trauma, which may explain a predilection for arising in the peristomal skin.

Diagnosis of peristomal pyoderma gangrenosum is made clinically and requires a high index of suspicion. Lesions characteristically begin spontaneously with a firm, pink, or

FIGURE 55-14. Peristomal pyoderma gangrenosum (photo credit: Janice Colwell, APRN, CWOCN).

purple hemorrhagic nodule at the peristomal skin in contact with the stoma appliance. The nodule typically enlarges and ulcerates rapidly, to produce a painful and occasionally purulent ulcer with a raised border [35]. Thin bridges of persisting epidermis may be seen spanning the ulcer. Biopsies of the ulcer margin typically reveal nonspecific epidermal neutrophil infiltration, edema, and perivascular lymphocyte infiltration. Although skin biopsies may exclude other dermatologic processes such as malignancy and infection, biopsies are usually not helpful in diagnosing pyoderma due to a lack of pathognomonic histologic findings [39, 40].

There is currently no standard treatment algorithm for pyoderma gangrenosum. Management of peristomal pyoderma utilizes a multidisciplinary approach to treat causative underlying disorders with early and aggressive wound and stoma care [39]. Pyoderma often parallels intestinal IBD activity and may indicate occult, active, intestinal disease. Topical, intra-lesional, and systemic steroids and antibiotics have been used to successfully treat peristomal pyoderma [41]. Following a stepwise approach, increasingly powerful systemic immunomodulators and biologics have also successfully healed peristomal pyoderma [39]. Absorbent-type dressings such as protective foam, calcium alginate, and hydrogel dressings covered with an occlusive dressing can be used to create a protective dry barrier over the wound while controlling for wound seepage [40]. Treatment efficacy can be assessed by monitoring the characteristically raised and undermined wound edge that flattens as the wound heals [39].

A combination of intra-lesional steroid injections and ulcer debridement has been reported to completely heal 40 % and partially heal an additional 40 % of parastomal pyoderma patients [42]. These acceptable results should be interpreted cautiously, however, since over 50 % of treated patients ultimately required stoma re-siting for disease control. A 50 % healing rate with medical therapy including a combination of topical, intra-lesional, and systemic steroids and antibiotics, systemic cyclosporine, and infliximab has also been reported [36]. Ultimately, stoma re-siting may be necessary for treatment refractory peristomal pyoderma, but relocation does not guarantee against pyoderma recrudescence.

Peristomal Varices

Akin to esophageal, gastric, and rectal varices, portosystemic venous shunts may also develop between the stoma and abdominal wall arising to peristomal varices in the setting of chronic portal hypertension. Parastomal varices are identified as a circumferential blue or purple subcutaneous ring extending from the mucocutaneous junction to the peristomal skin (Figure 55-15). Additional clinical findings of parastomal varices include raspberry appearance of the stoma, visibly dilated stomal submucosal veins, peristomal caput medusa, and easy bleeding hyperkeratotic skin [43]. Peristomal varices may also be found within the stomal lumen. Commonly seen in IBD patients with concomitant primary sclerosing cholangitis, parastomal varices can also

FIGURE 55-15. Peristomal varices (photo credit: Janice Colwell, APRN, CWOCN).

be seen in ostomates with alcoholic cirrhosis and those with extensive metastatic burden to the liver. The incidence of peristomal varices is unknown, but may occur in 27–50 % of ostomates with portal hypertension [44, 45].

Peristomal variceal hemorrhage can be heavy and occasionally life-threatening. Approximately 40 % of patients with parastomal varices will bleed and require transfusion, with the average time from stoma formation to first hemorrhage being 70 months [43]. Following stabilization and correction of any coagulopathy, hemorrhage can typically be first treated with local measures such as digital pressure, application of epinephrine soaked gauze, and suture ligation [46]. Suture ligation of the bleeding varix is not typically durable but may temporize heavy bleeding. Approximately 85 % of patients will re-bleed after local non-operative management of parastomal hemorrhage [43]. Portal decompression, most commonly with a transjugular intrahepatic portosystemic shunt (TIPS), is approximately 5 times more effective than local non-operative measures in durably treating hemorrhage and cured variceal bleeding in nearly 80 % of patients [43, 47, 48]. Moreover, liver transplant may be indicated depending upon the etiology of liver failure, but may only be possible for a fraction of patients with stomal varices [43]. Alternative non-operative treatments using injection sclerotherapy, octreotide, and percutaneous embolization may effectively treat parastomal varices [43, 44, 49–51]. Following local treatments, proper and gentle stoma care with a flexible flange should be employed since the friable varices dwell at the skin–pouch interface [52].

Surgical mucocutaneous disconnection may be employed when local therapy fails and portal decompression is not possible. This local surgery involves a cylindrical incision around the mucocutaneous junction to the level of the anterior fascia with identification and ligation of varices and rematuration of the stoma. Preoperative peristomal infiltration of dilute epinephrine may assist with hemostasis during this potentially bloody procedure [46]. The surgeon should pre-

pare for significant blood loss and necessary blood products should be available for transfusion. Varices will recur over time, but the local procedure can be performed repeatedly, if needed. Stoma re-siting procedures can be carefully considered for suitable variceal patients experiencing concomitant pouching difficulties arising from a parastomal hernia or poorly constructed stoma. The risks of this highly morbid procedure in a high-risk patient need to be cogently balanced with anticipated benefits and life expectancy.

While a stoma is not always avoidable, special situations may arise where portal hypertensives and early cirrhotics can be offered stoma-sparing surgery with the goal of potentially avoiding parastomal varices. Stoma avoidance is particularly germane in the setting of primary sclerosing cholangitis (PSC)-associated inflammatory bowel disease where reports of peristomal variceal hemorrhage can occur in up to 53 % of patients within 4 years of total proctocolectomy with end ileostomy [53]. Since patients with ulcerative colitis and PSC can successfully undergo restorative proctocolectomy with an ileal-pouch anal anastomosis (IPAA) and avoid a permanent stoma and varices [54, 55], IPAA is the treatment of choice [56]. If necessary, IPAA may be performed safely following TIPS or liver transplant [57, 58]. Although IPAA avoids a permanent stoma, unexplained pouchitis can develop in over 50 % of patients with PSC within 4 years of pouch creation [55].

Stoma Prolapse

Bowel proximal to an end stoma may intussuscept through the matured stoma creating stoma prolapse (Figs. 55-16 and 55-17). Loop stomas may prolapse bowel from either limb. Stoma prolapse is categorized as fixed or sliding depending upon the mobility of intussusceptum. A mobile sliding prolapse classically describes the problematic variant that can be seen in up to 8 % and 47 % of end and loop stomas, respectively [59]. Stoma prolapse is theorized to arise from a combination of a mobile bowel mesentery, increased intra-abdominal pressure, enlarged stoma trephine, or fixation failure of the opposing everted stomal serosa surfaces. Stoma prolapse ranges from mild cosmetic concerns to moderate difficulties pouching, up to rare and extreme cases of incarceration and strangulation.

Minimally symptomatic stoma prolapse may be managed with reassurance, modification of stoma appliances, and addition of an external fixation device. Significantly symptomatic stoma prolapse may require surgical revision in suitable operative candidates via local parastomal or open abdominal approaches. Sundry, heterogeneous, and anecdotal reports describe various stoma prolapse repair techniques, but no compelling method prevails. In the absence of steadfast evidence, conventional wisdom dictates local procedures are first attempted relegating more extensive intra-abdominal procedures for recurrent or complicated prolapse. Prolapsing temporary loop stomas are best treated with timely reversal. Prolapsing permanent stomas can be treated with local amputation of the prolapse with re-anastomosis, local excision of the stoma and intussusceptum with de novo stoma creation, or prolapse reduction and fixation. Some advocate concomitant seromyotomies to promote serosa-to-serosa bonding along the apposed serosal surface of the everted matured stoma to minimize future prolapse.

Intra-abdominal correction of stoma prolapse has been described using myriad techniques, largely focusing on fixation of the intussusceptum and corresponding mesentery.

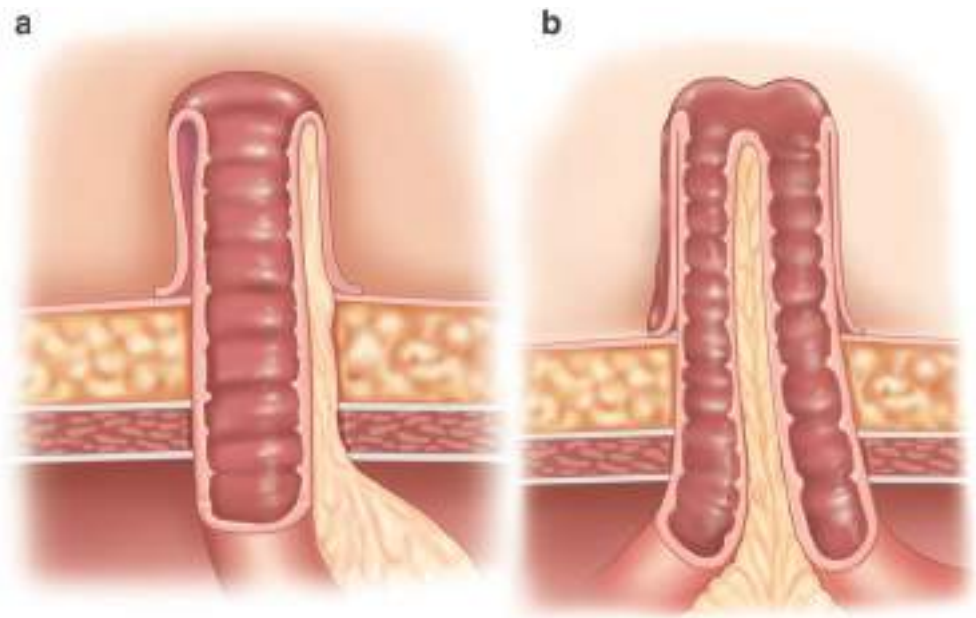

FIGURE 55-16. (**a**) Prolapsed end stoma. (**b**) Prolapsed loop stoma.

FIGURE 55-17. Prolapse of a prolapsed loop transverse colostomy [photo credit: Wound, Ostomy, and Continence Nurses Society (http://www.wocn.org/page/ImageLibrary)].

Intra-abdominal techniques may be preferable when prolapse is associated with concomitant parastomal hernia. Intra-abdominal approaches facilitate suture fixation of prestomal mesentery and/or bowel conduit directly to peritoneum with variable rates of success. Some propose routing pre-stoma conduit through a pre-peritoneal tunnel lateral to the linea semilunaris prior to exiting through a trans-rectus trephine, fixating bowel and mesentery intra-abdominally although the utility of this technique is debatable (Figure 55-18a). Prolapsing permanent loop colostomies commonly prolapse the distal limb and can be converted to an end or loop-end stoma by dividing the distal limb. Alternatively, the distal limb of a loop colostomy may be sutured to the peritoneum to limit excursion (Figure 55-18b). Ultimately, a prolapsing stoma can be moved to a new site using any of the above adjuncts to mitigate future prolapse, although isolated stomal prolapse without associated parastomal hernia rarely benefits from stoma relocation.

Rarely, prolapsed stomas will become incarcerated and reduction may become increasingly difficult to reduce as cumulative lymphatic and vascular compression worsens stomal engorgement and edema. Besides attempts to reduce a viable incarcerated prolapse may be aided with sedation, anxiolytics, and analgesics, whereas strangulated prolapse mandates immediate surgery. Topical ice and table sugar have been reported to decrease edema within the prolapsed stoma and ease reduction. Incarcerated prolapse may rarely progress to infarction and require immediate surgery (Figure 55-19).

Transient short-segment stomal "pseudoprolapse" may be seen during pregnancy owing to increased intra-abdominal pressure related to uterine displacement of abdominal viscera. Such prolapse is typically less than 3 cm long and resolves following delivery. Pregnancy-related pseudoprolapse does not typically merit surgical revision unless symptoms persist beyond the postpartum period [60].

Parastomal Hernia

A stoma, by definition, is an intentionally created hernia. Invariably, nearly all hernias will enlarge over time as intra-abdominal forces fatigue tissue [61]. A stoma trephine is susceptible to the same continuous intra-abdominal pressures and may enlarge over time to allow unintended protrusion of intra-abdominal contents whereby creating a parastomal hernia (Figure 55-20). As a result, many argue nihilistically that with time, every stoma will ultimately develop a parastomal hernia. The incidence of parastomal hernias is widely estimated between 30 and 50 %; however, detecting the true numerator is limited by heterogeneous definitions, observation periods, and means of diagnosis [62]. Increasing waist circumference, age, and stoma trephine diameter have been associated with parastomal herniation [63, 64]. Parastomal hernias range from small hernias incidentally found on imaging to large hernias containing significant lengths of bowel and omentum (Figure 55-21). Pain, obstruction, disdainful bulges, and pouching difficulties can arise from parastomal hernias, but a significant proportion are asymptomatic. Physical detection of an occult parastomal hernia may require complete removal of the stoma appliance assembly, careful digitation of the stoma, and examination of the patient in the standing position using Valsalva maneuvers. An abdominopelvic computed tomography (CT) scan may be necessary to detect an occult parastomal hernia in obese patients since abdominal wall thickness may obfuscate physical examination findings. Special positioning (e.g., prone or lateral) or maneuvers to increase intra-abdominal pressure (cough, straining, or Valsalva) during the CT scan may help identify an occult parastomal hernia. Therefore, patients who will be undergoing a CT may be coached by the surgeon to strongly Valsalva when told by the technician to hold still for the actual X-ray.

The need for parastomal hernia repair is dictated by the degree of symptoms. An asymptomatic parastomal hernia does not mandate repair. Mild symptoms arising from a parastomal hernia may be ameliorated with appliance modifications or a modified abdominal binder or stomal support belt (Figure 55-22). Suitable-risk patients with intermittent obstructions, intolerable discomfort, and significant pouching difficulties attributable to a parastomal hernia may be considered for elective repair. Incarcerated hernias causing complete obstruction or worrisome for strangulation require immediate surgery.

Given the high prevalence of parastomal hernias, several methods for parastomal hernia repair have been reported over the past half-century, but the majority of published data lies within small case series. Surgical approaches have been divided into three broad categories: local repair, transabdominal repair, and re-siting [62]. Local repair involves a peristomal incision remote to the stoma wafer area with

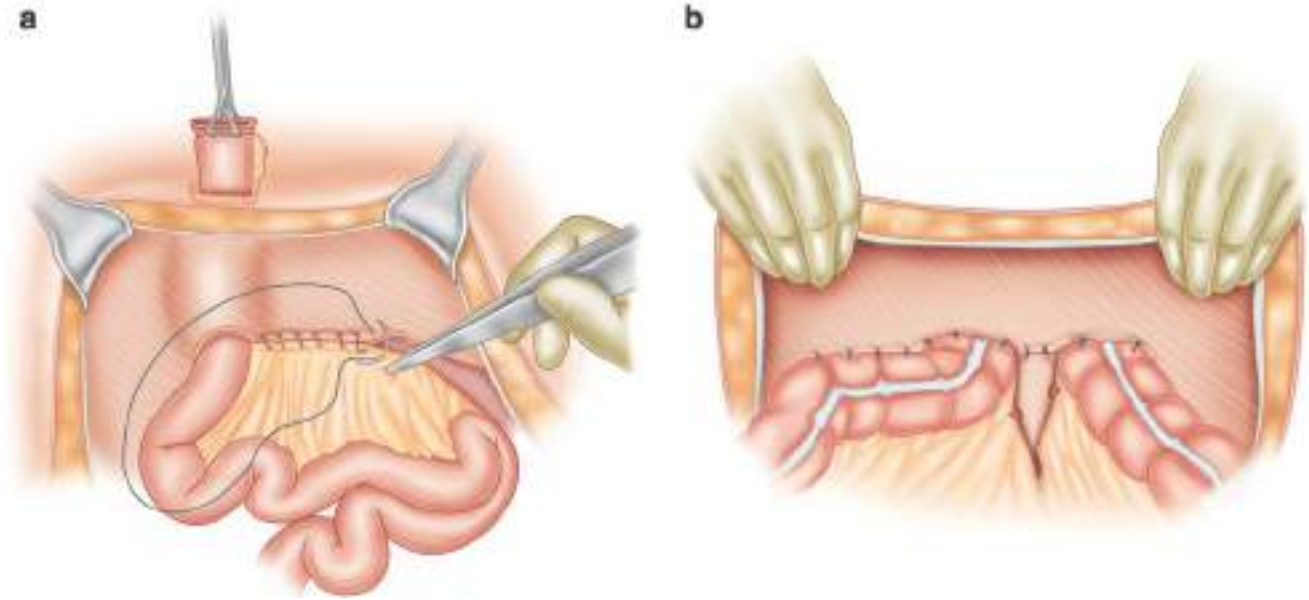

FIGURE 55-18. (**a**) Retroperitoneal tunneling of an end ileostomy with suture pexy of the pre-stomal mesentery to limit prolapse. (**b**) Suture pexy of the distal limb of a loop colostomy to mitigate prolapse of the distal limb.

FIGURE 55-19. Stomal prolapse with distal ischemia and infarction [photo credit: Wound, Ostomy, and Continence Nurses Society (http://www.wocn.org/page/ImageLibrary)].

reduction of hernia contents, hernia sac excision, and suture closure of the hernia defect. Mesh overlay reinforcement may or may not be used (Figure 55-23). Local primary suture repair is an attractive option due to avoidance of a laparotomy, but obtaining tension-free repair is impossible. As realized with ventral hernia repair techniques, primary repair and on-lay mesh techniques have higher rates of recurrent parastomal hernia and are considered inferior to trans-abdominal approaches with mesh underlay [61, 65]. Stoma relocation, although attractive and more effective than local primary repair [66], can be a significant undertaking that jeopardizes midline and former stoma site hernias and does not guarantee against herniation at the new site.

FIGURE 55-20. Parastomal hernia.

Trans-abdominal mesh underlay repair of parastomal hernias offers theoretical advantages to local repair since the same intra-abdominal forces responsible for hernia protrusion are also securing the intra-abdominal reinforcement. As a result, the European Hernia Society has adopted underlay mesh repair as the standard method for repairing incisional hernias [61], and it seems plausible to extrapolate the same rationale to

FIGURE 55-21. A 77-year-old man with a 19-year-old end ileostomy with a large parastomal hernia and seroma.

parastomal hernia repairs. Trans-abdominal approaches can be used through laparoscopic or open techniques using a variety of biologic and permanent prosthetic meshes. Both open and laparoscopic approaches involve lysing all abdominal wall adhesions to identify the stoma trephine and completely reduce hernia contents. Typically an intra-abdominal mesh is then fixed in intraperitoneal or retro-rectus position using either a "keyhole" slit or Sugarbaker underlay to cover and reinforce

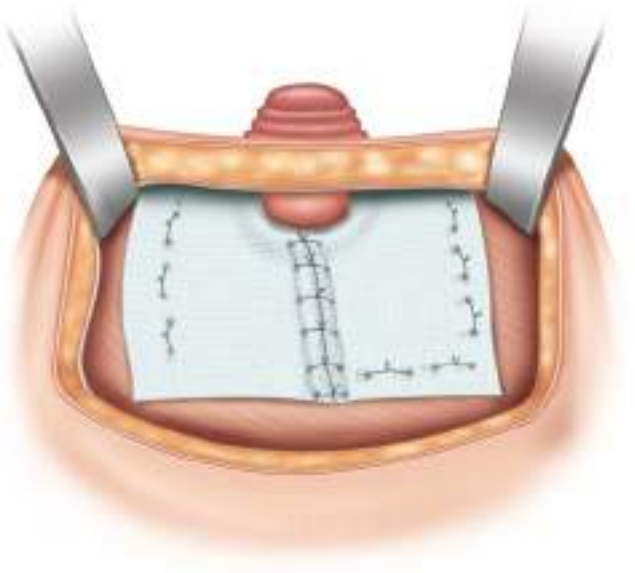

FIGURE 55-23. Local repair of parastomal hernia with prosthetic mesh overlay.

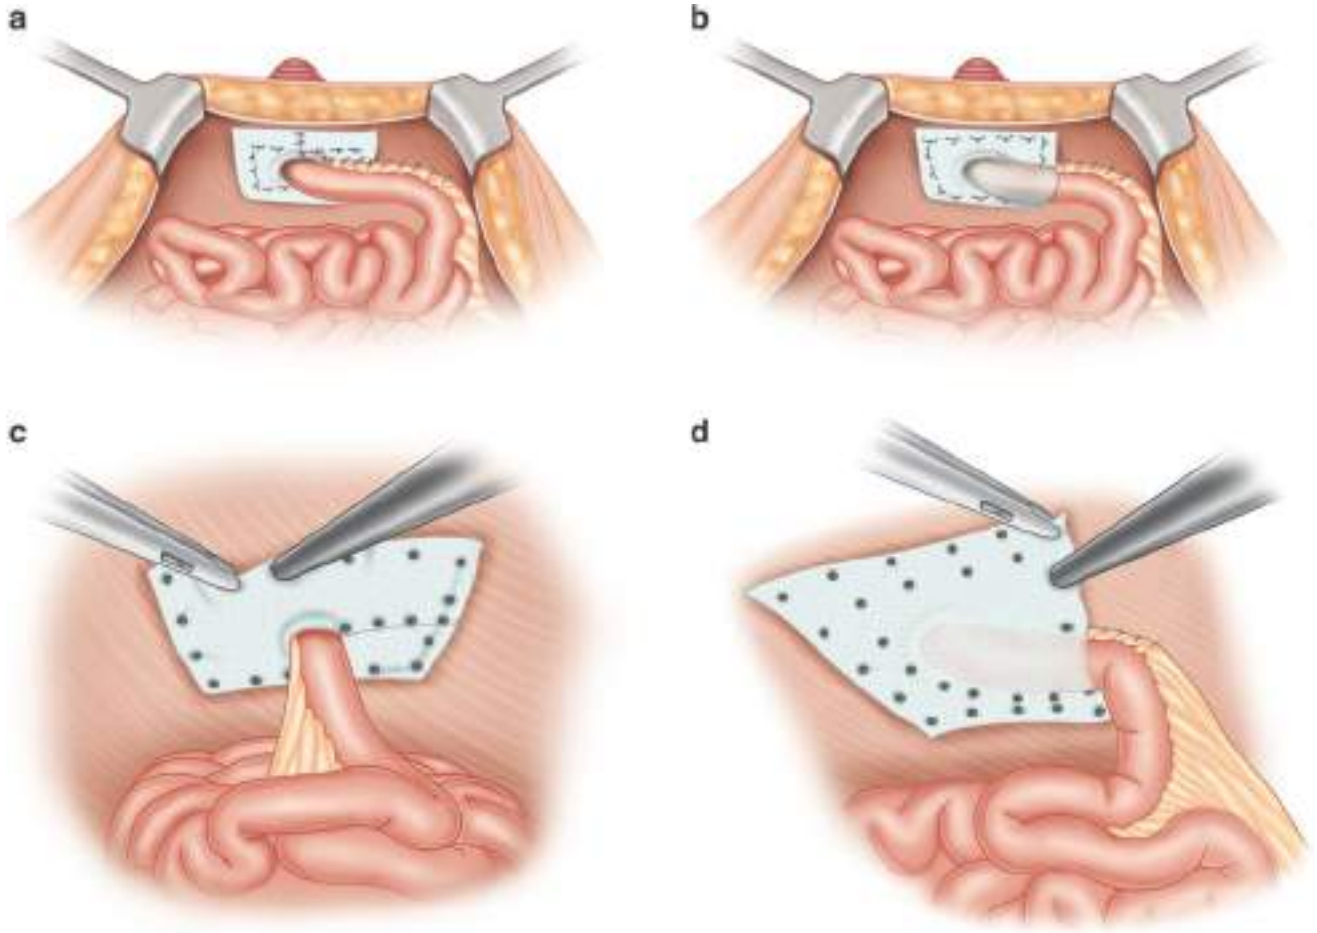

FIGURE 55-24. Intra-abdominal parastomal hernia repair with (**a**) open "keyhole," (**b**) open Sugarbaker overlay, (**c**) laparoscopic "keyhole," and (**d**) laparoscopic Sugarbaker techniques with "double crown" tack technique.

the trephine and surrounding abdominal wall (Figure 55-24) [67]. Hernia repair mesh can be fixed to the abdominal wall through a variety of techniques. A percutaneous suture-passing device can be used to obtain trans-fascial mesh fixation with suture. Two concentric circles of tacks can be used to secure the mesh perimeter to form a "double crown" of mesh fixation (Figure 55-24d). Typically, a combination of trans-fascial suture fixation and tacks is used to robustly fix the mesh to the abdominal wall, but care must be taken not to obstruct or impinge upon the bowel conduit, particularly with the Sugarbaker technique.

The discussion of mesh selection is particularly relevant at the time of this text's publication, owing primarily to an overwhelming variety of mesh types for the surgeon to choose. Permanent non-absorbable prosthetic mesh and bioabsorbable substrates have been used for parastomal hernia repair with variable early success [68], but no particular mesh has demonstrated superiority. Surgical dogma has historically contraindicated the use of permanent prosthetic meshes in contaminated fields out of concern of mesh infection. Use of costly, infection-resistant, biologic meshes in potentially contaminated fields (such as a stoma) initially appeared to avoid theoretical concerns of mesh infection; however, several recent studies suggest that cheaper permanent prosthetic meshes may be equally safe for contaminated hernia repairs, which questions the value-added benefits of costly biologic meshes at this time [69–72].

Despite the high prevalence of parastomal hernias, evidence-based guidance determining the optimal surgical approach is hampered by a bevy of heterogeneous, retrospective, case series lacking steadfast definitions, standardized management algorithms, and clinical trials [73]. The best evidence at this time arises from a large systematic review and meta-analysis that evaluated 30 studies comparing local versus intra-abdominal repair techniques [73]. In this study, which excluded stoma re-siting, the authors found recurrence rates approaching 70 % with local primary suture repair and recommended this technique be abandoned. The authors further report that open and laparoscopic intra-abdominal approaches with mesh have similar effectiveness, but laparoscopic Sugarbaker approaches are superior to keyhole configuration when mesh is used.

Since the above meta-analysis, a complex approach combining open stoma relocation, retro-muscular dissection, posterior component separation, and retro-muscular mesh placement for parastomal hernia repair was reported for 48 patients [74]. The midline incision, former stoma site, and new stoma site were reinforced with a variety of meshes. In this challenging patient group, a variety of meshes were used in patients with a mean BMI of 31, 70 % of which had simultaneous incisional hernia, and each having undergone an average of 4.3 prior repair attempts. The authors report encouraging recurrence rate of 11 % at a mean follow-up of 13 months. While encouraging, results are early and the surgery was a feat: the mean operative time was 258 min and subsequent length of stay was nearly 11 days. Nonetheless, this "belt and suspenders" approach may be useful for patients with recurrent parastomal hernias with concomitant midline incisional hernias.

The high incidence of parastomal hernia and post-repair recurrence has led several investigators to evaluate the use of prophylactic implanted mesh at the time of permanent end colostomy creation to avoid hernia formation. The majority of studies and subsequent pooled meta-analyses have shown placement of prophylactic mesh to be effective in reducing, but not eliminating, parastomal hernias [75–79]. In a prospective randomized trial of patients undergoing permanent end colostomy, placement of a lightweight polypropylene prosthetic mesh underlay decreased clinical parastomal hernia from 41 to 15 % and radiographic parastomal hernia from 44 to 22 % at a mean follow-up of 29 months without mesh-related complications [77]. The exact type, size, and mesh location are debatable. A multicenter, prospective randomized trial evaluating usage of intra-abdominal placement of biologic mesh for permanent stomas showed no beneficial effects of mesh implantation [80]. ASCRS suggests that lightweight polypropylene mesh may be placed at the time of permanent ostomy creation to decrease parastomal hernia rates [7]. A this time, it is difficult to explicitly define the role of routine mesh placement for permanent stomas. First, mesh and mesh implantation can be costly and not innocuous. Added to the fact that only a fraction of parastomal hernias require repair and prophylactic mesh is not completely effective in preventing hernias, the cost–benefit balance of routine mesh use is murky. For patients undergoing creation of a permanent colostomy with expected long-term postoperative survival, routine placement of an affordable mesh appears to be a reasonable practice based on the best information available at this time; however, the authors acknowledge this practice is in infancy and await additional evidence to definitively address this fluid concept.

Peristomal Abscess

Rarely, an ostomate may develop a peristomal abscess. Peristomal tenderness, swelling, and erythema may indicate a subcutaneous collection. Peristomal abscesses are typically seen in the early postoperative period resulting from intraoperative contamination; however, late peristomal abscesses can be seen in the setting of penetrating Crohn's disease of the stoma or from an intra-abdominal source. Initial management of a peristomal abscess includes drainage via image-guided or standard operative techniques. To avoid pouching problems, the drainage catheter should either be inserted remote to the peristomal skin–appliance interface or directly through the mucocutaneous junction (Figure 55-25). If fistulization from the stoma is suspected following drainage, further endoscopic or radiographic evaluation may determine if the abscess is arising from a diseased stoma.

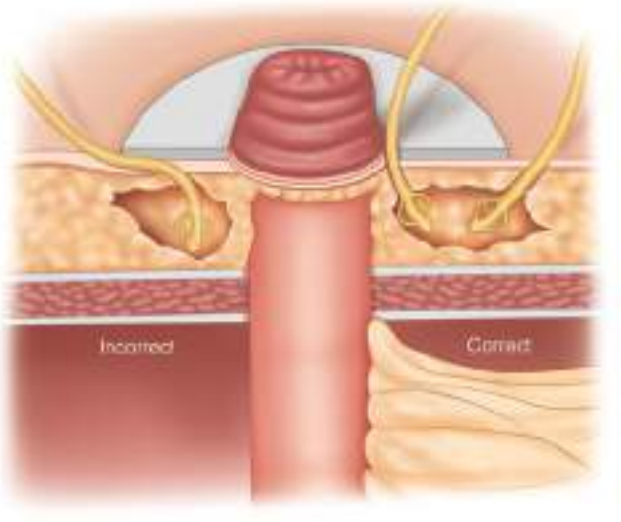

FIGURE 55-25. Percutaneous drainage of a parastomal abscess.

High Output Small Bowel Stomas

Normal ileostomy outputs are typically between 800 and 1200 mL/day, and outputs exceeding 1200–2000 mL/day are considered to be high [81]. High stoma outputs can cause severe fluid, electrolyte, and nutritional deficiencies and are typically seen with small bowel stomas and rarely proximal (i.e., ascending or proximal transverse) colostomies. High output stomas can be transiently seen in the new ostomate as ileus resolves and the initial deluge of bowel contents exits the body. Approximately half of postoperative high output stomas will resolve spontaneously within 2 weeks [81]. With time and resumption of a normal diet, stoma outputs typically plateau to a level proportional to the length of remaining proximal bowel, but high outputs can commonly necessitate treatment. This section will focus on small bowel stomas (ileostomy, jejunostomy), the most common culprit in high output situations.

Once postoperative ileus resolves and stomal outputs reach a steady state, daily output assessments determine the need for treatment. Small bowel stomas outputting less than 1200 mL/24 h are usually well tolerated without clinical derangements and do not typically require treatment.

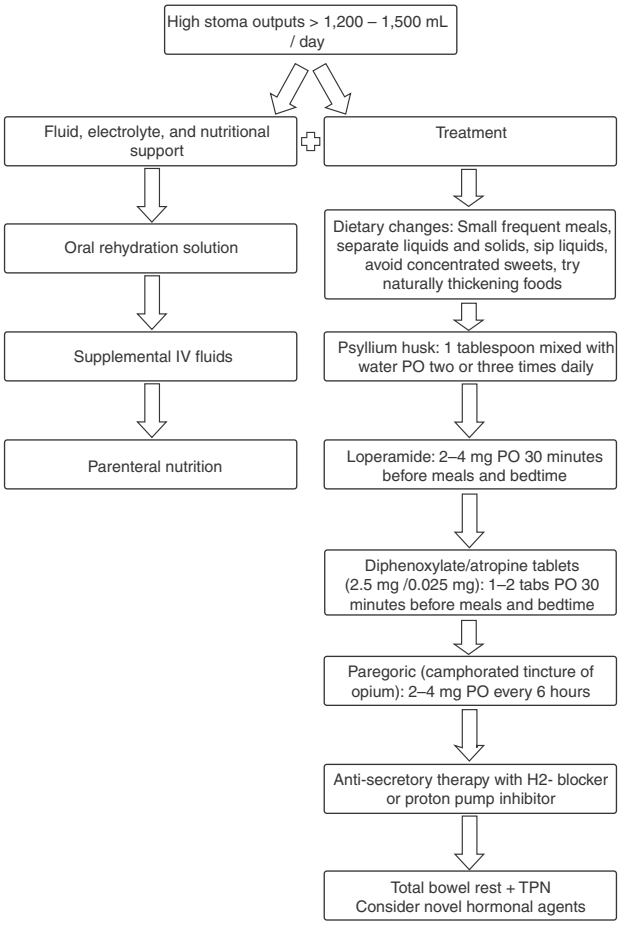

FIGURE 55-26. Proposed management algorithm for management of high output small bowel stomas.

Outputs between 1200 and 1500 mL/day are borderline high and may cause problems for some ostomates. Persistently high stoma outputs can be treated with dietary, behavioral, and medical means via a proposed algorithm described in Figure 55-26. Behavioral alterations include avoidance of large bolus feedings in lieu of smaller, more frequent aliquots. Large meals can be replaced with smaller frequent meals, fluids can be sipped rather than gulped, and solids and liquids can be consumed at different times to minimize bolus effects. Concentrated sweets including juice, soft drinks, and candy should be limited to decrease the effects of osmotic diarrhea. Breads, crackers, peanut butter, and bananas may naturally thicken stoma outputs and help decrease volumes. The addition of psyllium powder mixed in water helps to absorb excess fluid from the intestinal tract and thicken outputs. Hypotonic oral fluid restriction (500–1000 mL/day) and treatment with the cheap and easily made World Health Organization oral rehydration solution (Table 55.3) [82] help limit sodium loss and may produce a more favorable osmotic intestinal gradient [81]. It has been shown that most high output patients can avoid IV fluid and electrolyte supplementation if oral intake is restricted to 500–1000 mL/24 h of oral rehydration solution [83].

TABLE 55-3. Oral rehydration solution

Ingredients
- 3/8 tsp salt (sodium chloride)
- ¼ tsp table salt substitute (potassium chloride)
- ½ tsp baking soda (sodium bicarbonate)
- 2 tbsp + 2 tsp sugar (sucrose)
- Add tap water to make 1 l
- Optional: Nutrasweet® or Splenda® based flavoring of choice, to taste

Directions: Mix dry ingredients with water and serve. Best sipped slowly over long periods of time

Contains 27 g of sucrose, 70 mEq/L of sodium, 20 mEq/L of potassium, and 30 mEq/L of bicarbonate. The final osmolarity is approximately 245 mOsm/L

tbsp tablespoon, *tsp* teaspoon

Following dietary and behavioral changes, pharmacotherapy may be required to manage high output stomas. Medical therapy typically begins with stepwise titration of antimotility agents beginning with loperamide and adding diphenoxylate/atropine. It is useful to take such antimotility agents approximately 30 min before meals (three times daily) to preemptively slow transit time before eating. Rarely, intestinal transit may be so rapid that tablet medications do not have enough time to completely dissolve, leaving elixir forms of antimotility agents preferable. Anti-secretory therapy with either H2 or proton bump blocking agents may be added to decrease stoma outputs by reducing gastric secretions. If dietary, anti-secretory, and antimotility therapies fail, oral opium tincture (Paregoric, camphorated tincture of opium) or oral codeine phosphate can be added. Paregoric can be costly and can cause sedation and is typically added as a later measure for recalcitrant high output stomas. Common medicines to manage high output stomas are detailed in Table 55.4.

Unexpected and persistently high stoma outputs merit a work-up to exclude other potentially treatable causes. Cross-sectional abdominal imaging or a small bowel fluoroscopic series should be performed to exclude a partial bowel obstruction, which can cause paradoxically high outputs. High outputs can be caused by small bowel Crohn's disease, which can be evaluated with small bowel enteroscopy through the stoma or cross-sectional imaging. *Clostridium difficile* enteritis is a reported cause of both small and large bowel high output stomas and can be evaluated with stool testing. Steatorrhea may develop in patients with significant ileal resections and can be treated with oral cholestyramine. Pancreatic insufficiency may rarely cause persistently high stoma outputs and can be remedied with a trial of pancreatic enzyme replacements.

During periods of high stoma outputs, fluid, electrolyte, and nutritional support may be necessary. Periodic surveillance of serum electrolytes, daily weights, and strict recording of inputs and outputs guide resuscitation and replacements. Short gut situations with a high jejunostomy may not respond to standard therapies and may require parenteral fluids or nutrition. On rare occasions with critically proximal stomas, patients may require fasting and total parenteral nutrition as a last resort to sustain euvolemia.

Table 55-4. Common medicines for control of high output stomas

Medication	Starting dose	Maximum daily dose
Psyllium	1 tablespoon BID	1 tablespoon TID
Loperamide tab	2–4 mg PO QID	16 mg (4–8 tabs)
Loperamide liquid	2–4 mg PO QID	80 mL (16 mg)
Diphenoxylate-atropine tab	2.5–5 mg PO QID	20 mg (4–8 tabs)
Diphenoxylate-atropine liquid	2.5–5 mg PO QID	40 mL (20 mg)
Codeine tab	15–30 mg PO QID	240 mg (60 mg PO QID)
Codeine elixir	15–30 mg PO QID	240 mg (80 mL)
Paregoric 0.4 mg morphine/1 mL Paregoric (45 % alcohol)	5 mL PO QID	37.5 mL PO QID (150 mL/day)
Opium tincture 10 mg morphine/1 mL opium (19 % alcohol)	0.3–1 mL PO QID	1.5 mL PO QID (6 mL/day)

Adapted from Parekh and Seidner [3]

Octreotide, a somatostatin analogue; teduglutide, a glucagon-like peptide 2 analogue; and human growth hormone all show promise in managing the most recalcitrant high output stoma associated with short gut syndrome [84, 85].

Stoma Reversal

Preoperative Preparation

The surgeon should have a clear understanding of the patient's anatomy prior to attempting stoma reversal. For patients with a stoma created by another surgeon, it is crucial to review the prior operative and pathology reports to understand the surgical indications, encountered pathology, and remaining anatomy. Record review is particularly important when reversing an end colostomy performed for diverticulitis or malignancy, since additional resection of the distal stump, descending colon, and splenic flexure mobilization may be needed to complete an adequate resection. Close or threatened margins found on oncologic pathology reports may merit endoscopic anastomotic evaluation to exclude cancer recurrence prior to stoma reversal. Endoscopic mucosal evaluation may be helpful prior to reversing stomas in IBD, ensuring that disease activity is controlled in the defunctioned bowel before attempting reversal, but the endoscopist must be aware that diversion colitis may grossly and histologically mimic IBD [86].

If a diverting loop stoma was used to protect a distal anastomosis, the authors prefer to use a lower gastrointestinal fluoroscopic contrast study to exclude anastomotic leak, stricture, and obstruction prior to stoma reversal. Similarly, for patients undergoing reversal of an end stoma, preoperative fluoroscopic and endoscopic studies are important to evaluate the remaining anatomy and quality of both distal and proximal segments of bowel—particularly when reversing another surgeon's stoma. Fluoroscopic abnormalities can be further examined with endoscopy allowing mucosal evaluation, tissue sampling, and anastomotic dilation, if needed. Coloanal, distal colorectal, and ileal pouch-anal anastomoses may be additionally assessed and gently dilated with digital rectal exam. Several groups espouse selective, rather than routine, use of lower GI contrast studies for anastomotic evaluation prior to stoma reversal and note that most anastomotic complications can be diagnosed without imaging [87–91]. Although intra- and postoperative surprises are not completely avoidable, the authors feel preoperative evaluation including record review, imaging, and endoscopy is the best way to avoid unexpectedly complex stomal reversals.

Timing

Timing of stoma reversal may impact the ease of the procedure. Diverting loop stomas are typically reversed within 2–3 months after creation once the surgeon is satisfied with the distal anastomosis (or pathology) that required diversion. Limited evidence suggested that loop ileostomy reversal performed less than 8.5 weeks following coloanal or ileoanal anastomosis may be associated with increased risk of complications [92]. Recently, several small studies have challenged this notion. A Turkish study showed that 88 % of loop ileostomy patients could be reversed during the same admission as the index operation without increasing morbidity, whereby avoiding high rates of stoma-related complications [93]. Nineteen patients undergoing loop ileostomy reversal within 10 days of the index operation revealed increased rates of wound infections, but otherwise similar complication profiles compared to normal interval closure patients [94]. Another retrospective study revealed patients who underwent loop ileostomy reversal less than 12 weeks from the interval operation had less postoperative nausea and vomiting than patients closed after 12 weeks [95]. Results from a Scandinavian prospective randomized trial comparing loop ileostomy reversal at 2 versus 12 weeks after low anterior resection are in press at the time of this publication and are eagerly awaited to provide evidence-based guidance to surgeons [96]. Until more rigorous evidence is available supporting safe early closure, the authors recommend loop ileostomy closure at approximately 8–12 weeks postoperatively as dictated by the clinical situation.

The use of adjuvant chemotherapy introduces another consideration in the timing of stoma reversal. If adjuvant chemotherapy is planned, conventional wisdom dogmatically

dictates keeping a diverting stoma through the duration of treatment to minimize postoperative reversal complications and diarrhea. Conversely, chemotherapy may further compound dehydration resulting in readmission for up to 11 % of ileostomy patients [97] and ostomates must be monitored carefully for dehydration during chemotherapy. A recent small retrospective review showed that loop ileostomy reversal in the midst of colorectal cancer chemotherapy had comparable morbidity and cancer-related outcomes in select patients compared to post-chemotherapy reversal [98], although this practice is not widely adopted at this time. Patient choice plays a large role in this situation, and a thorough discussion is helpful in choosing the ideal time for stoma reversal.

The optimal time for end stoma reversal remains a contentious issue with conflicting guidance in the literature [99]. It is generally considered that early postoperative adhesions become less tenacious and vascular with time, which may ease a challenging intra-abdominal dissection. Retrospective comparisons between early (<15 weeks) and late (>15 weeks) end colostomy reversal detail similar morbidity, but increased length of stay, subjective adhesion density scores, and small bowel injuries favoring later surgery [100]. An older study associated early Hartmann's reversal (<3 months) with increased leaks, sepsis, and death compared to colostomy reversals taking place after 6 months [101]. Although small series have shown no timing-dependent outcome differences [99, 102], the balance of low-level evidence suggests delaying end stoma reversal for 3–6 months eases future surgery in patients having undergone open end colostomy creation.

Technical Consideration of Loop Stoma Reversal

Once the surgeon is satisfied with the quality of the protected distal anastomosis (or pathology) (see section "Preoperative Preparation"), loop colostomy or ileostomy reversal can typically be performed as a local procedure through a peristomal circular incision under general anesthesia. The entire abdominal midline should be included and prepared in the operative field; in the rare event an unplanned laparotomy is required. A circumferential skin incision is made just outside the mucocutaneous junction and sharply deepened until subcutaneous fat is seen (Figure 55-27). Clamps may be placed on the skin rim to retract the stoma anteriorly to expose the interface between the serosal surfaces of the bowel limbs and the subcutaneous tissues. A cylindrical sharp dissection is performed on the serosal surfaces of the bowel limbs heading posteriorly until the anterior rectus sheath is encountered. If the patient is obese and the fascia is deep, clamps can be used to grasp and elevate the fascia; alternatively, radial 1–2 cm counter-incisions extending from the cut skin edge may allow deeper exposure. The rectus muscle is dissected from the bowel serosa and can be distinguished from the bowel by the longitudinal orientation of muscle fibers. Circumferential dissection continues until the abdomen is entered. Limited intra-abdominal adhesiolysis is performed to enable adequate mobilization of the bowel loop for eventual anastomosis and fascial closure. Care should be taken to avoid injury to the stoma mesentery during dissection, especially during loop colostomy reversal since marginal artery injury can result in distal colonic ischemia.

If the stoma is everted, sharp adhesiolysis may be used to flip the everted bowel wall into a normal configuration. The skin disk and mucocutaneous junction is excised and debrided back circumferentially to soft and supple bowel suitable for closure. Partial and full thickness bowel injuries can rarely occur during loop stoma closure. Bowel assessment can be performed by injecting dilute povidone-iodine solution via a bulb syringe while digitally occluding each bowel limb to pressurize the dissected bowel limbs and evaluate for injury (Figure 55-28). Injuries can be suture repaired or resected depending upon the nature and location of injury. Rarely, tenacious adhesions or deep bowel injury may require

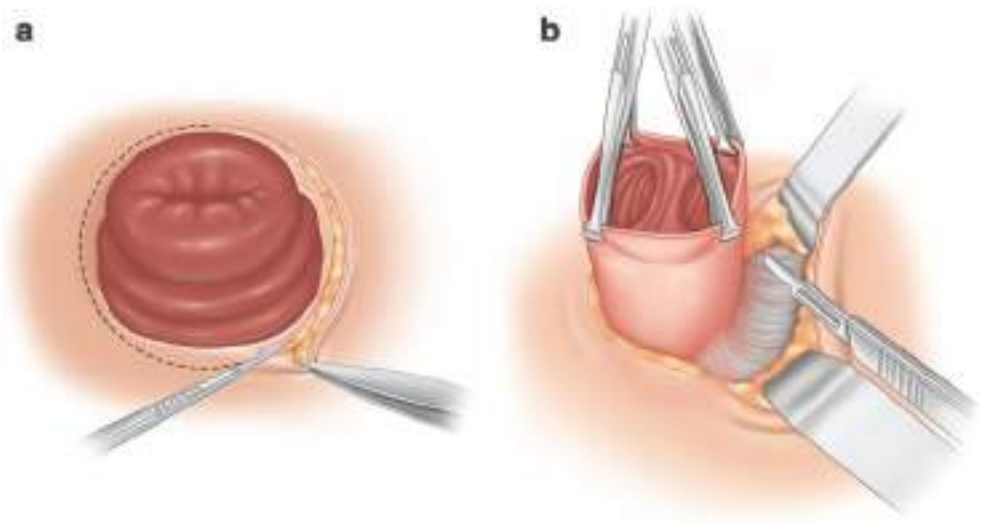

FIGURE 55-27. (**a**) Incision of the stomal mucocutaneous junction. (**b**) Elevating the stoma with clamps to expose the subcutaneous stomal dissection.

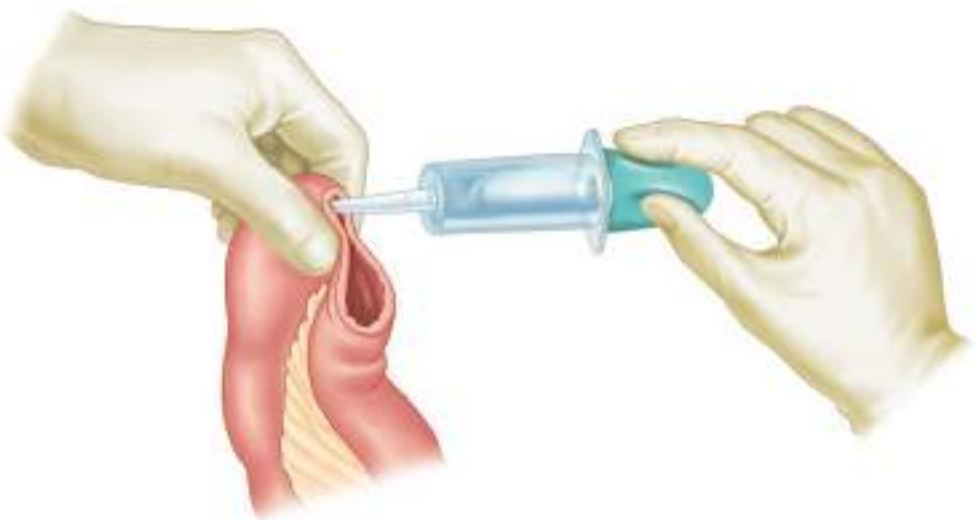

FIGURE 55-28. Pressurized leak testing of injured bowel during loop stoma closure.

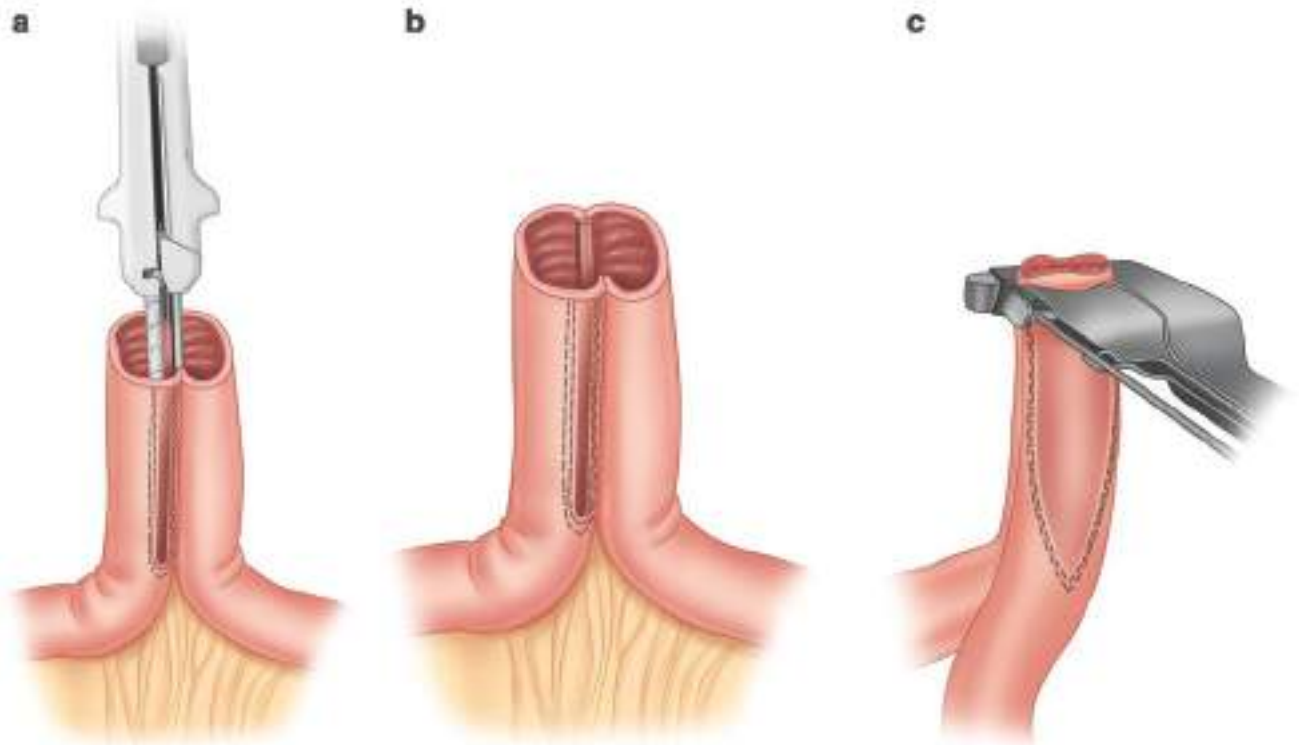

FIGURE 55-29. A stapled side-to-side anastomosis.

a laparotomy for repair. The bowel portions that comprised the stoma can be resected or left in situ at the surgeon's discretion. Once the bowel is adequately mobilized and inspected, a stapled or hand-sewn closure is performed.

A side-to-side (functional end-to-end) stapled closure is performed by inserting the limbs of a linear cutter stapler (GIA type) into each limb of the loop stoma (Figure 55-29). Care is taken to ensure the limbs are opposed along the anti-mesenteric surfaces prior to firing the stapler. The common portion of bowel wall that connects both bowel limbs may be divided or resected to improve anti-mesenteric opposition. The common enterotomy is then closed with either suture or an intersecting fire of another GIA- or TA-type stapler. The completed anastomosis may

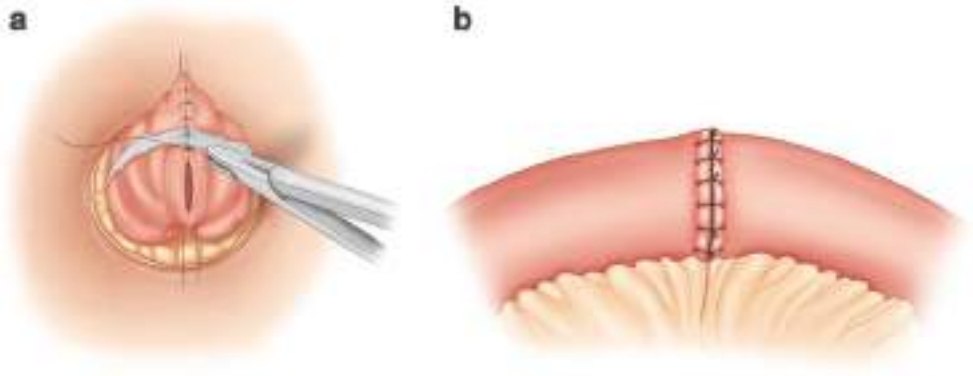

FIGURE 55-30. Handsewn loop closure for (**a**) colostomy and (**b**) ileostomy.

be oversewn at the discretion of the surgeon and a suture (i.e., "crotch stitch") may be placed at the confluence of the bowel limbs. Alternatively, a hand-sewn anastomosis is performed with either running or continuous suture in one or two layers to longitudinally close the defect (Figure 55-30). The completed anastomosis is then reduced into the abdomen. Adequate intra-abdominal adhesiolysis must be completed prior to fascial closure to avoid injury to bowel adherent to peritoneum. The fascia is closed with interrupted or running suture. The skin can be closed with or without a drain, left partially open with wicks, or left completely open to heal secondarily.

Mode of loop ileostomy closure has long been a source of debate amongst surgeons based largely on preference and training pedigree. Several meta-analyses and three single-center prospective randomized control trials have shown stapled and loop closures are equivalent with regard to anastomotic leakage, wound infection, overall complications, and cost; however, stapled closure was faster, caused less postoperative bowel obstruction, and was associated with shorter hospital stays [103–107]. It is postulated that the narrow luminal diameter produced with hand-sewn closure techniques is prone to edema and early obstruction compared to widely patent stapled anastomoses. Recently, a large multicenter trial showed stapled and hand-sewn anastomoses to have similar rates of postoperative bowel obstruction [108]. As a result, ASCRS Clinical Practice Guidelines (CPG) state that stapled and hand-sutured techniques are both acceptable for loop ileostomy closure [7].

Wound closure at the former stoma site is also a contentious issue that has been studied extensively. Several studies have compared various techniques including traditional linear wound closure, closure over a suction drain, and skin-level purse-string cerclage technique (which leaves a small opening at the center of the wound). Purse-string techniques are shown to have significantly lower wound infection rates and improved patient satisfaction [109, 110]. ASCRS CPG recommends stoma-site skin re-approximation should be performed when feasible, and purse-string skin closure may have advantages compared with other techniques [7].

Technical Considerations of End Stoma Reversal

Undoubtedly, reversal of an end stoma can be a substantial surgical undertaking and may be a larger operation than the initial stoma creation. The patient and surgeon should be prepared for an extensive and potentially hostile operation. In addition to the preoperative preparation described above, the surgeon may selectively use ureteral stents to aid in ureteral identification in a potentially hostile operative field. A fully prepared surgeon should have pelvic retractors, proctoscopes, EEA sizers, and vaginal retractors available in the operating room. Lastly, the surgeon should note the adequacy of the current stoma and site. If the current stoma site is in a poor location, the patient can be marked for a new stoma site should a temporary loop ileostomy be required.

Once the surgeon is satisfied with the quality of the protected distal anastomosis (or pathology), an end stoma can be reversed using open or laparoscopic approaches [111, 112]. The patient is typically placed in modified Lloyd-Davis (low lithotomy) or split leg position allowing access to the anus. For open reversal of an end stoma, the stoma is prepared in the surgical field. A sterile, countable, gauze sponge and adherent plastic drape can be used to sequester end colostomy contamination from the midline wound. The abdomen is entered sharply and adhesions are lysed to identify the bowel conduit leading to the end stoma. The distal bowel conduit is identified, and may be mobilized if necessary, and inspected for anastomotic suitability. In case of a rectal stump, scarring and retraction may rarely require mobilization and resection of the previous rectal closure line; however, it is crucial to ensure that the anastomosis is in the rectum and not sigmoid (see below). Once adequate intra-abdominal adhesiolysis is performed, the stoma is mobilized back into the abdomen by incising the stomal mucocutaneous junction and cylindrically dissecting subcutaneous adhesions until the abdominal dissection is met (Figure 55-31a). Care is taken to avoid mesenteric injury and devascularization of the stoma since bowel length preservation may aid in reaching low pelvic anastomoses.

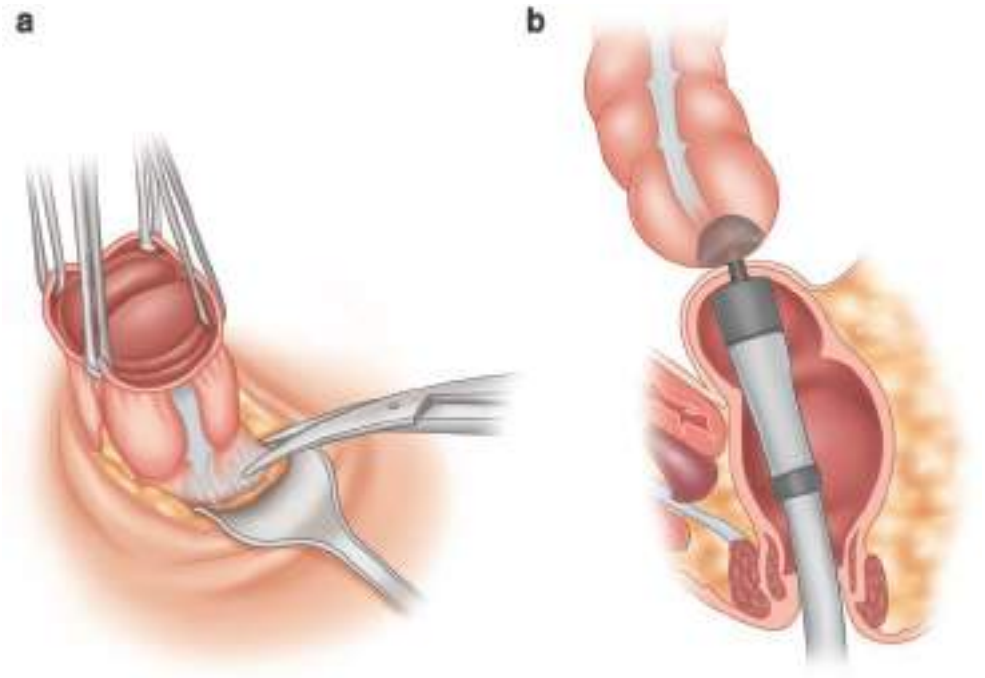

FIGURE 55-31. (**a**) Mobilization of an end colostomy. (**b**) Stapled end-to-end colorectal anastomosis.

After the end stoma is reduced into the abdomen, the surgeon may need to perform additional mobilization of the former stoma to obtain tension-free reach to the target distal bowel. For end ileostomy reversals, generous small bowel mobility does not typically require much additional mobilization. Colorectal anastomoses may require additional lengthening maneuvers including mobilization of the flexures and high vascular ligation to obtain tension-free reach into the pelvis. For an end colostomy reversal following sigmoid diverticulitis, the surgeon must ensure the adequacy of the initial resection at time of stoma reversal with particular attention paid to previous resection margins. Occasionally, a surgeon may create a sigmoid stump rather than a rectal stump during emergency surgery, and a completion sigmoid colectomy may be necessary at the time of stoma reversal to ensure an adequate diverticular resection. Similarly for cancer, the oncologic adequacy of the initial resection must be assessed and remedied at the time of stoma reversal, which may require additional bowel resection or lymphadenectomy.

Once the distal and proximal bowel conduits are adequately mobilized and prepared, an anastomosis is created with either stapled or hand-sewn techniques at the surgeon's discretion. For colorectal anastomoses following Hartmann's procedure, a stapled end-to-end anastomosis (EEA) is commonly performed (Figure 55-31b). For stapled anastomoses, the surgeon must ensure the stapler can easily be passed to the transected rectal staple line. This may not always be easy or possible since the rectal stump can become corrugated, contracted, entrapped, or lost in a hostile pelvis. Lighted deep pelvic retractors, proctoscopes, vaginal retractors, EEA sizers, and copious lubrication may aid in identification of the rectal stump. If the stapler is unable to be advanced fully to the proximal rectal transection line, the end of the colon can be anastomosed to the side of the anterior rectal wall, but the end-to-side anastomosis must be several centimeters from the proximal rectal margin to avoid ischemia to the remaining bridge of rectal wall. Moreover, if an anterior end-to-side rectal anastomosis is performed, the surgeon must assure the vagina and/or bladder is fully mobilized away from the intended rectal anastomotic site to avoid catastrophic iatrogenic fistulas. An anastomotic air-leak test should be performed to interrogate anastomotic quality. If a leak is discovered, the anastomosis can be resected and recreated, revised, or protected with a diverting loop ileostomy at the surgeon's discretion.

Laparoscopic end stoma reversal with colorectal or ileorectal anastomosis is predicated upon the same principles and techniques described above, but are modified to reflect the nuisances of laparoscopy. After similar preoperative work-up and positioning, surgery typically commences with incision of the mucocutaneous stomal junction and subcutaneous stomal dissection. Once the stoma is completely freed from peritoneal attachments and un-everted, the anvil to an EEA stapler is secured in place and the anvil–stoma combination is reduced into the abdomen. The former stoma site is occluded with a airtight, twisted, plastic, wound retractor or plugged with a balloon-tipped Hasson trocar as pneumoperitoneum is generated. Additional laparoscopic working ports are placed to complete the necessary adhesiolysis, pelvic dissection, and rectal mobilization exactly as performed for an open procedure. An intracorporeal EEA stapled rectal anastomosis is then completed as described above.

TABLE 55-5. Select published complications rates for stoma reversal [99, 108, 112, 113, 116, 125–127]

Stoma reversal type	Loop ileostomy reversal (%)	Loop colostomy reversal (%)	End colostomy reversal with colorectal anastomosis (%)
Superficial surgical site infection	3–13.5	5–20	14–43.8
Deep space infection/leak	2–4	2–4	1.5–21
Bowel obstruction/ileus	5–16	4	23
Hernia (clinically diagnosed)	0–50	2–38	3–31

Stoma Reversal Complications

Loop stoma reversal is often considered a minor procedure when compared to the index operation; however, complications can occur more frequently than most surgeons acknowledge (Table 55.5). Regardless of technique, loop ileostomy reversal is generally well tolerated with low risk of anastomotic leakage; however, early wound infections and late-term incisional hernias may occur. Reversal of an end stoma is associated with high morbidity, and stoma reversal is often more challenging than the initial operation. Given the gravity of some end stoma reversals, proper surgical planning is essential to assure the best surgical outcomes, while preoperative patient counseling can best manage perioperative patient expectations.

Special Considerations

The Difficult Stoma

Increasing rates of obesity present a particular challenge to the colorectal surgeon. Unfortunately, obesity is associated with increased risk of stoma-related complications [10], so the patients who require the highest quality stomas to avoid problems paradoxically can be the most challenging stomas to create. Acutely inflamed and chronically foreshortened bowel mesentery also may hinder stoma creation, even in thin patients. Special tips and tricks can help the surgeon create difficult stomas in complex situations. Since stoma height has been identified as an independent risk factor for problematic stomas, it is not surprising that the majority of tips involve means of obtaining adequate, tension-free reach of an adequate length of stomal conduit above skin level.

Simple measures are first employed when dealing with the difficult stoma. In obese patients with a thick abdominal wall, the surgeon may find the supra-umbilical abdominal wall to be thinner whereby easing reach and minimizing tension on a stoma (Figure 55-32). In the super morbidly obese, a subxiphoid loop transverse colostomy may be the easiest stoma to create if temporary diversion is necessary. If superior stoma sites are not plausible, and the surgeon still struggles to deliver bulky bowel through a thick abdominal wall, the stoma can be delivered in a stepwise fashion. First, the subcutaneous tissues can be completely elevated off of the anterior rectus sheath and the stoma can be delivered completely through the muscular layer. The stoma can then be delivered through the subcutaneous tissues and skin in a second step. Alternatively, use of a plastic sleeve wound retractor with or without water-soluble lubricant may provide a slick conduit to help deliver thickened bowel and mesentery through a challenging trephine. Some advocate performing subcutaneous lipectomy to minimize abdominal wall distance; however, this may lead to a difficult-to-pouch recessed stoma and should be used judiciously, if at all.

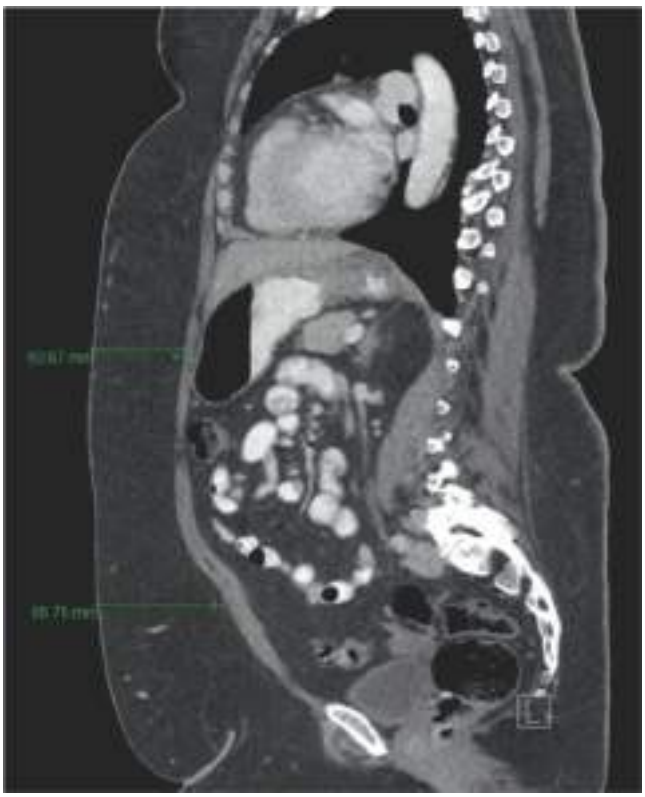

FIGURE 55-32. The abdominal wall may be thinner above the umbilicus in the obese patient, easing creation of a potentially difficult stoma.

A loop-end stoma is a unique ostomy configuration that may allow additional reach of an end ileostomy (Figure 55-33) or colostomy (Figure 55-34) in obese patients or those with a foreshortened mesentery. The loop-end stoma

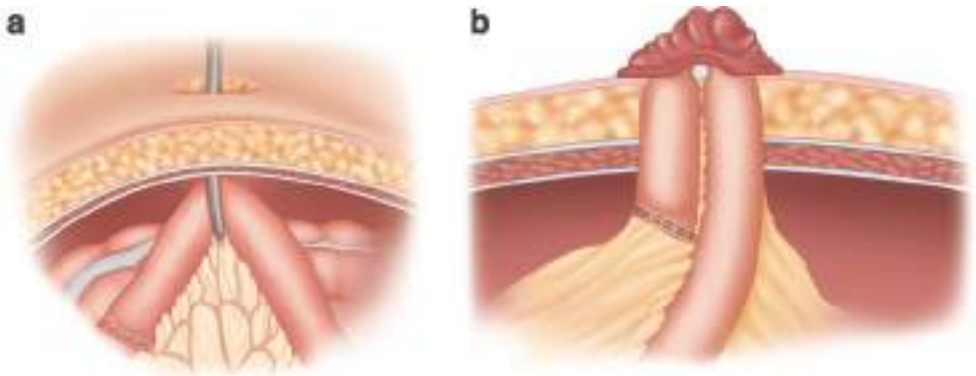

FIGURE 55-33. Loop-end ileostomy.

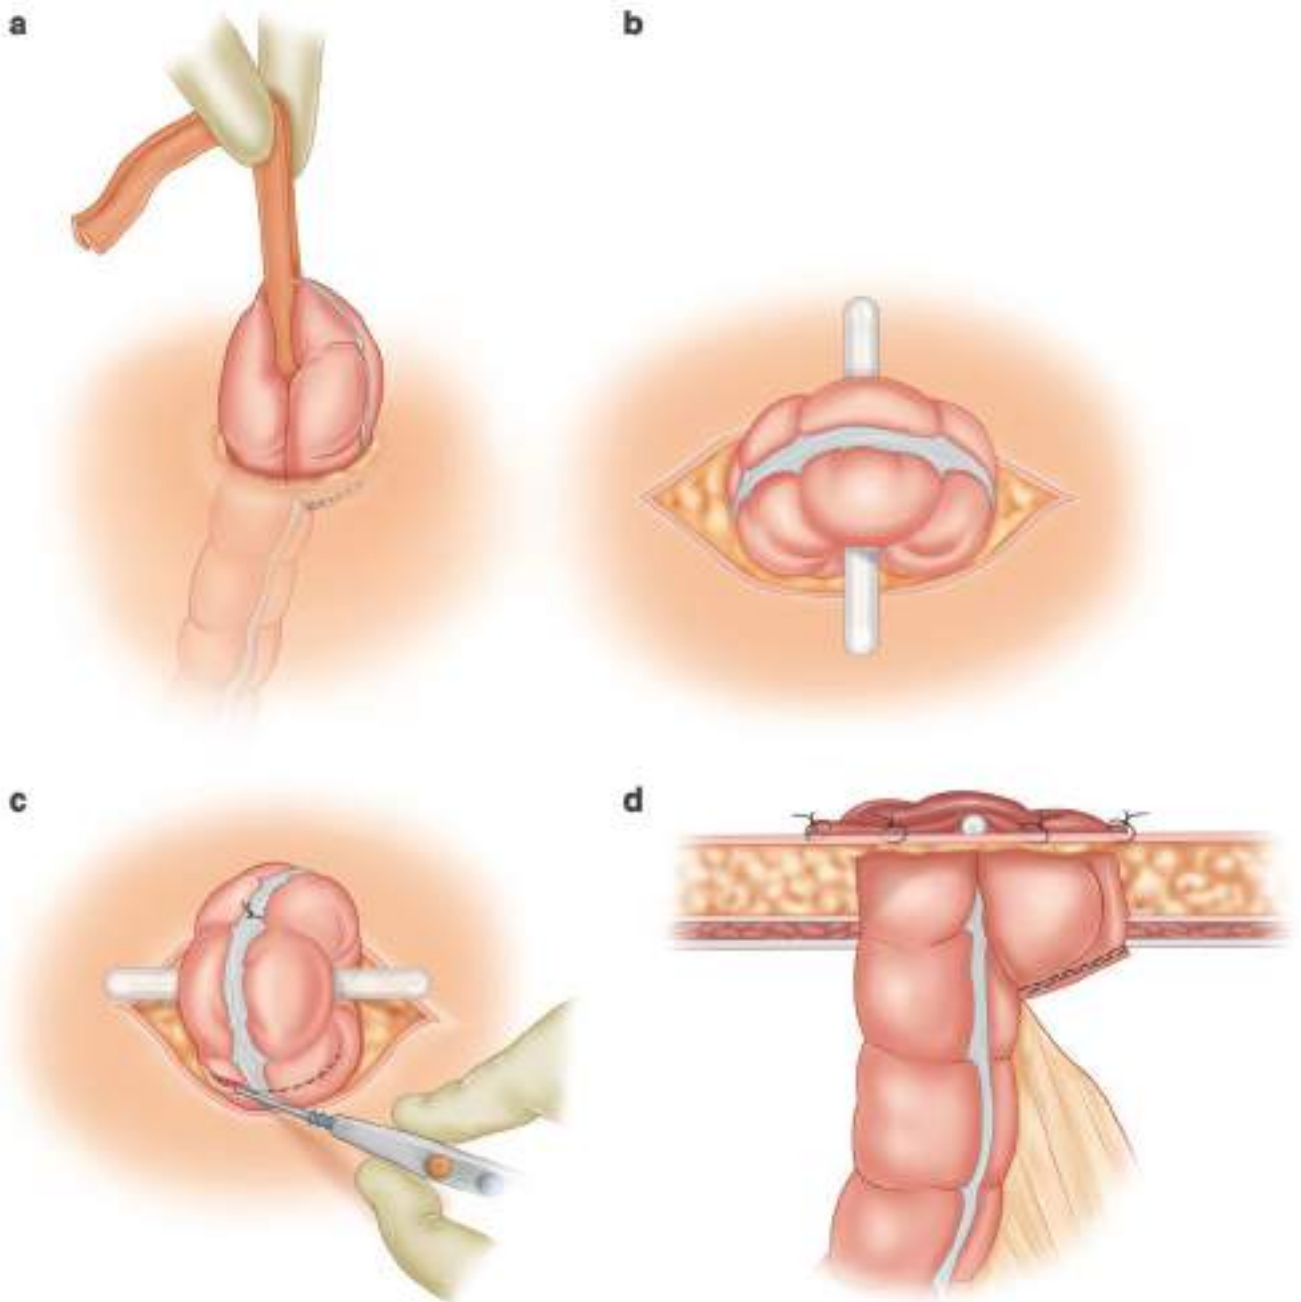

FIGURE 55-34. Creation of a loop-end colostomy.

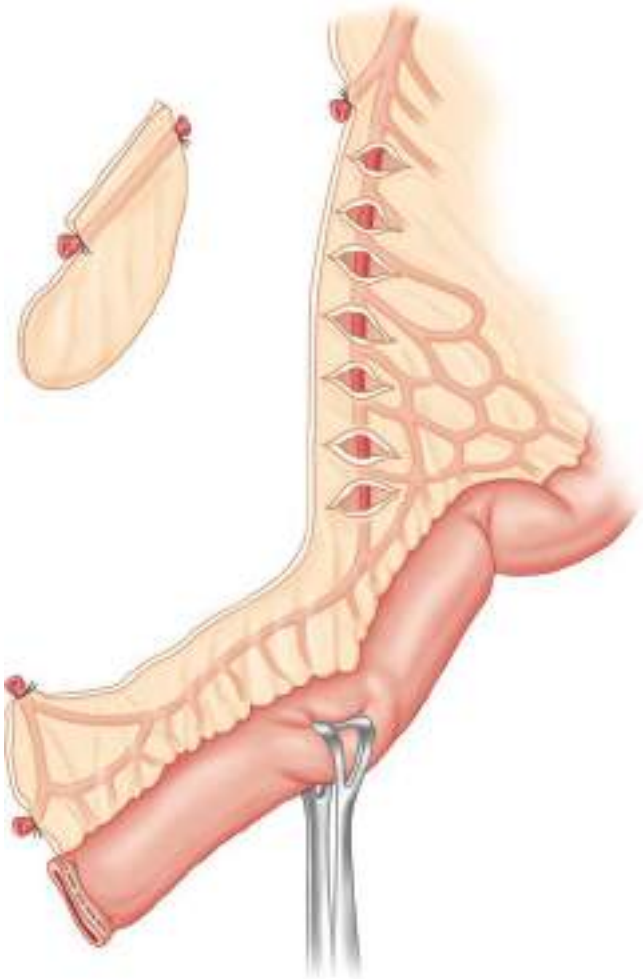

FIGURE 55-35. "Pie crusting" of the bowel mesentery to obtain additional length prior to stoma creation. If a difficult end ileostomy is fashioned from the terminal ileum, the surgeon may find it helpful to ligate the ileocolic artery proximally to obtain reach.

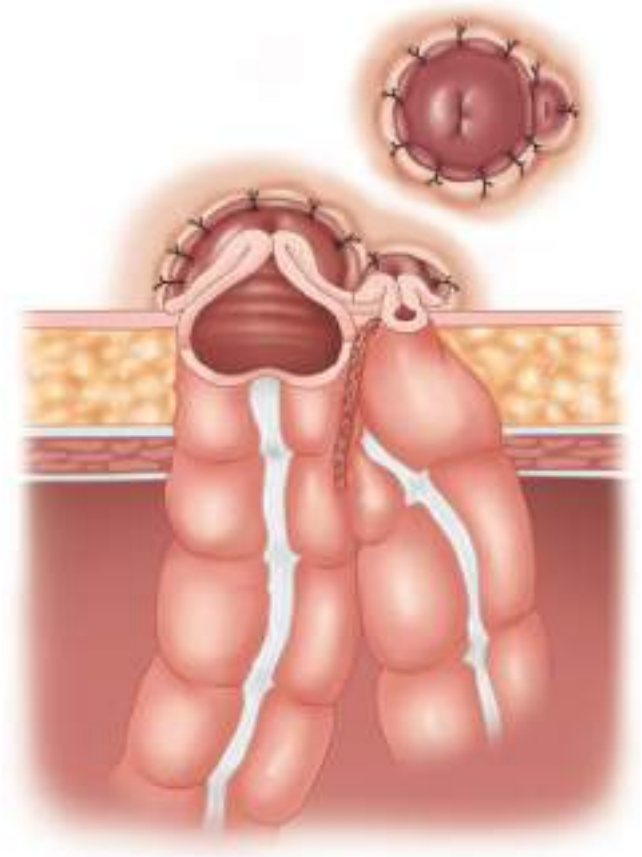

FIGURE 55-36. A Prasad-type end-loop colostomy.

configuration is useful when the tip of the intended stoma conduit is tethered by the mesentery and the bowel immediately proximal to the end is more mobile. The loop-end arrangement preserves the mesentery to the entire stoma, whereby assuring adequate perfusion. A loop-end stoma is created similarly to a loop stoma, which is aided by passing a narrow Penrose drain through a mesenteric defect at the mesentery–bowel interface to deliver the loop. The stoma is matured as a loop ileostomy or colostomy as detailed previously (see section "Technical Considerations of Stoma Creation").

Two to three centimeters of additional bowel reach can be obtained by sequentially scoring the peritoneal surface of the stomal mesentery perpendicular to the course of the vessels (Figure 55-35). Such "pie crusting" should be carefully performed by only dividing the peritoneum while protecting the underlying vessels. In the case of a small bowel stoma, both peritonealized mesenteric surfaces may need to be scored to obtain maximum reach.

In the acute setting when it may be inadvisable to create an anastomosis, both segments of bowel may be exteriorized in a Prasad-style end-loop stoma (Figure 55-36). This configuration is most commonly used when there is a bowel perforation related to diverticulitis or trauma but may be employed in any situation when primary anastomosis is inadvisable. The unique aspect of this stoma is that both bowel limbs are exteriorized and eventual re-anastomosis may often be performed with a local procedure without laparotomy.

Challenging situations may require the surgeon to compromise on the tenets of stoma creation and the ideal stoma at the ideal location with the ideal bowel segment may not be possible. If a surgeon is forced to decide between making a poor stoma in a good location versus making a good stoma in a poor location, a general consensus amongst stoma care professionals is that a poor stoma in a good location is the lesser of two evils [12]. Rarely, thickened bowel and mesentery may prohibit stoma eversion and maturation. In these cases where eversion and maturation is not possible, the

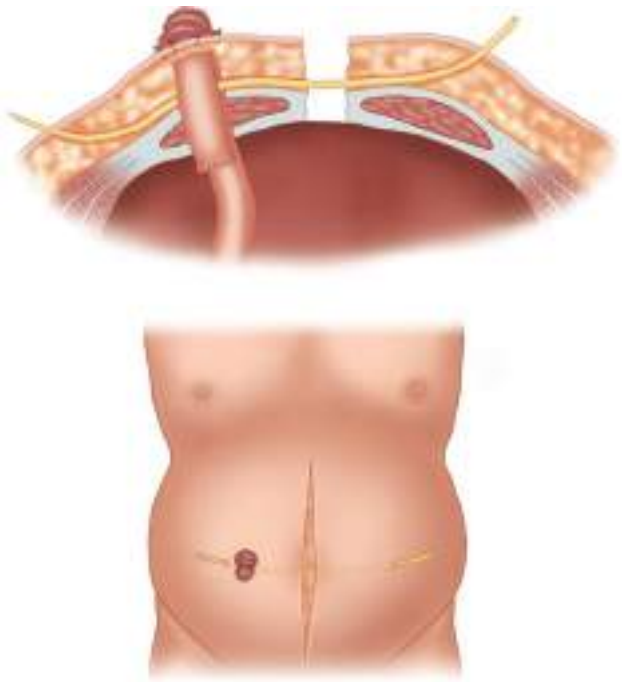

FIGURE 55-37. Supporting a difficult loop enterostomy at the fascial level with a filiform catheter.

stoma can be simply opened without maturation and secured to the skin well above skin level. While reactive serositis and late-term stricture may develop, this temporizing measure may get the patient through until the bowel is suitable for stomal revision or reversal. Seldom, a remarkably hostile abdomen may prohibit stoma delivery through a traditional stoma trephine despite exhausting all lengthening maneuvers. In these rare situations, a stoma may be fashioned through the midline incision. Although a stoma placed in an incision is prone to wound and hernia problems, it may temporize or palliate an otherwise unsustainable surgical situation. Infrequently, a heavy mesentery or friable bowel may cause a stoma support rod to tear through the mesenteric aspect of a loop stoma. Instead, the bowel can be supported by two stoma rods placed alongside one another to distribute the tension over a greater surface area. Alternatively, the mesentery can be braced at the fascia level rather than the skin level. In this method, a long malleable or pliable tube (e.g., thin chest tube, filiform, follower, plastic vascular tunneling device) is passed through a skin incision remote from the stoma site down to the anterior fascia of the abdominal wall where it pierces an avascular portion of the stoma mesentery before rising through the skin on the opposite side of the stoma (Figure 55-37). This tube is subsequently removed in several days when the stomal bowel and mesentery adhere to the subcutaneous tissues and are at minimal risk for retraction.

Temporary Fecal Diversion: Loop Ileostomy Versus Loop Colostomy

The ideal level of temporary protective fecal diversion following colorectal or coloanal anastomosis has long been debated by colorectal surgeons. It is generally acknowledged that loop ileostomy and loop colostomy have similar complication rates, but different complication profiles [7]. Clinical and patient-reported outcomes between temporary loop ileostomy versus loop colostomy have been compared in several recent trials and meta-analyses with inconsistent results [113–115]. Loop ileostomies, although more prone to dehydration, re-admission, and post-reversal obstruction, are found to have less post-closure sepsis and less pre- and postoperative hernias and may offer improved quality of life compared to loop colostomy [116–118]. ASCRS CPG recommends loop ileostomy preferentially over transverse loop colostomy for temporary fecal diversion in most cases, but acknowledges that there may be particular circumstances favoring a loop transverse colostomy [7]. For instance, a distal colorectal obstruction may best be palliated with a transverse loop colostomy that allows both afferent diversion and efferent retrograde venting. Additionally, a transverse loop colostomy may be easier to fashion in the obese than a loop ileostomy (see section "The Difficult Stoma").

Genitourinary Stomas

Although colorectal surgeons do not typically perform reconstructive genitourinary procedures, familiarity with such procedures is important for several reasons. First, a colorectal surgeon may be asked to help with stoma care and complications and assist with urinary stoma revisions. Additionally, a thorough understanding of urinary stoma construction and anatomy can prove invaluable during urgent and emergent re-operations on patients with previous genitourinary reconstructions. Moreover, genitourinary reconstruction may be necessary for patients with locally advanced pelvic malignancies that require multi-visceral resection. Lastly, patients with neurogenic bowel and bladder may require synchronous urinary and fecal diversion, so conscientious understanding of the urologic aspects of a synchronous operation is crucial.

The simplest reconstructive urinary diversion is the ileal conduit (Figure 55-38) [119]. This procedure typically harvests a 10–15 cm segment of ileum (typically at least 15–20 cm proximal to the ileocecal valve) to serve as a conduit between ureters and the skin. Enteric continuity is restored with an ileo-ileostomy and the left ureter is tunneled through a sigmoid mesenteric defect. Both left and right ureters may be anastomosed separately (in a "Bricker" fashion) or sewn together and a single ureto-ileal performed

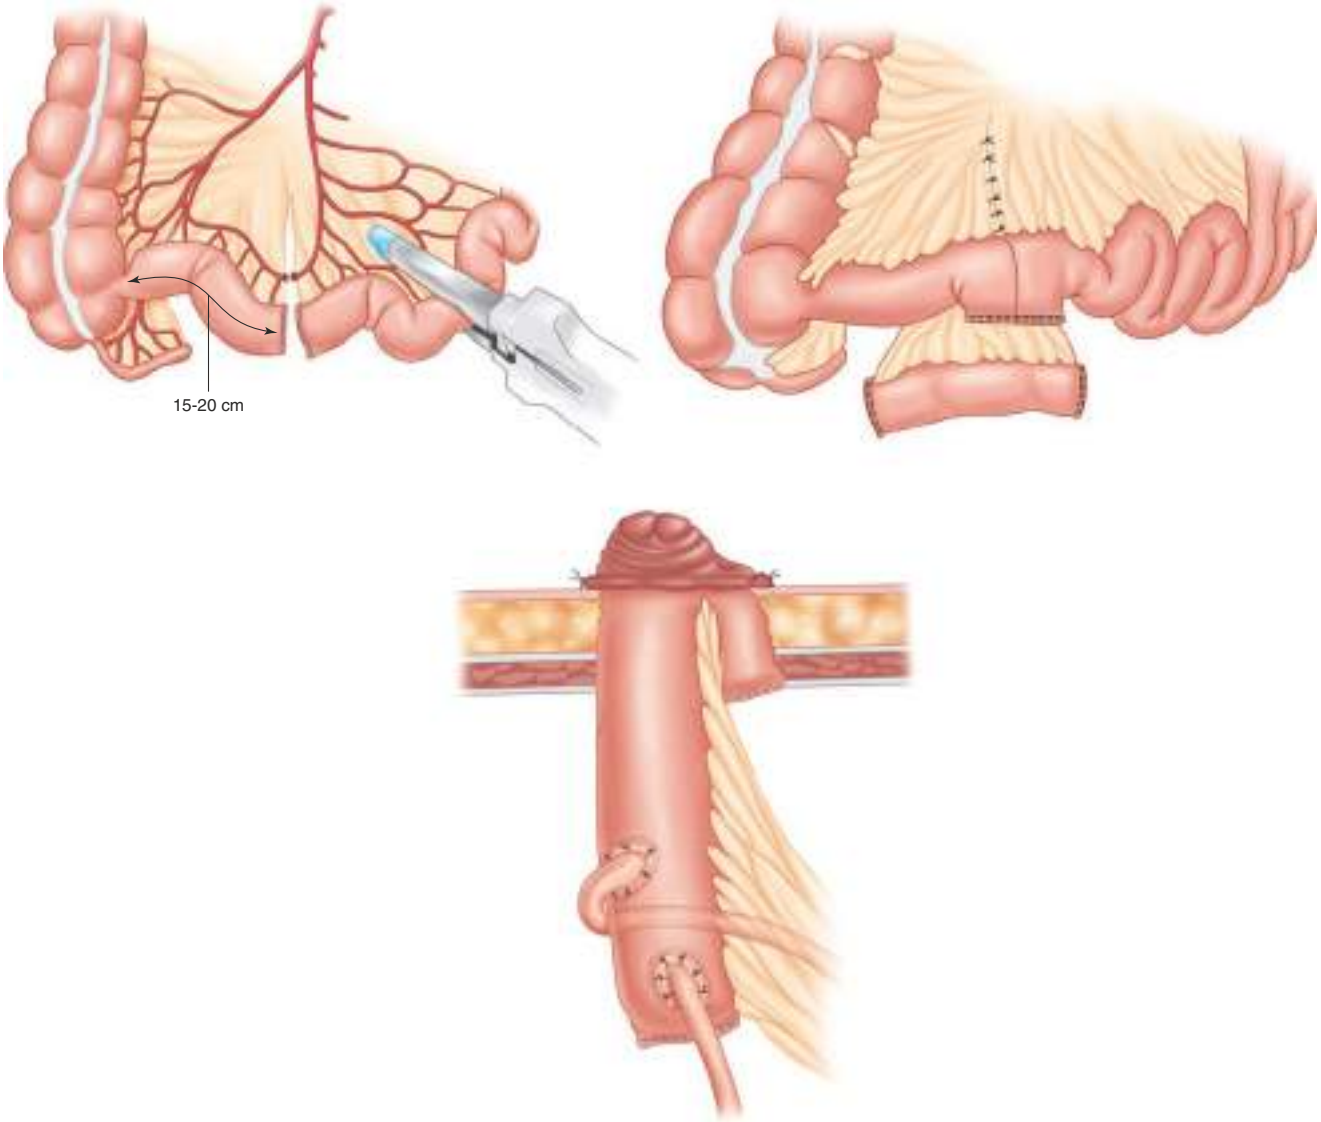

FIGURE 55-38. The ileal urinary conduit: (**a**) a segment of mid ileum is resected, (**b**) an ileo-ileostomy is created, and (**c**) the harvested ileal conduit is anastomosed to the ureters and matured as a stoma.

(called a "Wallace" anastomosis). The proximal end of the conduit is usually oversewn to limit stone formation. The open end of the conduit is delivered through a stoma trephine and matured to the skin. The stoma is matured in either an end or loop-end configuration. The surgeon must be keenly aware of the left ureter's aberrant course during re-operation and left colon mobilization. Moreover, the tenuous ileal conduit mesentery must be preserved at all costs during re-operation, since inadvertent injury can result in conduit infarction and convert a simple adhesiolysis to an extensive and complex urinary reconstruction. The mesentery for the conduit will always be inferior to the new ileo-ileostomy.

Urologic surgeons may augment or replace urinary bladders with harvested ileal segments for myriad indications [120]. Akin to the ileal conduit, a similar segment of mid ileum is harvested and configured as either a panel or pouch to augment or reconstruct the bladder to increase its capacity. Regardless of the ileal configuration, enteric continuity is restored with an ileo-ileostomy and a fragile mesenteric pedicle spans from the closed mesenteric defect to the pelvis. This ileal mesentery pedicle can be a nidus for obstruction and internal herniation, and extreme care should be taken to preserve the mesentery to avoid devascularization of the reconstructed urinary bladder.

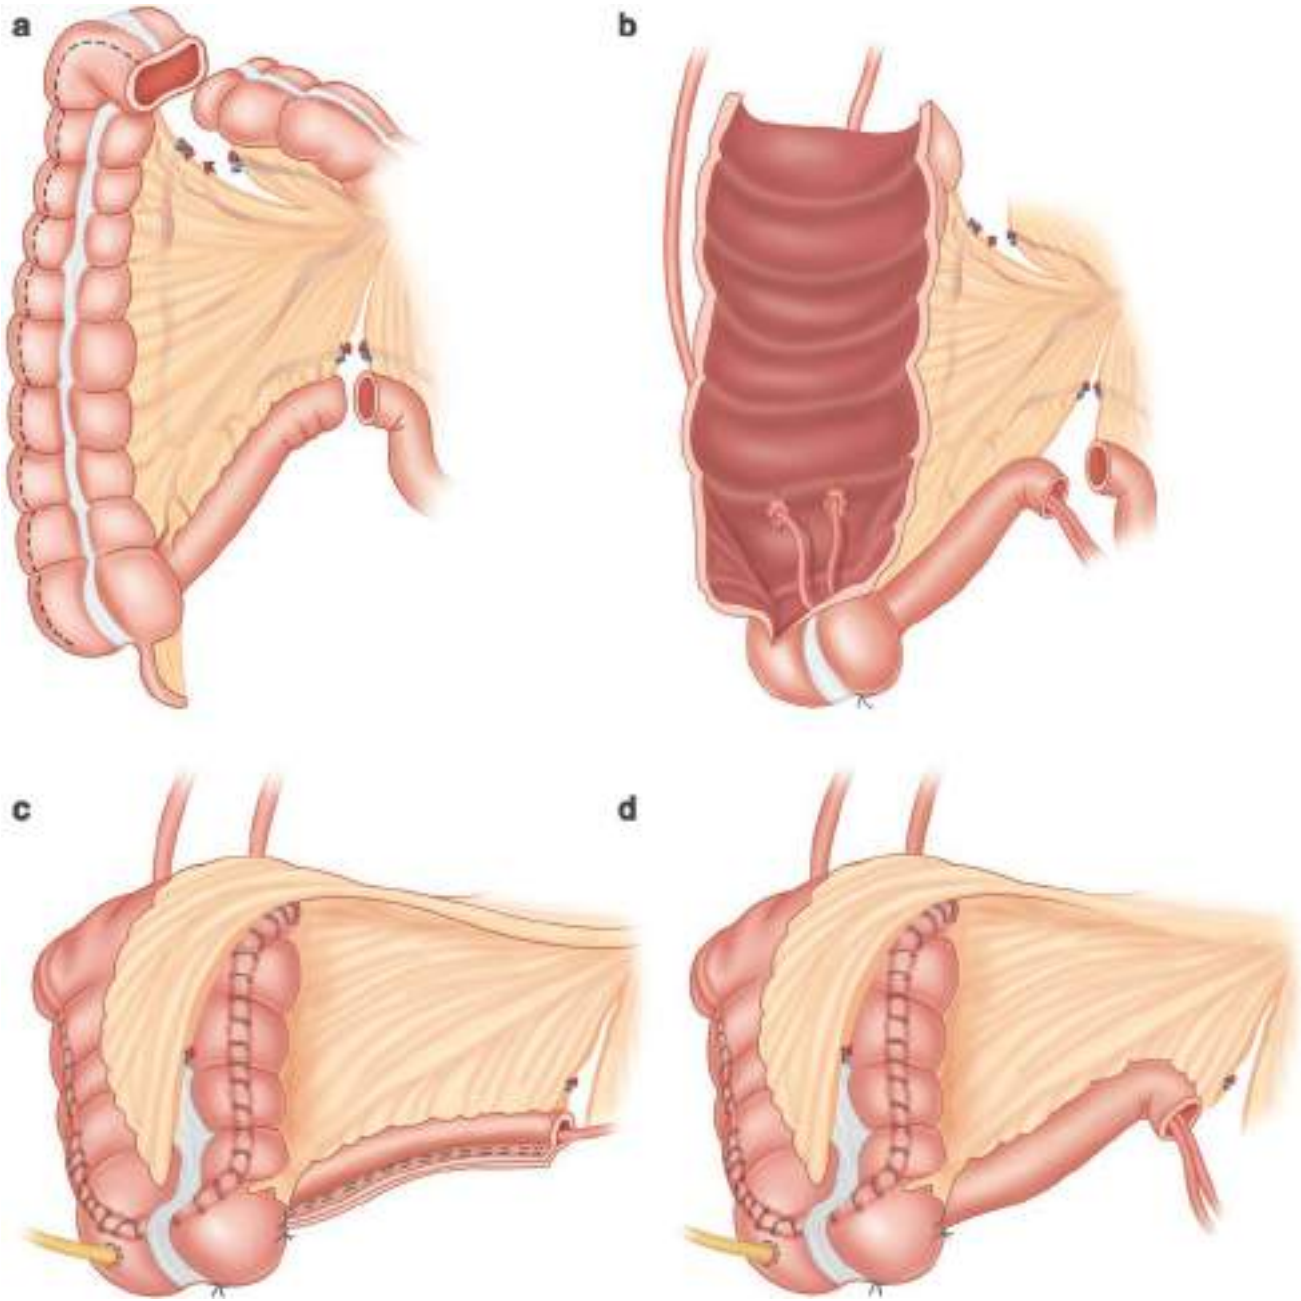

FIGURE 55-39. The Indiana pouch.

Several types of catheterizable urinary stomas may provide appliance-free urinary continence to patients in need of genitourinary diversion. These catheterizable stomas are brought to the umbilicus or the right lower quadrant. Most pouches are created from the right colon with the appendix or the terminal ileum as the channel for catheterization. An Indiana pouch follows similar principles as the ileal conduit; however, the right colon and ileum are harvested en bloc to create a large intra-abdominal urinary reservoir (Figure 55-39) [121]. The ileocolic segment is anastomosed to the bilateral ureters, and a narrow, skin-level, stoma is created that serves as a valve and permits intermittent catheterization. A Mitrofanoff appendicovesicostomy utilizes an appendiceal conduit to create a catheterizable stoma for the

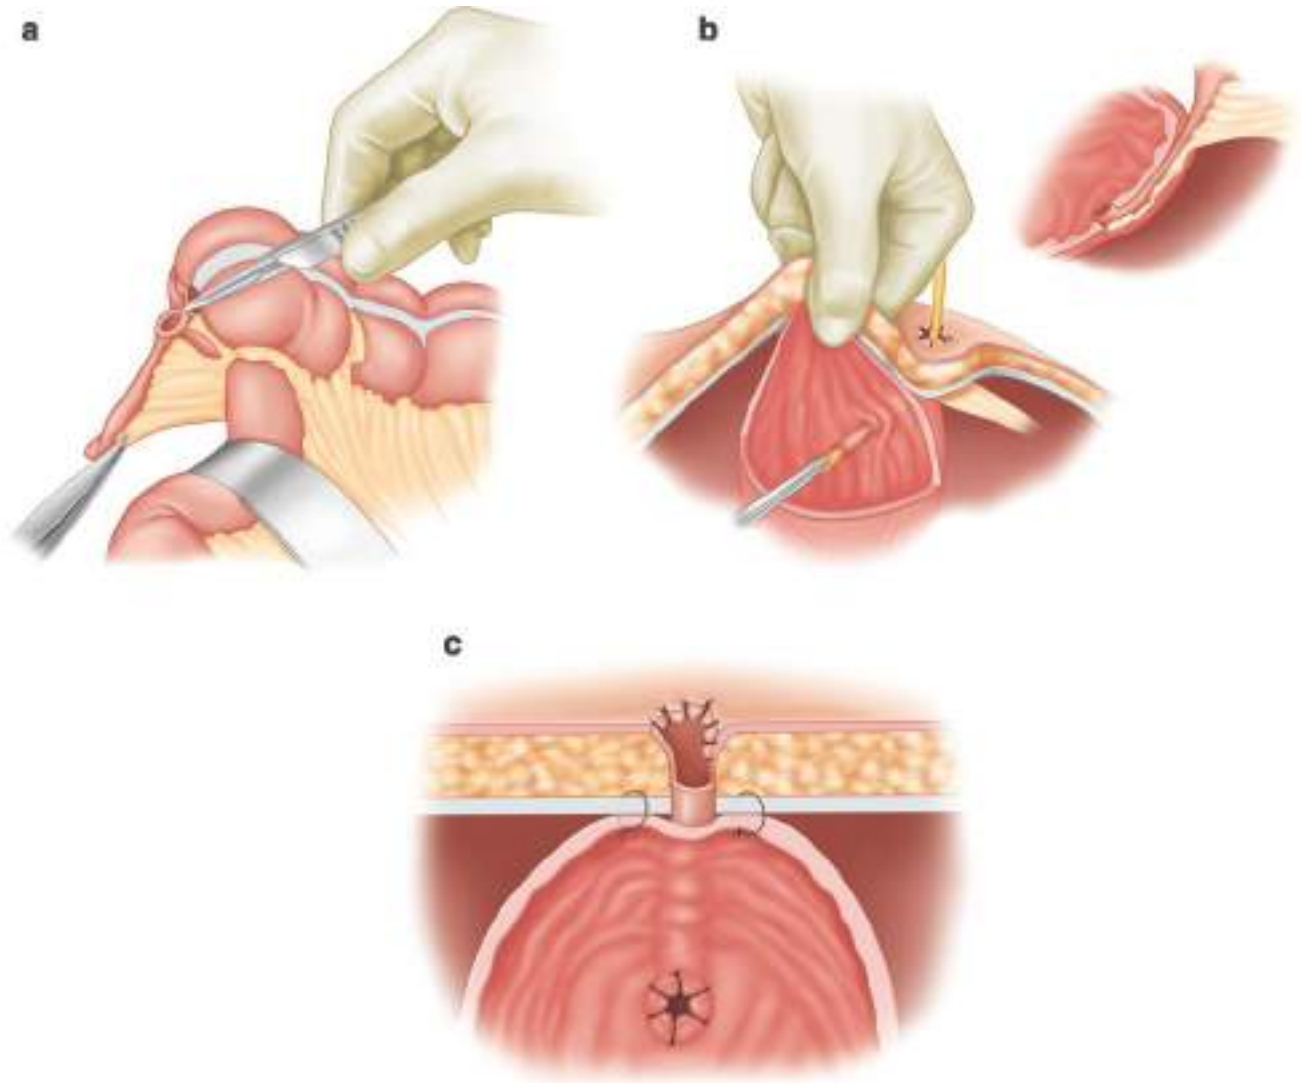

FIGURE 55-40. Mitrofanoff appendicovesicostomy.

bladder or neobladder (Figure 55-40) [122]. A Monti conduit is similar to the Mitrofanoff appendicovesicostomy but utilizes a pedicled segment of tubularized ileum to create a narrow, catheterizable, urostomy (Figure 55-41) [123].

The Turnbull Blowhole Colostomy

Rarely, difficult situations may arise where colectomy or proper fecal division is inadvisable due to prohibitively high operative risk. For example, gravid patients with fulminant colitis may be unsuitable for colectomy out of concern of patient or fetal demise. Occasionally, profound comorbidities such as sepsis or cardiovascular collapse may also make a total colectomy inadvisable. In these situations, a limited upper midline laparotomy with loop ileostomy and Turnbull blowhole colostomy can be fashioned quickly to divert and decompress a toxic colon until the patient can sustain a proper resection (Figure 55-42) [124]. In these challenging situations, a limited 10-cm supra-umbilical laparotomy can be made to accommodate a hand to explore the abdomen. A loop ileostomy can be made through a separate stoma trephine and the loop of transverse colon can be brought out through the midline incision. The midline fascia is closed around the bulge of the transverse colon loop and then a watertight seal is created between the seromuscular surface of the colon and

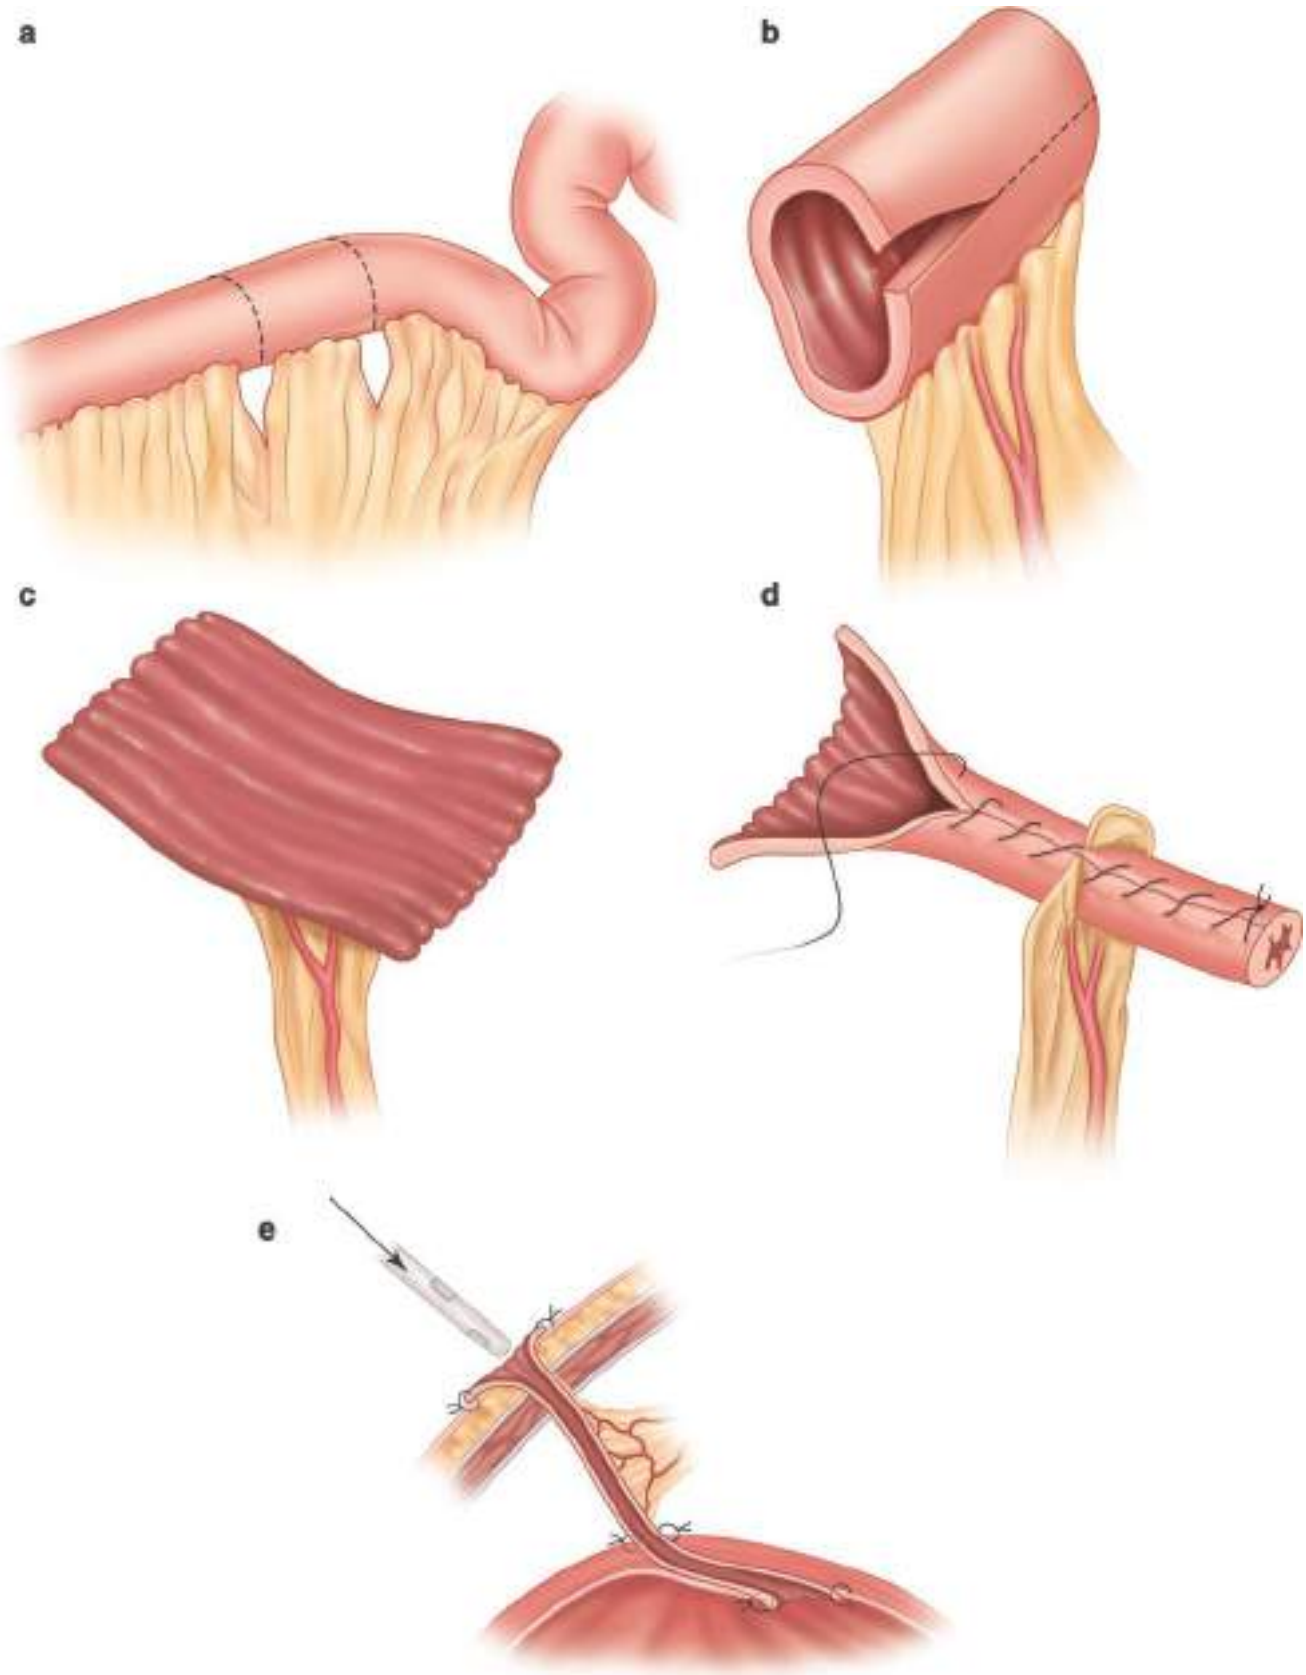

FIGURE 55-41. The Monti procedure.

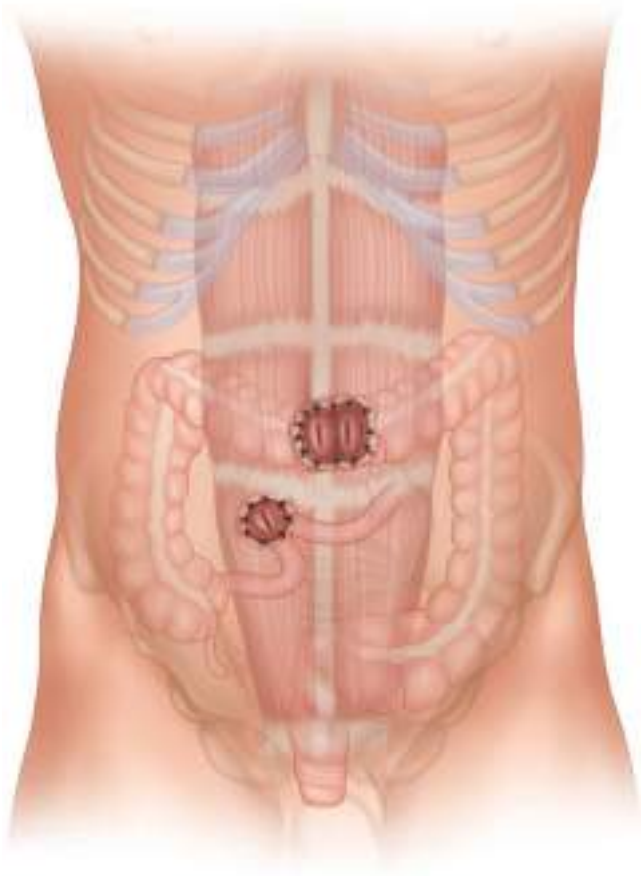

FIGURE 55-42. The completed Turnbull blowhole colostomy and loop ileostomy.

the surrounding peritoneum with one or two layers of continuous suture (Figure 55-43). Once the peritoneal cavity is sequestered from potential bowel spillage, the colon is incised and the bowel edge is sutured to the skin. The ileostomy is then matured. The blowhole stoma is suboptimal due to prolapse and pouching difficulties owing to the flat nature of the stoma, but it can be a useful temporizing adjunct when no other options exist.

For rare patients too ill to tolerate a general anesthetic, the Turnbull blowhole colostomy can be performed under local anesthesia with the aid of a fluoroscope. A fluoroscopic projection of the upper abdomen is obtained with the patient supine on the operating table. The colon is identified fluoroscopically by its characteristic bowel gas pattern and a metallic coin is then used to mark the intersection of the transverse colon and the midline. The spot is then marked and local anesthetic is infiltrated through the subcutaneous tissues and a 4-cm midline incision is made directly over the colon. Local anesthetic is infiltrated layer by layer as the fascia and peritoneum are carefully divided and the abdomen is entered. The anterior seromuscular surface of the colon is grasped through the incision and sutured circumferentially to the peritoneum to limit intra-abdominal stool contamination. A colotomy is made and the stoma is fasted to the skin as described above.

Ileostomy and Foodstuff Bolus Obstruction

Early postoperative edema may cause transient ileostomy obstruction at the level of the rectus fascia. Such edema typically subsides before return of bowel function, but lasting edema can cause an obstruction. In the setting of bowel obstruction symptoms, ileostomy obstruction may be suspected when there is peristomal pain with either thin, nonbilious, hydrops-type fluid ileostomy effluent or no output at all. Cross-sectional imaging may reveal an abrupt transition in bowel caliber as the stoma traverses the abdominal wall. If acute postoperative ileostomy obstruction is suspected, a 14-18-French Foley (or red rubber) catheter can be gently placed at the bedside to bypass the level of obstruction and decompress the bowel proximal to the ileostomy. To place a catheter, a two-piece stoma appliance should be used. With the stoma flange in place and bag removed, a well-lubricated catheter is inserted into the stomal os as small aliquots of water are gently injected through the catheter with a Toomey syringe to create a water cushion ahead of the catheter tip. Gentle pressure is applied to the catheter as water is injected to push the bowel wall away from the catheter tip whereby avoiding bowel wall injury and perforation. The catheter is advanced as long as resistance is not met beyond the fascial obstruction and secured to the stoma appliance with suture or dental floss to hold the catheter in place. If a Foley catheter is used, the balloon should not be blown up out of concern of injuring the bowel. The catheter should be used sparingly, as both short- and long-term use of indwelling stoma catheters can cause bowel perforation.

The relatively narrow luminal diameter of an ileostomy may occasionally cause bolus obstruction by non-digestible foodstuffs. High-residue foods such as nuts, seeds, shellfish, sausage casings, and raw produce are poorly digested and may pass through the ileostomy in large chunks. Rarely, such foodstuffs may become lodged within the ileostomy and require ileostomy irrigation to disimpact the food bolus. To irrigate an ileostomy, a Foley (or red rubber) catheter is placed as described above to a distance just beyond the fascia (typically <6 in. from the skin surface). A Toomey syringe is then used to slowly irrigate out the bolus obstruction with 30–50 mL aliquots of water until the bolus is dislodged. This process may take 1–2 h.

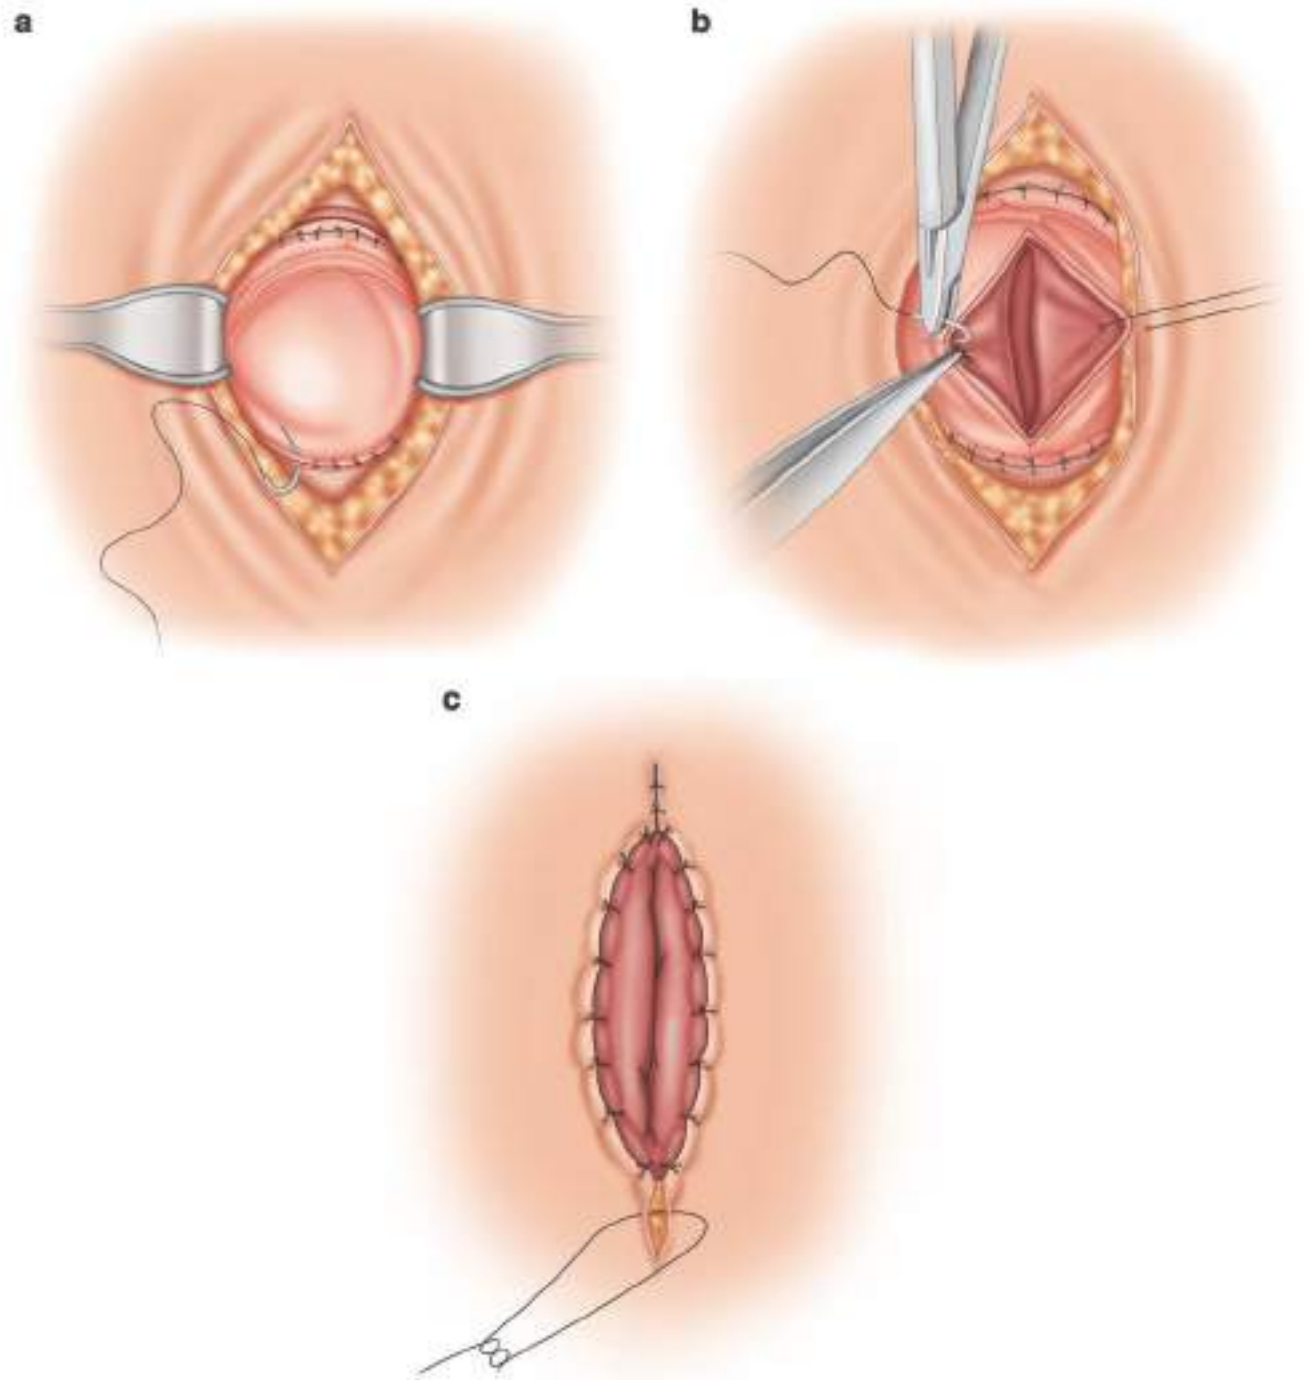

FIGURE 55-43. Creation of a Turnbull blowhole colostomy.

Functional Complications After Colon and Rectal Surgery

Dana M. Hayden and Alex Jenny Ky

Key Concepts

- Low anterior resection syndrome (LARS) is extremely common after proctectomy with a multifactorial etiology including damage to sphincters, variations in RAIR, intestinal motility changes, autonomic and somatic nerve injury, and pelvic floor dysfunction.
- Radiation and pelvic sepsis may contribute to deterioration of bowel function.
- Symptoms may include incontinence to stool or flatus, urgency, fragmentation of stool, difficult evacuation, and a sense of incomplete evacuation.
- Alternative reconstructions utilizing colonic pouch or side-to-end anastomosis may be associated with better bowel function when compared to straight anastomoses.
- Pelvic nerve damage during TME can impair urinary and sexual function as well as bowel function.
- Sexual dysfunction occurs in both males and females and may manifest in women as dyspareunia and failure to lubricate with arousal. In men, erectile dysfunction and retrograde ejaculation may occur.
- Colorectal surgeons may underappreciate the magnitude of bowel dysfunction after rectal cancer resection and its impact on quality of life.
- There is no accepted treatment algorithm for bowel dysfunction after proctectomy; symptom control utilizing medications to slow and bulk stools, protection of the perianal skin, physical therapy, colonic irrigation, and in some cases sacral nerve stimulation are currently recognized therapies.

Introduction

Colorectal cancer is the third most common cancer in men and women in the United States and approximately one-third of these cases are rectal cancers [1]. Total and partial mesorectal excisions (TME) are commonly performed, and although colorectal surgeons are very adept at discussing potential complications of these operations, they may not be as thorough in the discussion of functional outcomes. Bowel dysfunction after low colorectal or coloanal anastomoses is extremely common and underappreciated. This dysfunction has been termed: low anterior resection syndrome (LARS). This chapter will discuss symptoms, etiology, and current treatment recommendations. Additionally, other potential functional problems that may be seen after a proctectomy will be covered.

Low Anterior Resection Syndrome

Symptoms and Prevalence

During rectal cancer resection, sphincter-preserving surgery has been considered desirable to permanent stoma if oncologic outcomes are equivalent. The introduction of high-resolution imaging along with the tailored use of neoadjuvant radiation therapy has improved the ability of the surgeon to accomplish sphincter preservation [2]. However, the presumption that quality of life (QOL) would be improved without a permanent stoma has not borne out in the literature [3]. Both a Cochrane review and a meta-analysis indicated that QOL was equivalent between those who underwent abdominal perineal resection (APR) and those with sphincter preservation [4]. Although this finding has not been fully elucidated, many patients experience altered bowel function after low anterior resection (LAR), potentially offsetting the benefits of preserved intestinal continuity [3]. It is estimated that 50–90 % of patients undergoing LAR experience at least some degree of bowel dysfunction postoperatively [5]. The constellation of symptoms including fecal incontinence, urgency, frequent small bowel movements, and clustering of stools has been referred to as low anterior resection syndrome (LARS) [5]. Other postoperative problems after LAR include evacuatory dysfunction [4]. A pragmatic definition

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_56

of LARS is any disordered bowel function after rectal resection leading to a detriment in quality of life [4]. After LAR, oncologic outcome is naturally the primary parameter evaluated; however, bowel function is more commonly being emphasized and studied [6].

The reported incidence of LARS is variable, depending on the definition, the particular study, length of follow-up, and tools used for symptom assessment. Fecal incontinence may occur in 6–87 % of LAR patients, with 5–87 % having urgency, and 8–75 % of patients reporting three or more bowel movements per day [2]. LARS may also be accompanied by tenesmus, rectal or anal pain, difficult defecation, impotence, and dyspareunia [2]. Skin irritation resulting from multiple bowel movements can also be debilitating.

In a recent international multicenter study, Juul and colleagues correlated LARS and quality of life. The study included 796 patients from 4 different countries. Patients completed a questionnaire which provided a LARS score (Figure 56-1) and the EORTC QLQ-C30 questionnaires. Patients with major LARS dysfunction fared worse than those with no LARS issues in global QOL, physical, emotional, role, social functioning, and fatigue. These findings held true for patients with major LARS symptoms when compared to those with minor symptoms [5]. Diarrhea had the strongest correlation to a decreased in QOL [5].

Previous accepted philosophy regarding LARS was that the bowel dysfunction was transient, mainly resolving 12 months after surgery [4]. Long-term studies now report the presence of adverse effects up to 15 years after surgery, with the prevalence of fecal incontinence varying from 0 to 71 % and evacuatory disorders from 12 to 74 % [4]. Chen et al. examined patients who had undergone LAR/TME with a median follow-up of 14 years and found 42 % suffered from major LARS symptoms and 22 % had minor LARS symptoms [7]. These long-term results suggest that LARS results from permanent changes rather than short-lived postoperative inflammation and healing [4].

Etiology of LARS

The exact pathophysiology of LARS remains unclear; however, it appears to be multifactorial. Several studies have demonstrated that anatomical, sensory, and muscular changes have likely been altered by LAR surgery [8]. Other contributing factors include neorectal capacity, compliance, sphincter function, pelvic floor function, colonic motility, and postprandial bowel response [8].

Several studies have concentrated on physiologic changes after LAR surgery. Patients with LARS can have loss of the rectoanal inhibitory reflex (RAIR)—reflecting disordered internal anal sphincter function and anorectal sampling alteration [2]. This alteration may lead to poor discrimination between liquid or gas contents in the rectum [2]. Absence of RAIR has been correlated with poor bowel function and when found to recover (over time), the patient may experience a reduction in nocturnal urgency and incontinence [2]. Persistent disturbance in RAIR has been associated with long-term fecal soiling [2]. A study by Kakodkar et al. examined anorectal function in normal healthy volunteers compared to preoperative and postoperative values in patients undergoing LAR/TME surgery. The authors found that bowel dysfunction can continue 1 year after surgery. Poorer outcomes were associated with a lower reservoir capacity, shortened high-pressure zone, and an absent RAIR [9].

Some studies evaluating anal sphincter function after LAR have shown a decrease in mean anal resting pressure and maximum squeeze pressure that does not recover over time (4, 10). These changes may be due to direct injury to the sphincter complex during stapler insertion [2]. Efthimiadis et al. reported a significantly decreased anal resting pressure, loss of RAIR, and unchanged squeeze pressures [10]. By 6 months, they noted these changes recovered. They suggest that decreased compliance of the neorectum lowers the capacity of the reservoir, leading to more frequent stools. Reduced reservoir compliance also leads to increased pressure as stool fills the neoreservoir. Higher pressure in the neorectum and lower anal canal pressure can result in frequent stools and soiling, even with small volumes of stool [10]. Small, poorly compliant reservoirs have also been found to have sensory alterations that contribute to incontinence [2]. A direct association between decreased rectal compliance and deterioration in fecal continence scores has been reported [4].

It has been postulated that the unfavorable functional results such as fecal urgency and incontinence noted with LAR are due to the reduced neoreservoir volume with conventional end-to-end colorectal or coloanal anastomosis. This has led to the development of alternative configurations of the proximal colon in an effort to improve the reservoir [4]. These will be discussed in depth later in this chapter.

Other research has focused on the association between intestinal motility and LARS. Emmertsen et al. reported that patients with major LARS problems had an increased postprandial response and higher neorectal pressures after eating compared to patients without LARS, suggesting that severe bowel dysfunction after LAR/TME may be related to abnormal gastrointestinal motility [8]. Another study also indicated that LARS patients with high stool frequency had increased contractions and increased neorectal tone in response to a meal whereas normal healthy patients did not [8]. Animal studies have shown increased number and duration of colonic migrating complexes after LAR, equivalent to high amplitude propagating contractions responsible for mass movement of stool in humans [4]. A study of meal-induced colonic motility reported significantly earlier contractions in patients with increased bowel frequency compared to those without [4]. In a study of 60 patients after LAR, 26 had small, irregular waves at the site of the neorectum and the presence of these waves was associated with fecal soiling, urgency, and multiple evacuations [4].

The aim of this questionnaire is to assess your bowel function.

Please tick only one box for each question. It may be diffiult to select only one answer as we know that, for some patients, symptoms vary from day to day.

We would kindly ask you to choose one answer which best describes your daily life. If you have recently had an infection affecting your bowel function, please do not take this into aaccount and focus on answering questions to reflect your usual daily bowel function.

Do you ever have occasions when you cannot control your flatus (wind)?

☐ No, never
☐ Yes, less than once per week
☐ Yes, at least once per week

Do you ever have any accidental leakage of liquid stool?

☐ No, never
☐ Yes, less than once per week
☐ Yes, at least once per week

How often do you open your bowels?

☐ More than 7 times per day (24 hours)
☐ 4-7 times per day (24 hours)
☐ 1-3 times per day (24 hours)
☐ Less than once per day (24 hours)

Do you ever have to open your bowel again within one hour of the last bowel opening?

☐ No, never
☐ Yes, less than once per week
☐ Yes, at least once per week

Do you ever have a strong urge to open your bowels that you have to rush to the toilet?

☐ No, never
☐ Yes, less than once per week
☐ Yes, at least once per week

FIGURE 56-1. LARS score questionnaire. Adapted from Emmertsen K, Laurberg S. Low anterior resection syndrome score: development and validation of a symptom-based scoring system for bowel dysfunction after low anterior resection for rectal cancer. Ann Surg 2012;255(5):922–8 [8].

Autonomic denervation may also contribute to poor functional outcome despite standardization of surgery and TME to preserve autonomic nerves [2]. A Japanese study showed that preservation of the colonic and pelvic nerves resulted in less stool fragmentation [8]. It is suggested that the partially denervated colon might contribute to fragmentation of stools due to the absence of a negative feedback of the defecation reflex [8].

Rectal evacuatory dysfunction is also described as part of LARS. This includes infrequent defecation, incomplete rectal emptying, and excessive straining [4]. A suggested mechanism is loss of rectoanal coordination, manifesting as

impaired rectal contraction and paradoxical anal contraction [4]. Patients with a rectal evacuatory disorder can also have lowered rectal sensation possibly due to impairment of the parasympathetic and sympathetic nerve supply to the rectum [4].

Risk Factors for LARS

Incontinence is multifactorial in LARS patients. Worse functional outcomes have been associated with a lower anastomotic distance to the anal verge, male gender, and younger patients [2, 3, 6, 11] Any form of pelvic sepsis—anastomotic leak/dehiscence or abscess—can lead to scarring and reduction in the neorectum compliance. This leads to a poorly distensible neorectum and reduced storage capacity [2, 3, 11].

Some studies have indicated that preoperative radiation is also a risk factor for fecal incontinence after LAR [6]. Radiation may affect bowel function through several mechanisms. Radiation effects are dose dependent, altering the rectal musculature, innervation, and a direct effect on sphincter morphology [2]. Bowel function can also be altered secondary to radiation-induced small bowel toxicity and pelvic neuropathy [2]. Results from the Dutch TME trial demonstrated that 39 % of patients who had a TME alone were incontinent at 5 years compared to 62 % of those treated with surgery and preoperative radiotherapy [6]. In a study performed by Parc et al., patients with a neorectal reservoir who received neoadjuvant chemoradiation reported more frequent bowel movements per day and more nocturnal urgency for up to 24 months following surgery compared to patients without radiation [12]. Short-term radiotherapy also can have a detrimental effect. One study found that short-course radiotherapy had a negative effect on sexual function and daily functional activities [4].

A recent large population-based study of patients who had undergone LAR/TME found that patients who suffered from major LARS were more likely to have had neoadjuvant radiation compared to those without radiation [3]. Higher rates of LARS were found in patients with total versus partial TME and those with a symptomatic anastomotic leak. Younger (<64 years) patients and females also had a higher risk of major bowel dysfunction [3]. The study found no differences in functional outcomes between different anastomotic reconstruction types or short versus long-course radiation [3]. These results are dissimilar to other studies that demonstrated worse function in males and worse function after short-course radiation [11]. With regard to radiation, it is important to keep in mind that few prospective studies evaluated LARS in relation to contemporary radiotherapy protocols [4, 11]. Therefore, prospective studies utilizing modern radiation therapy are needed to elucidate the relationship of LARS to radiation therapy.

Evaluation of Bowel Dysfunction After LAR

Several QOL questionnaires and fecal incontinence scoring systems have been used to quantify LARS. The LARS score (Figure 56-1) is calculated from a validated scoring instrument evaluating bowel function after sphincter-preserving surgery for rectal cancer [12]. The questionnaire has been developed and validated in a nationwide cohort of Danish patients who received LAR with or without radiotherapy for localized rectal cancer between 2001 and 2007. The instrument was designed to reflect the severity of bowel dysfunction and its impact on QOL [12]. Questions pertaining to incontinence of stool or gas, symptoms of urgency, number of bowel movements, and clustering of bowel movements per day are included [5]. A composite score between 0 and 20 indicates “no LARS,” 21–29 “minor LARS,” and 30–42 “major LARS” [5]. This questionnaire has been translated into numerous languages. It correlates with many of the scales in the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core Module (EORTC QlQ-C30) [12].

Studies have shown that rectal cancer specialists lack an understanding of which bowel dysfunction symptoms truly matter to patients after sphincter-preserving surgery. Additionally, despite the high prevalence of LARS, care providers do not appreciate how these symptoms affect QOL [12]. Chen et al. found considerable discrepancy between the specialists’ perspective of what mattered to the patient and the patient’s actual views [7]. For instance, few clinicians realized the importance patients placed on incontinence to flatus and its impact on them. Likewise most clinicians overestimated the importance of liquid and solid stool incontinence while underestimating the impact of urgency and clustering on QOL [7]. Thus, postoperatively, it is crucial for rectal cancer specialists to ask that right questions, inquire as to what bothers the patient the most, and identify LARS. This will allow appropriate and timely management of symptoms. It is also important to provide pertinent, honest information to the patient prior to rectal cancer treatment [7].

Treatment for Bowel Dysfunction After LAR

There is currently no specific treatment consensus or treatment algorithm for LARS. Current therapies target distressing symptoms and include medications such as loperamide and codeine, the use of pelvic floor physiotherapy and biofeedback, and rectal irrigation [11]. Studies specifically looking at medications to treat LARS are lacking and represent a focus for future studies.

Pelvic floor rehabilitation targets the same therapies as when used for other forms of fecal incontinence. This includes pelvic floor muscle training, biofeedback, and rectal balloon training [6]. Visser at el performed a systematic review that showed incontinence scores significantly

improved in 4/5 studies and stool frequency decreased in 2/5 studies after pelvic physical therapy in patients with LARS [6]. QOL measures, vitality, and mental functioning on SF-36 also improved. Rehabilitated patients had less depression and better self-perception in FIQL scores [6]. One study demonstrated improved functional outcomes based on anorectal pressures and rectal capacity, but two other studies did not show any differences in physiologic measures [6]. The authors concluded that pelvic floor rehabilitation is useful for improving functional outcome after LAR [6]. Another study that was retrospective and non-randomized evaluated 70 patients who underwent biofeedback for LARS. There was significant improvement in fecal incontinence scores and decreased bowel frequency [4]. Therefore, it appears that pelvic floor physical therapy and rehabilitation may be an important treatment option for some LARS patients.

Retrograde Colonic Irrigation

Retrograde colonic irrigation (RCI) has also been proposed as a potential treatment option for fecal incontinence and stool fragmentation after LAR. Also known as transanal irrigation (TAI), water is introduced into the rectum and left colon. The irrigation is designed to assist in the evacuation of feces. The impact of RCI varies considerably. Koch et al. reported that 57 % of patients became "mostly" continent with RCI. Fourteen percent still reported trouble controlling flatus and 29 % had difficulty controlling liquid stools. The side effects were mild and the procedure is inexpensive and noninvasive [13]. Therefore, this represents another treatment in the armamentarium of doctors caring for LARS patients.

Sacral Nerve Stimulation

Sacral nerve stimulation (SNS) has shown promising early results in small studies of patients with fecal incontinence after rectal resection [4]. SNS improves function by decreasing antegrade colonic motor activity and increasing retrograde activity [4]. In a 2015 systematic review of SNS for the treatment of LARS, an overall intention to treat success rate of 74.4 % was found [11]. Of the 34 patients who had enough improvement to warrant permanent stimulator placement, 32 (94.1 %) had treatment "success" [11]. Patients reported subjective and objective improvement in LARS symptoms. Incontinent episodes decreased in all studies [11]. Another study utilizing SNS to treat LARS reported decreased nocturnal defecation, fragmentation, urgency, and soiling. SNS also led to an improvement in the time to defer defecation [11]. Thus, SNS appears to be a promising therapy for some patients with LARS.

Colorectal Reconstructions and Effects on Function After Colorectal Surgery

As surgeons have been able to attain a higher incidence of sphincter preservation when operating on low rectal cancers, an increasing frequency of bowel dysfunction has been reported. The first reported anastomoses were typically straight (SA) colorectal or coloanal [13]. Analysis of the functional outcomes after LAR with SA led to a description of a wide spectrum of symptoms including urgency, frequency, stool fragmentation, and fecal incontinence. It was speculated that reduced reservoir volume related to the bowel used for a conventional end-to-end colorectal or coloanal anastomosis contributed to urgency and fecal incontinence. In an effort to improve bowel function, surgeons developed alternative configurations of the proximal bowel used for the anastomosis with the goal to improve the function of the neoreservoir [4, 14]. The colonic j pouch (CJP), the transverse coloplasty (TC), and the side-to-end anastomosis (STEA) have been utilized to improve the function and capacity of the neorectal reservoir with the goal of improving bowel function (Figure 56.2).

Colonic J Pouch

The colonic j pouch (CJP) is constructed by folding the sigmoid or descending colon onto itself and stapling the antimesenteric walls to create a larger lumen (Figure 56-2). There have been several prospective randomized studies comparing the SA with the CJP. The CJP led to reduced bowel frequency, less fragmentations, fewer spasms, and less urge incontinence for up to 12 months when compared to SA [13]. There have been fewer studies that looked at longer-term results. While most studies still reported some functional advantage, one study noted the functional improvement with the CJP apparent at 1 year disappeared by 24 months [15]. In contrast, others reported decreased frequency and stool fragmentation in CJP patients at 24 months and at 5 years [13]. Fecal continence was better at 3, 4, 5, and 9 years when compared to SA [13]. A meta-analysis performed by Heriot and colleagues confirmed these long-term results. In 2240 patients, those with CJP had decreased daily frequency, decreased fecal urge incontinence, less incomplete evacuations, and used less antidiarrheal medications at 1 and 2 years when compared to patients with SA [15].

Initially the size of the CJP mirrored the ileal J pouch. Comparison of bowel function in patients with a larger pouch (>6–12 cm) versus a shorter (4–6 cm) CJP showed no differences in clinical outcomes or complications. However, difficult or incomplete defecation was found to be higher in patients with longer pouches [16]. Patients with longer CJP were also noted to require more laxative for defecation [16]. Hence, a CJP of 4–6 cm was felt to be the ideal size.

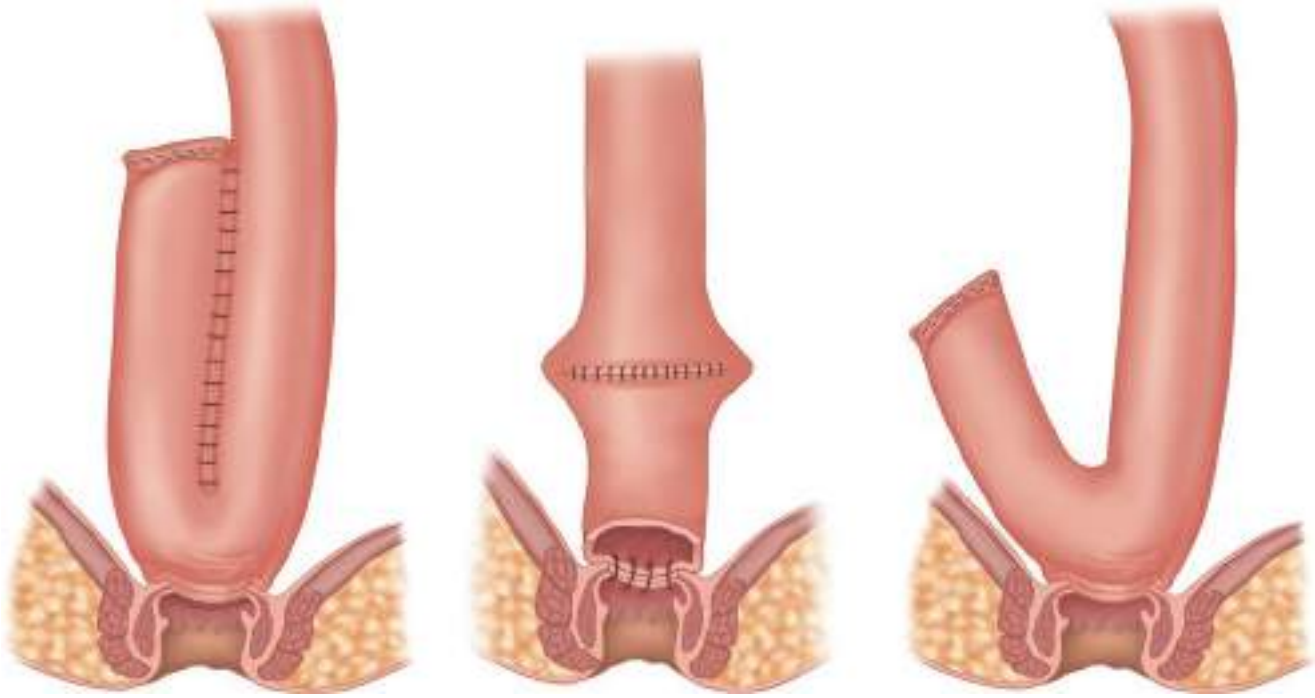

FIGURE 56-2. Alternative colorectal anastomotic reconstructions after low anterior resection.

Transverse Coloplasty

A transverse coloplasty (TC) construction is an alternative colorectal reconstruction that was first described in 1999 and first performed in humans in 2001 [17]. TC involves cutting the colon wall longitudinally for 7–10 cm between the taenia, starting at approximately 4 cm from the distal cut edge of the colon [17]. The colotomy is then closed transversely and looks similar to a Heineke–Mikulicz stricturoplasty (Figure 56-2). Although TC was thought to decrease the evacuation difficulties that were found with CJP, multiple studies did not illustrate any significant differences [15, 17]. In a multicenter randomized prospective trial, Fazio and colleagues did show functional benefits of the CPJ when compared to TC [18]. There was less stool fragmentation and less digestive spasms after CPJ when compared to TC at 4, 12, and 24 months. Other outcomes such as urge incontinence and antidiarrheal medication use were not significantly different. They also did not find any functional advantage of TC over SA. Therefore, adoption of TC has recently slowed secondary to nearly equivalent functional outcomes and at least one study showing higher anastomotic leak rates [19].

Side-to-End Anastomosis

The side-to-end anastomosis (STEA) is another alternative reconstruction after a low anterior resection (Figure 56-2). This technique was described by Baker in 1950 and has gained popularity in the United States, Germany, and France. An anastomosis is created 3–6 cm upstream from the cut edge of the proximal colon on the antimesenteric side to the distal rectum or anal canal [13]. The open end of the proximal colon is then closed. A few prospective studies have looked at functional outcomes after STEA. In short- and long-term follow-up, most do not show any significant differences in bowel function when compared to CJP. Two studies did show less evacuation difficulties [13]. Siddiqui et al. performed a meta-analysis on studies comparing STEA and CJP. Only urge incontinence was less after STEA at 6 months, but this was no longer significant after 24 months [20]. Anastomotic leak rates may be lower after STEA compared to SA. However, the leak rate appears similar when comparing STEA with CJP [7, 13]. Evacuation problems may also occur with STEA. Utilizing a 3 cm vs. 6 cm blind limb of the STEA seemed to be associated with less evacuation problems [21].

In summary, in an effort to reduce bowel dysfunction after a low anterior resection, a CJP or STEA may be utilized. The size of the CJP should be 4–6 cm and the blind limb of the STEA should be 3 cm to reduce the risk of difficulty in evacuation of stool.

Sexual and Urologic Dysfunction After Surgery for Rectal Cancer

Nerves of the Pelvis

Sexual and urologic dysfunction after proctectomy is multifactorial; however, the main etiology is related to direct injury to the pelvic nerves. There are several locations where

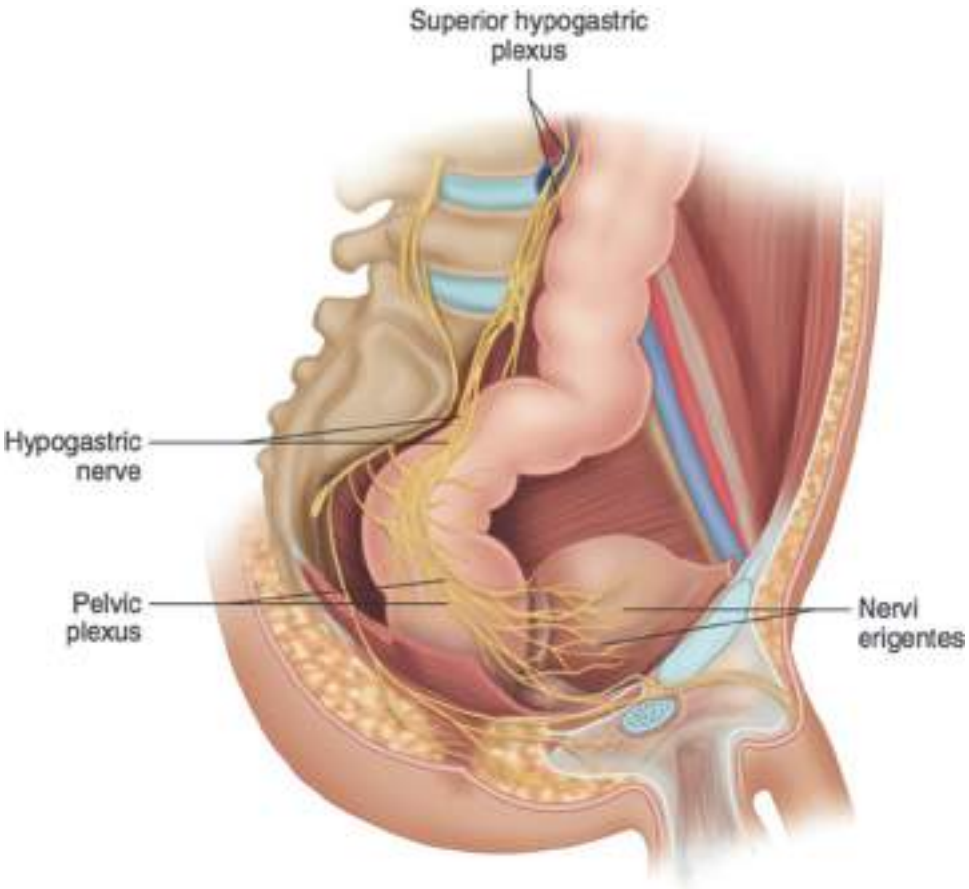

FIGURE 56-3. Pelvic nerve anatomy and potential sites of injury. Damage to the superior hypogastric plexus during high ligation of the interior mesenteric artery (IMA) or to the hypogastric nerves of the sacral promontory during mobilization of the upper mesorectum results in retrograde ejaculation. Damage to the pelvic plexus during the lateral dissection or to the nervi erigentes or the cavernous nerves while dissecting the anterior plane may result in erectile dysfunction.

pelvic nerves can be damaged during TME (Figure 56-3). Within the pelvic plexus, there are both sympathetic and parasympathetic nerves. The sympathetic roots originate from L2 and L3. They comprise the superior hypogastric plexus (or the aortic plexus), which becomes the hypogastric plexus under the parietal peritoneum at the level of the aortic bifurcation. At the sacral promontory, these fibers form the hypogastric nerves, which run laterally to the internal iliac arteries and ureters, to join the pelvic autonomic plexus at the lateral pelvic wall. The parasympathetic fibers originate from S3 to S4 in males and from S2 to S4 in females. They run along the nervi erigentes and the inferior hypogastric plexus.

Below the peritoneum, the hypogastric plexus sits anterior and lateral to the rectum. The inferior hypogastric plexus is the autonomic pelvic plexus on the lateral pelvic wall, in close proximity to the prostate in males. In females, it is anterior and lateral to the rectum, running by the vagina and cervix. The parasympathetic fibers are responsible for erection, increasing blood flow to the penis or clitoris, as well as providing lubrication to the vagina. The sympathetic fibers are responsible for ejaculation and orgasm. These sympathetic fibers also inhibit the detrusor muscle, stimulating contraction of the bladder neck, affecting the urinary continence mechanism [22–25]. With the adaption of total mesorectal excision and a focus on pelvic nerve-sparing surgical technique, the incidence of sexual dysfunction is lower but still significant. The ligation of the inferior mesenteric artery and dissection of the retrorectal space can cause damage to the superior hypogastric plexus and/or hypogastric nerves at the sacral promontory. This can result in retrograde ejaculation. Anterolateral dissection and division in the area described as the "lateral ligament" can damage the pelvic plexus resulting in erective dysfunction. Dissection in the anterior plane particularly on the rectal side of Denonvilliers' fascia can damage the nervi erigentes or cavernous nerves and also lead to erectile dysfunction. Perineal dissection can indirectly or directly damage the pudendal nerve (Figure 56-3) [14, 26].

Sexual Dysfunction After Surgery for Rectal Cancer

The goal of rectal cancer surgery is to remove the tumor and cure the patient. However, negative outcomes like sexual dysfunction can result from this therapy. There has been more awareness and focus on sexual dysfunction in men (versus women) after surgery for rectal cancer and interestingly this is not always discussed preoperatively [25]. Sexual

dysfunction in men consists of erectile dysfunction (ED) and retrograde ejaculation. However, difficulty with orgasm and libido and issues with body image are also reported [27]. Postoperative female sexual dysfunction includes problems with vaginal lubrication, dyspareunia, arousal, and orgasm. These problems are harder to quantitate. With advances in the surgical technique of TME, the incidence of sexual dysfunction has been reduced but remains a significant postoperative problem. Besides nerve damage, other risk factors include significant blood loss, preoperative radiation, anastomotic leak, and the presence of a stoma [28]. Validated tools that have been developed to evaluate sexual dysfunction after rectal cancer surgery include the International Index of Erectile Function (IIEF), the Female Sexual Function Index (FISI), and the EORTC QLQ-C30 and EORTC QLQ-CR38 to measure QOL in colorectal cancer patients.

Studying patients who were sexually active before surgery, Hendren et al. reported that 29 % of women and 45 % of men after proctectomy for rectal cancer perceived deterioration in their sexual function [27]. Only a small percentage of patients recalled a preoperative discussion regarding the risk of sexual dysfunction after surgery [27]. Patients may be embarrassed to discuss this highly personal topic. Therefore, healthcare providers should counsel patient preoperatively regarding potential risks and initiate the conversation postoperatively in an effort to address concerns.

Retrograde ejaculation can be treated with medications including tricyclic antidepressants, antihistamines (chlorpheniramine), and decongestants like ephedrine sulfate and phenylephrine, which can help close the bladder neck during ejaculation [29, 31]. For patients reporting ED postoperatively, a trial of sildenafil citrate, tadalafil, or vardenafil can be considered. At low dose, these medications do not cause erection but can increase blood flow to the area around nerves to promote healing [30].

Sexual dysfunction in females after rectal cancer resection has not been examined extensively. There are both physiologic etiologies and components of body image that contribute to sexual dysfunction. Besides nerve injury which can lead to decreased clitoral sensation and vaginal lubrication, dyspareunia can also be secondary to fibrosis after radiation leading to reduced pliability of the vagina [34]. Medications and creams which improve lubrication along with pelvic floor physical therapy have been the mainstay of treatment. Newer treatments, such as flibanserin, warrant further investigation.

Urologic Dysfunction

Bladder dysfunction commonly happens after pelvic surgery and can occur in 30–70 % of patients after surgery for rectal cancer. Damage to the visceral nerves during proctectomy can decrease bladder sensitivity. Injury of the sympathetic nerves via damage to the hypogastrics may be responsible for female urgency and stress incontinence [32]. The patient may experience loss of the filling sensation of the bladder secondary to denervation of the detrusor muscle. This can also predispose patients to voiding problems and overflow incontinence. Posterior bending of the bladder that may occur during and following abdominoperineal resection can also contribute to voiding dysfunction. Persistent incomplete emptying of the bladder due to any of the above mentioned mechanisms may predispose patients to urinary tract infections.

Some patients may have preexisting urinary dysfunction as a result of age, chronic inflammation, benign prostate enlargement, or prostate cancer in males and stress incontinence or urgency in multiparous females. In addition, any damage to the pudendal nerves can contribute to decreased bladder sensitivity and impotence. Postoperative urinary symptoms are often temporary and only 10 % of patients will require medical or surgical treatment. Any voiding issue that persists after 3 months may be permanent, requiring more aggressive management [29].

Perianal Skin Irritation After Colorectal Surgery

Skin irritation is common after rectal cancer surgery. This results from frequent and/or loose stools and improper wiping techniques. Additionally, pliability of the skin can be reduced from chemoradiation further compounding the problem. Frequent bowel movements result in constant wiping which excoriates the top layer of the delicate skin around the anus. In addition, digestive enzymes in fecal matter have been noted to contribute to irritation of the perianal skin [33, 35]. The first-line of treatment is skin protection that is provided by barrier creams. Two examples are Desitin™ or Balmex^{R}. The barrier cream should be applied like frosting to fully coat the area. When wiping after defecation, the patient should wipe against the cream and avoid completely wiping it off. If there is a fungal component, antifungal powders or creams should be added. For severe itching and pain, a short course of steroid cream can provide dramatic relief (particularly for itching). However, the use of steroid cream should be confined to short-term use since it has the potential to thin the skin [33]. Counseling is helpful regarding wiping and having the patient avoid the urge to “over-wipe.” Use of wet toilet paper also lessens the friction upon the anal skin with wiping. Using warm baths or showers after bowel movements and colonic irrigation with enemas or tap water may also eliminate stool from sitting on the skin or leaking from the rectum after defecation. An enterostomal therapy nurse or skin care nurse specialist may be invaluable to provide additional suggestions for patients with resistant skin irritation.

Managing stool frequency and consistency are also important. Fiber supplements are recommended in an attempt to bulk the stool. Patients are advised to take agents such as psyllium mixed in the least amount of fluid in an attempt for the fluid in the stool to saturate the ingested fiber. The use of antidiarrheal medications such as diphenoxylate hydrochloride/atropine sulfate or loperamide are trialed to slow stool frequency. The patient can take up to eight doses of each of these two types of medications daily; however, this amount typically is not needed. They should take one pill in the morning upon awakening and then titrate the dose. The medication should be taken *before* meals (not after defecation as the package insert may advise). Loperamide can be obtained in a liquid form and the dose can further be titrated down if the 2 mg pill slows the bowel motility too much.

Conclusions

Functional outcomes after colorectal surgery are now becoming recognized as important contributors to quality of life and measures of our performance as surgeons. The significance of postoperative function should be a focus of preoperative discussion as technical advances now allow more sphincter-preserving surgeries at the risk of increased bowel problems. Bowel dysfunction along with urinary and sexual dysfunction can significantly impact and lessen quality of life postoperatively. The cause of these functional disorders is multifactorial including damage to the anal sphincters, variations in RAIR, intestinal motility changes, autonomic and somatic nerve injury, and pelvic floor dysfunction. Compliance of the neorectum, pelvic sepsis, and radiation can also contribute to postoperative dysfunction. Important steps the surgeon can take to lessen the risk of dysfunction after proctectomy include proper TME technique, avoidance of nerve injury, creation of a healthy, tension-free anastomosis, consideration of alternative colorectal reconstructions (colonic J pouch or side-to-end versus a straight anastomosis), and avoidance of amenable risks factors for pelvic sepsis. Also, the appropriate selection of patients for sphincter preservation cannot be understated. When bowel dysfunction does occur, initial treatment focuses on optimizing the patient's diet and alterations in bowel habits. For more severe symptoms, biofeedback, colonic irrigation, and sacral nerve stimulation have been found to improve function. Stool bulking and decreasing stool frequency along with barrier creams can improve perianal skin irritation after colorectal surgery. For patients who report urinary or sexual dysfunction, medications may improve symptoms. Lastly, pelvic floor rehabilitation with biofeedback should also be considered as this may improve the quality of life after LAR.

Part V
Pelvic Floor Disorders

57
Common Tests for the Pelvic Floor

Dana R. Sands and Amy J. Thorsen

Key Concepts

- Pelvic floor disorders affect a significant portion of the population and account for relevant portion of patients seen in colorectal clinics.
- Proper history and thorough physical examination is the cornerstone of the evaluation of patients suffering from functional disorders.
- Specialized tests to evaluate structure and function augment the evaluation of this complex patient population.

Introduction

Disturbances in bowel evacuation and continence are common in North America.

In a population based study of nearly 2000 non-pregnant women, Nygaard et al. found 15.7 % of women had at least one pelvic floor disorder. In women aged 80 or older, the prevalence approached 50 % [1]. Although 9 % of women in this study experienced symptoms of fecal incontinence, another recent survey found nearly 20 % of women age 45 or older have experienced accidental bowel leakage at least once per year [2]. Constipation appears to be a more frequent complaint of patients, affecting up to 20 % of North Americans [3–5]. The direct annual costs associated with ambulatory care for pelvic floor disorders were estimated at $412 million dollars in 2006, compared to $262 million in 1997 [6]. As the population ages, health care expenditures in treating pelvic floor disorders are expected to escalate. Given the psychosocial stresses that accompany pelvic floor disorders, the true cost of these disorders to society is probably extremely underestimated.

Functional disorders account for approximately a quarter of a typical colorectal practice's referrals. A traditional approach is to start the evaluation ruling out significant pathology, such as neoplastic or inflammatory bowel disease, with lower endoscopy. This chapter will focus on the next steps in evaluating patients with fecal incontinence, obstructive defecation, and rectal prolapse. Pelvic floor testing includes anatomic evaluations, functional investigations, and exams that evaluate both anatomy and function of the pelvic floor.

History

A detailed history is critical in the management of patients with pelvic floor disorders. Patients will often give limited details, and self-diagnose ("I have hemorrhoids") to avoid feeling embarrassed about their condition. The patient should be comfortable and clothed during the interview. The onset, duration, and evolution of symptoms should be elicited. Patients should be queried about other possible pelvic floor complaints; rectal prolapse can easily cause constipation or bowel leakage, and symptoms of fecal incontinence may develop after years of obstructed defecation. A high incidence of urinary incontinence and vaginal vault prolapse is prevalent in these patients, and presently there are treatment options that can address multi-compartment complaints in these complex patients.

Addressing stool consistency is key, as well as the factors that may have changed it. Diet changes, food intolerances, and allergies should be identified. Changes in medications and supplements can cause disturbances as well. Surgeries such as cholecystectomy and gastric bypass surgery often alter stool consistency and frequency.

Trauma to the pelvic floor—whether it be surgical, obstetric, or psychological—is also common. Previous surgeries for hemorrhoids, fissures, or fistulas may affect sphincter integrity. Posterior compartment prolapse and dyssynergic defecation may be seen after hysterectomy or cystocele repair. Vaginal delivery, especially that associated with forceps or vacuum instrumentation, can cause sphincter injury, levator avulsion, and pudendal nerve injury. A history of sexual abuse and underlying psychological disturbances are

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_57

often significant factors that need to be addressed for successful management of these patients.

Questionnaires

Unlike hypertension or diabetes, the response to treatment of pelvic floor disorders cannot be assessed by measuring a vital sign or following serial laboratory values. Pelvic floor disorders have multiple symptom components, and eliciting these details can sometimes be difficult in a patient that is embarrassed. Lastly, each individual's situation is different; the impact of once weekly liquid stool incontinence will affect a teacher differently than a patient homebound due to other medical conditions. Hence, symptom scales and quality of life questionnaires can be an important clinical and research tool in managing the pelvic floor patient.

Fecal Incontinence

Fecal incontinence has been graded and scored in a variety of ways. Grading scores assign a value to a specific kind of incontinence. Values tend to reflect physician impression of severity based on sphincter function; i.e., incontinence to solid stool is graded more severe than incontinence to liquid stool. Severity scales, more commonly utilized by clinicians and researchers, screen for different types of incontinence, assign a value for each category, and produce a summary score based on the total of values per category. Severity scores may differ in their inclusion of the symptoms of incontinence to flatus, mucous incontinence, staining, urgency, pad usage, and lifestyle variation. Inclusion of more symptoms may be seen in severity scales that involved patients in their development. Although inclusion of more aspects of anal incontinence may more accurately reflect the patient experience, some of these measures may duplicate some aspects of the symptoms within the score and may add in components of impact instead of severity. Urgency is a common component that can be difficult to measure, but it may also be reflected significantly in lifestyle alteration. Pad usage may better reflect patient meticulousness or concomitant urinary incontinence rather than be a discrete component of fecal incontinence severity. Pad usage also appears to be less common in male patients with fecal incontinence [7].

Jorge and Wexner [8] developed the first scoring system to take into account both pad usage and lifestyle alteration as well as the consistency and frequency of fecal incontinence [Cleveland Clinic Florida Fecal Incontinence Score (CCF-FIS)] (Table 57-1). All types of incontinence, and all categories, are weighted equally. There are five frequency categories which aid in discrimination for change for patients with both frequent and infrequent anal incontinence. In an internet based study assessing the prevalence of fecal incontinence in women age 45 or older, women who sought care for their condition had a mean score of 10.7, versus a mean of 7.5 in women who did not seek care for their symptoms [2]. Today, the CCF-FIS is one of the most widely used scores in assessing the severity of fecal incontinence.

In 1999, Vaizey et al. [9] introduced a modification of the CCF-FIS scale. Adjustments included diminishing the significance of pad usage, including a measure to account for the use of antidiarrheal medications, and inclusion of a measure to note the presence of urgency. Although five frequency categories are maintained, the lowest frequency measured, "never" is equal to less than once per four weeks. Hence patients who have anal incontinence less than this frequency can have a total score of 0, equal to "perfect continence." The need to use a pad or constipating medication is present or absent, and not measured in frequency. Urgency, described as "the ability to defer defecation 15 minutes," is also given a single score if present, despite if this is a symptom the patient experiences daily or rarely. The Vaizey or St. Mark's incontinence score appears to correlate with patients' perception of bowel control. When 423 patients ranked their perception of control on a scale of 0–10, a significant correlation ($r=-0.52$) was seen with their Vaizey score. This correlation was maintained despite patient age, gender, or type of incontinence, and was sensitive to change with treatment [10].

A weighted scale utilized in measuring incontinence is the Fecal Incontinence Severity Index (FISI). In contrast to other scoring systems, the FISI is the first continence severity score to involve patients in its development [11]. The FISI was developed in a multicenter trial sponsored by the American Society of Colon and Rectal Surgeons. Thirty-four patients and twenty-six colon and rectal surgeons ranked a grid of four types of anal incontinence (gas, mucus, liquid, and solid) at five different frequencies. A frequency category to include multiple accidents per day was included, but episodes of frequency less than once per month were not

Table 57-1. Cleveland Clinic Florida/Wexner Fecal Incontinence Grading Scale [8]

	Never	Rarely (<1/month)	Sometimes (>=1/month, <1/week)	Usually (>+1/week, <1/day)	Always (>=1/day)
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Wears pad	0	1	2	3	4
Lifestyle alteration	0	1	2	3	4

included. Severity assessment rankings for surgeons and patients correlated very highly [11]. Surgeons tended to assign higher weight to infrequent episodes of solid stool incontinence compared to patients. This may reflect the surgeon's impression of sphincter integrity as being a measurement of severity, whereas the patient's ranking may more reflect personal hygiene and social embarrassment. Many patients comment that loss of solid stools is easier to manage than loss of liquid stools.

When the FISI is administered, a decision needs to be made whether to use the physician or patient weighting. Although the physician weight may better imply severity in terms of sphincter function, the patient weight may better reflect patient satisfaction to treatment. Given the calculations required to determine the FISI, the score is more cumbersome tool to use in the clinical setting.

Although some severity scales include a measurement of lifestyle alteration, the true impact of fecal incontinence for an individual patient cannot be captured when measuring severity alone. The Fecal Incontinence Quality of Life Scale (FIQL) was developed as a collaboration between the American Society of Colon and Rectal Surgery and the University of Minnesota Clinical Outcomes Research Center. The FIQL, through 29 questions, taps aspects of life for patients with fecal incontinence that may interfere and affect social functioning and self-image. The results are tabulated in four subscale scores: Lifestyle, Coping/Behavior, Depression/Self Perception, and Embarrassment (Table 57-2) [12]. Bordeianou et al. [13] examined the relationship between fecal incontinence severity and its relationship to quality of life prospectively in 502 patients. Fecal incontinence severity correlated moderately with disease specific (FIQL) quality of life, and only weakly with generic quality of life (SF-36). Based on these results, the authors recommended using both questionnaires when evaluating treatments for fecal incontinence.

Constipation

Frequency of bowel movements is a common measurement of severity of constipation by both patients and physicians. This fails to take into account other factors, such as incomplete emptying, difficult evacuation, and pain experienced by these patients. Although many constipation scores exist, some include components measuring symptoms of irritable bowel syndrome or upper gastrointestinal disorders. Several scoring systems may be useful to the colorectal surgeon.

The Cleveland Clinic Florida Constipation Score (CCF-CS) [14], developed in 1996, is a score commonly used in clinical trials in the treatment of obstructive defecation. Eight variables are assessed (frequency of bowel movements; difficult or painful evacuation; completeness of evacuation; abdominal pain; time per attempt; type of assistance including laxatives, digitations, or enemas; number of unsuccessful attempts at evacuation in a 24-h period; and duration of constipation). Seven items are scored at a frequency of 0 (none of the time) to 4 (all of the time), and one item at 0–2. A cut-off score of 15 suggests constipation, with a score of 30 indicating severe constipation.

The Patient Assessment of Constipation-Symptom (PAC-SYM) is a brief, easily administered questionnaire that provides a score developed to assess symptom frequency and severity based on the Rome II criteria. Three symptom subscales—abdominal, rectal, and stool—are evaluated through 12 items on a scale of 0–4, with 4 being the most severe. The PAC-SYM does not clearly discriminate constipation subtypes, but has demonstrated excellent discriminant validity between those patients with constipation who have responded to interventions and those who have not [15].

To evaluate the impact of symptoms, the Patient Assessment of Constipation-Quality of Life was developed in 2005 [16]. Twenty-eight items are grouped into four subscales: physical discomfort, psychosocial discomfort, worries and concerns, and satisfaction. The scores range from 0 to 96, with lower scores corresponding to a better quality of life.

Physical Examination

A complete physical exam should be performed on the pelvic floor patient. Although the prone jack-knife position is preferred by many colorectal specialists, a perineal exam in the left lateral decubitus position may be more acceptable to these patients. The perineum should be inspected for thinning, scars, fistulas, excoriation from soiling, or prolapsing hemorrhoids that can contribute to symptoms. A patulous appearing anus may indicate a rectal prolapse. Clinical neurologic function can be assessed by checking sensation to pinprick as well as the presence of the anocutaneous wink reflex. By lightly stroking the perianal skin, the external anal sphincter should reflexively contract via the reflex arc between nociceptors of the pudendal nerve, integration by spinal cord segments S2–S4, and motor efferents to the external sphincter.

Digital rectal examination can detect anorectal masses, strictures, or fecal impactions that can cause symptoms. An assessment of function can also be obtained by noting anal resting tone, the increment and durability of the patient's squeeze, and the ability of the puborectalis to relax when the patient pushes. Rectoceles can be noted and occasionally internal intussusception can be appreciated. Anoscopy and proctoscopy can aid in the diagnosis of hemorrhoid or mucosal prolapse, proctitis, and neoplastic disease.

Gynecological assessment may help detect other pelvic floor disorders that require treatment. Inspection of the introitus at rest may reveal evidence of postmenopausal atrophy, lichen sclerosus, and even evidence of a cystocele or rectocele. With the vulva parted, a patient may more likely

TABLE 57-2. Fecal Incontinence Quality of Life Scale [12]

Q1. In general, would you say your health is:

(1) Excellent
(2) Very Good
(3) Good
(4) Fair
(5) Poor

Q2. For each of the items, please indicate how much of the time the issue is a concern for you due to accidental bowel leakage. (If it is a concern for you for reasons other than accidental bowel leakage then check the box under Not Apply, (N/A).)

Due to accidental bowel leakage	Most of the time	Some of the time	A little of the time	None of the time	N/A
a. I am afraid to go out.	1	2	3	4	( )
b. I avoid visiting friends.	1	2	3	4	( )
c. I avoid staying overnight away from home.	1	2	3	4	( )
d. It is difficult for me to get out and do things like going to a movie or church.	1	2	3	4	( )
e. I cut down on how much I eat before going out.	1	2	3	4	( )
f. Whenever I am away from home, I try to stay near a restroom as much as possible.	1	2	3	4	( )
g. It is important to plan my schedule (daily activities) around my bowel pattern.	1	2	3	4	( )
h. I avoid traveling.	1	2	3	4	( )
i. I worry about not being able to get to the toilet in time.	1	2	3	4	( )
j. I feel I have no control over my bowels.	1	2	3	4	( )
k. I can't hold my bowel movement long enough to get to the bathroom.	1	2	3	4	( )
l. I leak stool without even knowing it.	1	2	3	4	( )
m. I try to prevent bowel accidents by staying very near a bathroom.	1	2	3	4	( )

Q3. Due to accidental bowel leakage, indicate the extent to which you AGREE or DISAGREE with each of the following items (If it is a concern for you for reasons other than accidental bowel leakage then check the box under Not Apply, (N/A).)

Due to accidental bowel leakage	Strongly agree	Somewhat agree	Somewhat disagree	Strongly disagree	N/A
a. I feel ashamed.	1	2	3	4	( )
b. I cannot do many of the things I want to do.	1	2	3	4	( )
c. I worry about bowel movements.	1	2	3	4	( )
d. I feel depressed.	1	2	3	4	( )
e. I worry about others smelling stool on me.	1	2	3	4	( )
f. I feel like I am not a healthy person.	1	2	3	4	( )
g. I enjoy life less.	1	2	3	4	( )
h. I have sex less often than I would like to.	1	2	3	4	( )
i. I feel different from other people.	1	2	3	4	( )

(continued)

TABLE 57-2. (continued)

j. The possibility of bowel accidents is always on my mind.	1	2	3	4	( )
k. I am afraid to have sex.	1	2	3	4	( )
l. I avoid traveling my plane or train.	1	2	3	4	( )
m. I avoid going out to eat.	1	2	3	4	( )
n. Whenever I go someplace new, I specifically locate where the bathrooms are.	1	2	3	4	( )

Q4. During the past month, have you felt so sad, discouraged, hopeless, or had so many problems that you wondered if anything was worthwhile?
(1) Extremely So—to the point that I have just about given up
(2) Very Much So
(3) Quite A Bit
(4) Some—Enough to bother me
(5) A Little Bit
(6) Not at All

Scale scoring

Scales range from 1 to 5, with 1 indicating a lower functional status of quality of life. Scale scores are the average (mean) response to all items in the scale (e.g., add the responses to all questions in a scale together and then divide by the number of items in the scale. Not Apply is coded as a missing value in the analysis for all questions.)

Scale 1. Lifestyle, ten items: Q2a Q2b Q2c Q 2d Q2e Q2g Q2h Q3b Q3l Q3m

Scale 2. Coping/Behavior, nine items: Q2f Q2i Q2j Q2k Q2m Q3d Q3h Q3j Q3n

Scale 3. Depression/Self Perception, seven items: Q1 Q3d Q3f Q2g Q3i Q3k Q4

Scale 4. Embarrassment, three items: Q2l Q3a Q3e

reveal anterior or posterior vaginal wall prolapse or stress urinary incontinence when asked to cough. Speculum examination assesses the cervix, if present, as well as the integrity of the vaginal epithelium. Pelvic floor strength can be assessed by placing the examining digit about 2 cm inside the introitus, hooking the pelvic floor muscles, and asking the patient to squeeze to prevent "passing gas." Bimanual examination of the vagina and rectum can assist in the clinical detection of enteroceles if widening of the rectovaginal septum is appreciated when the patient bears down.

Commode examination is extremely helpful in assessing patients for possible rectal or hemorrhoid prolapse. Vaginal wall prolapse and perineal descent may also be detected simultaneously. The patient is asked to sit on the commode or on a specialized chair (with the buttocks spread and reassurance that there are protective absorbent pads on the floor). The patient is asked to bear down as if defecating. A mirror is used to assess for any vaginal or rectal protrusion or if the patient is on a commode, they lean forward and the anal area is then viewed.

Anatomic Evaluation

Ultrasound 2D

Ultrasonography is the determination of an object's properties by measuring the transmission of sound waves through that object. The appearance of tissue on the ultrasound screen represents its echogenicity compared to surrounding structures. Lesions that return minimal echo, such as water, will appear black on the screen and are **anechoic**. Tissue that reflects more waves than the neighboring tissues will appear whiter, or **hyperechoic**, on the monitor. Tissue that reflects ultrasound beams less than the adjacent tissues appear darker, or **hypoechoic**, on the screen. Collagen and fat, which can be mixed into the striated fibers of the puborectalis muscle and external anal sphincter, tend to have higher reflectivity and will appear hyperechoic, whereas muscle with its high water content, such as the smooth muscle of the internal anal sphincter, tends to be hypoechoic.

In the late 1980s and early 1990s, St. Mark's Hospital first described the utility of evaluating patients with fecal incontinence with endoanal ultrasound. External anal sphincter defects were accurately identified and findings correlated highly with needle electromyography (EMG) mapping [17–19]. Given ultrasonography had similar accuracy and improved patient tolerance, endoanal ultrasound has replaced needle EMG in the anatomic assessment of patient with bowel incontinence.

Endoanal ultrasound can identify patients that may benefit from surgical sphincter repair with overlapping sphincteroplasty [20]. This procedure requires an isolated sphincter injury, and is not useful in patients without sphincter injuries or in patients with multiple sphincter defects in different locations. Endoanal ultrasound may also play an essential

role in selecting patients for other treatment options, including the artificial anal sphincter [21, 22] sacral nerve stimulation [23–25], and injectable biomaterials [26–28].

Anal ultrasonography is also used in the assessment of treatment results. Obstetric sphincter defects repaired primarily at the time of delivery may increase in size with time, and the size of the defect corresponds to an increased risk of fecal incontinence [29]. Several studies have demonstrated that patients with persisting sphincter defects after overlapping sphincteroplasty have impaired outcomes [20, 30]. Endoanal ultrasound can also evaluate anatomic outcomes after treatment of fecal incontinence with injectable biomaterials [27, 31].

Evaluation of anal sphincter integrity with endoanal ultrasound is a critical step in planning the operative repair of most rectovaginal fistulas [32, 33]. Preoperative anal ultrasound may change operative strategy and improve surgical success in treating patients with cryptoglandular anal fistulas [34–38]. Anal fistulas secondary to Crohn's disease may have characteristic findings on ultrasound. The presence of a hypoechogenic rim with a surrounding hyperechoic region around abscesses and fistulae has been designated the Crohn's Ultrasound Fistula Sign (or CUFS) and may represent a peri-fistula inflammatory process specific to Crohn's disease [39]. Further, Blom et al. [40] have suggested that on three-dimensional endosonography, Crohn's fistulae are more often bifurcating in structure, are wider than cryptogenic fistulae, and tend to contain more hyperechoic debris. Endoanal ultrasound can also be used to determine the appropriate timing of seton removal in patients treated with infliximab therapy for perianal Crohn's disease. If setons are not removed until the fistula tract is narrow and minimal hypoechoic inflammatory changes are seen on ultrasound, Schwartz et al. demonstrated long-term healing in 76 % of patients [41].

Prior to the procedure, the patient is instructed to perform two enemas to eliminate any residual stool that may interfere with imaging. At our institution, the exam is performed in the left lateral decubitus position. When a 2D probe is used, this is placed in the upper anal canal after lubrication of the probe and anal canal. Correct placement is confirmed by seeing the characteristic horseshoe pattern of the hyperechoic puborectalis muscle (Figure 57-1). Images at the different levels of the anal canal are acquired by manual withdrawal of the probe. The normal mid-anal canal appears as two intact concentric circles: an inner hypoechoic internal sphincter and an outer hyperechoic external sphincter (Figure 57-2). The distal anal canal is noted by the absence of the internal sphincter and presence of the hyperechoic subcutaneous external sphincter only. Given its short length, it can be difficult to identify sphincter injuries at this level.

Applying digital pressure to the posterior vaginal wall during the exam can facilitate identifying anterior sphincter injuries as well as allow perineal body measurement. This is defined as the distance between the hyperechoic finger and the inner aspect of the internal anal sphincter [42]. A perineal body measurement <10 mm has been associated with an anterior sphincter injury [42].

FIGURE 57-1. Female puborectalis.

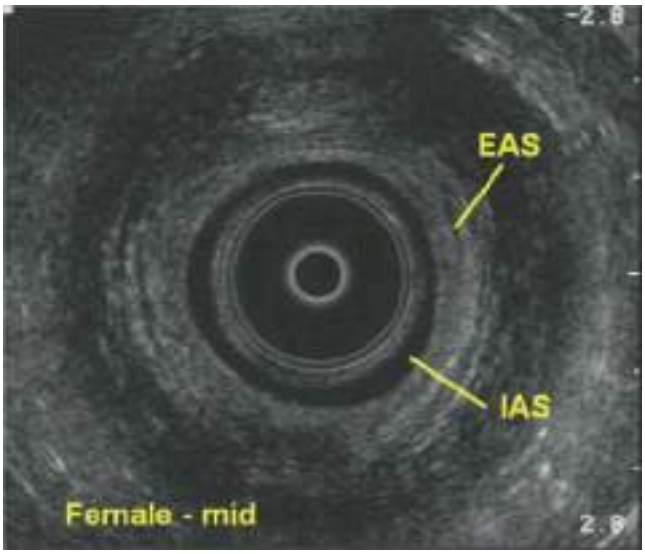

FIGURE 57-2. Female mid-anal canal.

During review of the images, abnormalities of the internal and external sphincters are recognized. Scarring, thinning, and hypertrophy of the structures may be noted. The angle of sphincter disruption can be measured (Figure 57-3a).

The interpretation of endoanal ultrasound is operator dependent, especially in the evaluation of external anal sphincter integrity [43]. The external anal sphincter has similar echogenicity to its surrounding tissues, which increases the difficulty of visualizing its borders on endoanal ultrasound. Using 2D probes, a false positive anterior sphincter defect may be identified in 5–25 % of normal patients; accu-

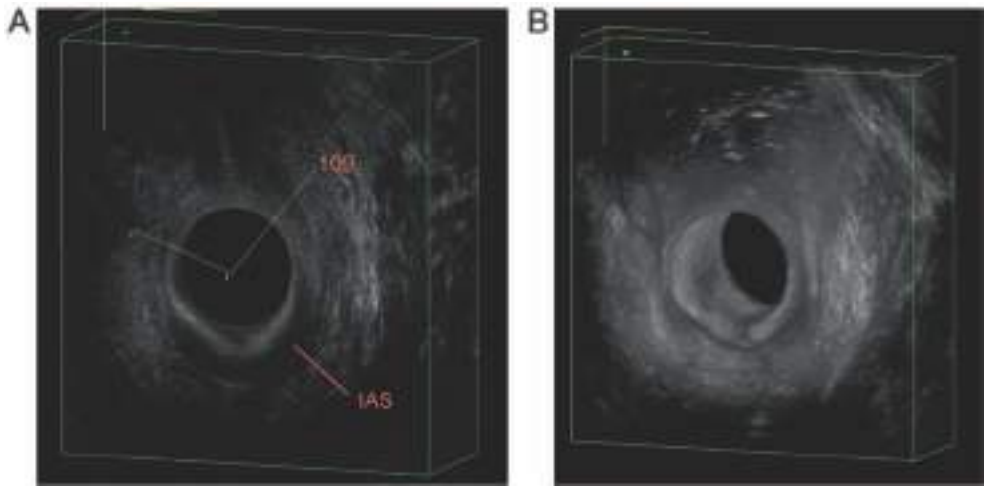

FIGURE 57-3. (**a**) Endoanal ultrasound revealing combined external sphincter defect (measuring 109°) with significant retraction of the internal sphincter (IAS). (**b**) The external sphincter defect can be more easily appreciated on 3D rendered imaging.

racy can be improved by limiting imaging to the distal 1.5 cm of the anal canal [44].

Ultrasound 3D

With the development of three-dimensional endoanal ultrasound, the visualization of the sphincter anatomy is facilitated and the diagnostic accuracy improved [45]. In our institution (AJT), endoanal ultrasound is performed using a Pro Focus 2202 Ultrasound scanner (Bruel and Kjaer, Naerum, Denmark) and a 6- to 16-MHz probe (type 2050; Bruel and Kjaer) with depth of focal zone 0.5–2.5 cm. This probe enables automatic volumetric acquisition of images over a 6 cm axis without movement of the probe. The tip of the probe is placed at the level of the puborectalis, and we use the 13 MHz frequency for evaluating patients with fecal incontinence. After recording the dataset, images can be reconstructed and manipulated in the coronal, sagittal, and axial planes. The software permits visualization of anatomic structures from different angles and distances can be accurately measured. Volume rendering software provides reconstructions to improve visualization performance.

Christensen et al. evaluated the differences between 2D and 3D ultrasound in the evaluation of anal sphincter injury. Inter-observer agreement was 98.2 % in 3D ultrasound compared with 87.9 % with two-dimensional imaging [46]. Rendering software features may help improve visualization of the borders of the internal and external sphincter from surrounding structures, as well as aid in evaluation of external anal sphincter atrophy (Figure 57-3b) [47]. With sagittal and coronal imaging, anal sphincter length can be assessed. In the absence of sphincter injury, significant shortening of the anterior external anal sphincter can be seen after vaginal delivery [48]. West et al. found loss of sphincter volume in parous females did not correlate with symptoms of fecal incontinence [49].

Dynamic US

Given the limitations of physical examination, the concerns of ionizing radiation, and the costs and accessibility of dynamic magnetic resonance imaging, pelvic floor ultrasound is emerging as a viable option in imaging and understanding pelvic floor dysfunction. Unlike other modes of dynamic imaging, meshes and tapes can be seen on ultrasound. The clinical applications for pelvic floor ultrasonography are listed in Table 57-3 [50].

Three separate probes are used to perform pelvic floor ultrasound in four separate steps. The majority of the exam is performed in a modified lithotomy position (frog-legged). An enema prep is recommended for anorectal scanning. Dynamic imaging is performed with the patient at rest, during cough, with squeeze, and with push. Video clips are saved for subsequent review.

Transperineal scanning is performed with a 6 MHz linear transducer such as the B-K 8802 probe. The probe is placed with minimal pressure on the perineum from the mons pubis to the anal margin. Dynamic midsagittal images of the pelvis are recorded with this probe. Transvaginal ultrasound is then performed with a biplane probe, such as the B-K 8848 transducer with a 3D mover. This allows axial and midsagittal imaging of the anterior compartment and the posterior compartment. The transducer should be placed lightly into the vagina without significant pressure on the surrounding structures to prevent distortion of the anatomy. Dynamic images are again obtained and stored. Transvaginal assessment is then completed with a 360-degree rotational probe, such as

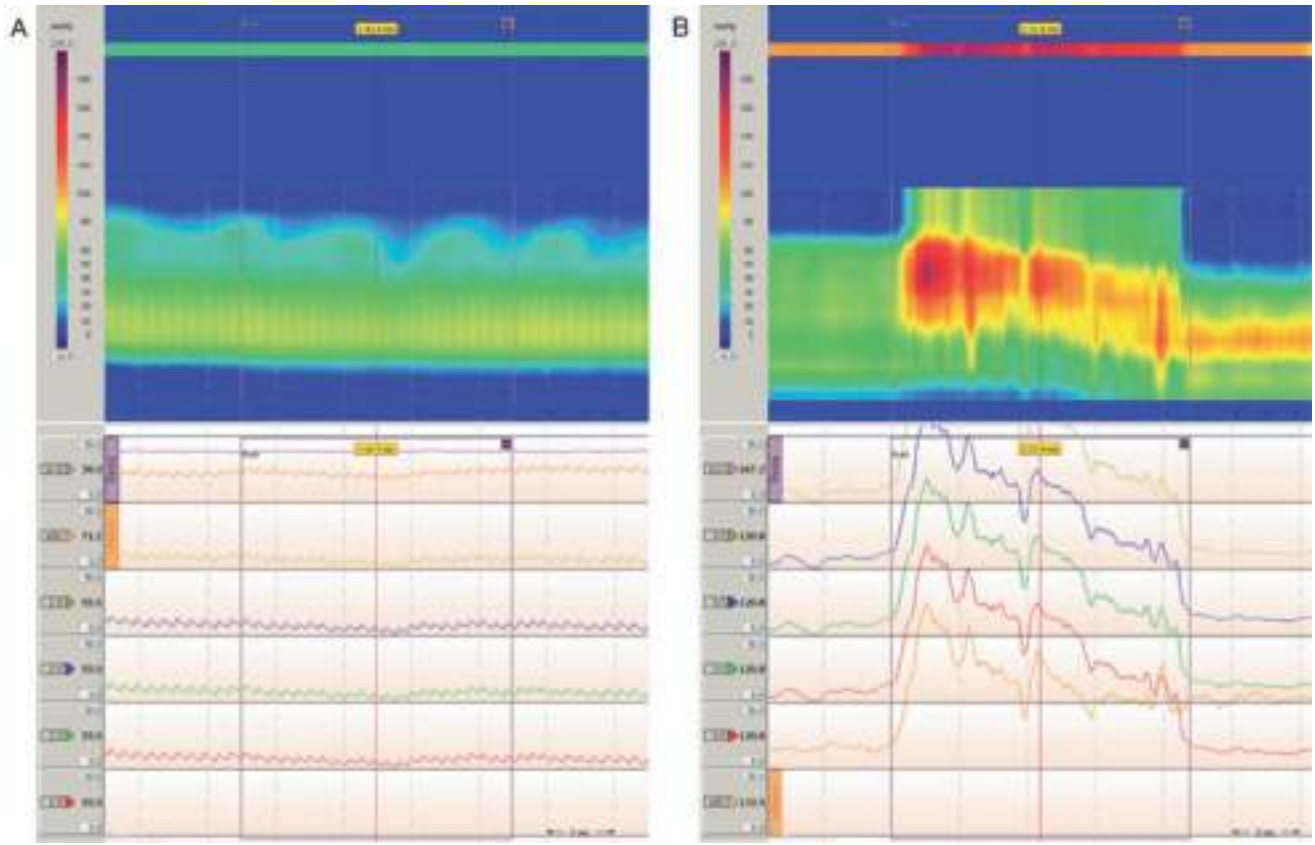

FIGURE 57-4. Appearance of Valsalva on high-resolution manometry. (**a**) Normal relaxation. (**b**) Paradoxical contraction.

TABLE 57-3. Indications for dynamic pelvic floor ultrasound [50]

Urinary incontinence
Symptoms of voiding dysfunction
Recurrent urinary tract infection
Fecal incontinence
Pelvic organ prolapse: cystocele, enterocele, rectocele, uterine prolapse
Symptoms of obstructed defecation: straining at stool, chronic constipation, vaginal or perineal digitation, and sensation of incomplete bowel emptying
Suspected pelvic floor dyssynergy
Pelvic, vaginal, or anal pain
Follow-up after pelvic floor surgery

the B-K 2052 probe. Static images are achieved and later analyzed at four axial planes [51]. Lastly, endoanal ultrasound is performed with the 2052 or similar transducer as previously described.

In static imaging, transvaginal ultrasound may reveal levator trauma not seen on endoanal ultrasound, given the levator ani attachments to the pubic rami can be easily visualized. Levator ani avulsion has been associated with decreased pelvic floor strength [52, 53]. DeLancey et al. found women with pelvic organ prolapse have an odds ratio of 7.3 for having a major levator injury compared with asymptomatic women [52].

Dynamic transperineal ultrasound has been evaluated and compared with standard defecography. In an early study, good agreement was seen in the diagnoses of rectocele, rectoanal intussusception, and rectal prolapse. No differences were noted in the measurement of the anorectal angle at rest, anorectal junction position at rest, or anorectal junction movement during straining. The anorectal angle at strain was also similar [54]. More recent studies have suggested trans-

perineal ultrasound has a lower detection rate for prolapse compared with defecography [55, 56].

An alternative technique, called echodefecography, has been described by Murad-Regadas [57, 58]. A 3D 360-degree probe, such as the B-K 2050 or 2052, is used to perform the exam. The patient is examined in the left lateral decubitus position after a cleansing enema. For scan 1, the probe is placed into the anal canal, and a scan of the distal 6 cm is obtained at rest. The angle between the puborectalis and a line perpendicular to the axis of the anal canal is measured. In scan two, the same anatomy is scanned with 15 s at rest, 20 s of maximal push, and 15 s of rest. Comparing scans 1 and 2, normal relaxation is noted if the angle increases by a minimum of one degree; paradoxic contraction is noted if the angle decreases by at least one degree. For scan 3, 120–180 ml of ultrasound gel is introduced into the rectum. The transducer tip is placed at 7 cm from the verge. The anatomy is scanned for 15 s at rest, 20 s at maximal push, and 15 s at rest, similar to scan 2. During this examination, middle and posterior compartment prolapse, such as rectocele, intussusception, and enteroceles may be noted.

Using the Murad-Regadas technique, echodefecography was compared with defecography in 86 women evaluated at six centers. Echodefecography identified 37 of 42 rectal intussusceptions, but identified an additional four not seen on traditional defecography. There was good concordance in identifying grade 3 enteroceles, however, grades 1 and 2 enteroceles could not be identified with the ultrasound technique. Anismus was identified more commonly in the echodefecography group, and two rectoceles may have been missed by the technique due to insufficient straining [59].

Using dynamic endoanal ultrasonography, in a protocol similar to the method described above, Vitton et al. compared their technique to dynamic MRI and traditional defecography in the evaluation of posterior compartment disorders. Using defecography as the gold standard, concordance rates were similar between ultrasonography and magnetic resonance imaging. Patients strongly preferred the ultrasound exam over the other two procedures [60]. Given the exam is not performed upright, similar to dynamic MRI, there is concern the exam may be less sensitive for prolapse compared with defecography. However, for surgeons who have ultrasound available in their office, dynamic ultrasonography may be a convenient method of tricompartment imaging of pelvic floor dysfunction.

MRI

Magnetic resonance imaging has been used to assess sphincter integrity in the evaluation of fecal incontinence [61–63]. Images can be generated either with an external phased array coil or with an endoanal coil. The latter may be less commonly available and more uncomfortable for the patient. Endoanal ultrasound appears to be superior in evaluating the internal anal sphincter [64]; both methods appear to be equivalent at detecting external anal sphincter integrity [64, 65]. Magnetic resonance imaging of the anal canal may better detect external sphincter atrophy that can adversely affect the outcomes of sphincteroplasty [66, 67]. Given the lower costs and accessibility, endoanal ultrasound is presently the more commonly performed exam in the anatomic evaluation of patients with fecal incontinence. The utility of magnetic resonance imaging in the dynamic evaluation of pelvic floor function is discussed later in this chapter.

Functional Evaluation

Anal Manometry

The study and recording of pressures in the anal canal has been practiced for over a century. Gowers described measuring the pressures in the anal canal of patients with spinal cord injuries in 1877 [68]. Early investigators sought to determine the contribution of the internal and external sphincters to overall anal canal pressure and function [69].

Anal manometry offers physicians valuable information regarding several aspects of anorectal function. For this reason, it is one of the most commonly utilized diagnostic tests in the evaluation of pelvic floor function. Manometry has been described in the evaluation of patients with fecal incontinence [70], constipation [71, 72], anal pain [73], fissure [74], and Hirschsprung's disease [75].

There are several systems and probes utilized to perform manometry, each with its own potential advantages and disadvantages. There are no standardized protocols that can create challenges in interpretation. In addition, age and gender have been shown to influence results [76].

The basic equipment necessary to perform manometry consists of a probe to sense pressure, a recording device, a monitor, and software system for analysis.

The probes can be either water perfused or solid state including the newer high-resolution and high-definition technologies. A non-latex balloon is tied to the end of the probe where a final pressure sensor is located to measure rectal pressures and reflexes.

Water perfused catheters utilize a thin plastic tube with 4–8 radially situated side holes. There is a central channel for balloon inflation. A pneumohydraulic pump is used to attain a consistent perfusion rate of 0.2–0.4 ml/min [77]. Pressure is measured at each of the side holes within the anal canal. This system is advantageous with respect to cost, however, potential shortcomings are the inability to measure in the sitting position and the potential artifact due to reflexes triggered by the sensation of the fluid in the anal canal. Proper calibration is essential.

Solid-state microtransducer is a thin flexible tube with embedded microtransducers which provide a direct measurement of pressures within the anal canal. These catheters are

more expensive and fragile but are felt to give more accurate and reproducible results [78].

High-resolution manometry represents the newest technological advance in the evaluation of anal function. Initially reported for the evaluation of esophageal function [79], high-resolution manometry has gained traction in the realm of anorectal physiologic testing [80]. Several probes are currently available (Table 57-4).

These devices provide enhanced resolution and greater detail due to the increased number of sensors. The sophisticated software provides the user with easy to understand color topographic analysis of the anal canal pressures. This can lead to improved understanding of the anal canal function. When compared to water perfused systems, high-resolution anal manometry was found to correlate well with respect to pressure measurements, but was noted to have decreased variability during the dynamic portions of the study as well as decreased time to perform the study [81]. Some have noted an increase in measured resting and squeeze pressure using the high-resolution probe compared to the water perfused probe. It was theorized that this increase, which was consistent, was a result of improved sensitivity of the measurements with the 256 sensors in the high-resolution probe [82].

Manometry Technique

Patients do not need formal bowel prep for this study. After an attempted evacuation attempt prior to the procedure, or there is significant residual stool, an enema can be given. It is important to provide proper education to the patient prior to the procedure as anxiety can lead to unreliable results.

The patient is placed in the left lateral decubitus position and a digital rectal examination is performed. Particular attention is paid to the presence of any anal abnormalities on examination such as blood, masses, or tenderness. Postoperative patients with a low anastomosis should be evaluated for stenosis or disruption prior to placement of any probe, catheter, or balloon.

As has been previously mentioned, there is no standardized technique for the manometric evaluation of the anal canal. The basic concept is that of a balloon tipped catheter placed within the anal canal with the balloon in the distal rectum to measure pressures during various maneuvers. The water perfused systems can utilize a station pull through technique, whereby the catheter is inserted to the 6 cm level and static measurements at rest and squeeze are taken at 1 cm intervals along the length of the anal canal. The continuous pull through technique measures pressures along the length of the anal canal as the catheter is slowly withdrawn, rather than taking incremental measurements. High-resolution probes have the advantage of simultaneous measurement of pressure within the entire canal as the sensors are situated over the length of the probe within the anus.

After initial probe placement, a period of equilibration is necessary in order to allow the anal sphincter to return to baseline activity. This typically takes about 5 min. Several wave patterns are seen which demonstrate the intrinsic nature of the internal sphincter.

Slow waves are the most common. They occur with a frequency of 10–20/min and are low amplitude. They have an increasing frequency in the lower anal canal and may cause an upward movement of rectal contents, possibly playing a role in continence [83].

Ultraslow waves are high amplitude and occur with a frequency of less than 2/min. These are associated with anal hypertonia but also can be found in normal subjects [77].

Intermediate waves occur with a frequency of 4–8/min. These are the least common and are seen in patients with neurologic injury.

The components of the examination include measurements of static pressure at rest and squeeze, dynamic measurements with cough and Valsalva, assessment of the rectoanal inhibitory reflex (RAIR) as well as evaluation of rectal sensation and compliance.

Resting Pressure

The concept of anal canal "tone" has long been understood. Through the early work of Masius in animal models, the spinal cord reflex contribution to anal canal resting pressure became known in the late 1800s [84]. The internal anal sphincter tone is the primary determinant of the resting pressure. It is recognized, however, that up to 30 % of the resting pressure can come from the external anal sphincter tone and 15 % from the anal cushions themselves [85, 86]. Pressures are recorded within the anal canal with the patient at rest after the equilibration period. The resting pressure is defined as the difference between the intra-rectal pressure and the anal canal pressure. The stationary or continuous pull

Table 57-4. Anorectal manometry probes

	Manufacturer	Diameter	Length	Sensors/row	Rows	Interval
HRAM	Given Imaging, Yokne'am Illit, Israel	4.2 mm		10	12	6 mm
3d HRAM	Medical Measurement Systems, The Netherlands	4 mm	15 cm	1–4	8	10 mm
3d HDAM	Given Imaging, Yokne'am Illit, Israel	10.75 mm	10 cm	16	16	4 mm

through technique can be used. The high-resolution probe will allow for measurements along the length of the canal without moving the probe, thereby reducing the chance of unintentional excitation of the internal sphincter by the movement of the probe. The standard probe is placed 5 cm above the anal margin. After equilibration, measurements are taken at either 1 cm intervals or continuously as the probe is withdrawn by a motorized pulling device at a rate of 5 mm/s.

The sphincter length can be calculated with the pull through technique by measuring the length of the anal canal where the pressure is at least 5 mm greater than the intra-rectal pressure. The high pressure zone is defined as the length of the anal canal over which the pressures are greater than half the maximum resting pressure [87].

Controversy exists over the effect of gender on mean resting pressure. While several studies suggest that men have higher pressures, the larger series with evenly matched groups have failed to show this difference [88]. Age has been shown to have an influence on resting pressure as well, correlating with decreases in both genders in older age groups [89].

Squeeze Pressure

The squeeze pressure is obtained by placing the probe within the anal canal and asking the patient to contract the anal muscles. It is important to avoid the use of accessory muscles of contraction. The squeeze pressure should be generated by the external anal sphincter. The intra-rectal pressure is subtracted from this number. In order to truly isolate the striated muscle contribution, the resting pressure can be subtracted to determine the squeeze increment. This measurement will assess the contribution of the external anal sphincter and puborectalis only. The duration of squeeze can also be measured as the time that a patient can sustain squeeze pressure greater than 50 % of the maximal squeeze pressure [90]. Decreased squeeze pressures are frequently the result of external anal sphincter dysfunction, correlation with other physiologic studies can determine the etiology (traumatic or neurologic). A diminished squeeze duration has historically been associated with fecal incontinence [91], however, more recently, researchers have found an inverse relationship between external anal sphincter fatigue and incontinence [92].

Cough Reflex

A rapid rise in intra-abdominal pressure, such as with cough, causes a reflex contraction of the external anal sphincter. This is the normal state and is mediated by a polysynaptic pathway of spinal origin. The cough reflex is preserved after mid thoracic spinal injury but lost with cauda equina lesions [93]. The cough reflex helps to maintain continence during rapid rise in intra-abdominal pressure.

Valsalva

Relaxation of the external anal sphincter during Valsalva maneuver facilitates defecation. Conversely, contraction of the striated puborectalis or external anal sphincter during attempted defecation will result in constipation secondary to outlet obstruction [94]. Non-relaxation or paradoxical contraction of these muscles can be demonstrated at the time of anal manometry. After an equilibration period, the patient is asked to feign defecation. It is expected to visualize an increase in the intra-rectal pressure with a concomitant decrease in the anal canal pressures. Failure to decrease or an increase in anal pressures with feigned defecation can aid in the diagnosis of dyssynergic defecation. Four types of dyssynergic defecation have been described:

Type 1 Intra-rectal pressure rises with an increase in intra-anal pressure.
Type 2 No intra-rectal pressure increase, increase in intra-anal pressure.
Type 3 Intra-rectal pressure rises, no/minimal change in intra-anal pressure.
Type 4 No intra-rectal pressure increase, no/minimal change in intra-anal pressure.

Care must be taken in the correlation of manometric findings of non-relaxation of the sphincter and clinical findings. It has been demonstrated that paradoxical sphincter contraction is also a common finding in healthy patients as well at the time of manometric evaluation, presumably a result of patient's unease during the procedure itself [95]. It has even been demonstrated that patients with non-relaxation at the time of manometry can go on to have normal testing when the manometry was repeated in the patients home setting [96]. Figure 57-4 demonstrates the normal and paradoxical responses to Valsalva seen on manometric evaluation.

Rectoanal Inhibitory Reflex

The rectoanal inhibitory reflex (RAIR) can be elicited by filling a balloon within the rectum. The volume required in approximately 50 cc but can be larger in conditions of megarectum and hyposensitivity [97]. Distension of the rectal wall causes an initial contraction of the external sphincter followed by a relaxation of the internal anal sphincter. This was first noted by Gowers in 1877 [68] and is felt to aid in the sampling mechanism of the anal canal. This mechanism allows discrimination of solid liquid and gas has been shown to be an important component of continence [98]. Presence of the reflex confirms a functioning myenteric plexus and therefore the absence of Hirschsprung's disease. The absence of a reflex is associated with Hirschsprung's disease and visceral neuropathy [99]. It should be noted that the absence of a reflex is often related to technical factors such as inadequate balloon volume. In the event of a negative reflex, testing at several levels within the canal and at a larger balloon

volume may elicit the response. Fecal incontinence and constipation have been associated with altered patterns of the RAIR [100, 101]. Figure 57-5 demonstrates the rectoanal inhibitory reflex seen on high-resolution anorectal manometry.

Rectal Sensation

Rectal sensation is assessed by incrementally inflating a balloon in the rectum with small volumes. The patients first sensation and urge to defecate and maximum tolerated volumes are recorded. The rectum itself does not contain pain sensing nerve fibers. The rectum is sensitive to distension via mucosal receptors and nerves in the pelvic fascia and pelvic floor musculature via the S2–4 nerve roots [102]. Alteration in rectal sensation is associated with fecal incontinence and constipation:

- First sensation: the lowest volume of air that the patient senses a fullness in the rectum.
- Urge to defecate: the lowest volume of air that produces a sustained desire to defecate.

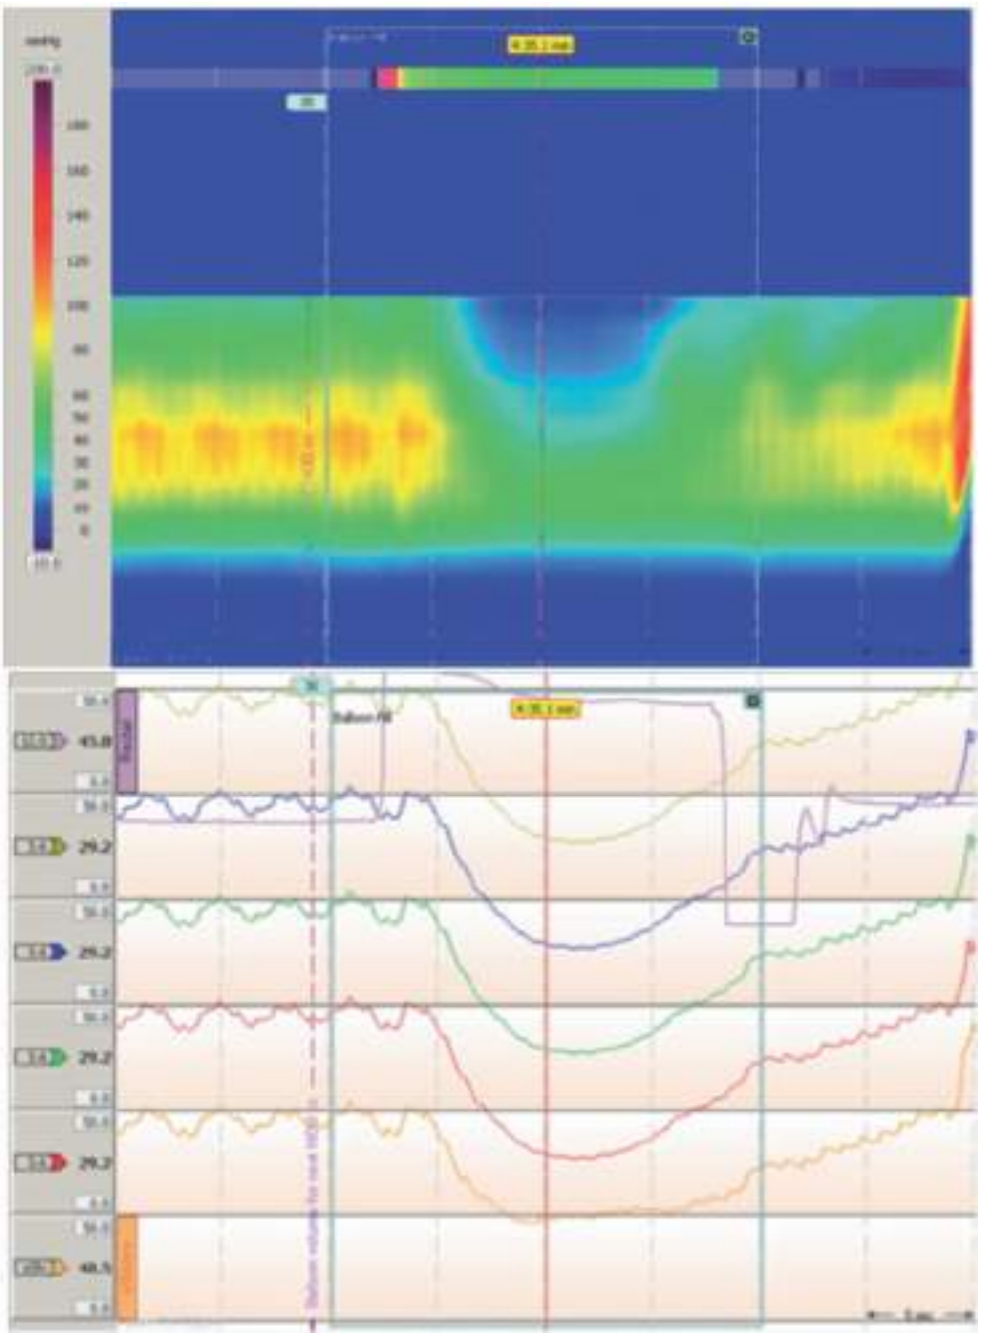

FIGURE 57-5. Appearance of RAIR (rectoanal inhibitory reflex) on high-resolution manometry.

- Maximal tolerated volume: the maximum volume that a patient can tolerate. It is of note that most balloons can hold 300 cc, so if the maximum tolerated volume is 300 cc, the rectum may have dramatically decreased sensation.

Compliance

Rectal compliance measures the distensibility of the rectum. This can be altered in conditions such as proctitis and after radiation. The balloon is inflated and the change in rectal pressure with the change in volume is calculated.

Balloon Expulsion

The balloon expulsion test is a relatively simple method to grossly assess evacuatory function. As is often the case in pelvic floor physiology testing, there is no standardized method of performing the test. In general, a balloon attached to catheter is placed into the rectum and inflated. In the seated position, the patient attempts to expel the balloon. The ability and time taken to expel the balloon are measured.

Variables in the technique include the type of balloon, the material used to fill, the amount filled (standard 50 cc vs. volume that produces urge to defecate [103]).

Most studies use 1 min as the cut-off point for the normal time taken to expel the balloon [104].

Neurophysiologic Testing

The neurophysiologic evaluation of the anorectum provides important functional evaluation of the anal canal. Electromyography records electrical activity of the external anal sphincter and puborectalis muscles during rest, squeeze, and attempted defecation. The integrity of the motor unit is assessed. EMG can be used as a tool to map the anal sphincter and identify defects. First described in 1930 [105], historically, EMG was the gold standard for evaluating sphincter defects, More recently, however, ultrasound was found to have high correlation with EMG [106]. EMG still remains a useful tool in the detection of sphincter defects when the ultrasound is inconclusive as can be the case in areas of dense scarring. In addition to the potential of anal sphincter mapping, the EMG can be used to identify areas of injury, where prolonged action potentials and polyphasic responses will be seen. With severe injury, or complete denervation, electrical silence will be noted. In areas that have undergone repair and reinervation, the action potentials will be prolonged and the regrouping of muscle fibers will create polyphasic potentials. The irregularity of the motor unit potentials has been correlated with neurologic injury [107]. There are four methods of EMG assessment:

- concentric needle
- monopolar wire
- single fiber
- surface anal plug.

Needle EMG

Needle EMG provides the examiner with detailed information about the electrical activity of the anal sphincter muscle. Quadrant by quadrant, the examiner can assess the function of the motor units. The test, while informative, is often not well tolerated. Although no longer a mainstay in the evaluation of anal sphincter defects, concentric needle EMG is important in the evaluation of neurogenic fecal incontinence [108, 109].

Surface

The surface anal electrode (Figure 57-6) has the advantage of increased patient comfort as no needles are used. The study provides a global assessment of anal sphincter function but cannot provide isolated quadrant activity. This technique is useful in the evaluation of constipation and dyssynergia. The technology is commonly used in biofeedback therapy as well. The anal canal responses to squeeze and attempted defecation are recorded. The absence of a needle insertion reduces the potential for a false recording due to pain. The expected response to attempted defecation is a decrease in electrical activity. Failure to decrease or an increase in activity

FIGURE 57-6. Surface EMG (electromyography) electrode.

constitutes non-relaxation or paradoxical contraction of the puborectalis, respectively. Correlation between the anal sponge and needle EMG has been well established in evaluation of constipated patients [110, 111].

Pudendal Nerve Terminal Motor Latency

Pudendal nerve terminal motor latency (PNTML) measures the time taken from stimulation of the nerve intrarectally to measurement of a muscular response at the level of the anal sphincter. The technique was first described by Kiff and Swash from St. Mark's Hospital in 1984 [112, 113]. A disposable electrode was introduced in 1988 [114]. The Dantec St. Mark's electrode is most commonly used to assess PNTML (Figure 57-7). Stimulating electrodes at the fingertip and receiving electrodes situated 4 cm distally at the base of the finger allow for measurement of the muscular response to nerve stimulation. The study has been shown to be reproducible with low intra- and inter-observer variability [115]. After placement of the electrode, the examiner inserts the finger into the anal canal and after localization of the coccyx posteriorly, the finger is brought laterally to the ischial spine while delivering electrical impulses. Once the nerve is located, the time measured to elicit a muscular response is recorded. Normal latency is 2.0±0.2 ms [116]. The study is technique dependent and a learning curve has been reported [117]. PNTML has been advocated in the evaluation of fecal incontinence, rectal prolapse, and constipation. Its clinical significance has been debated particularly with respect to patients with incontinence. Studies of patients suffering from idiopathic incontinence found no association with incontinence severity or manometric findings [118], while others draw a direct correlation with manometric findings [119]. These discrepancies may be attributable to the complex and multifactorial etiology of fecal incontinence. The test is still utilized in the evaluation of fecal incontinence and other functional disease states to evaluate the integrity of the pelvic floor innervation.

Transit Testing

Assessment of the transit time of the gastrointestinal tract is an integral component of the evaluation of constipation and

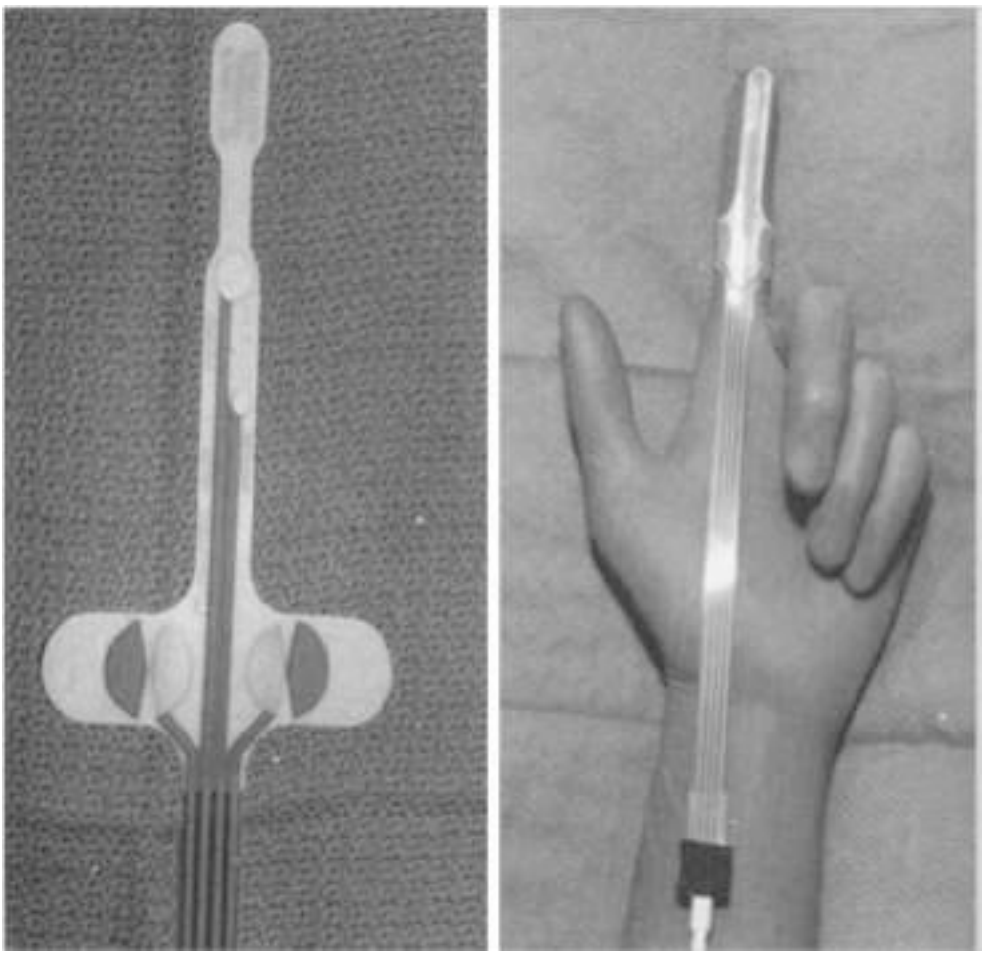

FIGURE 57-7. St. Mark's electrode.

other colorectal complaints. Historically, this was accomplished with ingestion of radio-opaque markers. More recently, however, advances in technology have given physicians the ability to understand segmental transit times as well as the whole gut transit time. There are four main methods to assess GI transit: radio-opaque markers, scintigraphy, breath testing, and most recently, the wireless motility capsule. Each method has its advantages and drawbacks with respect to cost, radiation exposure, and information provided.

Radio-Opaque markers

The ingestion of radio-opaque markers to assess gastrointestinal transit has been utilized since the 1960s. In 1969, the first reports utilized solid cylindrical pellets specifically to assess colonic transit. These were modified to a cut section of radio-opaque polythene tubing. The patients ingested 20 pellets and serial radiographs were taken of both the patient and the stools passed [120]. Fortunately, the technique was simplified to include only abdominal radiographs and stool transport to the radiology suite is no longer necessary. Currently, a single capsule containing 24 markers (Sitzmark Radio-opaque Markers, Konsyl Pharmaceuticals Inc, Fort Worth, TX) is ingested and serial radiographs are taken. There are several protocols for the study, however, all require cessation of all laxatives 48 h prior to and for the duration of the study. The simplest protocol utilizes plain abdominal X-rays on days 1, 3, and 5. A normal study requires passage of 80 % of the markers by day 5. The number and distribution of the markers are noted. Patients with colonic inertia will have greater than five markers evenly distributed throughout the colon (Figure 57-8). Outlet obstruction should be considered with there is a stacking of markers at the rectosigmoid junction [121]. The X-ray on day 1 will document grossly normal gastric and small bowel transit if all of the markers are located in the colon at this point. There are alternate techniques, which require the ingestion of multiple distinct capsules (1/day for 3 days) followed by an abdominal X-ray on day 4. The segmental transit times are then calculated by the distribution of the markers [122].

These marker studies have the benefit of decreased cost; however, the patient is subjected to the ionizing radiation of the serial X-rays.

The use of radio-opaque markers has been described to evaluate small bowel transit [123], however, this technique requires repeated fluoroscopic examination and radiation exposure.

Breath Testing

Breath testing has been described for the evaluation of several conditions including carbohydrate malabsorption, intolerance, and bacterial overgrowth. In the evaluation of gastrointestinal transit, breath testing can provide estimation of both gastric emptying and orocecal transit time.

FIGURE 57-8. Abdominal radiograph demonstrating retention of radio-opaque markers.

Gastric emptying is assessed using nonradioactive isotope. ^{13}C-labeled substances are ingested and metabolized after passing the pylorus. Ultimately, there is conversion to $^{13}CO_2$, which is exhaled. Several substances can be labeled to measure the solid and liquid phases of gastric emptying. Breath samples are collected for 4 h. Both mass spectrometry and infrared analyzers have been used to detect and measure the presence of $^{13}CO_2$ [124]. The results can be affected by pulmonary conditions resulting in CO_2 retention.

Orocecal transit time is frequently assessed with the use of the lactulose breath test. Hydrogen is the measured component. The premise is that the lactulose, a nonabsorbed sugar, is ingested and the anaerobic bacteria of the GI tract, found in the colon, metabolize it producing CO_2 and H_2. The H_2 is absorbed and circulated to the lungs where it is ultimately exhaled and measured in breath samples. The time taken to increase the exhaled H_2 ppm greater than 20 ppm is considered to represent the orocecal transit time. This time is not a true representation of small bowel transit time as it can be affected by conditions that delay gastric emptying. Normal orocecal transit time ranges between 40 and 170 min [125]. It is known that approximately 15–20 % of people are "non-fermenters" and will not produce hydrogen at all. Conditions

such as bacterial overgrowth can lead to a false and early rise in the measured breath hydrogen.

This technique has been validated in comparison with scintigraphy with lactulose and avoids the use of radioactive isotopes [126]. Scintigraphy without lactulose was shown to have a decreased transit time when compared to studies performed with lactulose [127]. Presumably, this was related to the osmotic effects of the lactulose and should be considered in the evaluation of H_2 breath tests.

Scintigraphy

The use of nuclear medicine to assess gastrointestinal transit has been most commonly described for the evaluation of gastric transit. Initial reports in 1970 describe the use of ^{129}Cs [128]. Since this time, as is the case with many tests of GI physiology, there has been little standardization of testing methods. In an attempt to simplify and standardize the technique, international controls were established in 2000. ^{99}Technetium labeled fat free egg substitute or egg whites are given in a low fat meal. The percentage of retained gastric contents is measured at 60, 120, and 240 min. Delayed gastric emptying is defined as residual of greater than 10 % at 4 h [129].

Small intestinal scintigraphy has largely been used in research settings due to its limited availability and lack of standardization. Recent reports of evaluating small bowel transit in the setting of a whole gut transit time have attempted to better define the study [130]. Utilizing a standard ^{99}Tc labeled solid meal and ^{111}In water, gastric emptying, followed by small bowel and colonic transit was measured. The percent of the meal that reached the cecum at 6 h was calculated. The colonic transit was evaluated by assessing the pattern of the tracer and percent excretion at 24, 48, and 72 h. A recent position paper by the American and European Neurogastroenterology and Motility Societies found strengths in the quantitative information provided but drawbacks in the lack of standardization, cost, radiation exposure, and time taken to complete the study [131]. Colonic scintigraphy has also been evaluated. Studies have shown the ability to delineate segmental colonic transit [132]. The clinical implications of these findings are still unclear. Colonic transit scintigraphy also has limited availability and requires radiation exposure and repeated imaging.

Wireless Motility Capsules

The wireless motility capsule represents the newest technology used in the evaluation of gastrointestinal transit. The device is ingested orally and records temperature, pH, and pressure as it passes through the GI tract. It has been approved by the FDA for evaluation of gastroparesis in 2006 and colonic transit in the setting of constipation in 2009. The technology had the advantages of the avoidance of all ionizing radiation, performance in the ambulatory office setting, standardization of technique with the ability to assess motility in all portions of the GI tract. The WMC (smartPill; Given Imaging Corp, Yokne'am Illit, Israel) is a single use indigestible capsule that measures 26.8 mm × 11.7 mm. The pH, temperature, and pressure sensors are housed within the capsule that transmits data every 20 s for 24 h then every 40 s for the remainder of the study. The battery lasts for a minimum of 120 h. The activated capsule is ingested by the patient and a data receiver is worn for the next 5 days. At the completion of the study, the receiver interfaces with a laptop and the data is interpreted. Prior to the study, an overnight fast is required. All medications that can affect motility or pH are discontinued prior to the test. After ingestion, a standardized meal is consumed. Following this, the patient is kept NPO for 6 h to assess gastric emptying time. Following this initial period, patients can eat and drink normally. They are asked to record meals, sleep, and bowel movements for the duration of the study. Use of the WMC is contraindicated in patients with dysphagia, strictures, or anatomic bowel obstruction. An initial drop in pH signifies passage of the capsule from the stomach in to the small bowel. A subsequent drop in pH signifies passage in to the cecum. If the ileocecal valve is incompetent, this change might not be observed [133]. In patients where the pH drop is not observed, changes in pressure wave frequency of amplitude may signify the passage from small bowel into the colon [134]. Abrupt decrease in temperature is noted when the capsule exits the body. With this information, gastric emptying, small bowel transit, colonic transit, and whole gut transit times can be determined [135].

Anatomic and Functional Evaluation

From the surgeon's viewpoint, the use of dynamic imaging of the pelvic floor is crucial in evaluating patients with obstructive defecation. Dynamic imaging can differentiate between functional causes, such as anismus, and mechanical etiologies, such as intussusception and rectal prolapse. The use of dynamic imaging in patients with pelvic floor prolapse may better identify patients requiring multi-compartment repair and prevent recurrences [136, 137]. Given surgical correction of rectal intussusception (RI) can improve bowel continence [138], and the possibility that sacral neuromodulation may be less effective in treating fecal incontinence in patients with high grade RI [139], dynamic imaging is performed routinely in some centers in the evaluation of fecal incontinence.

Defecography

Defecography, also referred to as evacuation proctography, assesses dynamic changes in rectal wall, anal canal, vaginal, and pelvic floor morphology during the defecation process

[140, 141]. Although many centers use retrograde rectal and vaginal contrast, some may add bladder contrast to perform dynamic pelvicography [142]. Others advocate the use of oral contrast or peritoneal contrast to better delineate enteroceles and peritoneoceles [143, 144]. The rectal barium contrast is thickened to simulate stool weight and consistency. The volume introduced may be standard [144] or tailored to the individual until a strong, sustained urge to defecate is achieved [145]. The patient is then comfortably placed on a radiolucent commode attached to a fluoroscopic table. Images may be obtained in the lateral and occasionally in the antero-posterior view. A disposable plastic bag collects evacuated barium below the commode.

One of the advantages of defecography is that it is performed in the upright sitting position. This may approach more physiologic conditions, allowing the natural movement of the abdominal muscles, the weight of the intestines, and the influence of gravity's effect on rectal evacuation be evaluated [140]. Images are obtained when the patient is asked to squeeze and contract the external sphincter and puborectalis, at rest, and with Valsalva. If the patient digitates to facilitate or initiate evacuation, images during these maneuvers are performed.

A recent report of defecography in normal volunteers reported a mean radiation dose of 0.6 mSv (effective dose 01–1.0 mSv) [146]. Goei and Kemerink estimated the mean effective dose at 4.9 mSv for female patients and 0.6 mSv for males, given the testes receive only scattered radiation [147]. For comparison, an individual's environmental radiation exposure is estimated at 2.5–3.0 mSv/year, and the effective dose from a single barium enema would be 7.0 mSv.

Normal Parameters

The pubococcygeal line (PCL) refers to a line between the tip of the coccyx and the pubis. Given it is a static, unchangeable point, it is used to assess the mobility of the pelvic floor. In a normal patient, no more than one third of the rectum will lie below this line; perineal descent can be noted if a greater percentage of rectum lies below the PCL. Radiologists often define the presence of pelvic organ prolapse when pelvic viscera descend below the PCL [148].

The anorectal angle (ARA) refers to the angle between the anal canal and the posterior rectal line. At rest, the ARA approximates 90°. With squeeze, the imprint of the puborectalis muscle on the posterior rectal wall increases, and the ARA should decrease to about 75°. This is associated with elevation of the anorectal junction (ARJ), the highest point of the anal canal [149]. With strain, the puborectalis should normally relax, decreasing its imprint on the posterior rectum, increasing the anorectal angle to 110–180°, and allowing the ARJ to descend no more than 3.5 cm from its resting position. A lack of relaxation of the puborectalis with strain and persistent impression of the muscle on the posterior rectum can be consistent with anismus or paradoxic contraction of the pelvic floor [150]. A common criticism of the clinical value of ARA measurement is high intra- and inter-observer variation [151, 152].

Rectocele

A rectocele is a bulging of the rectal wall. Usually this is a ventral wall bulge in female patients given laxity in the rectovaginal septum (Figure 57-9). Lateral and posterior rectoceles have also been described in male and female patients [153]. Rectoceles are very common, and may be seen in up to 93 % of asymptomatic females, regardless of parity [146]. The size of the protrusion from the anterior rectal wall can be measured; rectoceles smaller that 2 cm are regarded as clinically insignificant. The pattern of deformation as well as the degree of emptying of the rectocele is noted during defecation. If the patient admits to using perineal or vaginal digitation, the impact of the maneuver in assisting evacuation can be observed during imaging.

Rectal Intussusception

Rectal intussusception represents the invagination of the rectal wall by more than 2 cm during straining. The invagination can be circumferential or asymmetric, and the extent may be intra-rectal or intra-anal [154, 155]. Rectal intussusception is also common, and may be seen in up to 39 % of symptomatic patients [156] and 20 % of asymptomatic volunteers [146]. Rectorectal intussusceptions are often asymp-

FIGURE 57-9. Fluoroscopic defecography with vaginal (v) and rectal contrast. An anterior rectocele (Rc) is noted; the size can be measured from the expected anterior rectal wall (*arrow*) to the anterior aspect of the protrusion.

tomatic, whereas rectoanal intussusceptions may cause symptoms of fecal incontinence, obstructive defecation, or rectal pain.

Rectal Prolapse

Rectal prolapse occurs when full thickness rectal wall protrudes past the anus. Dynamic imaging can evaluate whether the prolapse is isolated to the posterior compartment, or whether it is associated with anterior and middle pelvic compartment prolapse. Combined multi-compartment pelvic prolapse repairs appear to be safe and have lower rates of symptomatic recurrence [136, 137].

Enterocele and Sigmoidocele

An enterocele refers to the presence of small bowel loops in the pouch of Douglas [157]. If oral contrast is used, opacified loops of small bowel can be seen in the rectovaginal septum. If there is no contrast, widening of the rectovaginal septum is indicative of an enterocele's presence. A sigmoidocele occurs when redundant sigmoid colon fills the peritoneal sac in the pouch of Douglas. Although sigmoidoceles are less common than enteroceles, both pathologies cause symptoms of incomplete evacuation.

Descending Perineum Syndrome

Perineal descent has been described as both a dynamic and static measurement in the defecography literature. During Valsalva, the anorectal junction (ARJ) descends normally. A descent of more than 3.5 cm may indicate perineal hypermobility [158, 159]. This can result in nerve and muscle stretch with resultant loss of function. Other patients have an abnormal position of the perineum at rest, and subsequently have no ability to move the pelvic floor with push [160]. An abnormal perineal position does not appear to correlate with severity of symptoms [161]. Descending perineum syndrome can be caused from chronic constipation and be associated with fecal incontinence.

Dynamic MRI

Given the complexity of pelvic floor anatomy and the concerns of the carcinogenic effects of ionizing radiation, dynamic MRI has been advocated as a viable alternative to cystoproctography. Advances in magnetic resonance imaging allow rapid acquisition of dynamic images with improved spatial resolution and soft tissue details in a single breath. Images can also be analyzed in multiple planes. The majority of studies are performed in a closed configuration MR in the supine position. Rectal contrast consisting of ultrasound gel or a gadolinium based MR contrast mixed with potato starch is instilled via a rectal catheter [162, 163]. The patient performs the same maneuvers as described with fluoroscopic defecography, and the images and video loops are analyzed for the same parameters (Figure 57-10).

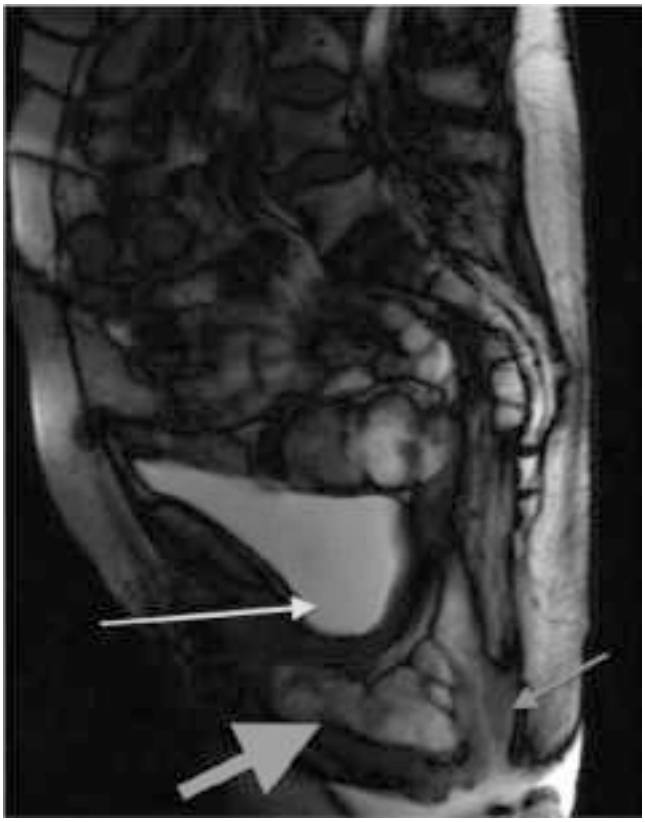

FIGURE 57-10. MR Defecography. The *short thin arrow* marks a rectal intussusception, associated with an enterocele (*short thick arrow*). The *long thin arrow* marks a cystocele. *Courtesy of Dr. Sidney Walker, Center for Diagnostic Imaging, Minneapolis, MN.*

One of the main criticisms of dynamic MRI is that it is not performed in the physiologic state: the upright sitting position. When performed upright in an open magnet system, images have a lower signal to noise ratio with less soft tissue resolution, with subsequent loss of detail in evaluation of pelvic supporting structures. This leads to increase interobserver variation in determining reference points [164, 165]. In a comparison of fluoroscopic cystoproctography with dynamic pelvic MRI, MRI underestimated prolapses that are not rectoceles by 10–15 % [166]. Critics also note that patient embarrassment is a limitation with both examinations, but this can be exacerbated when requesting the patient to defecate in the supine position [167].

Conclusion

Disorders of bowel evacuation and continence are distressing to patients, and the factors leading to dysfunction are frequently multifactorial. Although each test has its limitations, anatomic and functional evaluation of the pelvic floor and gastrointestinal tract aids the evaluating surgeon in the diagnosis and treatment of these conditions.

Evaluation of Constipation and Treatment of Abdominal Constipation

Muneera R. Kapadia and Madhulika K. Varma

Key Concepts

- There are three constipation subtypes which can be differentiated by symptoms and diagnostic testing, although there can be overlap between subtypes.
- Initial treatment of constipation includes behavioral modification and medication.
- Surgical management of constipation is reserved for severe slow transit constipation that is not responsive to medications.

Prevalence

Constipation is an extremely common complaint and in North America alone it is estimated that 63 million people suffer from constipation. The prevalence has been estimated between 2 and 27 % and accounts for 2.5 million physician visits annually [1, 2]. Women report a two- to three-fold higher incidence of constipation than their male counterparts. In a survey study of 600 healthy women from Spain, almost a third had functional constipation symptoms [3]. In another study of patients presenting to European tertiary care centers for idiopathic constipation, 92 % were women, and furthermore, women were more likely to have a diagnosis of slow transit constipation [4]. There is a higher incidence of constipation in non-Caucasians as well as individuals with less education and lower income. Additionally, multiple studies have found older patients have a higher prevalence of constipation, particularly over the age of 65 [5–8].

Etiology of Constipation

Defecation is a complex process that results from stool formation, gastrointestinal motility, and pelvic floor function. Constipation may result from dysfunction of any portion of the defecatory process. Contributing factors may include diet, medications, neurologic or endocrine disorders, psychosocial issues, colonic disease, or pelvic floor abnormalities (Table 58-1). Often patients may have constipation with no identifiable cause.

Rome Criteria and Constipation Subtypes

In an effort to standardize the definitions associated with constipation, a symptom-based classification was established by consensus approach. The most recent iteration was created by the Rome Committee in 2006 and is termed the Rome III Criteria [9]. For functional constipation, criteria (Table 58-2) must be met for the last 3 months, with symptom onset at least 6 months prior to diagnosis [10].

Constipation can be further categorized into the following subtypes: slow transit constipation, normal transit constipation, or pelvic constipation. Slow transit constipation or abdominal constipation is a motility disorder and stool moves through the colon at a slow rate. In some patients, only the colon is affected, while in others, there may be involvement of other portions of the gastrointestinal tract. Patients with slow transit constipation may not have bowel movements for days to weeks at a time, despite using laxatives and enemas. Normal transit constipation, also termed constipation predominant-irritable bowel syndrome, is a functional disorder characterized by normal transit through the gastrointestinal tract, however, stools are hard and defecation may be difficult. Additionally, patients may complain of abdominal pain and bloating that is relieved by defecation. Pelvic constipation includes lack of coordination of the pelvic floor during defecation, rectal hyposensitivity, or constipation from impingement, such as rectocele, enterocele, and sigmoidocele. There may also be associated full thickness rectal prolapse, internal intussusception, and solitary rectal ulcer syndrome. Pelvic constipation results in

1. Must include *2 or more* of the following[a]:
a. Straining during at least 25 % of defecations
b. Lumpy or hard stools in at least 25 % of defecations
c. Sensation of incomplete evacuation for at least 25 % of defecations
d. Sensation of anorectal obstruction/blockage for at least 25 % of defecations
e. Manual maneuvers to facilitate at least 25 % of defecations
f. Fewer than 3 defecations per week
2. There are insufficient criteria for irritable bowel syndrome
3. Loose stools are rarely present without the use of laxatives
4. There are insufficient criteria for irritable bowel syndrome

[a]Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis

excessive straining, need for digital manipulation, and incomplete evacuation. Each of these constipation subtypes may occur either in isolation or in various combinations, which may create treatment challenges. The focus of this chapter is to discuss the evaluation and management of slow transit constipation; irritable bowel syndrome and obstructed defection will be discussed in detail elsewhere.

History and Physical Examination

Evaluation of constipation should always begin with a thorough history (Table 58-3) and physical examination. Information collected should include details regarding stool consistency, caliber, and frequency as well as onset and duration of symptoms. Stool consistency can be described using the Bristol Stool Form Scale (Figure 58-1). A stool diary kept by the patient which details stool form and frequency may provide valuable data for providers. The patient should be questioned regarding dietary intake, fluid consumption, and exercise habits. Patients may note bloating, pain with defecation, and need for significant straining or digital maneuvers to evacuate, which may aid physicians in differentiating between constipation subtypes. Finally, a detailed medical history, including psychiatric illness, and surgical history should be obtained. Patients complaining of constipation have a 20–30 % incidence of physical and sexual abuse and therefore this must also be specifically queried [11]. Medication history, including over-the-counter medications, fibers, laxatives, and enemas, should be noted. Scoring systems and constipation-specific quality of life indices may be helpful in determining severity and effect of constipation (see Chap. 57 for details).

Physical examination, while important, is often unremarkable in patients with constipation. The abdominal examination may be notable for distention. Examination of the pelvic floor should include digital rectal examination and the patient should be asked to contract and relax the sphincter muscles to assess for dyssynergia. The presence of a rectocele should be noted. Anoscopy is used to evaluate the anorectal mucosa for abnormalities. Valsalva should be performed on the commode and the perineum should be studied for perineal descent and prolapse of the rectum, bladder, or uterus.

Diagnostic Testing

Initial laboratory testing for slow transit constipation should include a complete blood count, chemistry panel, calcium level, and thyroid function tests to exclude metabolic abnormalities such as diabetes, hyperparathyroidism, or hypothyroidism. Colonoscopy is appropriate to rule out a mechanical obstruction from malignancy or strictures related to diverticular disease or inflammatory bowel disease. Additional radiologic or functional testing may be beneficial for patients who are not responsive to medical therapy (Figure 58-2). These tests may help to distinguish between constipation subtypes and most commonly include transit studies, anorectal testing, and defecography.

Colonic transit studies provide an estimate of gastrointestinal motility. There are three general ways of assessing transit time: radiopaque markers, scintigraphy, and capsule studies. The most commonly performed transit studies involve radiopaque markers. There are several procedural variations of these studies [12, 13], however, most often they include ingestion of radiopaque markers by the patient and abdominal radiographs taken after 5 days. During the study period, patients are advised not to take laxatives. In normal subjects, at least 80 % of the markers should pass within 5 days; if more than 20 % of the markers are retained in the colon, the transit study is considered abnormal (Figure 58-3). If the markers are distributed throughout the colon, slow transit constipation is suggested. Traditionally, markers distributed mostly in the rectosigmoid colon suggest obstructed defecation, however, this has been challenged by Cowlam et al. who examined 108 patients with functional constipation [14]. Their findings demonstrated that patients with obstructed defecation had no difference in marker distribution as compared to other functional constipation patients, and therefore they could not be diagnosed alone based on markers. Other studies have also questioned the accuracy of interpreting this type of transit study [15].

Colonic scintigraphy involves ingestion of an isotope (indium 111 or technetium 99) in a coated capsule or with a test meal. Gamma camera images are subsequently obtained

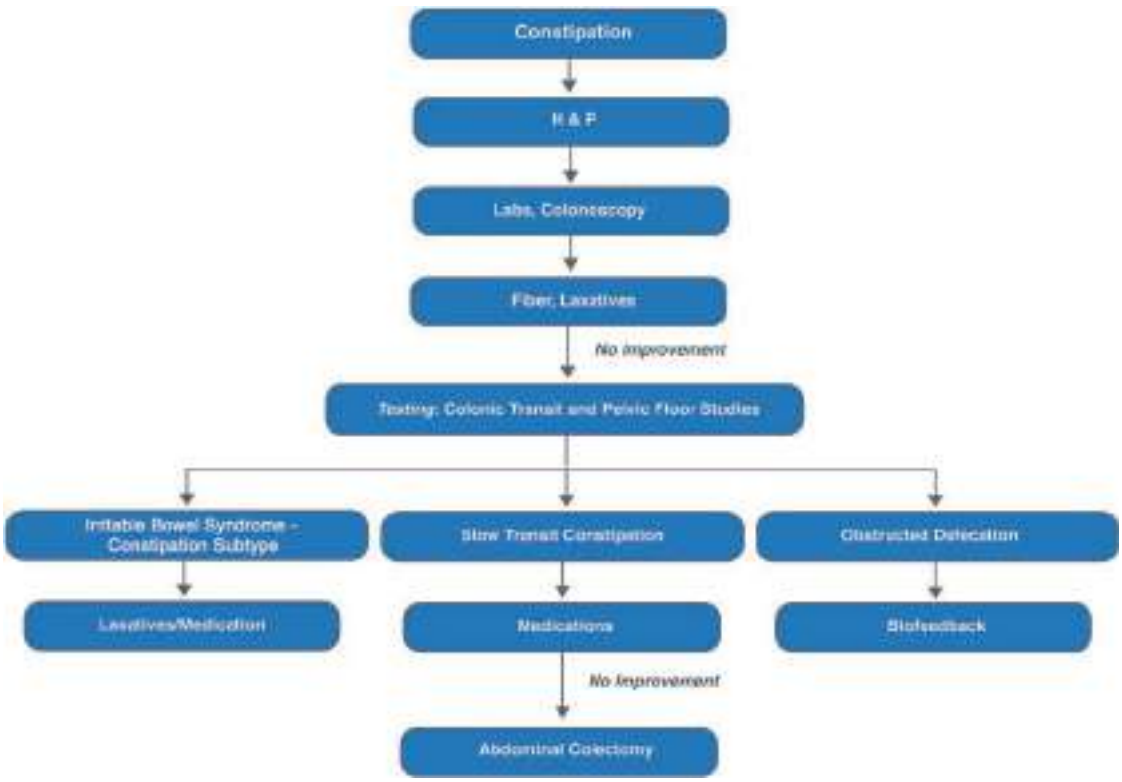

FIGURE 58-2. Workup and treatment schematic for constipation.

FIGURE 58-3. Radiopaque marker study 5 days following ingestion of the Sitz marker capsule.

and transit times are generated by following the passage of the isotope through the intestinal tract. Eising et al. studied 32 patients with constipation and were able to distinguish between slow transit constipation and obstructed defecation [16]. Scintigraphy studies have been demonstrated to be reliable [17], however, cost and availability limit use.

The wireless motility capsule is a newer technology which allows for measurement of gastric, small bowel, and colonic transit times using pH change and temperature. The capsule has been demonstrated to have good sensitivity and specificity for evaluating colonic transit [18] and when compared to radiopaque markers, an 87 % agreement was demonstrated in differentiating slow versus normal colonic transit [19].

There are several examinations which may be performed to determine anorectal and pelvic floor function. Anal manometry evaluates resting and squeeze pressures in the anorectum and provides information regarding rectal sensation. Anal manometry can diagnose pelvic floor dysfunction, and if the rectal anal inhibitory reflex (RAIR) is present, a diagnosis of Hirschsprung's disease can be excluded [20]. Rectal electromyography may demonstrate non-relaxation of the pelvic floor. Additionally, rectal balloon expulsion provides a simple assessment of ability to evacuate. Failure to evacuate the balloon suggests dyssynergia.

Defecography allows for dynamic study of the rectum and pelvic floor. Contrast is inserted into the rectum and vagina, and fluoroscopy is performed during defecation. It may identify paradoxical contraction of the pelvic floor, internal intussusception, full thickness rectal prolapse, rectocele, or enterocele, which can contribute to obstructed defecation. Dynamic MRI similarly gives an impression of the pelvic floor during defecation of contrast, but is not available in all centers.

Slow Transit Constipation

In slow transit constipation or colonic inertia, there is diminished colonic propulsion resulting in markedly reduced stool frequency. The clinical presentation may be somewhat varied and patients may suffer from abdominal pain, bloating, nausea, and incomplete defecation. A diagnosis of slow transit constipation must be confirmed by transit studies. Once the diagnosis is made, the first step in management is medical treatment.

Medical Management of Slow Transit Constipation

The management of constipation should always begin with appropriate counselling, which includes listening to and validating the patient's complaints. It is important for patients to understand that daily bowel movements are not necessary and that there is a large variation in bowel habits across the normal population. The majority of patients have between 3 and 20 bowel movements per week [21], and men have increased stool frequency compared to women [22]. Minimizing patient anxiety can often go a long way.

Behavioral modifications are usually touted as the first step towards treating constipation and this includes increasing hydration and exercise, as well as dietary and medication changes. Some studies report that constipation is more prevalent in patients with sedentary lifestyles and that physical activity may increase stool transit time [23, 24]. Other studies have reported no such association between constipation and activity levels [25]. Despite this conflicting data, increased physical activity is often recommended for constipated patients; however, there is no direct evidence that exercise improves constipation. Fluid intake is also often encouraged in patients with constipation and is thought to soften stool and make it easier to pass. However, there is minimal evidence to support that increasing oral fluid intake improves constipation, except in dehydrated patients [26]. There are extensive lists of medications which contribute to the development of constipation. These medications should be reviewed and minimized, and alternatives should be considered when appropriate.

There are many medical treatments available for chronic constipation (Table 58-4). These include bulking agents, osmotic laxatives, colonic irritants, softening laxatives, and medications.

Lack of dietary fiber intake may contribute to the development of constipation. Fibers are bulking laxatives considered to be first-line therapy for the treatment of constipation. There have been studies which have demonstrated their benefit [27, 28]. Fiber is found in grains, fruits, vegetables, nuts, seeds, and beans and can be categorized as either soluble or insoluble. Examples of fiber include psyllium (Metamucil®,

Table 58-4. Medical therapy for treatment of slow transit constipation

Medical therapies	Examples
Bulking laxatives	Psyllium
	Methylcellulose
	Calcium polycarbophil
Osmotic laxatives	Lactulose
	Sorbitol
	Magnesium salts
	Polyethylene glycol
Stimulant laxatives	Senna
	Cascara
	Bisacodyl
Softening laxatives	Mineral oil
	Docusate
	Glycerine
Serotonin receptor agonists	Tegaserod
	Prucalopride
Prosecretory agents	Lubiprostone
	Linaclotide

Konsyl®), methylcellulose (Citrucel®), and calcium polycarbophil (Fibercon®). They soften and increase the size of the stool bolus by absorbing and retaining fluid with the stool. Therefore, fiber must be ingested with sufficient amounts of fluid to reach efficacy. Recommended daily fiber intake is between 25 and 35 grams. Side effects of fiber consumption include abdominal bloating and flatulence.

Osmotic laxatives promote accumulation of large volumes of fluid in the colon lumen by osmosis. The osmotically active particles can be derived from sugars or salts such as sucrose-based sorbitol and lactulose. Lactulose is degraded in the colon yielding the production of fatty acids, hydrogen, and carbon dioxide. MiraLAX® (polyethylene glycol 3350) is an over-the-counter osmotic laxative that increases the frequency of bowel moments and softens the stool. It is one of the most commonly recommended laxatives, found to be safe and effective for everyday use. Osmotic laxatives can also be based on nonabsorbable ions, commonly derived from magnesium or phosphate. Examples are magnesium hydroxide (Milk of Magnesia®) or sodium phosphate (Fleets® Phosphosoda). Caution must be exercised in patients with renal insufficiency as hypermagnesemia and renal failure can result. Polyethylene glycol-based products such as NuLYTELY or GoLYTELY are used in many bowel cleansing regimens but can also be used for constipation. However, chronic use can lead to electrolyte disturbances and dehydration.

Colonic irritants stimulate colonic motility, thereby diminishing constipation. Examples are anthracene derivatives, which include senna and cascara and are found in Senekot® and Pericolace®. Bisacodyl is another irritant and can be found in the agent Dulcolax®. Long-term use can generate a characteristic brown discoloration of the mucosa called melanosis coli. Additionally, sustained use of anthracene irritants may lead to poor colon function and therefore, such use is discouraged.

Softening laxatives change the stool composition, creating softer stools and they include mineral oil and docusate (Colace®). Mineral oil coats the stool, creating an emulsion. Docusate is a detergent which allows increased absorption of fluid into the stool bolus and there is conflicting data regarding its efficacy [29].

Enemas and suppositories are used to stimulate bowel movements. Strategies include promotion of defecation through rectal distension (saline enema), rectal irritation (soapsuds, bisacodyl), or physical softening of the stool (glycerine). Enema therapy can be habituating and therefore providers should be mindful of this potential dependency.

There are several medications which have been used to treat slow transit constipation. Lubiprostone (Amitiza®) is a bicyclic functional fatty acid which activates chloride channels to increase intestinal chloride secretion. This facilitates stool transit and has been demonstrated to be beneficial in the treatment of constipation [30, 31]. Common side effects include nausea, headaches, and diarrhea. Linaclotide (Linzess®) in a peptide agonist of guanylate cyclase which increases colonic smooth muscle cell contraction and promotes bowel movements. Studies have shown improvement in constipation over placebo [32, 33]. Both lubiprostone and linaclotide are approved for the treatment of slow transit constipation and constipation predominant-irritable bowel syndrome in the USA.

In patients taking opioid medications, methylnaltrexone and alvimopan can increase motility [34–37]. However this benefit does not seem to extend to patients with idiopathic constipation. Tegaserod, a 5-HT_4 receptor agonist, was initially introduced for the treatment of irritable bowel syndrome and subsequently extended for the treatment of slow transit constipation. It was later removed from the market because of findings that the drug was associated with increased risk of cardiovascular disease. To avoid these deleterious effects, a more selective 5-HT_4 agonist, prucalopride, has been developed. While prucalopride has been shown to increase number of bowel movements, it is not currently approved for use in the USA [38, 39].

Surgical Therapy of Slow Transit Constipation

Surgical therapy for constipation should only be considered after nonsurgical therapy has been completely exhausted. A thorough diagnostic workup, including transit studies confirming slow transit constipation, is important in order to select the appropriate operative treatment and to aid in preoperative counselling regarding outcome. In patients diagnosed with generalized intestinal dysmotility including both upper and lower gastrointestinal tracts, the incidence of recurrent constipation has been shown to be much higher than in patients with colonic inertia alone [40]. Given that constipation is a functional disorder, it is extremely impor-

tant to set patient expectations regarding outcomes and possible postoperative issues.

Abdominal Colectomy

In patients with constipation for whom surgical management is indicated, abdominal colectomy is usually the treatment of choice. Lane first reported this idea in 1908 when he published his series describing resolution of constipation symptoms in two-thirds of patients. The surgical procedure remains essentially unchanged since its initial description, although minimally invasive techniques have been successfully applied to this procedure [41, 42] and are commonly performed.

Webster et al. reported results in 50 patients who underwent total abdominal colectomy [43]. In the immediate postoperative period, 42 % of patients experienced complications, most commonly ileus. Anastomotic leak occurred in 4 %. Five patients had persistent constipation. At 12-month follow-up, patients averaged 3 stools per day and the most common complaint was abdominal pain in 19 % of patients. The majority of patients rated their results as "good" or "excellent." Regarding long-term follow-up, Pikarsky et al. reported results in 50 patients who underwent total abdominal colectomy at a median follow up of 106 months (range 61–122 months) [44]. Data was gathered via telephone interviews and the average frequency of bowel movements was 2.5 (range 1–6). Two patients required enemas/laxatives and two patients required antidiarrheal medications. Six patients had small bowel obstructions postoperatively, three of whom required laparotomy. Overall, patients were satisfied with their bowel function and had sustained benefit.

Variations of the procedure include subtotal colectomy with ileosigmoid anastomosis and subtotal colectomy with cecorectal anastomosis. These variations have been developed to reduce unwanted side effects of diarrhea and electrolyte abnormalities following total abdominal colectomy. Cecorectal anastomosis was suggested by Sarli et al. in an effort to leave a physiologic reservoir for colonic bacteria and thereby maintain normal postoperative stool consistency [45]. They reported their results in 19 patients at a median follow up of 64 months. Thirteen patients reported solid stool consistency, one reported constipation, and five reported diarrhea with the need to take antidiarrheals. In a follow up study of the same cohort of patients, 88.2 % reported that they would undergo surgery again given the same preoperative conditions [46]. In an effort to compare functional outcomes between ileosigmoid and cecorectal anastomoses, Feng et al. compared 79 patients who underwent ileosigmoid or cecorectal anastomosis at a mean follow up of 2 years [47]. Defecation frequency increased and abdominal pain and bloating diminished in both groups. However, more patients in the cecorectal group complained of persistent constipation, and overall ileosigmoid anastomosis led to higher patient satisfaction.

In 1999, Knowles et al. reviewed 32 series, which included ten or more patients treated for constipation with colectomy. There was a great deal of variation between the publications regarding data collection, preoperative workup, and surgical technique [48]. However, the overall success rate ranged from 39 to 100 %, with median reported to be 86 %. The median number of daily bowel movements was 2.9 (range 1.3–5) and the median frequency of incontinence was 14 % (range 0–52 %). The frequency of recurrent constipation was 9 % (range 0–33 %). Persistent abdominal pain was present in 41 % of patients. Additionally, because of poor functional outcomes, 5 % (range 0–28 %) of patients eventually underwent permanent ileostomy creation.

Given that constipation is a functional disorder, quality of life studies are extremely important in understanding patient outcomes. Hassan et al. evaluated 110 patients who underwent total abdominal colectomy with ileorectal anastomosis at a median follow up of 11 years. Prospectively collected annual functional surveys were available for 85 patients and demonstrated that 98 % of patients had improvement in constipation and 85 % were satisfied with their outcome. Additional quality of life questionnaires were completed by 59 respondents demonstrating that all reported their constipation improved, 83 % did not require any antidiarrheal agents and 85 % were satisfied with their bowel function.

FitzHarris et al. similarly sent quality of life questionnaires to 112 patients who previously underwent total abdominal colectomy with ileorectal anastomosis for constipation and had a 67 % response rate [49]. Of those, 81 % of patients were pleased with their frequency of stools. However 41 % reported abdominal pain, 21 % reported fecal incontinence, and 46 % had some diarrhea, and these symptoms negatively impacted quality of life scores. In a smaller study, Thaler et al. surveyed patients using the SF-36 Health Survey and found that while all patients had relief of constipation, patients had significantly lower quality of life scores compared with the general population [50]. More recently, Zutshi et al. surveyed 69 patients who underwent colectomy with ileorectal anastomosis at a median follow up of 10.8 years. Of the 35 respondents, 77 % reported that surgery was beneficial, but results of the SF-36 demonstrated low mental and social functioning scores [51]. These data must be considered when counselling patients and setting appropriate postoperative expectations.

There are special circumstances which should be noted. In some patients, concomitant pelvic floor dysfunction may be present. This may be diagnosed with defecography, electromyography, and anorectal manometry. Bernini et al. studied 16 patients with slow transit constipation and pelvic floor dysfunction who underwent a colectomy by distributing questionnaires [52]. Preoperatively, all patients underwent biofeedback, which resulted in pelvic floor relaxation confirmed by electromyography. Postoperatively 43 % of patients had complete resolution of constipation symptoms, six patients complained of incomplete evacuation, and three patients complained of diarrhea and incontinence. Only nine

patients were satisfied with the surgical outcome. More recently, Reshef et al. compared 144 patients who underwent colectomy for slow transit constipation with and without obstructed defecation [53]. At a median follow up of 43 months, 88 patients were available for phone interview. Short- and long-term outcomes were found to be equivalent between groups as was patient satisfaction. They concluded that total abdominal colectomy can be offered to patients with slow transit constipation with concomitant obstructed defecation.

Another group of patients that deserves mention are patients with associated small bowel and gastric dysmotility, or global dysmotility. Zmora et al. reviewed patients who underwent total abdominal colectomy and had preoperative small bowel transit studies [54]. There was no difference in postoperative function between patients that have normal and abnormal transit studies. Mollen et al. found similar results in a study of 21 patients [55]. However, Glia et al. studied 17 patients and found a trend towards better long-term results following colectomy in patients with normal preoperative antroduodenal manometry [56]. While these results are not definitive, preoperative functional evaluation for global dysmotility is still recommended. If concomitant delayed gastric or small bowel motility is determined, colectomy is not absolutely contraindicated; however, patients should be warned that they may have persistent postoperative abdominal symptoms.

Finally, patients with a history of sexual trauma have been shown to require more medical care for abdominal complaints following colectomy for constipation [57]. For this subset of patients, preoperative preparation should include evaluation and treatment of psychosocial/psychiatric issues as well as pelvic floor dysfunction and a discussion of possible postoperative abdominal symptoms.

Segmental Colectomy

In an effort to reduce the diarrhea associated with abdominal colectomy, some surgeons have advocated the use of segmental colectomy for the treatment of slow transit constipation. In some published reports, segmental colectomy has resulted in improvement of constipation [58, 59]. You et al. reported a group of 28 patients who underwent segmental colectomy based on the distribution of markers in the colon, of which three patients experienced recurrent constipation [60]. Similarly, Lundin et al. performed segmental resections on 28 patients studied preoperatively with radiopaque markers and scintigraphy and found to have impaired transit in one segment [61]. After a median follow up of 50 months, 23 patients were satisfied with the outcome, whereas five patients required additional surgery for constipation. Rectal sensation, based on preoperative manovolumetry, was diminished in patients who experienced treatment failure. Similar findings were demonstrated more recently by Ripetti et al., in 15 patients with slow transit constipation, seven underwent left-sided colectomy while the rest underwent total colectomy [62]. All but one patient in the segmental colectomy group had symptom improvement. In each of these studies, patients underwent careful and extensive evaluation prior to surgery and it must be reemphasized that evaluation by radiopaque markers may not be exact.

Proctocolectomy with Ileal Pouch Anal Anastomosis

Proctocolectomy with ileoanal pouch (IPAA) reconstruction has been described for slow transit constipation. Keighley et al. performed IPAA in patients who previously underwent total colectomy with ileorectal anastomosis and had recurrent difficulty with defecation [63]. Four of these patients subsequently underwent excision of their pouches because of dissatisfaction with functional results. The authors no longer recommend IPAA for slow transit constipation. Another group performed proctocolectomy with IPAA for 15 patients having less than one bowel movement per week with slow transit constipation and rectal inertia [64]. Preoperative workup in these patients demonstrated abnormal transit studies and abnormal defecography, specifically megarectum or rectal dysmotility. Two patients subsequently underwent pouch excision for intractable pelvic pain. At follow up, patients had a mean stool frequency of 5 per day and reported significant improvement in quality of life scores following surgery. Overall, this is a small and well-selected group of patients and proctocolectomy should be chosen carefully if being considered for slow transit constipation. Additionally, before considering pouch creation for constipation, pelvic floor relaxation should be studied and confirmed otherwise patients may have continued difficulty with defecation.

Ileostomy Creation

Fecal diversion for the treatment of slow transit constipation tends to be reserved for those patients who fail other surgical management. In a review of patients who underwent surgical intervention for constipation, 2–25 % of patients who underwent other surgical management went on to have end ileostomies [65]. Additionally, for those who may not tolerate colon resection, who have concomitant fecal incontinence or in whom it is uncertain as to whether the patient will benefit from colon resection, creation of a loop ileostomy may be an appropriate alternative. Loop ileostomy is relatively simple to reverse should the patient not derive the anticipated benefit. Scarpa et al. retrospectively reviewed outcomes in 24 patients with ileostomies created for constipation: 9 end ileostomies and 16 loop ileostomies [66]. One patient had persistent constipation after stoma creation with bloating and

infrequent output. Four patients underwent ileostomy closure, two of whom had recurrent constipation. Patients undergoing ileostomy creation should be warned that they may have persistent symptoms, especially if global intestinal motility is suspected. While it may seem to be an extreme measure, ileostomy creation is beneficial in some patients.

Antegrade Colonic Enema

The concept of the antegrade colonic enema (ACE) is to washout the colon via enemas delivered to the cecum. The concept was first described by Malone et al. for the treatment of fecal incontinence in children, and later the indications were extended to include intractable constipation. In the original technique, the appendix is reversed and a non-refluxing, catheterizable appendicocecostomy is created, through which the enemas are delivered [67]. There have since been many modifications to this procedure, including utilizing the appendix in situ, stoma creation using the ileum and/or cecum, permanent catheter implantation, and left colon placement [68–70].

While originally described in children, this procedure is increasingly used in the adult patients although the reported success rates are inferior [71–73]. This procedure is less invasive than colectomy and there is avoidance of an ileostomy or colostomy. Lees et al. reported that in 32 patients who underwent the ACE procedure for constipation, satisfactory function was achieved in 47 % at a mean follow up of 36 months [74]. Similarly, Worsoe et al. reported results in 69 patients who underwent ACE for constipation. Patients were surveyed regarding continued use of ACE and symptom resolution and 42 % reported success at a median follow up of 75 months [75]. Revisions of the stoma are common, and most often required for stenosis or leakage. Using an indwelling catheter reduces stenosis, but wound infection and long-term catheter dislodgement are common [70].

Sacral Nerve Stimulation

Sacral nerve stimulation is most widely utilized for the treatment of urinary and fecal incontinence. This therapy involves electrical stimulation of the sacral nerve roots. Patients undergo a test phase to determine if there is a therapeutic benefit and if so, the permanent device is implanted. Sacral nerve stimulation has been shown to increase bowel frequency, improve defecation, and reduce laxative use [76, 77]. While the exact mechanism which improves constipation is unknown, sacral nerve stimulation has been shown to increase colonic propagating sequences [78]. The largest series reported by Govaert et al. included 117 patients with constipation, of which 75 had slow transit constipation diagnosed by a transit study. All underwent percutaneous nerve evaluation (PNE), of which 52 % responded to therapy during the initial test period [79]. The success rate of PNE was lower in patients with slow transit constipation versus patients with normal transit constipation. A prospective European study was conducted in 62 patients with constipation. Transit studies were available for 27 patients prior to implantation and 20 patients had prolonged transit. At 6 months following sacral nerve stimulation, only nine patients had prolonged transit ($p=0.014$). In subjects with normalized transit times, defecation frequency increased from a median weekly stool frequency of 2.7–6.5 at 6 months [80]. Studies by Ortiz et al. [81] and Graf et al. [82] reported much lower success rated for sacral nerve stimulation in constipated patients. Further long-term studies and detailed evaluation of patient selection are indicated. At present, sacral nerve stimulation is not approved in the USA for use in patients with constipation.

Conclusion

Constipation can range in presentation from minor annoyance to a significant disruption of daily life. Initial management should include behavioral modification, fiber supplementation, or laxatives. In patients requiring additional therapy, differentiating between constipation subtypes is necessary and can be accomplished by a good history, transit studies, and pelvic floor testing. For patients with slow transit constipation who do not respond to medical management, surgical intervention may be appropriate. Care of the constipated patient requires patience, compassion, and the ability to tailor treatments to the individual.

Obstructed Defecation

M. Shane McNevin

Key Concepts

- Obstructed defecation syndrome is characterized by excessive straining at stool, incomplete rectal evacuation, and perineal splinting.
- The primary treatment for patients with obstructed defecation is dietary management and pelvic floor physical therapy.
- The primary treatment of patients with overt pelvic prolapse and obstructed defecation is surgical repair of the prolapse.
- Symptoms of obstructed defecation are not as reliably relieved as overt prolapse by surgical repair.
- Ventral mesh rectopexy or stapled transanal rectal resection are alternative surgical procedures which may more reliably relieve obstructed defecation symptoms.
- Sacral nerve stimulation may be an alternative for patients with rectal hyposensitivity and obstructed defecation failing non-operative management

Introduction

Pelvic floor disorders are a frequent source of morbidity in the developed world [1]. This is a much more common problem for women and almost one quarter of women in the USA will complain of at least one pelvic floor disorder in their lifetime. The incidence increases with age, parity, and obesity. Demand for pelvic floor services is expected to grow at twice the population rate in the future [2–4]. Suffice it to say that all of the medical specialties will frequently manage patients with pelvic floor complaints however colorectal surgeons will assume a disproportionate share of the diagnosis and management of patients with persistent or refractory symptoms of pelvic floor dysfunction.

Pelvic floor disorders typically present with overt pelvic organ prolapse and/or functional disorders of bowel or bladder evacuation. In the USA, 16 % and 9 % of women, respectively, will experience bladder or bowel incontinence. Pelvic organ prolapse affects 3 % of women [2]. Approximately 12–27 % of adults will seek care for constipation related complaints in their lifetime and over $1 billion is spent annually on constipation related goods and services [5]. Typically, constipation in association with pelvic floor disorders is manifested as obstructed defecation. Obstructed defecation syndrome is a well-defined symptom complex consisting of excessive straining at stool, need for perineal splinting, and incomplete rectal evacuation [6–8]. Not uncommonly, different manifestations of constipation co-exist, hence, global hindgut and pelvic evaluation is required for those treating this complicated group of patients [9–12].

This chapter will focus on disordered bowel evacuation in general and specifically on obstructed defecation syndrome. A review will be undertaken of the clinicopathologic features and clinical evaluation of the disorder, its frequent association with other manifestations of pelvic floor dysfunction and the outcomes of medical and surgical therapy for the disorder.

Etiology of Constipation

Lower gastrointestinal function involves the formation of stool, its transit through the hindgut and its subsequent expulsion from the body. As anyone involved in the care of the constipated patient knows, this is a complex and coordinated process and failure at any of the various points in the algorithm will result in constipation related complaints.

Unfortunately, constipated patients rarely present with a defined etiology of their constipation but instead will use various adjectives to describe their clinical situation. It is important that the patient be given the opportunity to clearly describe their symptom complex in their own words as our descriptors for defecatory dysfunction typically have different meanings for different people. Typically, symptom complexes are unique and dependent upon where in the process of

hindgut function failure occurs. Hence, a good and detailed history of the complaints and physical examination is frequently diagnostic and drives further testing and treatment options.

A wealth of different factors may affect lower gastrointestinal function (Table 59-1) and give rise to symptoms of constipation. A detailed history focuses on onset and duration of symptoms, stool frequency and consistency, dietary fiber and fluid intake, and associated medical and surgical history and medication usage. A history of physical, sexual or psychologic abuse, or dysfunction is not infrequently associated with constipation related complaints and should be explored [13, 14]. A bowel diary can be particularly helpful to objectify the patient's complaints if not clear based upon their subjective description. Physical examination should focus on abdominal findings such as distension, pain, or mass lesion. Anorectal and pelvic examination should focus on normal anorectal and genital anatomy and evidence of occult or overt pelvic prolapse. Patients should undergo endoscopic evaluation of the lower gastrointestinal tract as a matter of routine when evaluating new complaints centered on a change in bowel habits.

Functional Bowel Disorders

Over half of patients referred for specialty evaluation and care have functional bowel disorders [15]. The three main types are colonic inertia (slow transit constipation), constipation predominate irritable bowel syndrome (normal transit constipation), and obstructed defecation syndrome. Historical symptom description is usually diagnostic. Differentiation of the disorders or in patients exhibiting features of more than one etiology can be further evaluated with colon transit study (Sitz mark study; Figure 59-1) and pelvic floor testing [13].

Colonic inertia or slow transit constipation is characterized by infrequent (<1/week) bowel movements and cathartic dependence. Typically, patients will also describe significant symptoms of nausea, bloating, and fullness that do not necessarily improve with defecation. Many patients will deny the feeling of rectal fullness and need to stool. The diagnosis is established with colon transit study revealing elevated segmental and global colonic transit.

Constipation predominate irritable bowel syndrome or normal transit constipation is defined by the Rome criteria listed in Table 59-2. Most patients will have irregular bowel movements both in terms of consistency and frequency. Abdominal pain is a frequent co-morbid complaint that frequently improves with bowel evacuation. Colon transit evaluation frequently reveals normal segmental and global transit times.

Obstructed defecation is defined in Table 59-3. Typically it is characterized by the constant sense of rectal fullness and

FIGURE 59-1. Sitz mark study. The radiograph demonstrates Sitz markers scattered throughout the abdomen and pelvis.

Painful, excessive straining
Incomplete or fragmented evacuation
Perineal splinting

painful excessive straining at stool. Patients also describe a sense of incomplete evacuation and fragmented bowel habits. Patients will often manually support or compress the perineum (splinting) during defecation. Patients also tend to defecate frequently, unlike the other functional disorders, and their symptoms tend to be relatively refractory to cathartic therapy. Fecal pseudo incontinence is also a frequent complaint due to the inability to completely evacuate the rectum. Colon transit study typically reveals elevated global transit times with delay only in the recto sigmoid region.

Defecation Mechanics

The act of rectal evacuation is a complex and coordinated action requiring the interplay of several anatomic and functional factors for successful completion (Figure 59-2). Rectal filling with stool induces distension of the rectum and the sense of need to evacuate. The rectal contents are sampled by transiently relaxing the internal sphincter and contracting the external sphincter, the so-called recto-anal inhibitory reflex, allowing discrimination of rectal contents. When answering the call to stool we assume a sitting or squatting position, which increases the intra-rectal and intra-abdominal pressure. We then relax the levator ani, specifically the puborectalis muscle, and anal sphincter complex and defecation ensues.

Any disturbance in this process be it pelvic floor anatomic abnormalities, disorders of anorectal sensation, and/or discoordinated pelvic floor musculature will result in symptoms that we associate with obstructed defecation syndrome.

Evaluation of Obstructed Defecation

Endoscopy

Obstructed defecation syndrome can be mimicked by many intrinsic obstructive disorders of the anorectum and pelvis, hence, a careful physical examination and endoscopic examination of the anorectum is imperative. Cross sectional imaging can be valuable in cases where extra-luminal obstructive pathology is suspected.

Colon Transit Study

Colon transit study is helpful in differentiating types of functional constipation when the history is unclear or disorders co-exist [13]. The study involves ingestion of radio-opaque markers followed by a series of radiographs over several days documenting the transit time through the hindgut. This is performed while withholding cathartics and pro-motility agents. The most objective interpretation is the Metcalf technique that quantifies the total and segmental transit times through the right, left, and rectosigmoid colon, respectively. Unfortunately, the technique is not standardized and difficult to reproduce across pelvic floor centers [16].

Balloon Expulsion Study

The balloon expulsion study can be a useful adjunct to the other testing modalities to evaluate obstructed defecation. It involves the placement of a fluid filled balloon within the rectum and then the timed expulsion of the balloon from the rectal vault. Chiaroni et al. found that an expulsion time in excess of 2 min revealed good correlation of findings from anorectal manometry and electromyography in constipated patients [17].

Anorectal Manometry

Anorectal manometry is helpful in evaluating the patient with obstructed defecation (Figure 59-3). The most important information gleaned is the rectal sensory thresholds depicted by the first sensation of rectal fullness, the urge to defecate, and the maximal tolerable volume, which may denote rectal hyposensitivity. Additional information obtained is the presence of the recto-anal inhibitory reflex denoting appropriate anorectal innervation, excluding the diagnosis of short segment Hirschsprung's disease, and mean resting and squeeze pressures which may be associated with non-relaxation of the pelvic floor [18, 19].

Anorectal Electromyography

Anorectal electromyography is primarily useful for the evaluation of patients with obstructed defecation. It senses electrical activity in the pelvic floor musculature during rest, squeeze, and push, and can be useful to identify patients with paradoxic contraction of the puborectalis. Patients with abnormal electromyography should undergo confirmatory testing with dynamic defecography [18, 19].

Defecation mechanics

Rectal filling/distension → rectoanal inhibitory reflex →defecation response →

sit/squat increasing intra-rectal and abdominal pressure→ levator ani relaxation →

strain → increased intra-rectal/abdominal pressure →defecation

FIGURE 59-2. Defecation mechanics.

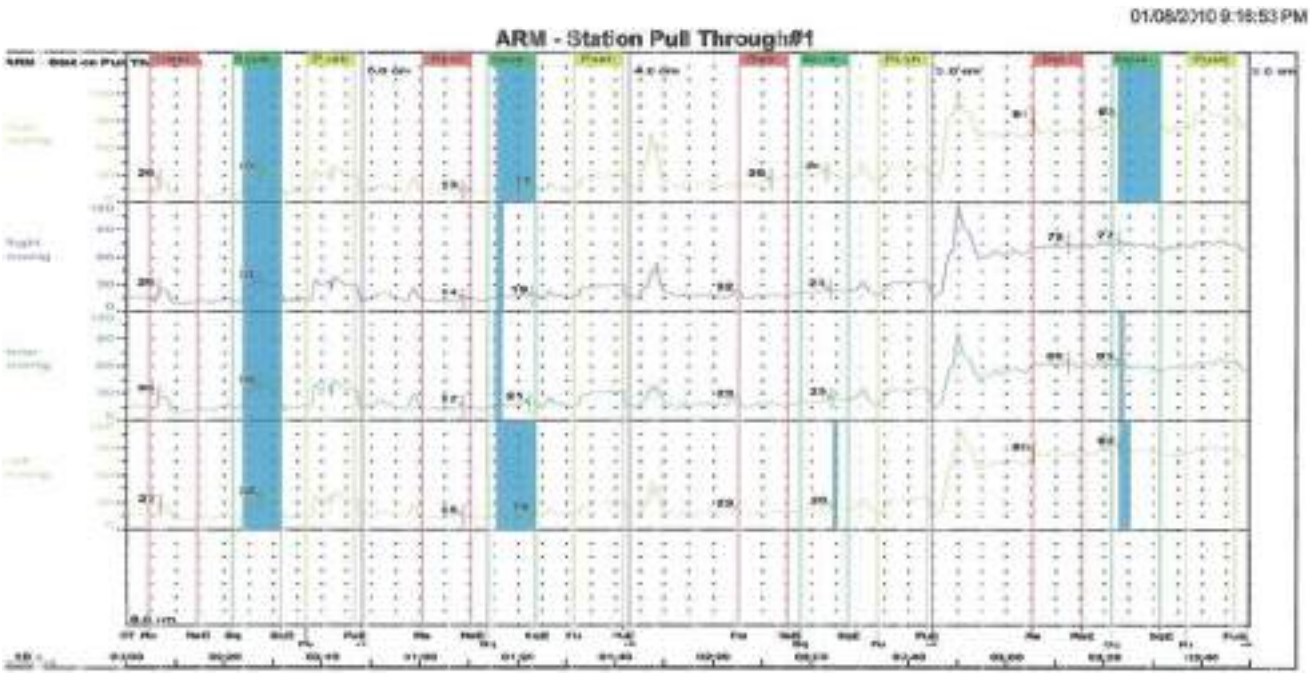

FIGURE 59-3. Sample of an anorectal manometry.

Defecography

Defecography is a particularly useful technique for the precise evaluation of the functional anatomy of the pelvic floor [13, 15, 20]. Defecography is performed with patient in the squatting position using a lateral fluoroscopic view as the patient expels a barium paste from the rectum (Figure 59-4). Further anatomic definition can be obtained by having the patient ingest oral contrast to opacify the small bowel, placement of contrast material within the vagina and bladder, and injection of water-soluble contrast material into the peritoneal cavity.

Magnetic resonance defecography and 3D ultrasonography have also been described as alternatives to traditional fluoroscopic defecography that obviates the need for radiation exposure and may improve the anatomic detail of the images obtained although quality comparative studies of the techniques are lacking [21–26].

Interpretation of Test Results

No one pelvic floor test is entirely diagnostic of pelvic floor dysfunction and a high degree of variability of test results both in terms of anatomy and function in symptomatic and healthy asymptomatic patients can be seen. This makes interpretation of results of pelvic floor tests challenging and determination of abnormal test results need to be made in conjunction with the history and physical examination findings of each particular patient [27, 28].

Etiology and Treatment of Obstructed Defecation

In evaluating and treating the patient with obstructed defecation multiple different and often co-existent etiologies and multiple different and often co-existent symptom complexes are present. Patients will also often present with significant existential anxiety regarding their symptoms. The most important first step is patient and careful listening and acknowledgment of the patient's symptoms and validation of the impact that these symptoms have on the patient's quality of life. Reassurance that, while the symptoms are quite obtrusive and debilitating, there is no significant underlying health or life threat, will allay many of the patient's fears. Keeping that in mind also informs treatment decisions. Our goal in treating these problems should be to provide as much

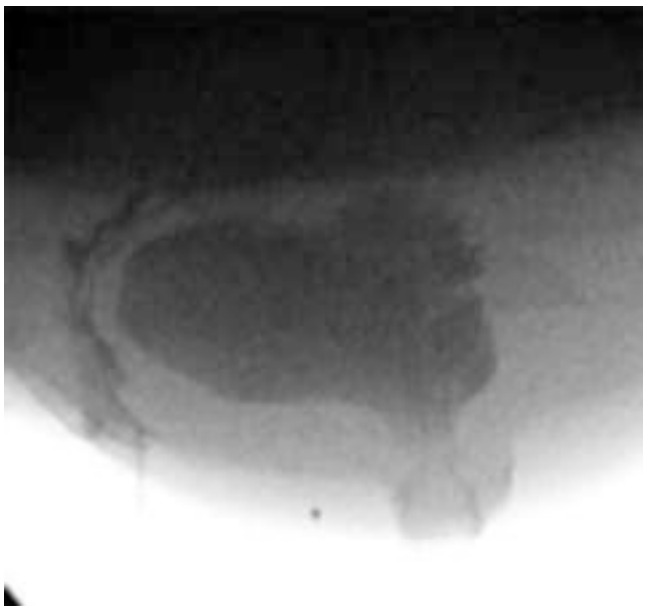

FIGURE 59-4. Defecography. This defecography demonstrates a large rectocele.

symptom relief as possible while exposing the patient to the least amount of risk and secondary treatment related side effects as possible.

With that in mind obstructed defecation as an isolated condition is primarily treated non-operatively. Traditional approaches have been to insure adequate hydration and fiber intake, modest daily physical activity, and pelvic floor physical therapy retraining [29–32].

Hydration/Lifestyle Modification

Recommended goals for daily hydration are 1–2 L/day of non-caffeinated fluids. This is typically in combination with increased fiber intake and daily exercise. As a stand-alone therapy, not surprisingly, increased hydration alone does not result in a change in bowel consistency or frequency [33]. Modest daily exercise has been shown to stimulate colonic motility and increase bowel frequency [34].

Fiber Intake

Recommended dietary fiber goals are 30–40 g/day of either soluble or insoluble fiber. Better outcomes are associated with increased hydration (>2 L/day). Quality studies documenting the efficacy of this approach are lacking and its use is primarily supported by small case series [35, 36]. Cathartic therapy, either stimulant or osmotic in nature, while important for certain etiologies of constipation is typically ineffective in management of obstructed defecation [37].

Pelvic Floor Physical Therapy Retraining

Pelvic floor physical therapy retraining is an essential component of comprehensive pelvic floor management. It is a more apt term to describe the comprehensive and complex bowel, bladder and pelvic floor treatment than the traditional term biofeedback. Biofeedback alone uses operant conditioning to reinforce positive behavior, thereby retraining the pelvic floor to optimize function. While widely used, techniques are not standardized and optimum techniques, frequency of encounters, and duration of therapy are unknown [38]. In many cases, a several week cycle (4–6 weeks with transition to a home program) of multiple pelvic floor exercises combined with a transanal probe (either electromyography or intra-rectal pressure monitor) displaying visual feedback to monitor pelvic floor activity during the squeeze-relax-push cycle is used. Pelvic floor physical therapy retraining uses, in addition to biofeedback, patient education on appropriate dietary management, proper defecation mechanics, and psychologic support of the patient as they learn techniques to manage their symptoms. The treatment sessions are typically performed by nurses or physical therapists with advanced training and interest in pelvic floor disorders. Outcomes can be very dependent on the affect and patience of the therapist and patient acceptance of this technique. Several studies in the last decade have demonstrated a therapeutic effect in patients with obstructed defecation [39–42]. Despite the lack of reproducible standardized techniques, it is a relatively inexpensive treatment option that has no treatment related risks or side effects satisfying our goals of obstructed defecation syndrome treatment.

Pelvic Organ Prolapse

Patients with pelvic organ prolapse present with prolapse symptoms, which is a sense of rectal or vaginal tissue protrusion, and/or functional obstruction of the rectum. Patients with isolated prolapse symptoms are usually reliably and durably improved with repair. It is important to keep in mind, however, that response of the functional rectal obstruction to repair of the anatomic prolapse is not as reliable, hence, it is important that surgeons and patients understand this and that their expectations for improvement are realistic [43, 44].

Rectal Prolapse: Overt

Patients with rectal procidentia typically present with rectal tissue protrusion with Valsalva or gravity that spontaneously reduces or requires manual reduction. Patients also frequently describe a mucous discharge and frequent bleeding, fecal incontinence, and obstructed defecation. Repair can be accomplished with either a trans-abdominal or perineal approach dependent upon patient age, medical co-morbidities,

prior surgery, body habitus, and performance status. Perineal procedures may be undertaken due to inability to tolerate an abdominal procedure at the cost of functional outcome and recurrence risk [45].

Abdominal rectopexy traditionally has been performed in healthy patients with good performance status. Laparoscopy and robotic technology have extended the indication in the elderly/frail population [46]. The procedure is conducted with posterior rectal mobilization and mesorectal fixation to the presacral fascia with or without mesh augmentation. A prominent side effect of this approach is persistence or worsening of obstructed defecation [47]. Sigmoid resection and preservation of the lateral rectal stalks have been associated with decreased postoperative obstructed defecation at the cost of increased surgical risk and elevated prolapse recurrence, respectively.

A newer alternative to posterior rectopexy is ventral mesh rectopexy [48]. This involves the anterior rectal mobilization and mesh fixation of the anterior rectum to the presacral fascia. Durable repair of the prolapse with this technique has been demonstrated and interestingly a lower incidence of persistent postoperative obstructed defecation is seen. This is also being explored as a treatment for obstructed defecation related to occult rectal prolapse. Most support for this technique comes from small, uncontrolled case series and objective and technical comparative results are lacking [49, 50]. See Chap. 60 for a complete overview of the treatment of rectal prolapse.

Rectal Prolapse: Occult

Occult or internal rectal prolapse is seen in patients presenting with isolated complaints of obstructed defecation or fecal incontinence. This is typically identified on defecography and complicating its association with obstructed defecation is the finding of radiographic internal prolapse in healthy, asymptomatic volunteers [51].

Initial treatment of this group of patients is non-operative with the techniques already described. Patients failing this approach with refractory, lifestyle-limiting symptoms can be considered for surgical intervention. It is important for patients and surgeons to recognize that inconsistent functional improvement is seen with surgical correction of the occult prolapse using the posterior rectopexy technique [44]. Ventral mesh rectopexy may become a valid option for this group of patients but objective studies documenting its efficacy are lacking at this time.

An alternative to posterior or ventral rectopexy for management of rectal intussusception is stapled transanal rectal resection (STARR). This may also be considered for some patients with rectoceles and refractory symptoms of obstructed defecation who have failed non-operative treatment. This approach uses a specialized transluminal gastrointestinal circular stapling device to resect the redundant anterior and posterior rectal walls, thereby reducing rectal volume and improving rectal sensitivity [52]. Results have been overall positive in terms of initial relief of the symptoms of obstructed defecation, though appreciable operative morbidity (up to 36 %) and long-term functional consequences including fecal urgency and incontinence, bleeding, rectovaginal fistula, persistent or recurrent obstructive defecation, and pelvic sepsis have all been described [53–57]. The difficulty in determining which patients would benefit from the STARR procedure along with the possible morbidity that can occur from the circular "anastomosis" have dampened the enthusiasm for this procedure.

Rectocele

Rectoceles arise from loss of anterior rectal support due to disruption of the rectovaginal fascia. This is typically related to traumatic disruption from prior obstetric trauma or simple age related decline in fascial integrity. Rectoceles are identified in up to 80 % of the adult population, the majority of which are asymptomatic and do not require treatment [58]. Symptomatic rectoceles come to clinical attention owing to overt vaginal prolapse and/or functional rectal obstruction (Figure 59-5). Associated symptoms may include anorectal or vaginal pain and sexual dysfunction. A detailed history and physical examination to define the presenting symptoms and its impact on quality of life is important. Clearly defining the problems most important to the patient and setting realistic expectations for medical and surgical treatment of this problem is critically important [2].

Patients whose primary complaint is posterior vaginal wall prolapse may be offered surgical reconstruction with the expectation of durable relief of their prolapse symptoms. Rectoceles can be repaired via the transvaginal (will be discussed in Chap. 63), transrectal, and transperineal approaches with or without levatoroplasty. The operative morbidity, risk of recurrence, vaginal anatomic distortion, and a significant risk of dyspareunia should not be underestimated and should be thoroughly discussed with the patient prior to surgery [59–61].

Many colorectal surgeons favor a transanal approach to repair of low rectoceles. Patients are typically placed in the prone position. A curvilinear incision is made over the poste-

FIGURE 59-5. Rectocele.

rior rectal mucosa just 1–2 cm distal to the distal edge of the rectocele. Prepping the vagina and using the index finger in the vagina to outline the rectocele edges is helpful. The mucosa is dissected off the rectocele until it is 1–2 cm cephalad to the proximal rectocele edge. Then the cephalad edge is sutures to the caudad edge with simple or figure of eight absorbable sutures (2-0 polyglycolic acid). Confirmation of the complete obliteration of the rectocele is confirmed with the finger in the vagina to palpate the closure. The mucosa is then advanced down and re-approximated with the distal cut edge. Alternatively, this can be performed with the use of a stapler to remove the redundant tissue (Figure 59-6).

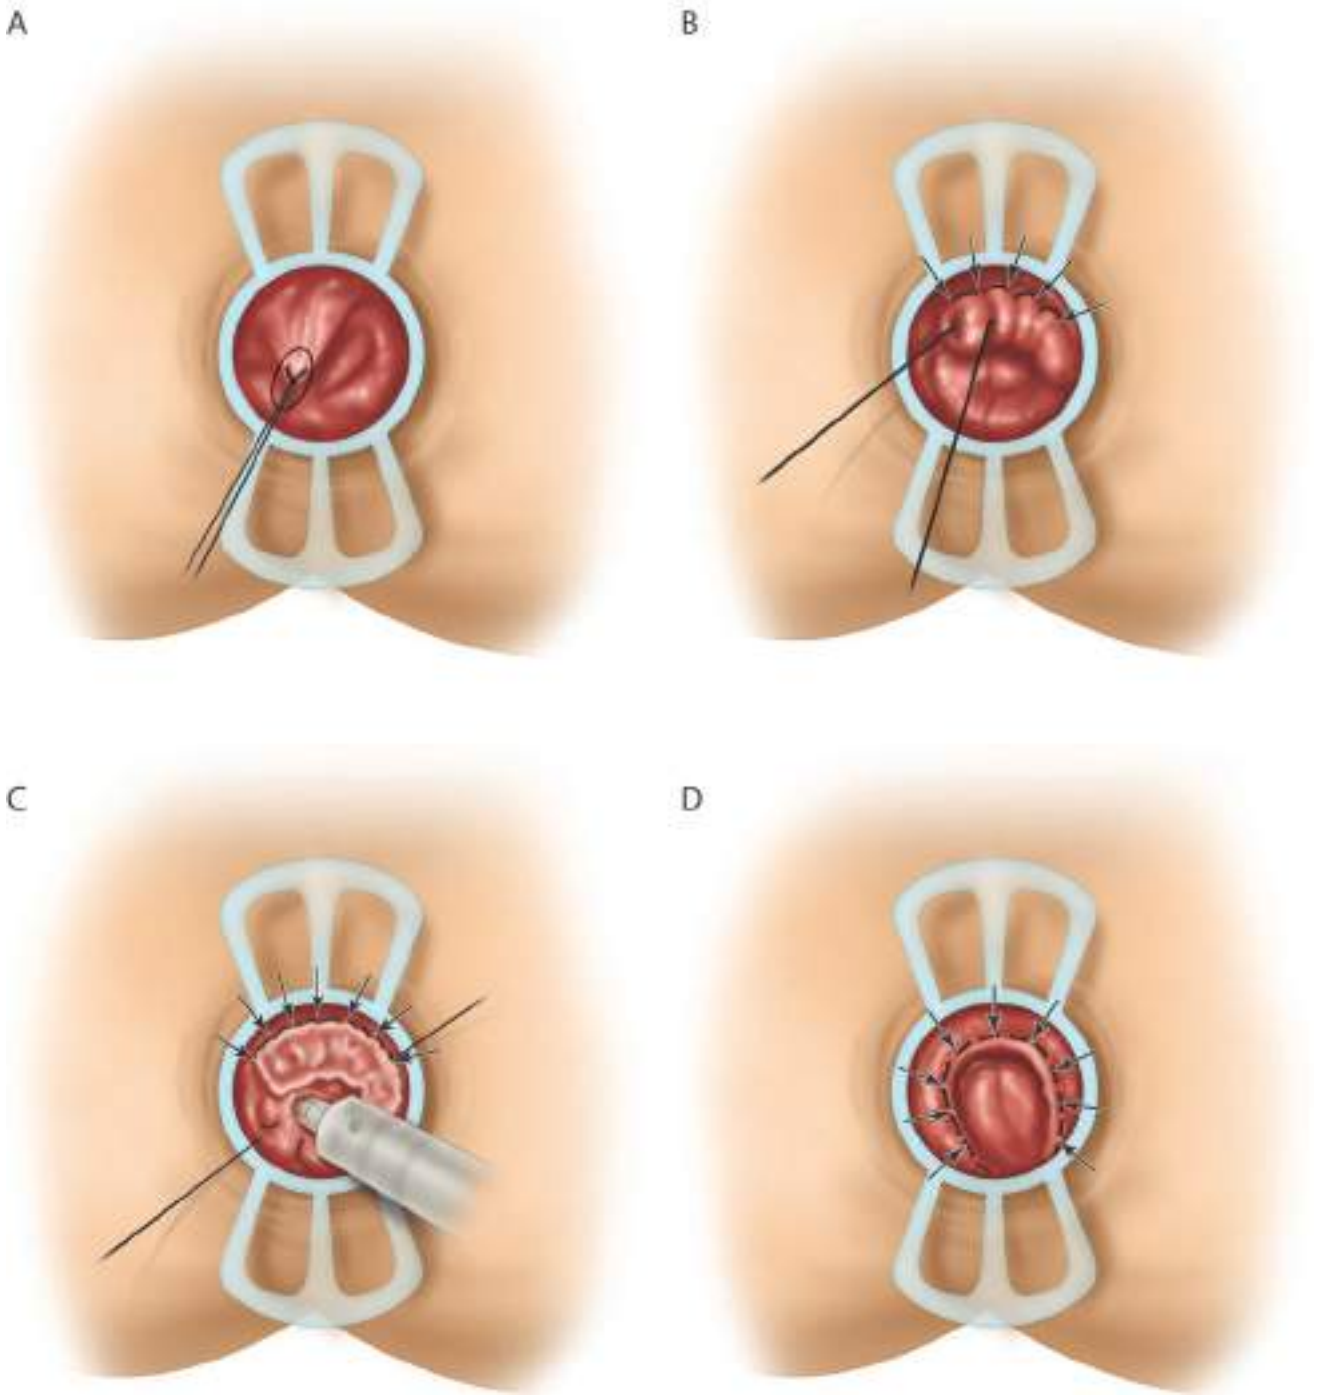

FIGURE 59-6. Transanal rectocele repair and mucosectomy (with a *circular stapler*). (**a**) The apex of the rectocele is identified and pulled down through a stitch (*circle*). (**b**) A running horizontal suture is placed through the base of the rectocele (*arrows*). (**c**) The exceeded prolapsed mucosa and the muscular layer were excised, keeping an opened wound with the edges joined by the previous manual suture (*arrows*). The pursestring suture is tied around the stapler's center rod. (**d**) The remaining stapled suture line (*arrows*).

In an attempt to lessen operative risk, improve recurrence rates, and lessen postoperative sexual dysfunction surgeons have utilized mesh based rectovaginal septal reconstruction. The technique remains controversial but most studies reveal no advantage in the use of mesh over native tissue repairs for posterior compartment defects. In light of this and in conjunction with the morbidity of mesh related complications leading to significant litigation, the technique has not been widely adopted. The clinical situation where mesh may be particularly advantageous is in cases of recurrent prolapse or patients at high risk of primary failure but only after carefully weighing the risks and careful discussion with the patient [62, 63].

Patients whose primary complaint is obstructed defecation in association with a rectocele are less reliably managed with surgical reconstruction [64–66]. These patients should be offered a trial of non-operative therapy as already discussed prior to consideration of surgical intervention. For patients failing non-operative therapy and who have significant lifestyle altering symptoms, all of the aforementioned rectocele repair techniques have been used with varying success and durability. It is very important that the patient have realistic expectations for improvement prior to undergoing surgical reconstruction.

Enterocele with or without Vaginal Vault Prolapse

Enterocele and vaginal vault prolapse may exist in isolation of each other, but are co-existent in the majority of cases. Patients present with complaints of vaginal prolapse and symptoms of obstructed defecation. Chronic pelvic and low back pain may also be present and is typically worse throughout the day while upright and relieved with recumbency. Dyspareunia is also a frequent complaint. As with other pelvic floor disorders, careful history and physical examination is essential. If an enterocele is clinically suspected, confirmation with defecography is usually definitive identifying the small bowel descending into the rectovaginal space (Figure 59-7). A less common finding is a sigmoidocele where a redundant sigmoid colon fixated at the rectosigmoid junction fills the rectovaginal space.

For symptomatic patients with a confirmed enterocele, sigmoidocele, or vaginal vault prolapse, intervention is appropriate. Again, anatomic prolapse symptoms are much more reliably repaired than are the functional bowel consequences of the disorder. Patients with primarily obstructed defecation, as the presenting symptom should be offered a trial of non-operative therapy prior to surgical intervention.

The surgical approach can be either trans-abdominal or transvaginal, and is often determined by overall patient performance status. For healthy patients with good performance status, an abdominal approach offers a more durable and functionally better repair. The gold standard is abdominal sacral colpopexy with either prosthetic or biologic mesh support. A number of plication procedures of the pouch of Douglas have been described to manage the enterocele and may be concomitantly performed [67]. Sigmoidoceles are most commonly addressed with an anterior resection. With surgeons increasingly facile with advanced laparoscopic or robotic techniques, this procedure has become less invasive [68, 69]. Multi-compartment prolapse is common and concomitant repair should be undertaken [70]. See Chap. 63 for additional information.

Patients with poor performance status or patients with relative contra-indications for abdominal surgery are considered for a transvaginal approach. Traditionally, the transvaginal approach has used sacrospinous ligament fixation to support the vaginal apex concomitant with high ligation of the enterocele sac [71]. For patients without any desire to preserve sexual function, a vaginal obliterative procedure, colpocleisis, is an attractive approach for its relative ease and safety [72]. For those patients who are inappropriate surgical candidates or who desire non-operative relief of their symptoms a pessary may be entertained [73].

Non-Anatomic Causes of Obstructed Defecation

Several different non-anatomic anorectal functional and pelvic support issues may negatively affect defecatory function and give rise to obstructed defecation. Another term frequently used to describe this complex is dyssynergic defecation but this term probably is better used interchangeably with obstructed defecation syndrome rather than as a descriptor of patients with obstructed defecation not associated with underlying pelvic prolapse. Paradoxic puborectalis contraction, rectal hyposensitivity often in conjunction with mega rectum, and abnormal perineal descent are often contributors to obstructed defecation syndrome.

Paradoxic puborectalis occurs when the levator ani is inappropriately contracted during initiation of defecation. In normal defecation, the levator ani is relaxed thereby straightening the anorectal angle, shifting the rectum posteriorly, and allowing comfortable bowel movement. When the puborectalis is inappropriately contracted the anorectal angle becomes more acute and rectal outlet obstruction ensues inhibiting rectal evacuation. Diagnosis is suggested by physical examination. Having the patient strain during digital rectal examination, the puborectalis is felt to contract against the examining finger. Confirmatory testing with a combination of anorectal electromyography and defecography is diagnostic. Conservative treatment with dietary modification and biofeedback results in improvement in 40–60 % of patients [74, 75].

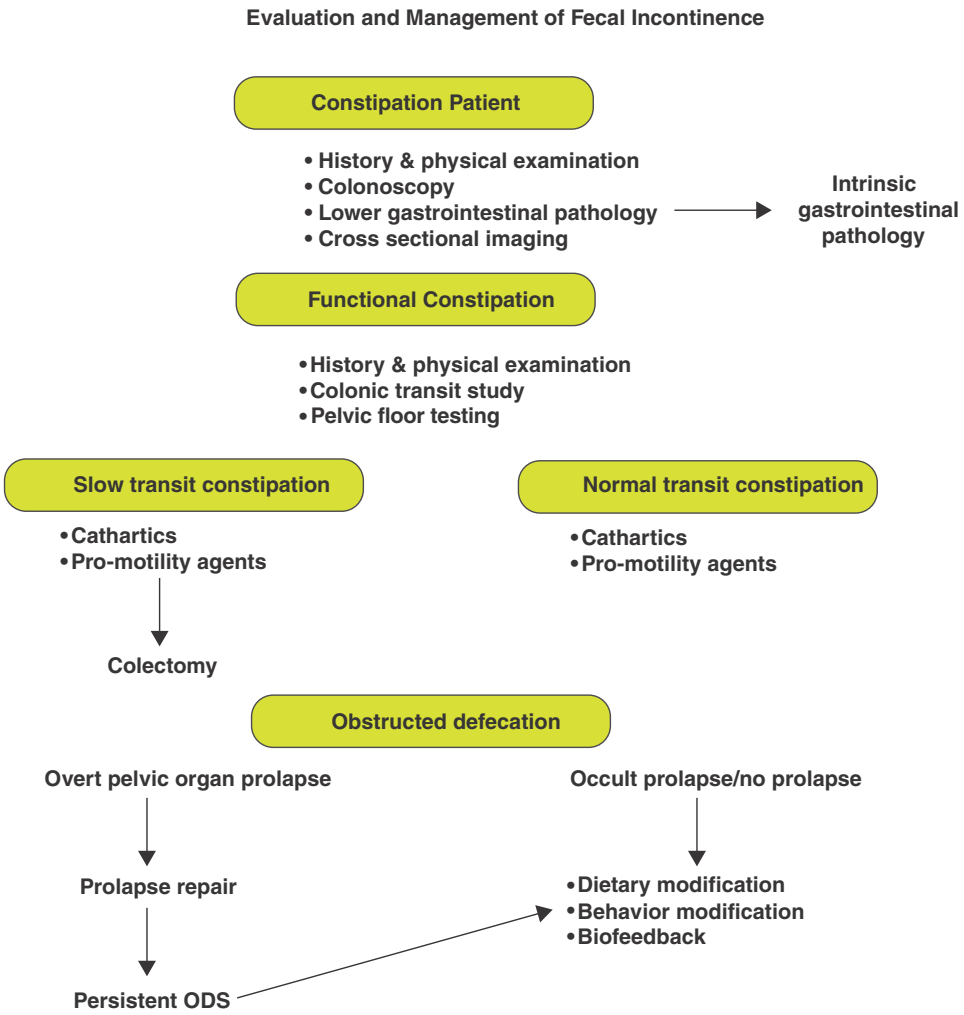

FIGURE 59-7. Algorithm for evaluation and management of functional constipation.

Rectal hyposensitivity is often seen concomitant with mega rectum. This is seen frequently in patients with neurologic or psychiatric impairment. However it is important to consider that a patient with megarectum could have short segment Hirschsprung's disease or a non-relaxing pelvic floor and these types of problems must be actively ruled out. Symptomatically, these patients present with typical obstructed defecation symptoms and may (or may not) have recurrent episodes of fecal impaction. Diagnosis is confirmed with defecography and anorectal manometry. Treatment is challenging and in conjunction with dietary and behavioral therapy, rectal stimulation with suppository, or enema therapy can be helpful. A technique being explored in clinical trials for this difficult group of patients failing nonoperative therapy is sacral nerve stimulation. Most studies published have grouped all forms of constipation together and have not clearly defined the etiology of refractory constipation. Overall results have been disappointing on an intent to treat basis but for the subgroup of patients that do benefit the results have been striking [76–78]. Knowles et al. in a randomized prospective double blind trial specifically treating patients with refractory obstructed defecation related to rectal hyposensitivity showed excellent results in terms of normalization of rectal sensation, ease of defecation, and improved Wexner scores in 10/13 patients. Eleven patients went on to permanent implant with nine patients have durable improvement at almost 2 years of follow-up [79].

Abnormal perineal descent results from loss of pelvic floor fascial integrity. Physical examination suggests the diagnosis when a pelvic floor bellows phenomenon is seen during straining. Defecography is diagnostic when descent greater than 2 cm past the static pelvic floor is seen. Treatment remains conservative with dietary manipulation and biofeedback. Unfortunately, treatment outcomes are relatively poor with less than 30 % experiencing major symptomatic improvement.

Fecal Diversion

As a last resort for patients with debilitating and refractory symptoms of obstructed defecation, fecal diversion may be considered. A very detailed and careful discussion clearly delineating the risks, benefits, and expected outcome of this therapy should be undertaken.

Algorithm for Evaluation and Management of Functional Constipation

An algorithm for evaluation and management of functional constipation is shown in Figure 59-7. Probably the single most important test to obtain is a good history and physical examination taken by a patient and empathetic surgeon. Further hindgut and pelvic floor functional testing is driven by the working diagnosis obtained in the initial encounter.

For patients with slow transit and normal transit constipation the initial treatment is non-operative with cathartic and pro-motility agents. Patients with slow transit constipation refractory to medical therapy may benefit from total colectomy but patients with normal transit constipation do not (Figure 59-8). A more detailed discussion of these disorders is undertaken in other sections of this text (see Chap. 58).

FIGURE 59-8. MR defecography demonstrating a cystocele, intussusception, and enterocele. Notice the small bowel loops extending down to the pelvic floor.

In patients with obstructed defecation, the most important first step is identifying whether patients have co-existing overt pelvic organ prolapse. For patient with overt pelvic prolapse, surgical correction of the prolapse is the first step, recognizing that the functional rectal outlet obstruction may or may not improve. For patients with isolated symptoms of obstructed defecation or persistent symptoms after pelvic prolapse repair, the initial treatment is non-operative with dietary and behavioral modification. Pelvic floor physical therapy retraining, while non-standardized, can be particularly effective. Recognizing the importance of the therapist in terms of their patience and empathy is critical to a successful biofeedback program.

For patients with refractory symptoms of obstructed defecation and significant lifestyle limitations due to the disorder, surgical intervention can be entertained. It is critically important that a detailed discussion of the goals, risks, and expected outcome of treatment be documented such that patient and surgeon expectations for improvement are realistic. In choosing an operative approach it is also important that we expose the patient to the least amount of risk and secondary treatment related side effects for this benign condition.

Conclusion

Patients with functional constipation are a challenging population that requires patient and empathetic care. The symptoms of this disorder are quite obtrusive and a major impediment to quality of life. A careful and methodical approach to evaluation and management of this group of patients can often result in major improvements. Considerable ongoing research, however, is still required to define the best practices and surgical techniques that may results in further functional benefits.

Rectal Prolapse

Brooke Gurland and Massarat Zutshi

Key Concepts

- Individuals with rectal prolapse may complain of a myriad of symptoms: mucus discharge, rectal bulge, rectal bleeding, fecal incontinence, constipation, tenesmus, pelvic and rectal pain and pressure. Correction of the prolapse does not guarantee functional improvement.
- Successful outcomes measures after rectal prolapse surgery include both prolapse recurrence rates and functional outcomes. The surgeon should be familiar with different abdominal and perineal procedures to choose the best operation for each individual in the setting of initial and recurrent rectal prolapse.
- Laparoscopic ventral rectopexy is associated with functional improvement, low morbidity, and low recurrence rates but has a high learning curve for proficiency and advanced training may be required.
- Robotic rectopexy can be offered safely to patients and has advantages when suturing in the pelvis is required.
- The paradigm for treatment rectal prolapse in the elderly has changed from perineal to abdominal minimally invasive procedures in elderly and high risk patients.
- Rectal prolapse may coexist with vaginal prolapse and multidisciplinary evaluation and treatment should be considered in symptomatic patients.

Introduction

Rectal prolapse or procidentia is defined as extrusion of the full thickness of the circular folds of the rectum through the anal muscles beyond the anal verge. If the rectal wall is prolapsed but does not extend beyond the anus, it is called occult (internal) rectal prolapse or rectal intussusception. Both full-thickness and internal rectal prolapse should be differentiated from mucosal prolapse which occurs when only the rectal or anal mucosa protrudes beyond the anus. Several anatomic conditions are associated with rectal prolapse including a laxity of rectal attachments, a deep Pouch of Douglas cul-de-sac, lack of fixation of the rectum to the sacrum, and a large redundant sigmoid colon (Figure 60-1).

The peak incidence of rectal prolapse is reported in women aged 70 and may be associated with a spectrum of pelvic floor disorders such as vaginal prolapse (enterocele, cystocele, rectocele) and urinary incontinence. These disorders are generally attributed to multiparity and pelvic floor weakness [1]. Women are six times as likely as men to present with rectal prolapse [2]. Approximately one-third of female patients are nulliparous and younger women; men with rectal prolapse tend to suffer from disordered defecation, dysmotility, psychiatric comorbidities, eating disorders, and autism or developmental delays [3, 4].

Symptoms of rectal prolapse may include the feeling of a bulge, mucus drainage and/or fecal accidents, constipation, tenesmus, rectal pressure, pelvic pressure and pain, and rectal bleeding. These symptoms can be debilitating and can result in isolation and depression in affected individuals.

Fecal incontinence is reported in 50–75 % of patients with rectal prolapse [5]. Mucus discharge frequently is described early in the disease process and this can evolve into frank fecal accidents as the prolapsed segment keeps the sphincters open permitting stool to leak. Chronic stretch, trauma, and continuous stimulation of the rectoanal inhibitory reflex by the prolapsing tissue can result in permanent sphincter damage. Pudendal neuropathy has been demonstrated in 50 % of patients with prolapse [6] and may be responsible for denervation related atrophy of the external sphincter musculature [7].

Constipation is reported in 25–50 % of patients with rectal prolapse [5, 8] and may be associated with colonic dysmotility or pelvic floor dyssynergia. Chronic straining can lead to

rectal prolapse or the prolapse can induce outlet constipation with the intussuscepting bowel in the rectum creating a blockage of the outlet which is exacerbated by excessive straining.

Patient Evaluation

The evaluation of rectal prolapse should include a complete pelvic floor history and physical examination. An assessment of risk factors should be considered and treatment of constipation with fiber or laxatives should be considered. A screening evaluation with endoscopy in adults is performed to exclude coexisting conditions. If the diagnosis of rectal prolapse is suspected, but not detected on initial examination, the patient should be evaluated standing, squatting or on the commode in the straining position. If rectal prolapse is still elusive and the history is suggestive of a prolapse, the patient can be asked to photograph the prolapse at home. For those patients with vaginal prolapse or urinary symptoms, urogynecological examination and urodynamics should be considered for multidisciplinary pelvic floor repair. Additional testing such as anorectal physiology testing rarely changes the operative strategy but they can often guide treatment for associated functional abnormalities [9]. Defecography may reveal associated defects such as cystocele, vaginal vault prolapse, and enterocele that may require treatment [10, 11].

Non-operative Treatment

Non-operative treatment of rectal prolapse has shown to produce only temporary or symptomatic relief. Reduction of incarcerated rectal prolapse can be performed by coating the prolapse with table sugar to reduce edema and gently push the prolapse above the sphincters [12]. Biofeedback was used to improve postoperative function but has not been reported as a primary therapy [13].

Surgical Approaches for Rectal Prolapse

A single common theory for the cause of rectal prolapse has not been substantiated but the anatomic basis includes a deficient pelvic floor through which the rectum herniates. A deep pelvic cul-de-sac, attenuated ligamentous attachments to the rectum and presacral fascia, and a redundant sigmoid colon are frequently associated with rectal prolapse [14].

Surgery is the only curative treatment for rectal prolapse. A range of surgical procedures are available which differ with respect to approach: abdominal versus perineal. Additionally, the surgeon must decide about the method of fixation that will be used and if bowel will be resected. The optimal operation for rectal prolapse is unclear. Surgeons are inclined to individualize the patient's treatment when it comes to approach thus making it difficult to evaluate and compare results from case series. Low accrual rates for randomized trials and poor quality data continues to be a challenge when reviewing the literature for rectal prolapse surgery. Deen et al. performed a small randomized controlled trial ($n=20$) comparing perineal rectosigmoidectomy with an abdominal approach [15]. The recurrence rate was 10 % for the perineal group compared to 0 % for the abdominal group and functional results were better in the abdominal group. The PROSPER Trial compared the surgical treatments for rectal prolapse in 293 patients [16]. Seventy-eight abdominal procedures and 213 perineal procedures were performed. Overall, rectal prolapse recurrence rates were higher than anticipated but recurrence was not significantly different between groups.

Description of Surgical Interventions

Anal Encirclement

The Thiersch procedure involves reduction of prolapse and placement of a subcutaneous suture or mesh material to encircle the anus, thereby narrowing the anal canal. This procedure does not eradicate prolapse but prevents further descent by providing a mechanical barrier. It is associated

with recurrence rates ranging from 33 to 44 % but can lead to problems with severe outlet constipation. It is rarely recommended and only reserved for patients at high risk of anesthetic complications [17]. In some patients with rectal prolapse and a permanent colostomy, the treatment may be considered to prevent the symptoms of protrusion and mucus drainage.

Perineal Procedures

Delorme

A mucosal sleeve resection was described by Delorme in 1900 and involves stripping the mucosa of the prolapsed segment, plication of the muscle layers, and re-approximation of the mucosa (Figures 60-2, 60-3, 60-4, and 60-5). This procedure is advocated for patients with a short segment of full-thickness rectal prolapse or for patients who are considered "high risk" for abdominal procedures such as those with a "hostile abdomen." Procedure related operative complications are low but prolapse recurrence rates are high in the range of 16–30 % [18–20] (For a description of the procedure, please see Video 60.1 Delorme procedure, reproduced with the permission of the Department of Colon and Rectal Surgery, The Cleveland Clinic Foundation, Cleveland, OH, USA).

Perineal Rectosigmoidectomy

The perineal rectosigmoidectomy or the Altemeier procedure involves excising the prolapsing rectum and creating a low end-to-end stapled colorectal anastomosis or a sutured coloanal anastomosis (Figures 60-6, 60-7, 60-8, 60-9, 60-10, 60-11, and 60-12). This procedure can be combined with a levatorplasty to "tighten" the pelvic floor muscles with the goal to improve continence [21]. Fecal incontinence can be exacerbated after a perineal rectosigmoidectomy which may be due to loss of the rectal reservoir confounded by poor sphincter function. Recurrence rates have been reported as high as 20 % and complications rates (<10 %) include suture line bleeding, pelvic abscess, or anastomotic leak [22] (For a description of the procedure, please see Video 60.2 Altemeier procedure, reproduced with the permission of the Department of Colon and Rectal Surgery, The Cleveland Clinic Foundation, Cleveland, OH).

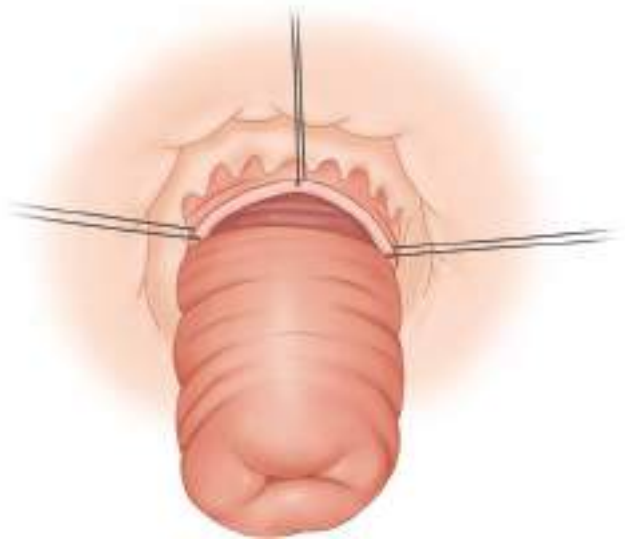

FIGURE 60-2. Delorme procedure. Two centimeters proximal to the dentate line, a circular line is marked out in the mucosa with the bovie. The area is injected with a vasoconstricting agent. An incision is then made through the mucosa but not full thickness through the entire rectal wall. The bovie is an excellent means to make the mucosal incision.

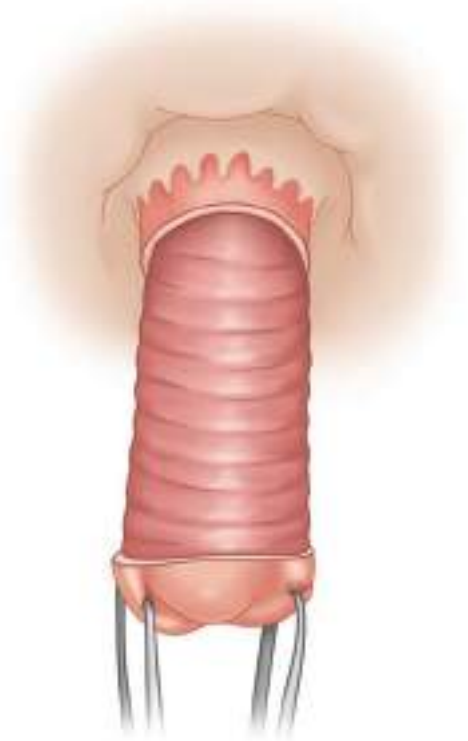

FIGURE 60-3. Delorme procedure. Working cephalad, a sleeve of mucosa is dissected off the muscular layer of the rectal wall. Liberal injection of saline with or without a vasoconstricting agent assists in developing the correct plane. Care is taken to achieve meticulous hemostasis as there are penetrating vessels in this plane of dissection which will need to be tied or coagulated.

Abdominal Procedures

Transabdominal Rectopexy

The goal of rectopexy is to anchor the rectum to the sacrum. This can be performed by open, laparoscopic, or robotic techniques. Fixation of the rectum with suture was first described by Cutait. The suturing is done to correct telescoping

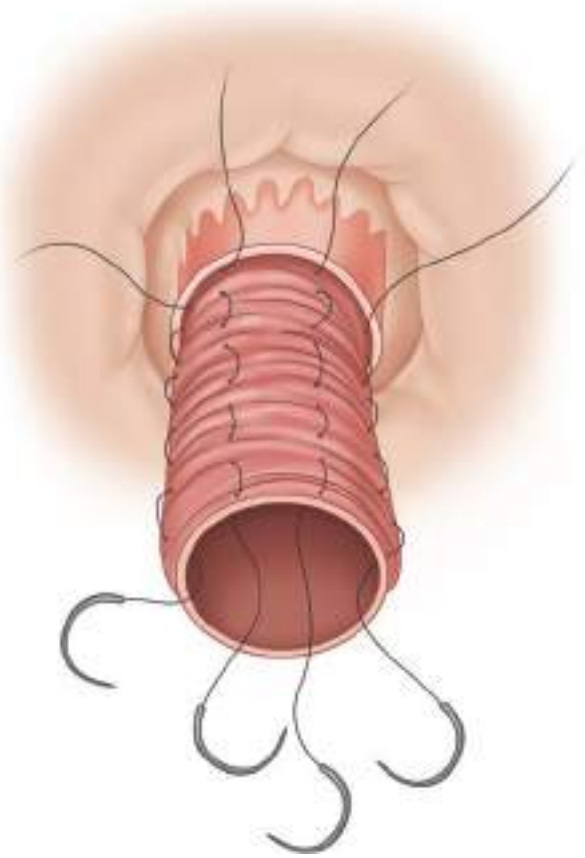

FIGURE 60-4. Delorme procedure. When there is tension at the plane of the mucosal dissection, this is completed. After ensuring that complete hemostasis exists, the muscular layer (the rectal wall) is approximated using sutures starting at the proximal cut mucosal end and including bites of the rectal wall every few centimeters until the other cut edge is reached at the anal region. Placement of these sutures is along the longitudinal axis of the rectal wall and are not full thickness but deep enough to ensure when tied they do not tear through the tissue. As these sutures are placed they compress the wall in an accordion (or concertina) like fashion. Four to six sutures are typically required to stabilize the compressed rectal wall.

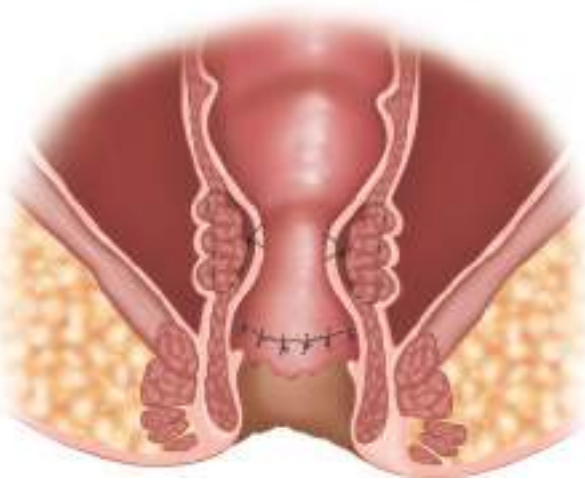

FIGURE 60-5. Delorme procedure. After the sutures that have been placed in the rectal wall are tied down, the two cut ends of the mucosa will be in close proximity. The mucosa is then reapproximated with sutures to create a neo-anastomosis in the anal canal proximal to the dentate line.

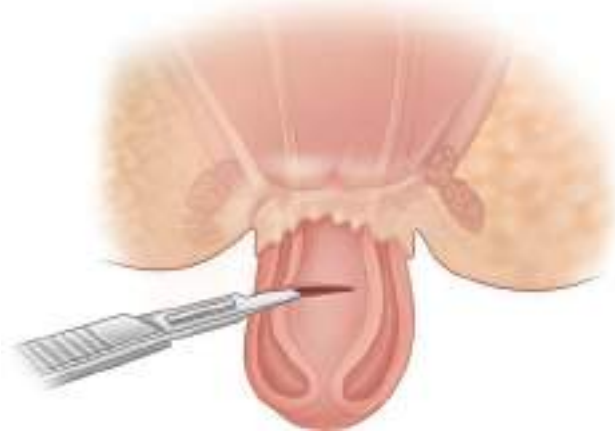

FIGURE 60-6. Altemeier procedure. A circular incision is mapped out approximately 2–5 cm cephalad to the dentate line in the rectal mucosa.

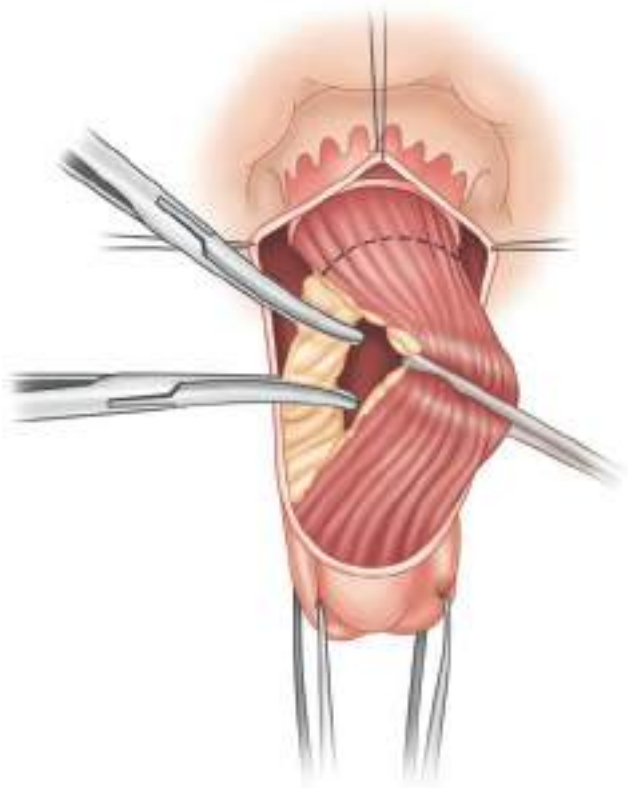

FIGURE 60-7. Altemeier procedure. The incision is deepened and is carried through the entire thickness of the rectal wall. The mesentery to the redundant prolapsed rectum is divided and tied, suture ligated, or cut and sealed using an energy device. Meticulous hemostasis is essential to avoid retracted blood vessels or a mesenteric hematoma.

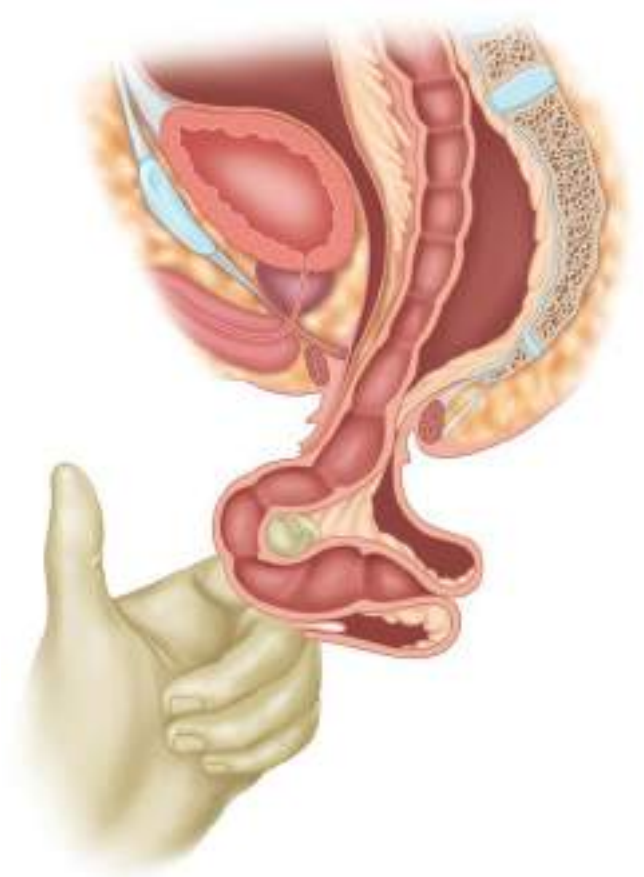

FIGURE 60-8. Altemeier procedure. The rectum is pulled out the anus and the mesentery divided stopping at a point just distal to where the rectum (or sigmoid) no longer easily can be pulled out the anus.

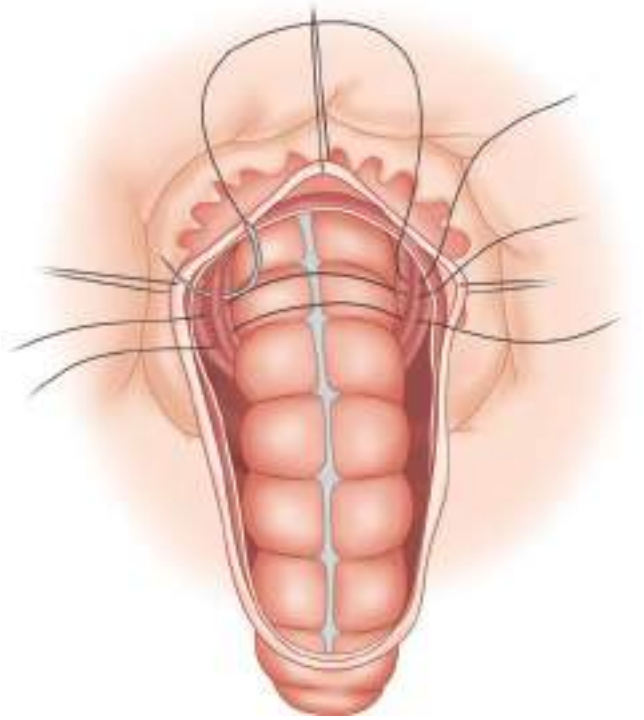

FIGURE 60-9. Altemeier procedure. Anteriorly the levator ani muscles may be approximated with sutures (levatorplasty) which may improve fecal continence.

of the redundant bowel and further fixation of the rectum is anticipated due to the resultant scarring and fibrosis [14]. Prolapse recurrence rates are reported from 0 to 9 % [23–25]. Mobilization of the rectum can vary based on the technique from circumferential to limited posterior and/or anterior and can include unilateral or bilateral division of the lateral rectal ligamentous attachments.

More extensive rectal mobilization and division of lateral stalks is associated with decreased recurrence rates but may precipitate new onset or worsening constipation [26]. New onset constipation after rectopexy is reported in 15 % of patients whereas 50 % described worsening of preoperative constipation [27]. Denervation of the rectum from the neural efferent nerves residing in the lateral ligaments is thought to contribute to worsening function. Unilateral preservation of a lateral stalk and unilateral fastening of the rectal mesentery to the sacrum should be considered to mitigate worsening function [9].

Transabdominal Resection Rectopexy

Sigmoid resection in conjunction with rectopexy was popularized by Frykman and Goldberg in 1969 [28]. It was thought that sigmoidectomy was associated with a lower recurrence rate and improved functional outcome with a minimal

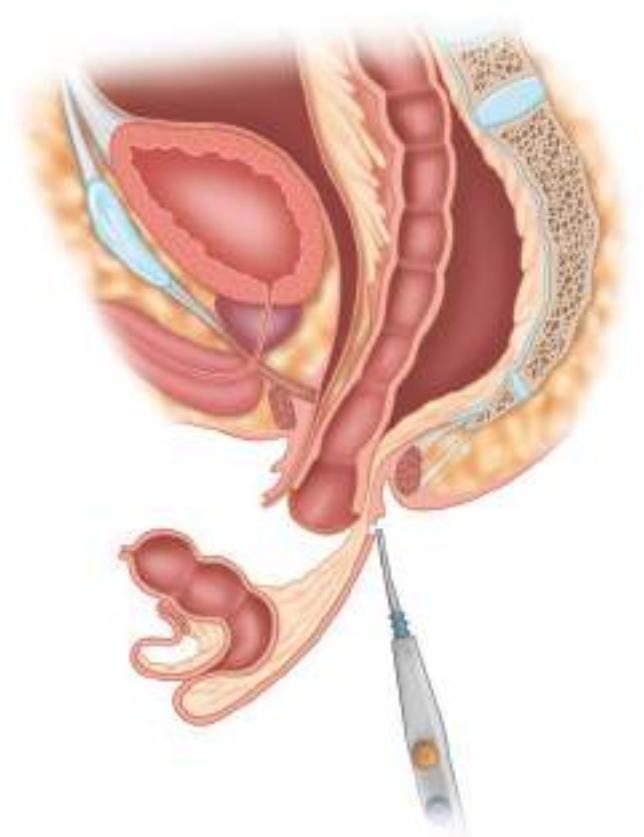

FIGURE 60-10. Altemeier procedure. The redundant rectum and sigmoid colon are excised. It is important to ensure that the proximal bowel has sufficient mesentery to avoid ischemia to this segment.

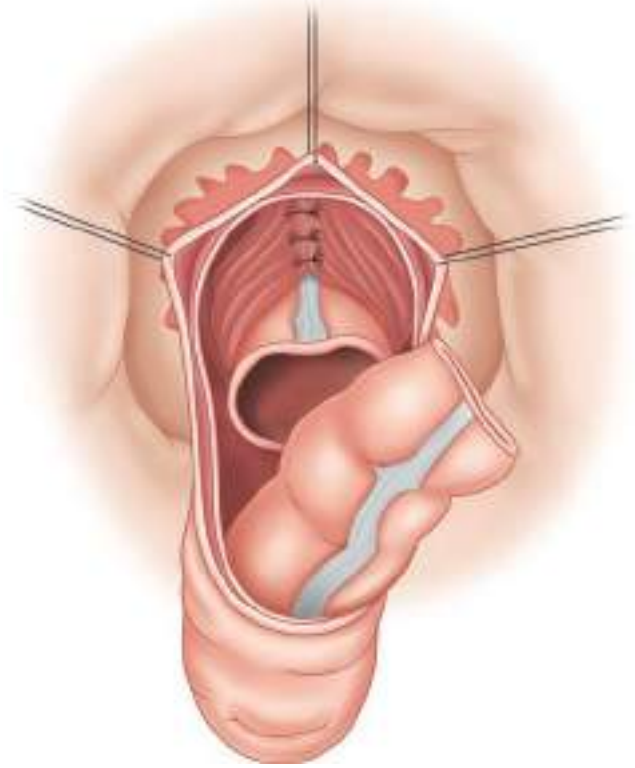

FIGURE 60-11. Altemeier procedure. The redundant rectum and sigmoid colon are excised. It is important to ensure that the proximal bowel has sufficient mesentery to avoid ischemia to this segment. This figure also demonstrates the completed levatorplasty.

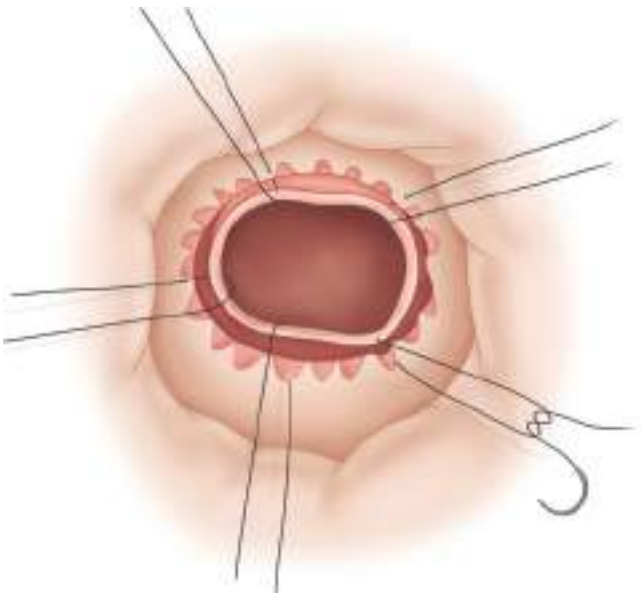

FIGURE 60-12. Altemeier procedure. A tension free end-to-end anastomosis is carried out using sutures (a circular stapled anastomosis also can be done).

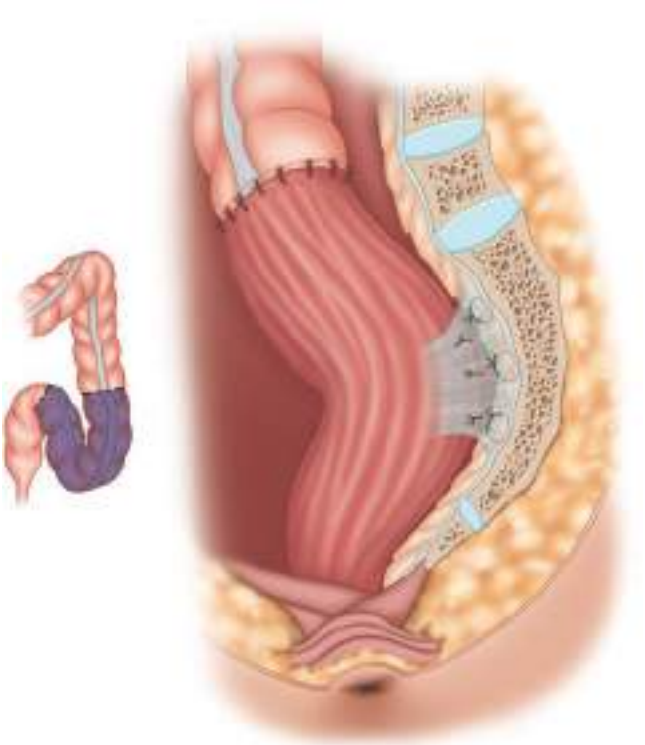

FIGURE 60-13. Resection/rectopexy. The sigmoid colon is excised and an end-to-end anastomosis performed. The rectum is mobilized and non-absorbable sutures are placed in the lateral rectal ligament. The suture is then placed in the anterior sacral ligament (tacks can also be used) to anchor the rectum securely to the sacrum at about the S1 level. It is important to position the needle to enter the sacrum at a right angle. The needle is pushed into the bone and minutely pulled back. Then the curve of the needle is followed when continuing the suture placement at the sacrum. This ensures the suture will be in the anterior sacral ligament. Two sutures on the right are typically placed. Sutures can be placed also on the left side of the rectum, but when tying them down, it is crucial to ensure the rectum is not kinked/occluded.

increase in morbidity [29, 30]. Sigmoid resection may reduce constipation in those who report the symptom preoperatively [31] and resecting the sigmoid may counteract new onset constipation which has been reported after extensive rectal mobilization (Figure 60-13). However, a sigmoid resection is thought to be unnecessary in individuals whose predominant complaint is fecal incontinence [32]. For some patients with confirmed slow colonic motility, sigmoid resection is an inadequate operation and a subtotal colectomy should be considered [33]. The American Society of Colon and Rectal Surgeons in its 2011 Clinical Practice Guideline *Practice Parameters for the Management of Rectal Prolapse* states that "a sigmoid resection may be added to rectopexy in patient with prolapse and preoperative constipation, but it is not necessary in those without constipation" [9].

In the USA, laparoscopic resection rectopexy currently is the most common treatment for full-thickness rectal prolapse [34, 35]. However in European countries, sigmoid resection is infrequently performed and laparoscopic ventral rectopexy is preferred.

Mesh Rectopexy

Fixation materials can vary from simple absorbable or non-absorbable suture to biologic or synthetic mesh. Placement of the mesh can include partial anterior rectal encirclement (Ripstein procedure), partial posterior rectal encirclement (Well's procedure), or partial anterior rectal encirclement (D'Hoore ventral rectopexy) prior to attachment of the mesh to the sacrum.

Ripstein Procedure (Anterior Sling Rectopexy)

Ripstein first described this procedure in 1952 [36]. After complete mobilization of the rectum, an anterior sling of fascia lata or synthetic material was fixed to the anti-mesenteric surface of the rectum and each of the sides then sutured to the sacral promontory. The goal is to restore the normal anatomic position of the rectum. Mortality rates are reported to be from 0 to 2.8 % and recurrence rates between 0 and 13 % [27, 37]. Functional outcomes include a trend towards improvement in continence and a mixed response to constipation [38]. One drawback of the original procedure was the potential of the mesh to obstruct the rectum. To limit the incidence of obstruction the procedure was modified to leave a gap in the mesh to avoid narrowing or kinking of the rectum [39]. Currently people performing this procedure will fix the mid portion of a rectangular piece of mesh to the sacrum and bring each arm around the rectum, suturing the arms to the sides of the rectum, leaving a gap in the anti-mesenteric rectal region. Roberts et al. reviewed their experience with Ripstein and noted a 52 % complication rate with a presacral hematoma reported in 8 % [40]. Recurrence rates in men were three times that in women (24 % vs. 8 %, respectively). They speculated that the difference in recurrence rates was due to technical difficulties in mobilizing the rectum in a narrow male pelvis [40]. The Ripstein procedure (even the modified form) is being used less and less due to the morbidity and potential for new rectal outlet difficulties.

Posterior Mesh Rectopexy

A posterior rectopexy utilizing the Ivalon® sponge was a popular procedure in the past. After nearly full mobilization of the rectum, a rectangular piece of sterilized Ivalon sponge was fixed to the presacral fascia using non-absorbable sutures. The rectum was then drawn upward out of the pelvis and the lateral edges of the sponge wrapped around the rectum to encompass three quarters of the circumference and sewn in place. Major complications included pelvic abscess (2.6–16 %) which required drainage and removal of the sponge. The recurrence rates were low presumably due to fixation from the inflammatory process resulting from the infection. However the infection rates were felt to be prohibitory and this sponge is no longer utilized in repairs.

Currently the posterior mesh rectopexy is fashioned after variations of the Well's procedure. Traditionally the rectum is only mobilized on the right enough posteriorly to allow safe suturing or tacking of a prosthetic material to the periosteum or anterior sacral ligament of the sacral promontory. The mesh is sutured to the rectum on the right side. Mortality rates range from 0 to 3 % and recurrence rates are reported to be 3 % [23, 25, 29].

Laparoscopic Ventral Rectopexy

Ventral rectopexy (VR) described by D'Hoore is based on correcting the descent in women of the posterior and middle compartment by mobilizing the rectovaginal septum down to the pelvic floor between the extraperitoneal rectum and the vagina [41]. The rectovaginal septum is reinforced with (traditionally polypropylene) mesh and the mesh is suspended to the sacrum, thus elevating the pelvic floor (Figure 60-14). VR can correct full-thickness rectal prolapse, rectoceles, and internal rectal prolapse and can be combined with vaginal prolapse procedures, such as sacrocolpopexy, in patients with multi-compartment pelvic floor defects.

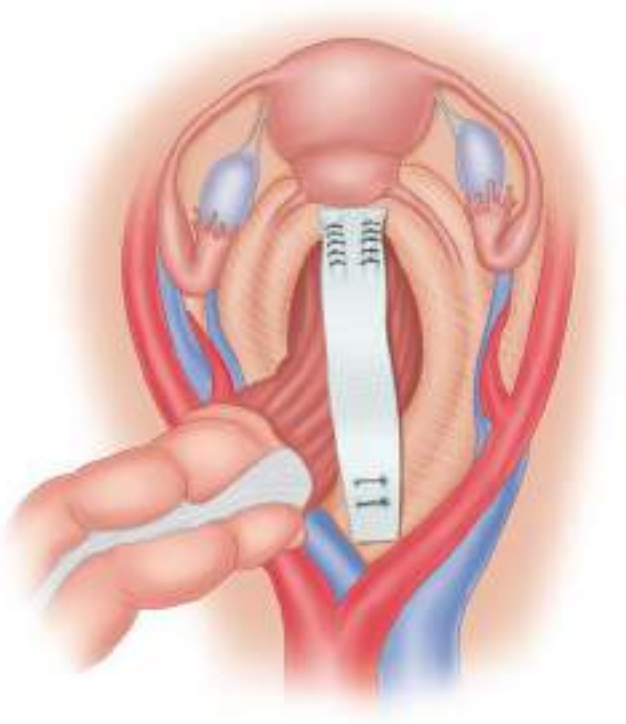

FIGURE 60-14. Ventral rectopexy. The anterior wall of the rectum is mobilized. The mesh (or graft) is attached with sutures to the anterior wall of the rectum. The mesh is then sutured to the anterior sacral ligament or tacked to the sacrum at about the S1 level.

Limiting dissection to the anterior rectum minimizes autonomic nerve damage associated with posterior dissection and division of the lateral stalks. A meta-analysis of 789 patients in 12 published series of laparoscopic VR reports recurrence rates for pelvic organ prolapse at 3.4 % (95 % CI 2.0–4.8) [42]. Complication rates varied between 14 and 47 %. The overall mean decrease in fecal incontinence score was 44.9 % (95 % CI 6.4–22.3) along with a significant decrease in constipation of 23.9 % (95 % CI 6.8–40.9). Laparoscopic VR is the current gold standard for treatment of rectal prolapse in European countries.

Laparoscopic VR is technically demanding and requires a complete ventral dissection of the rectovaginal septum (rectovesical in men) down to the pelvic floor and suturing skills within a confined space that further maximizes the difficulty. Mackenzie and Dixon reported that the proficiency gain learning curve for the relevant clinical and quality-of-life outcomes for laparoscopic VR was between 82 and 105 cases [43]. Proficiency with respect to reduced operating time was reached at 54 cases. Poor technique minimizes the functional benefit and increases the risk for complications. Recurrence after VR may be due to loss of fixation at the sacrum, inadequate mobilization in the rectovaginal space, or incomplete reduction of the prolapse [44].

Adverse outcomes that seem to be unique to VR include mesh complications such as rectal stricture, rectovaginal fistula, pain/dyspareunia, and mesh erosions [45]. Sacral discitis is an uncommon complication that can occur after any type of rectopexy or sacral colpopexy where tacks or sutures are applied to secure the mesh at the site of the sacral promontory [46]. In an analysis of 200 patients undergoing VR, Draaisma et al. noted two patients who experienced mesh infection complicated by discitis at the site of the proximal mesh fixation [47]. Bacterial translocation from the distal rectum to the mesh and ultimately, to the site of fixation at the sacral promontory may explain this complication.

Jonkers et al. retrospectively analyzed laparoscopic resection rectopexy (LRR) and laparoscopic ventral rectopexy (LVR) [48]. A reduction in constipation and incontinence was found in both cohorts but more complications occurred after LRR than LVR. In the absence of more rigorous clinical trials, European surgeons continue to avoid sigmoid resection in favor of VR [49].

Robotic Rectopexy

Robotic procedures offer the advantages of three dimensional visualization, tremor filtering, motion scaling, enhanced dexterity, and superior precision. Developments of robotic surgery have overcome some limitations of conventional laparoscopy such as the difficulties associated with rigid instruments, limited freedom of wrist movement, and technical challenges associated with operating in the confines of a deep pelvis. Disadvantages of robotic surgery include the loss of tactile feedback, the limited range of motion of the robotic arms, increased operative time, and higher equipment costs. Ventral rectopexy is ideally suited for robotic surgery. Robotic rectopexy improves visualization in the deep pelvis and suturing capability and facilitates dissection and mesh placement to the rectovaginal septum. Suturing the mesh to the perineal body, anterior rectum, and lateral rectal attachments is technically easier robotically than laparoscopic suturing. Robotic VR may have a faster learning curve than laparoscopic VR. There have been reports that functional outcomes are improved with robotic VR [50].

Systematic review and meta-analysis comparing the outcomes of robotic rectopexy (RR) versus laparoscopic rectopexy (LR) reveal similar recurrence, conversion, and reoperation rates [51]. The meta-analysis shows that operative time is significantly longer for RR but that RR is associated with a significantly lower blood loss, fewer postoperative complications, and shorter hospital course. However, blood loss was low in both groups (<200 cc) and overall complications were minor.

The cost effectiveness of robotic surgery is debatable. Heemskerk estimated that the cost of robotic compared to laparoscopic surgery exceeds $745 dollars [52]. The experience of the surgical team, learning curve, and surgeon's skill are important aspects that influence operative time and outcomes. Updated systematic analysis of costs could become important to justify increased expense (For a description of robotic rectopexy, please see Video 60.3).

Rectal Prolapse in the Elderly

When considering surgery for rectal prolapse in older patients, the balance between the morbidity of the procedure and overall outcome must be carefully considered. Traditionally age was used as one of the major criteria for deciding the approach (abdominal vs. perineal) for prolapse surgery. The rationale was that perineal procedures can be performed on frail patients with regional anesthesia without the complications and extended recovery associated with abdominal surgery. Fang et al. retrospectively queried the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) database, studying surgeon preference for abdominal (open and laparoscopic) versus perineal procedures as it related to age of the patient [53]. The perineal approach was more commonly performed in patients >80 and those at highest risk. Mortality after perineal procedures was 1.3 % compared to 0.35 % for abdominal procedures. There were no deaths in the laparoscopic group. With the acceptance of laparoscopic surgery for rectal prolapse having lower morbidity, surgeons have taken a closer look at a more durable abdominal procedure in elderly patients. Laparoscopic surgery has been proven to be safe in the elderly and is associated with decreased ileus, less wound infections, and a decreased length of stay [54]. Acceptable morbidity has been reported in the elderly patients who underwent a laparoscopic mesh rectopexy [55]. Robotic rec-

topexy has also been shown to be a safe and effective option in patients older than 75 years [56]. Therefore, with the new era of minimally invasive surgical techniques, an increasing number of elderly patients will be considered for an abdominal procedure to address their rectal prolapse.

Recurrent Rectal Prolapse: What Is the NEXT Operation?

Although many studies have described the management of primary rectal prolapse, there are few reports which address the ideal surgical treatment for recurrent rectal prolapse. Unfortunately, a systematic literature review of the surgical management of recurrent rectal prolapse failed to develop a treatment algorithm due to the use of multiple techniques and low quality studies [57]. Considering single center studies, Steele et al. reported significantly more re-recurrences after reoperation using a perineal procedure compared with an abdominal procedure for their patients with recurrent rectal prolapse ($p=0.03$) [58]. This means that perineal procedures which have a higher incidence of recurrence after the primary procedure have an even greater chance at re-recurrence if utilized again for recurrent rectal prolapse. There is a theoretical risk that a redo perineal rectosigmoidectomy can result in a devascularized segment of rectum [59]. However, Ding et al. reported that redo perineal rectosigmoidectomy is as safe and feasible as primary perineal rectosigmoidectomy as long as the prior anastomosis is included in resected specimen [60]. However, this report also supported the previously mentioned studies regarding a substantially higher recurrence rate if a perineal rectosigmoidectomy is used to treat recurrent rectal prolapse [60].

One note of caution, if the initial repair was a sigmoid resection and rectopexy it is not advisable to perform a perineal rectosigmoidectomy if there is recurrent rectal prolapse. Unless the entire colorectal anastomosis is resected when performing the perineal resection for recurrence a devascularized segment of rectum can remain. Similarly, resection rectopexy following a perineal rectosigmoidectomy should be performed with caution as the distal bowel requires an intact marginal artery for its blood supply. Aggressive mobilization could compromise the artery and lead to distal bowel ischemia.

Recurrent mucosal prolapse after a ventral rectopexy can be ameliorated with a Delorme rectal mucosal resection. If the prolapse is too large to be addressed with a Delorme, the recurrence could be addressed by reattachment of the mesh to the sacrum or reinforcement of the existing mesh. In some situations a suture rectopexy or more extensive rectal dissection and resection/rectopexy may be required. We would not advise trying to excise the mesh that is attached to the rectal wall as this could lead to perforation (Table 60-1).

Combined Vaginal and Rectal Prolapse Procedures

Pelvic floor weakness results in multi-compartment dysfunction. Combined anterior/middle and posterior compartment prolapses and resultant bowel symptoms are common in patients with pelvic floor weakness and prolapse [61]. Failure to appreciate multi-compartment pelvic floor disorders along with a lack of collaboration between surgical specialties has resulted in 10–25 % of women with urogynecologic disorders requiring a second surgery for their colorectal dysfunction

TABLE 60-1. Surgical options for treatment of recurrent rectal prolapse based on the initial procedure

Initial procedure	Redo procedure options	Avoid
Resection rectopexy	1. Repeat resection rectopexy (in setting of constipation) 2. Ventral rectopexy 3. Delorme—patients with mucosal prolapse or limited full-thickness prolapse	Altemeier (perineal proctosigmoidectomy)
Rectopexy	1. Redo rectopexy 2. Resection/rectopexy 3. Ventral rectopexy 4. Altemeier (perineal proctosigmoidectomy) 5. Delorme	
Ventral rectopexy	1. Redo ventral rectopexy (in setting of technical failure) 2. Resection/rectopexy 3. Rectopexy 4. Delorme	Altemeier (perineal proctosigmoidectomy)
Delorme	1. Rectopexy—ventral or sutured 2. Resection/rectopexy 3. Redo Delorme 4. Altemeier (perineal proctosigmoidectomy)	
Altemeier (perineal proctosigmoidectomy)	1. Ventral rectopexy 2. Rectopexy	Resection/rectopexy

[1]. Some units have reported on combined simultaneous treatment of both rectal and genital prolapse [62]. Abdominal sacrocolpopexy with rectopexy for combined middle and posterior compartment prolapse is a safe procedure with a low risk of recurrence and improves bowel function and quality of life [63, 64]. While there could be concern about a bowel resection and mesh placement during the same procedure, one retrospective case series reported no increased risk of complications when a synthetic mesh was utilized for an abdominal sacrocolpopexy was performed in conjunction with a sigmoid resection and anastomosis [65]. A complete history which investigates pelvic floor health, a comprehensive vaginal and rectal examination, and selective advanced testing are crucial to identify and offer optimal treatment when weakness exists in multiple pelvic floor compartments.

Solitary Rectal Ulcer Syndrome

Solitary rectal ulcer syndrome (SRUS) is a disorder of defecation which is often associated with rectal prolapse or internal intussusception. Patients afflicted with this problem present with rectal bleeding, difficult defecation, tenesmus, mucus discharge, and anal pain of unknown etiology. On occasion, the rectal bleeding can be severe enough to require transfusion. On examination there is typically thickened mucosa located anteriorly (Figure 60-15) with ulcers seen in about 23 % of cases and polyps or masses in 74 % [66]. If present, rectal ulcers can be single or multiple shallow ulcers with hyperemic margins and a pale base. Commonly these ulcers occur on the anterior wall just above the sphincter complex but may occur anywhere in the rectal ampulla. This uncommon condition may be misdiagnosed as a polyp or even a cancer because of the alarming appearance seen in some with SRUS. Colitis cystica profunda (CCP) is felt to be a related disorder that produces similar symptoms to SRUS and may have a similar gross appearance. Both are felt to have some element of trauma associated etiology which may be due to intussusception traumatizing the wall as it invaginates downward. This may lead to ischemia which has been speculated to be part of the etiology. Characteristically on biopsy SRUS has fibrotic obliteration of the lamina propria. There can be a thickened muscularis mucosa. Biopsies of CCP demonstrate mucous cysts lined by columnar epithelium deep in the muscularis mucosa. It is conceivable that with trauma from a cephalad prolapsing area of rectum, mucosa could be thrust beneath the surface to produce these mucous cysts. A correct diagnosis of both these conditions is made with accurate pathologic evaluation.

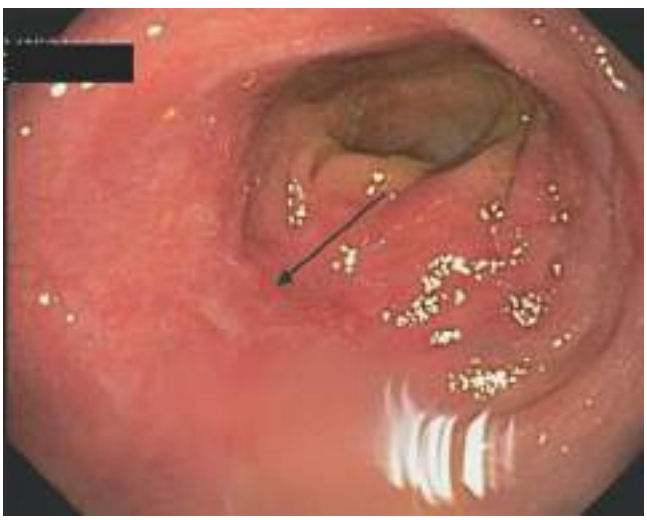

FIGURE 60-15. Solitary rectal ulcer. Inflammation and thickening of the anterior wall of the rectum with early stages of an ulcer.

The workup for both SRUS and CCP includes an in-depth history assessing for straining to defecate, rectal bleeding, and other anal symptoms. Endoscopy with biopsy is essential to make an accurate diagnosis. Treatment of these conditions is challenging and defecography and anal manometry may be useful to guide choices. Interestingly in SRUS, a thickened internal anal sphincter has been reported as a typical finding on endoanal ultrasonography [67].

Treatment is usually directed towards normalizing the defecatory disorder with diet modifications and bowel retraining utilizing pelvic floor physical therapy [68, 69]. Argon plasma coagulation has also been described as a potential treatment modality [70]. In our practice, transanal excision of the lesion is typically not favored as recurrence is particularly high. The Delorme procedure or a proctectomy with a coloanal anastomosis is another option, but again recurrence is high. One specific group of patients that may benefit from surgical intervention are those that have either internal intussusception demonstrated on defecography or overt rectal prolapse. These patients may be offered some form of rectopexy—either suture, mesh, or ventral rectopexy [71–73]. In our experience, anterior dissection may be particularly more challenging is missing the challenging than when dissecting for garden variety rectal prolapse not associated with SRUS or CCP, due to dense anterior fibrosis and inflammation.

In summary, this is a rare but frustrating condition most likely caused by some element of prolapse of the rectum. Conservative treatment is usually the favored approach as surgical intervention that utilizes excision of the lesion seems to have a high recurrence rate.

Conclusion

Surgery should always be considered the treatment of choice for rectal prolapse. The approach (perineal or abdominal) is debatable; however, current trends seem to favor abdominal procedures for all age groups unless the patient is extremely infirmed. Realistic expectations regarding functional outcomes should be reviewed prior to surgical intervention. Fecal incontinence may improve after surgery but full fecal

continence may not be attained. Additional therapy for fecal incontinence may be indicated after surgical healing. Constipation may improve, persist, or worsen after rectal prolapse surgery. Additionally some patients report new problems with constipation after rectal prolapse surgery. Treatment of pelvic floor pathologies should not be compartmentalized. Prolapse or dysfunction of other pelvic floor organs should actively be looked for and surgically addressed in conjunction with appropriate pelvic floor surgeons.

Evaluation and Treatment of FI

Ian M. Paquette and Liliana Bordeianou

Key Concepts

- A thorough history and physical examination, followed by a trial of conservative measures is the first step to managing FI.
- Preoperative physiology testing may aid in selection of treatment modalities, but does not predict the outcome of treatment.
- Overlapping sphincteroplasty is a successful treatment in patients with complete sphincter disruption.
- Sacral neuromodulation has been demonstrated to be successful in patients with and without a sphincter defect.
- Biomaterial injection and radiofrequency energy delivery appear to provide modest benefit in incontinence scores, but further data is needed to substantiate this.
- The artificial bowel sphincter has demonstrated excellent improvement in incontinence scores, but complications and need for revisions prevent it from being a first line treatment for FI.

Introduction

Fecal incontinence (FI) is defined as the uncontrolled passage of feces or gas [1–4]. It is estimated that at least 18 million adults in the USA suffer from FI, while these figures appear to approach 50 % in institutionalized patients and this is frequently cited as the precipitating reason to transfer to nursing homes [5–7]. Recently, Brown et al. used Neilson data to conduct a survey of >6000 women in the USA older than 45 years with an impressive 86 % response rate [8]. Their results indicated that nearly 20 % of respondents experience episodes of FI at least once per year, while 9.5 % experienced FI at least once per month [8]. This study also demonstrated that patients prefer the term "accidental bowel leakage" rather than fecal incontinence. Prevalence estimates are thought to be conservative since a recent survey indicated that only 28 % of these patients have ever discussed their symptoms with a physician [9]. Of those who did seek care, over 75 % sought care with an internist or family physician, while only 7 % discussed their concerns with a colorectal surgeon [9].

Normal continence is a complex interaction between sensory function, sphincter muscle function, pelvic floor muscle coordination, rectal compliance, and consistency of stool. Failure of any of these mechanisms can lead to impaired continence. The most common historical factor is often prior obstetric trauma in a female [10]. Sphincter disruption from obstetric injury is observed clinically in approximately 10 % of all vaginal deliveries, but occult sphincter damage may be identified in up to 21–35 % of vaginal deliveries. Additionally, other possible causes include sphincter damage from prior anorectal surgery such as fistulotomy, lateral internal sphincterotomy, denervation of the pelvic floor from pudendal nerve injury during childbirth, chronic rectal prolapse, neurologic conditions (spina bifida, or myelomeningocele), or a noncompliant rectum from inflammatory bowel disease, or radiation proctitis [4, 10]. A careful history can be helpful in delineating these precipitating factors.

Focused physical examination includes inspection of the perineal body to look for thinning, or evidence of a prior fourth degree laceration, an assessment of resting sphincter tone and squeeze augmentation, use of accessory muscles, and to rule out other conditions, such as rectal prolapse, anal fistula, or active proctitis. If a rectal prolapse is suspected, straining on the commode may be required to reproduce it. Proctoscopy can rule out the presence of neoplasm, or active proctitis as well.

Assessment Instruments

It is important to categorize the baseline severity of FI and to track this over time in order to monitor response to either conservative treatment or surgical therapy. The simplest method is a 2-week bowel diary, however a number of grading instruments are commonly used such as the Cleveland Clinic Florida (CCF) Incontinence Score [11], St. Marks Incontinence Score (SMIS) [12], or the Fecal Incontinence Severity Index (FISI) [13]. Other scales, such as the Fecal Incontinence Quality of Life (FIQL) [14] scale, are more reliable measures of quality of life, however, they are cumbersome to use and may be more beneficial in the setting of a research study. There is also emerging evidence that some of the current scoring systems may underestimate response to surgical treatment [15], while very few QOL scales demonstrate internal consistency or predictive validity [16], highlighting the need to develop better validated scales in the future. While we do not endorse one particular system, we do suggest tracking progress with objective measures over time.

Management

The management of fecal incontinence should always begin with attempting conservative measures. Conservative measures can take the form of medical management or lifestyle modification, and in some cases, will include an attempt at biofeedback/physical therapy retraining. Though no one regimen is ideal for every patient, we believe that all patients should at least fail a reasonable attempt at conservative measures prior to proceeding to more aggressive treatment options.

Medications and Lifestyle Modifications

After detailed questioning and review of a bowel diary, the first step is to attempt a medical regimen to control symptoms. If aggravating factors such as lactose, caffeine, or artificial sweeteners appear linked to symptoms, they should be discontinued. Optimizing stool bulk with a fiber supplement is often the easiest step to begin with. If a patient still has loose stools, antidiarrheal medications such as loperamide or diphenoxylate-atropine may be used to slow intestinal motility. A recent Cochrane review examined 16 trials of medical management of FI including 558 participants [17]. The majority of these trials examined FI in the setting of diarrhea and thus, examined the effects of antimotility agents on FI symptoms. The review concluded that most of the studies were small with limited follow-up and were more focused on treating diarrhea than FI [17]. Though the evidence does not conclude that any one regimen is more effective than another, few would argue the merits of a trial of medical measures prior to pursuing more advanced treatment options. In addition to oral medications, select patients experience benefit from scheduled enemas to attempt to control the timing of bowel movements to more socially appropriate times [18].

Biofeedback

Pelvic floor rehabilitation, or biofeedback, may be used in conjunction with medical management. An ideal candidate may be a patient who has some voluntary sphincter contraction rather than extensive or exclusive use of accessory muscles such as the gluteus muscles on examination when asked to squeeze. The literature on this topic is inconsistent with regard to study design and patient follow-up, making it difficult to determine the exact benefit of this modality. Though the designs of the studies vary, studies indicate at least some improvement in 64–89 % of patients [19–22]. However, a Cochrane review in 2006 concluded that no study reported any major difference between the results of biofeedback or any other form of conservative management [23].

Preoperative Testing

While some authors would suggest testing of patients during the first consultation, others tend to reserve testing for patients who may require surgical treatment. Testing most often includes anorectal manometry, ultrasound, and pudendal nerve testing.

Anorectal Physiology Testing

Anorectal physiology testing may be used in the evaluation of patients with FI. Results include resting and squeeze pressures, sphincter length, rectal compliance, and measurement of the rectoanal inhibitory reflex [24, 25]. Interpretation of the results of these tests is dependent upon the equipment used for measurement, and thus, each institution may have different baseline ranges for normal values. Though there is evidence that physiology testing results do not correlate with pre- and post-operative incontinence scores in patients undergoing sphincter repair [26], some authors suggest that results of these tests may help to guide treatment decisions [25, 26]. The ultimate goal would be to correlate the results of testing modalities to objectively select the best treatment option for an individual patient. However, further studies will be needed to fill this important gap in our current knowledge.

A point of further controversy is the value of pudendal nerve terminal motor latency (PNTML) testing. There is evidence that the pudendal nerves may be injured, most commonly in association with vaginal childbirth [27]. However, there is controversy as to whether PNTML testing is a useful adjunct in choosing a treatment algorithm. There appears to be no association of PNTML testing results with

response to sacral neuromodulation [28] and though some studies suggest a decreased efficacy of sphincter repair in the setting of pudendal neuropathy [29, 30], others have failed to corroborate this finding [31, 32].

Ultrasound

Ultrasound is a useful technique to document the presence of an internal or external sphincter injury. Thus, it may be an important adjunct to the workup of patients with a prior history of vaginal childbirth, or prior anorectal surgery. Ultrasound has been demonstrated to correlate with anal resting pressures, but does not correlate directly with objective incontinence scores such as the FISI [33]. Though there is a degree of inter-observer variability in diagnostic accuracy of endoanal ultrasound, the technique appears more reliable than transvaginal or transperineal ultrasound in detecting sphincter defects [34]. Whether or not to use ultrasound testing depends upon the treatment that is planned. While the presence of an ultrasound defined sphincter defect does not correlate with patient outcomes using sacral neuromodulation [28, 35], and studies of biomaterial injection have excluded patients with a sphincter defect [36, 37], preoperative ultrasound is a critical element in the planning of a sphincteroplasty operation [38].

Surgical Techniques

General Considerations

When conservative measures fail, patients should be carefully evaluated for appropriate testing such as anorectal physiology testing or endoanal ultrasound. When all of the above tests are normal, a defecography may be considered. Patients found to have rectal prolapse or full thickness intra-anal intussusception on exam and/or defecography should be considered for a surgical treatment of their prolapse (see Chap. 60). Others should undergo a rational sequence of treatments balancing the severity of their symptoms against the morbidity and the expected success rates of various surgical interventions. While data comparing the success of different treatment modalities for FI is not robust, a rational algorithm on how to sequence these treatments can still be derived (see Figure 61-1).

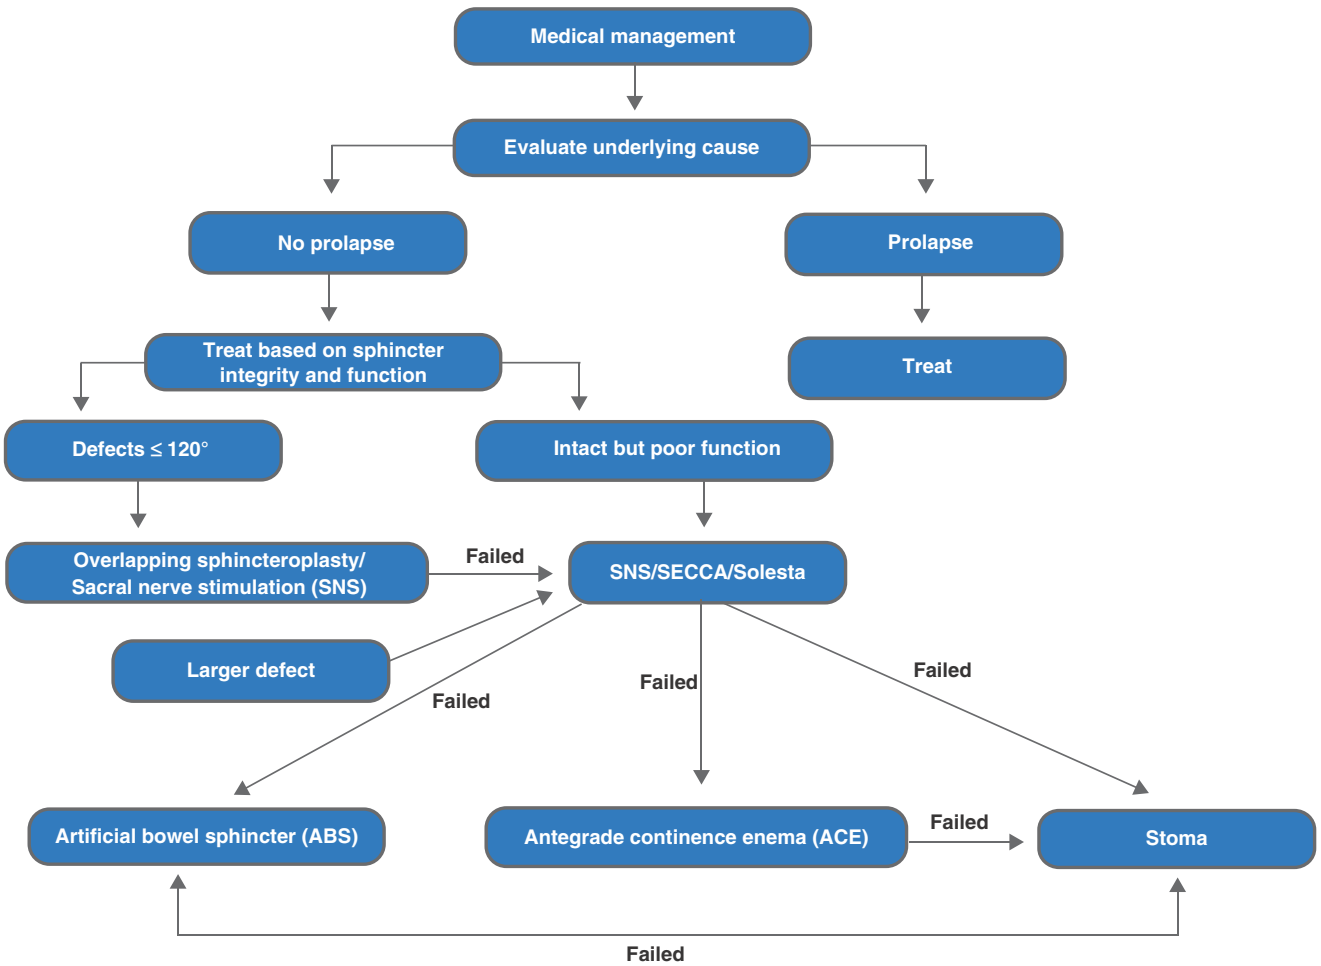

FIGURE 61-1. Step-wise algorithm aimed at managing patients presenting with fecal incontinence.

In the remainder of this chapter we will describe these treatments in further detail, limiting our discussion to the surgical approaches that are currently available in the USA.

Overlapping Sphincteroplasty

This procedure remains the gold standard for the treatment of fecal incontinence in young women with obstetric sphincter injury [39], which is usually confirmed by an anal ultrasound (Figure 61-2). It is also indicated in older women with severe FI and an external sphincter defect not larger than 120° on anal ultrasound. Though its efficacy in treating incontinence may decrease with increasing patient age and in the patients with coexisting pudendal neuropathy, both issues of age and relevance of pudendal neuropathy are still debated and decisions need to be made [40] on a case-by-case basis [30, 31]. Prior to offering this procedure, patients must be counseled regarding its efficacy in the short and long term. Patients should be advised that approximately 80 % of women can expect reasonable function (though not full continence) short term [41]. Patients should also understand that the efficacy of this repair deteriorates with time: by 10 years most women who undergo sphincteroplasty do become incontinent again [42–44]. There is some data suggesting that biofeedback after surgery may decrease or slow down the rate of this deterioration, but this study has not been reproduced [45].

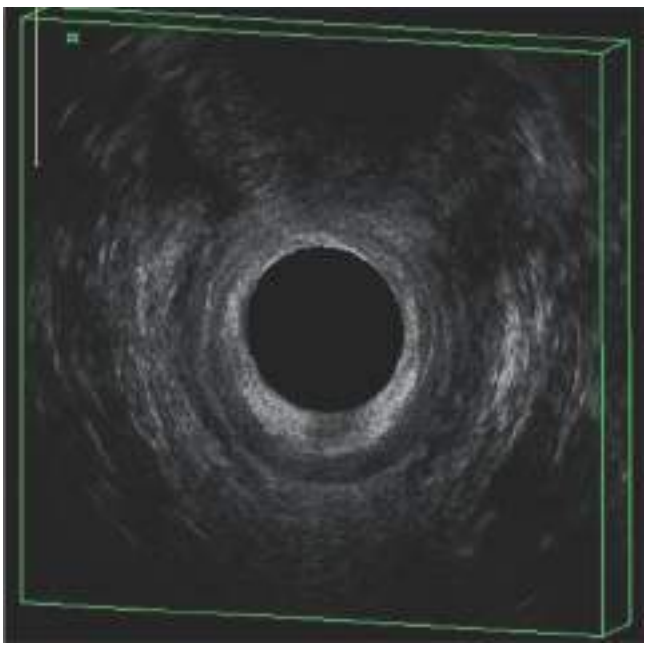

FIGURE 61-2. Three-dimensional ultrasound demonstrating the anterior sphincter defect. The internal sphincter appears hypoechoic (*dark*) and the external sphincter appears hyperechoic (*white*), with the incomplete ring anteriorly (*top*), indicating the sphincter defect.

Sphincteroplasty is performed following a full bowel preparation, under general or regional anesthesia, in either lithotomy or the prone jack-knife position (Video 61.1). A curvilinear incision is made on the perineal body, with the goal of separating the anus from the vagina (Figure 61-3). The injured external sphincter and the perineal body scar due to this injury is carefully separated from the skin, the ischiorectal fat, the anal mucosa/internal anal sphincter complex, and the vagina (Figure 61-4). In the patients with a coexisting internal anal sphincter injury the dissection around the anus is carried in the submucosal plane. Care must be taken not to buttonhole the vagina or the anus during this dissection. Separation of internal and external sphincters and individual repairs can be considered if the two are clearly identified. Otherwise the repair should be made en bloc. To repair the injury, the anterior scar is divided (Figure 61-5). Mobilization of the scar-sphincter complex should continue circumferentially around the anus, with the goal of ultimately overlapping the scar anteriorly [46]. Care should be taken not to extend the dissection beyond 180°, to avoid injury to the pudendal nerves that are coming in laterally to innervate the anus

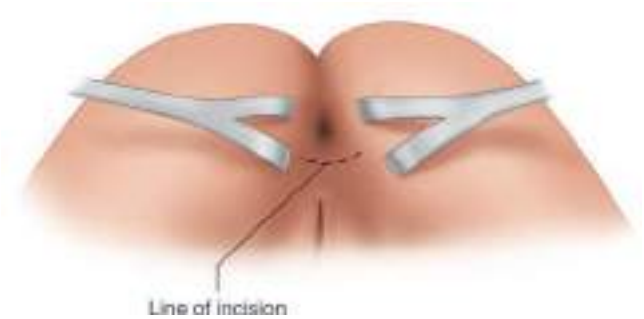

FIGURE 61-3. Overlapping sphincteroplasty: a curvilinear incision is made on the perineal body.

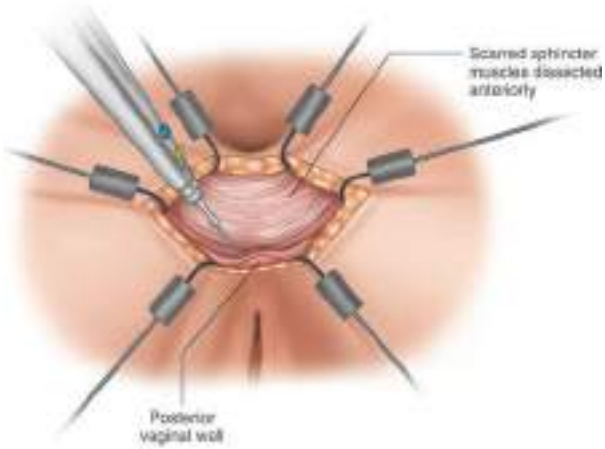

FIGURE 61-4. Overlapping sphincteroplasty: scar with attached retracted sphincter muscles are dissected anteriorly.

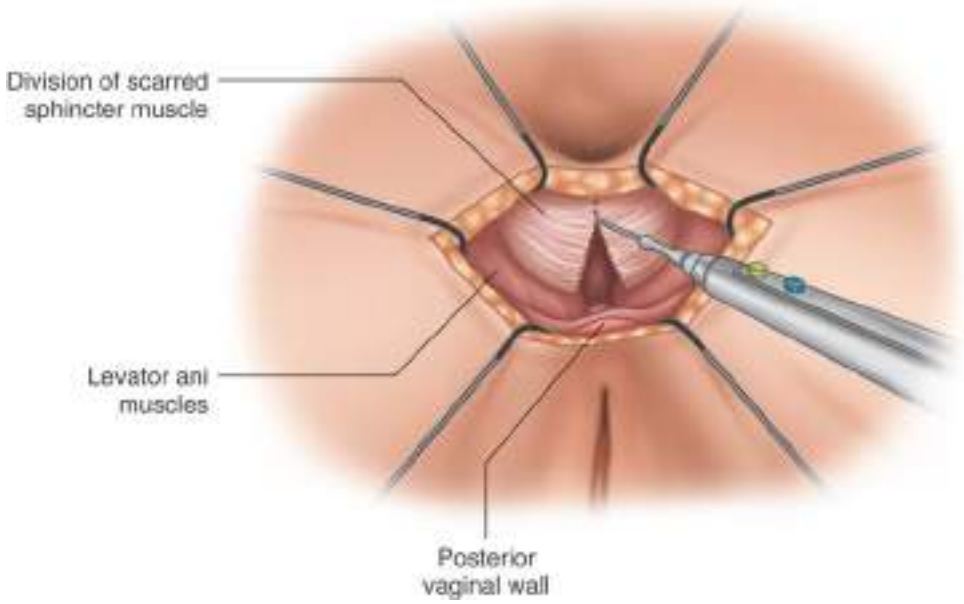

FIGURE 61-5. Overlapping sphincteroplasty: anterior scan/sphincter complex is divided.

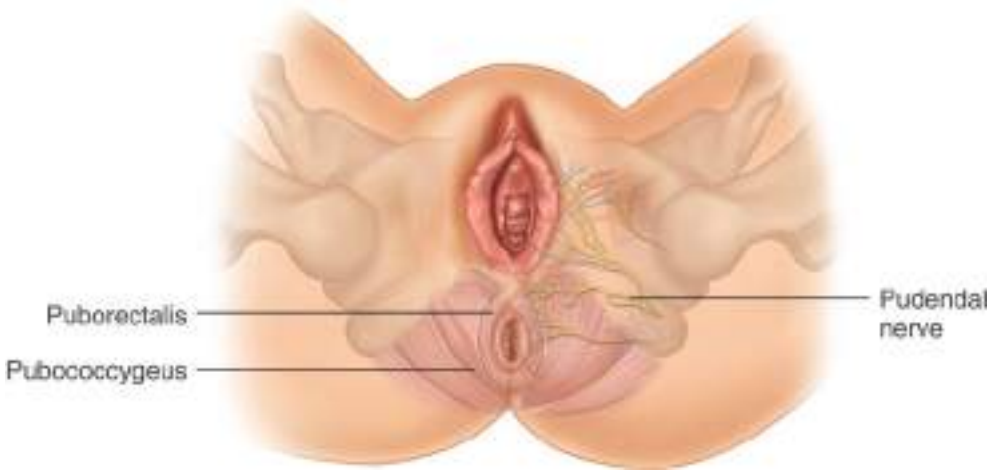

FIGURE 61-6. Overlapping sphincteroplasty: surgeons must be aware of the course of the pudendal nerve and aim to minimize pudendal nerve injuries at the sphincter of sphincter repair by avoiding dissection beyond more than 180-degrees anteriorly.

(Figure 61-6). Once dissection is completed, an anterior levatorplasty can be performed with absorbable sutures (Figure 61-7a). Following this, the sphincter-scar complex is overlapped and sutured in place with two or three non-absorbable (or very slowly absorbable) vertical mattress sutures able to withstand and hold together despite a predictable low level wound sepsis (Figure 61-7b) [47]. (After wound irrigation, the wound is closed as a "T" to decrease tension on skin, and the center of the incision is left open to facilitate drainage. A Penrose drain can be left in the opening. As with any perineal wound, the healing following this repair is slow and partial wound separation is common).

In patients with recurrent fecal incontinence after a repair, a repeat ultrasound can be considered to assess success of repair. Some argue that reintervention with a repeat repair can be offered [48], though data regarding success following repeat sphincteroplasty is slim and other options, such as sacral neuromodulation, may be more appropriate.

Sacral Neuromodulation

Sacral neuromodulation (SNM) is an FDA approved treatment for both fecal incontinence and overactive bladder. It works by modulating nerve impulses to the S3 nerve root.

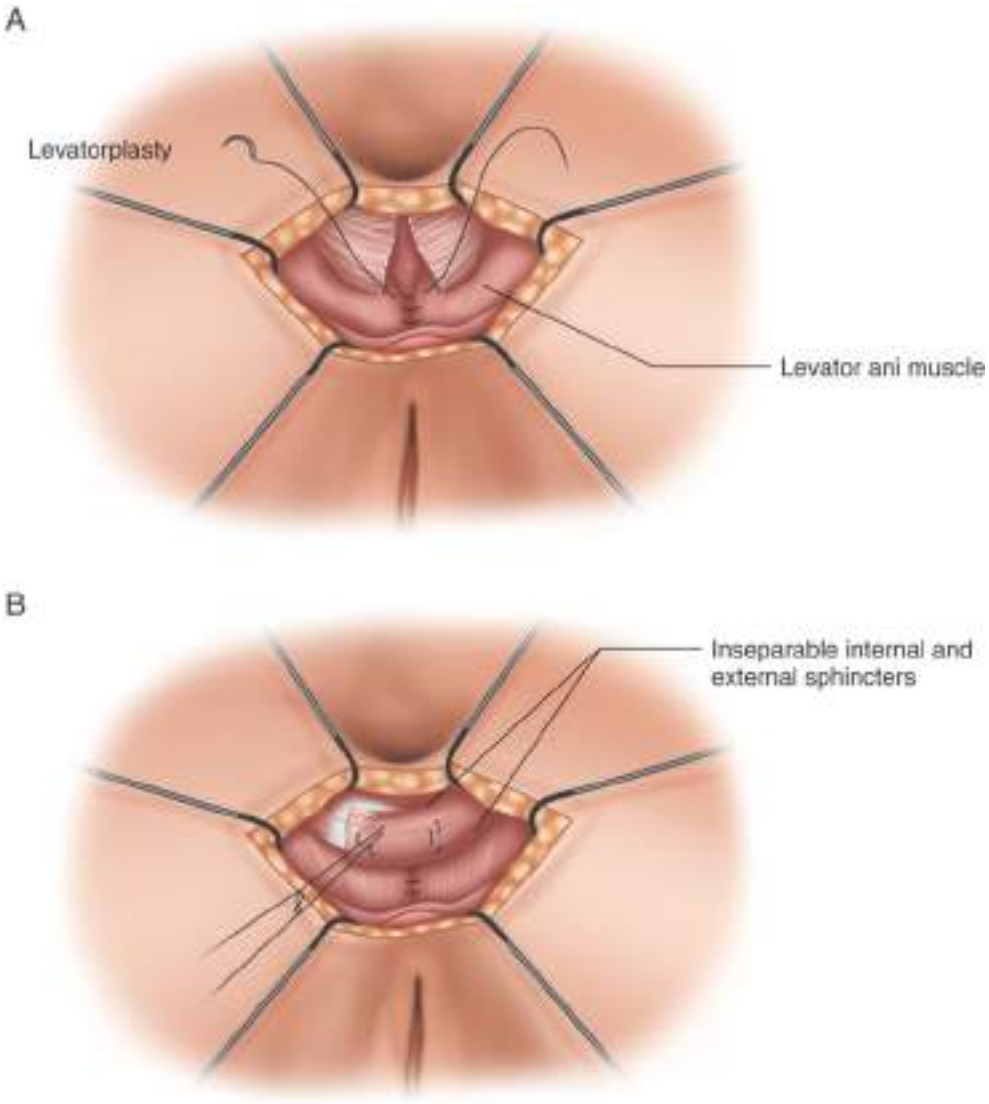

FIGURE 61-7. Overlapping sphincteroplasty: (**a**) levatorplasty is performed when appropriate, (**b**) scar-sphincter complex is overlapped to allow the ends of the retracted muscles to be realigned as close as possible to each other.

SNM appears to even be effective in patients with a disrupted sphincter complex on ultrasound, as studies have shown excellent efficacy in defects up to 120° [35, 49]. It also does not seem to work by directly augmenting sphincter function as measured by anorectal manometry [50]. It has been postulated that sacral neuromodulation promotes antegrade neuromodulation of the cerebral cortex—as seen in elegant brain MRI studies of patients with and without SNM [51].

Similarly, SNM may alter colorectal transport and motility [52]. Even more intriguing, other forms of neuromodulation such as percutaneous tibial nerve stimulation (PTNS) via a needle or a gel pad to the medial malleolus may also be effective in the treatment of fecal incontinence. Though as of now only SNM is FDA approved in the USA for the treatment of fecal incontinence, studies are being conducted worldwide to evaluate other methods of stimulation such as PTNS.

Though the full mechanism of action leading to an improvement in fecal continence following neuromodulation with SNM is still poorly understood, the beneficial effect of this treatment on fecal continence has been documented and replicated in several well-conducted studies both in the USA and all over the world [49]. SNM has been shown to result in a reduction in the severity and the frequency of fecal incontinence episodes, with 69–83 % of patients experiencing more than a 50 % improvement in weekly episodes of incontinence both short and long term [53–55]. Furthermore, 35–40 % may achieve full continence [49].

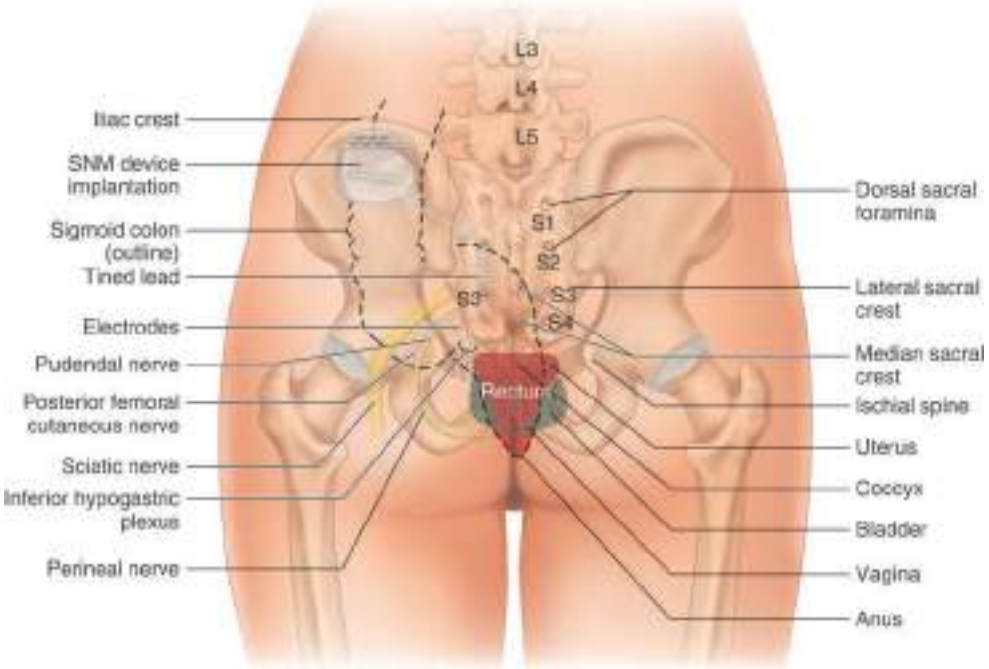

FIGURE 61-8. Sacral nerve modulation: the lead is placed through the S3 foramen and the implantable pulse generator is placed below the iliac crest and lateral to the sacrum.

Sacral neuromodulation is performed in two stages (Video 61.2). Fluoroscopy is used to identify the S3 sacral foramen, which is then accessed percutaneously by a needle. Once the needle location is confirmed radiographically, proximity of the S3 sacral nerve root is also assessed by gently stimulating the needle with a low electrical voltage. If the needle is appropriately placed, the surgeon is expected to observe a slight downward flexion of the patient's toes on the ipsilateral side as the needle, and the "bellows reflex"—a slight tightening of the gluteal and anal muscles. Once the needle is appropriately placed, a tined wire is passed through the needle and deployed in the same location (Figure 61-8). The wire is then tunneled under the skin to prevent infection and is connected to an external lead in its new location. The external lead is then tunneled one more time to yet another skin site prior to being connected to an external neurostimulator, which is then used to provide low voltage stimulation to the S3 root for a 1–2 weeks efficacy trial. Up to 90 % of patients report at least a 50 % reduction in fecal incontinence episodes and are then offered a second surgery, which involves the implantation of a more permanent hidden subcutaneous neurostimulator. This second procedure is again performed under local anesthesia, with mild sedation. The pocket hiding the coupling of the tined lead to the external neurostimulator wires is reopened. The external wires are discarded and a permanent neurostimulator is connected to the tined lead.

The first stage can also be done by placing a temporary wire rather than the tined lead. This is termed percutaneous nerve evaluation (PNE). In this procedure, the patient is placed in the prone position in the office. After a sterile prep and drape, a distance of 9 cm is measured cephalad from the tip of the coccyx and marked. The initial puncture sites are 2 cm lateral to this point. After instillation of local anesthetic, a finder needle is passed through the S3 foramen. When the patient is awake, it is not possible to turn the amplitude high enough to elicit a bellows response. Instead, the surgeon relies on sensory response to test stimulation. An S3 response is confirmed by sensation in the rectum, perineum, or vagina. Bilateral non-tined temporary leads are then placed. The patient then proceeds to keep a diary at home and the temporary leads are removed in the office in 1 week. If the test has been successful, the stage 2 procedure involves placement of the entire system in one setting. The benefit for this approach is to avoid one trip to the operating room, however, it is best suited for patients with daily incontinence, or more severe symptoms because the test period is only 1 week. This procedure may be performed with or without fluoroscopic guidance.

Despite the two-step approach currently used to place SNM, the procedures are well tolerated, and the infection rate is about 11 % [56, 57]. Long-term, the main drawback of the treatment is the need for revisions and replacements of the neurostimulator due to lead migration, infections or loss of battery power [49]. In addition, at this point the device is contraindicated in the patients needing body MRIs for other conditions (though MRI of the head and neck are approved).

Sphincter Augmentation Procedures

Several sphincter augmentation procedures have emerged as an alternative to sphincter repair, with varying success rates and complication profiles. These treatments include biomaterial injection and radiofrequency energy delivery. It is important to note that radiofrequency energy delivery is contraindicated if the patient has previously had a biomaterial injection.

Radiofrequency Energy Delivery

Radiofrequency energy delivery is performed under mild sedation, either in the operating room or the endoscopy suite. The treatment is administered via a patented anoscope (SECCA®). This anoscope allows insertion of four nickel-titanium curved needles at 5 mm intervals, for four separate levels from distal to proximal within the anal canal. These needles contain electrodes that administer radiofrequency energy to raise the temperature of the internal sphincter to 85°. Each electrode within the needle has thermocouples, measuring tissue and mucosal temperatures during energy delivery. In addition, the device assures that the mucosa is being cooled by chilled water to the base of each needle. Studies looking at the efficacy of this technique reported modest improvements in continence scores short and long term, though very few patients reported full resolution of symptoms [58–62]. Many studies reveal decrease of CCF score from a baseline of approximately 14 to a postoperative score around 10 [63]. Furthermore, long-term follow-up is very limited, though it appears that the short-term results are sustained in the long term [63].

The procedure is performed under moderate sedation in the jack-knife prone position. The dentate line is clearly identified. The needles are deployed in three or four quadrants at four levels within the upper anal canal, being careful about the anterior quadrant in females to avoid needle penetration into the vagina (Figure 61-9a). Once deployed, radiofrequency energy

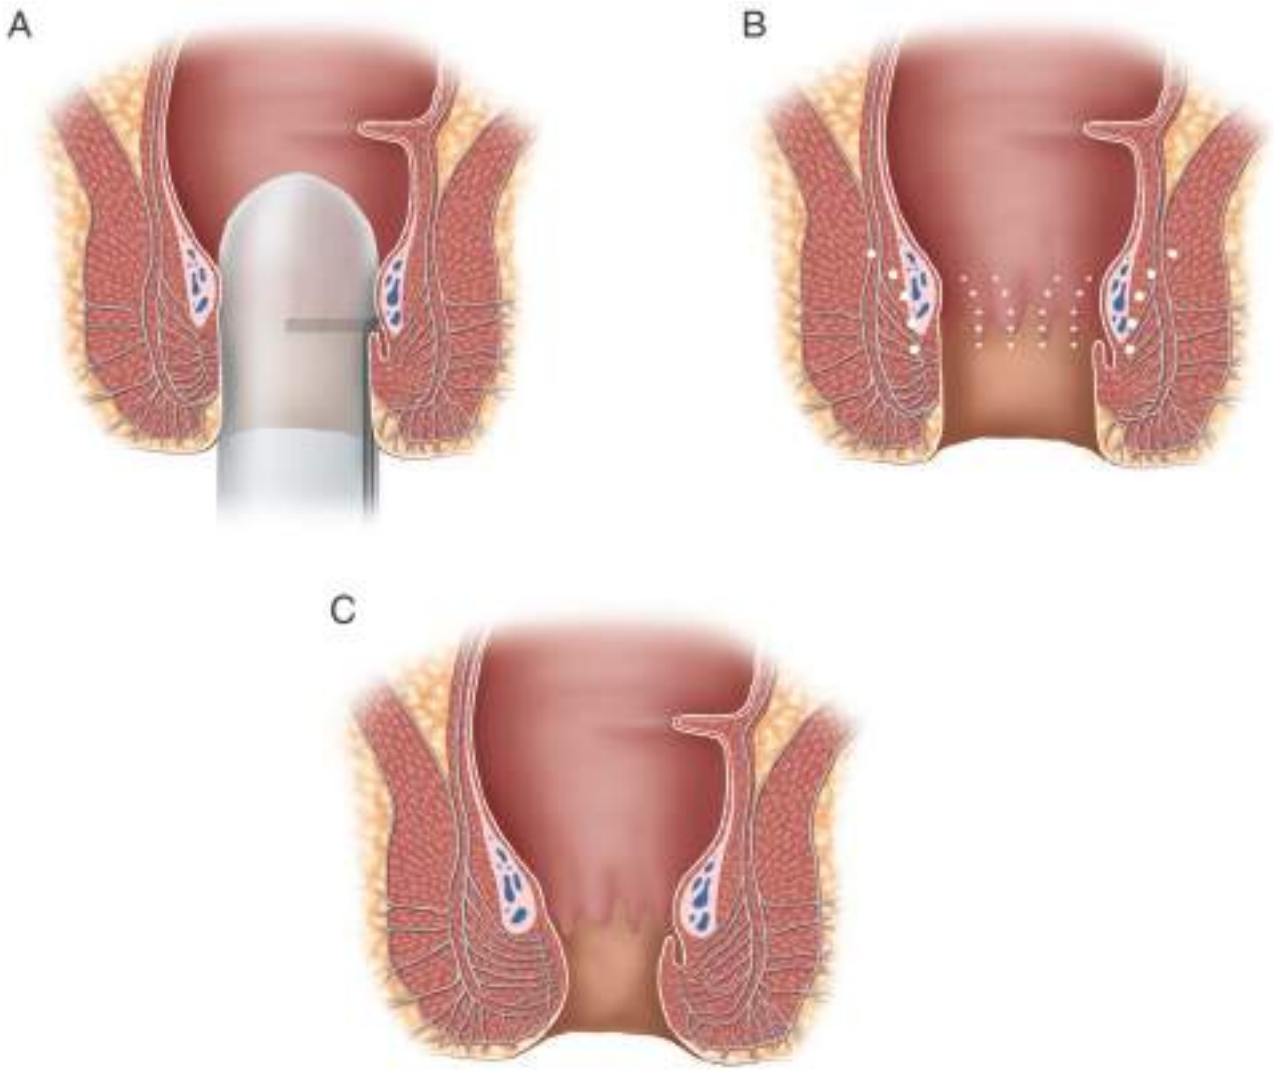

FIGURE 61-9. Secca procedure. (**a**) Anoscope wires are deployed in 3–4 quadrants circumferentially and are meant to enter the internal anal sphincter. (**b**) Radiofrequency treatment is performed at four levels within anal canal, both above and below the dentate line. (**c**) Procedure leads to internal anal sphincter thickening.

is administered to the internal anal sphincter where the device needles have penetrated the tissue. It is thought that the treatment results in a thickening of the internal sphincter complex via an increase in the thickness of the muscularis propria, a change in collagen cell composition and a decrease in the interstitial cells of Cajal [64] (Figure 61-9b, c). Common side effects include pain, infection, excessive scarring of the anus and, rarely, rectovaginal fistula formation [63].

Biomaterial Injection

Currently, NASHA Dx (Solesta®) is the only injectable agent approved by the FDA for the treatment of fecal incontinence in the USA. This substance is a stable, non-degrading dextranomer stabilized in hyaluronic acid. Its effect on the patients with FI was studied in a randomized controlled trial comparing Solesta to a sham injection. The trial showed that injection of Solesta® in the submucosal space in the upper anal canal led to a 50 % reduction in the severity of fecal incontinence in 52 % of patients as compared to the 30 % rate observed in the patients receiving placebo [37]. Most studies have offered patients a repeat injection and at least one study identified a higher degree of improvement in patients receiving a repeat injection [65].

Injections are performed with or without a local anesthetic, in a sterile fashion. The gel is injected between the mucosa and the internal sphincter, with or without ultrasound guidance (Figure 61-10). Care must be taken to place the gel above the dentate line. Complications are rare, though anal abscess and fistula can occur. The compound is contraindicated in patients with active inflammatory bowel disease, rectocele, previous pelvic radiation, full thickness rectal prolapse, and anorectal malformations [66]. Overall, Solesta injections are most effective for mild incontinence or seepage. Its role in the setting of a sphincter defect, when a second injection should be offered, and long-term efficacy need to be determined.

Sphincter Replacement Strategies

Most patients with persistent severe fecal incontinence despite all treatments listed above will benefit from a stoma or mini stoma alternatives described below. Few patients are considered for an artificial bowel sphincter. They must be motivated, without major medical comorbidities, and have sufficient healthy tissue surrounding their anal canal. A sufficient volume of healthy tissue surrounding the anus is

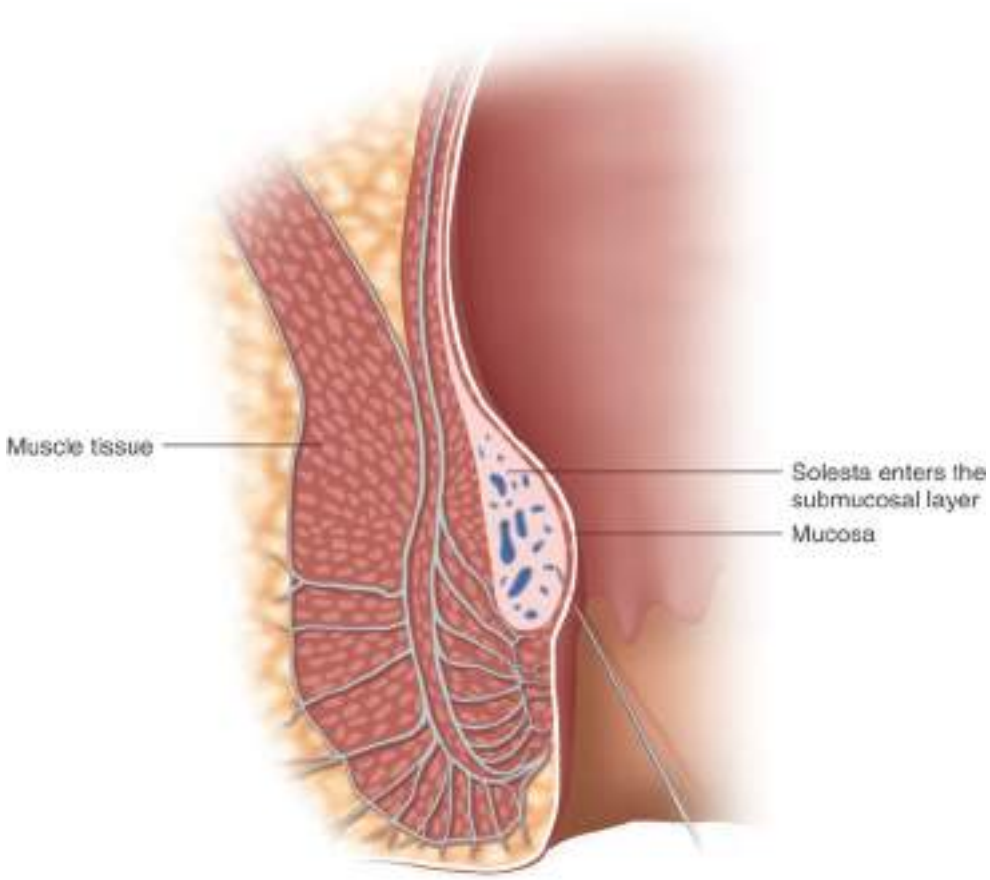

FIGURE 61-10. Biomaterial injection is performed by inserting the needle above the dentate line and into the submucosa.

necessary to provide implant coverage. The tissue also must also be healthy enough to allow wound healing without implant infection following placement. Thus, patients with a prior history of pelvic radiation, inflammatory bowel disease, diabetes, or immunosuppression are generally excluded. While the devices can be implanted under stoma coverage, most surgeons report reasonable outcomes without utilizing a stoma.

There are currently two artificial bowel sphincter devices, one of which (ABS) has been FDA approved for compassionate use for over 20 years. ABS is a fluid filled cuff that is placed around the anal sphincter through a perineal body incision or two incisions on either side of the anus. Thin plastic tubing is tunneled subcutaneously from the cuff to the scrotum (in the male) or the labia (in the female). This is connected to a pump that has a button that allows active deflation and passive re-inflation of the cuff. When the pump is compressed 8–10 times, this leads to the cuff deflating and fecal evacuation can occur (Figure 61-11). During deflation of the cuff by compressing the pump, fluid within the cuff is actively transferred through the pump into a storage balloon that is placed in the space of Retzius. The balloon is connected to the entire apparatus via another set of tunneled tubing. Then over the next 8–10 minutes the fluid is passively transferred back to the cuff via a one way valve in the pump. This in turn reinflates the cuff and closes the anus.

Since this device is a foreign body placed via an incision around the anus in a patient who is incontinent, it is not surprising that implantation of an ABS can be associated with major infections. Additionally, as many as 20 % of patients require revisions and removal of their device due to infection, erosion or device malfunction [67–69]. Ultimately only 50–80 % of patients have a remaining functional implant [67–72]. However, those who do keep their ABS in the long run report excellent fecal control of solid stool. Some retrospective series report normal continence in 65 % of patients and continence to solid stool in 98 %. In fact, some patients with new control of their fecal leakage may forget to open their devices on a regular basis and could develop fecal impaction [73, 74]. Even with regular device activation, new problems with rectal evacuation of stool and/or fecal impaction are commonly encountered in previously incontinent patients. These patients may respond to laxative or enema therapy but some ultimately have the device removed due to inability to satisfactorily moderate the evacuation difficulty. Long term all patients with an ABS remain at a high risk of requiring additional device revisions due to fluid leakage or delayed malfunction of the cuff itself, the tubing connecting the cuff to the manual control button, or the balloon reservoir in the space of Retzius. Yet another common cause for revisions is scar creation around the balloon in the space of Retzius. This in turn leads to poor anal cuff deflation and subsequent outlet obstruction [67–72]. Alternately, the scar can have calcifications which may puncture the balloon and also lead to device malfunction.

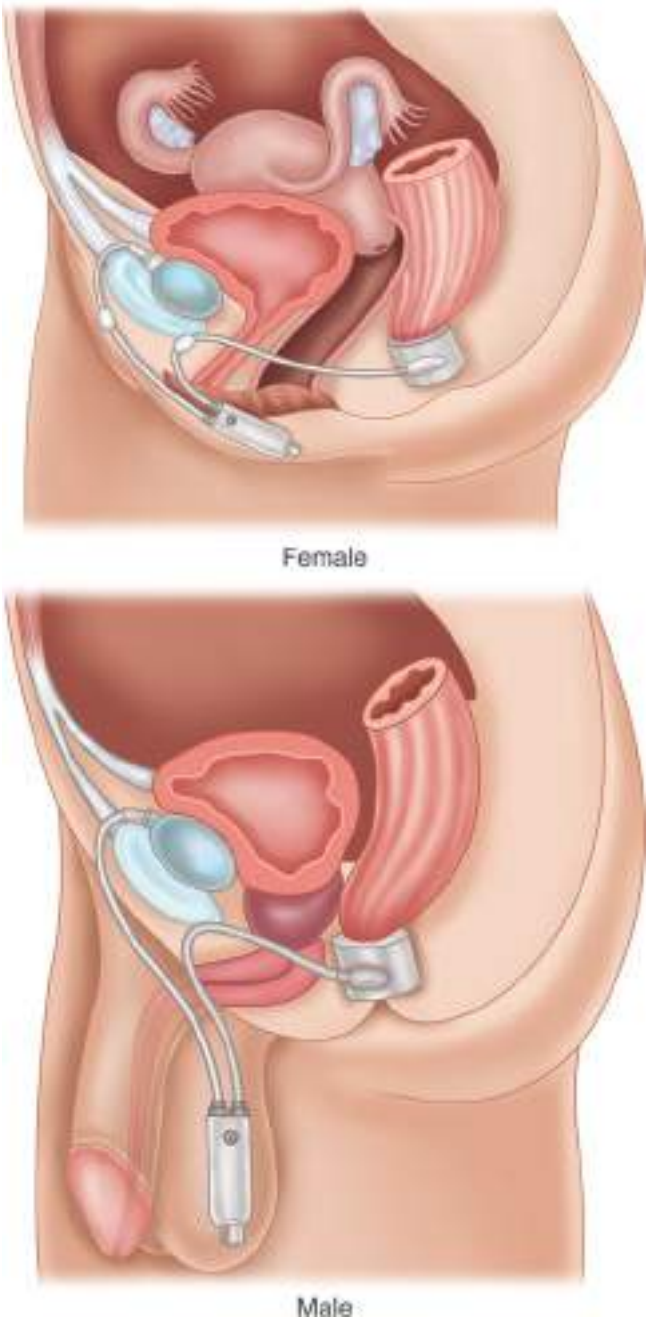

Figure 61-11. Artificial bowel sphincter placement in males and females. The cuff is placed to encircle the anus, while the balloon is located in the space of Retzius. The button is placed in the labia in females and in the scrotum in males.

An alternative device, the magnetic artificial sphincter (MAS), is currently under FDA review. The device contains small magnets on a flexible string. These magnets are placed on a string that surrounds the anal sphincter similar to the cuff of an ABS (Video 61.3). The device is carefully placed as high as possible around the anal sphincter, preferably just below the puborectalis muscle. The surgeon measures and then chooses the number of magnets needed to provide com-

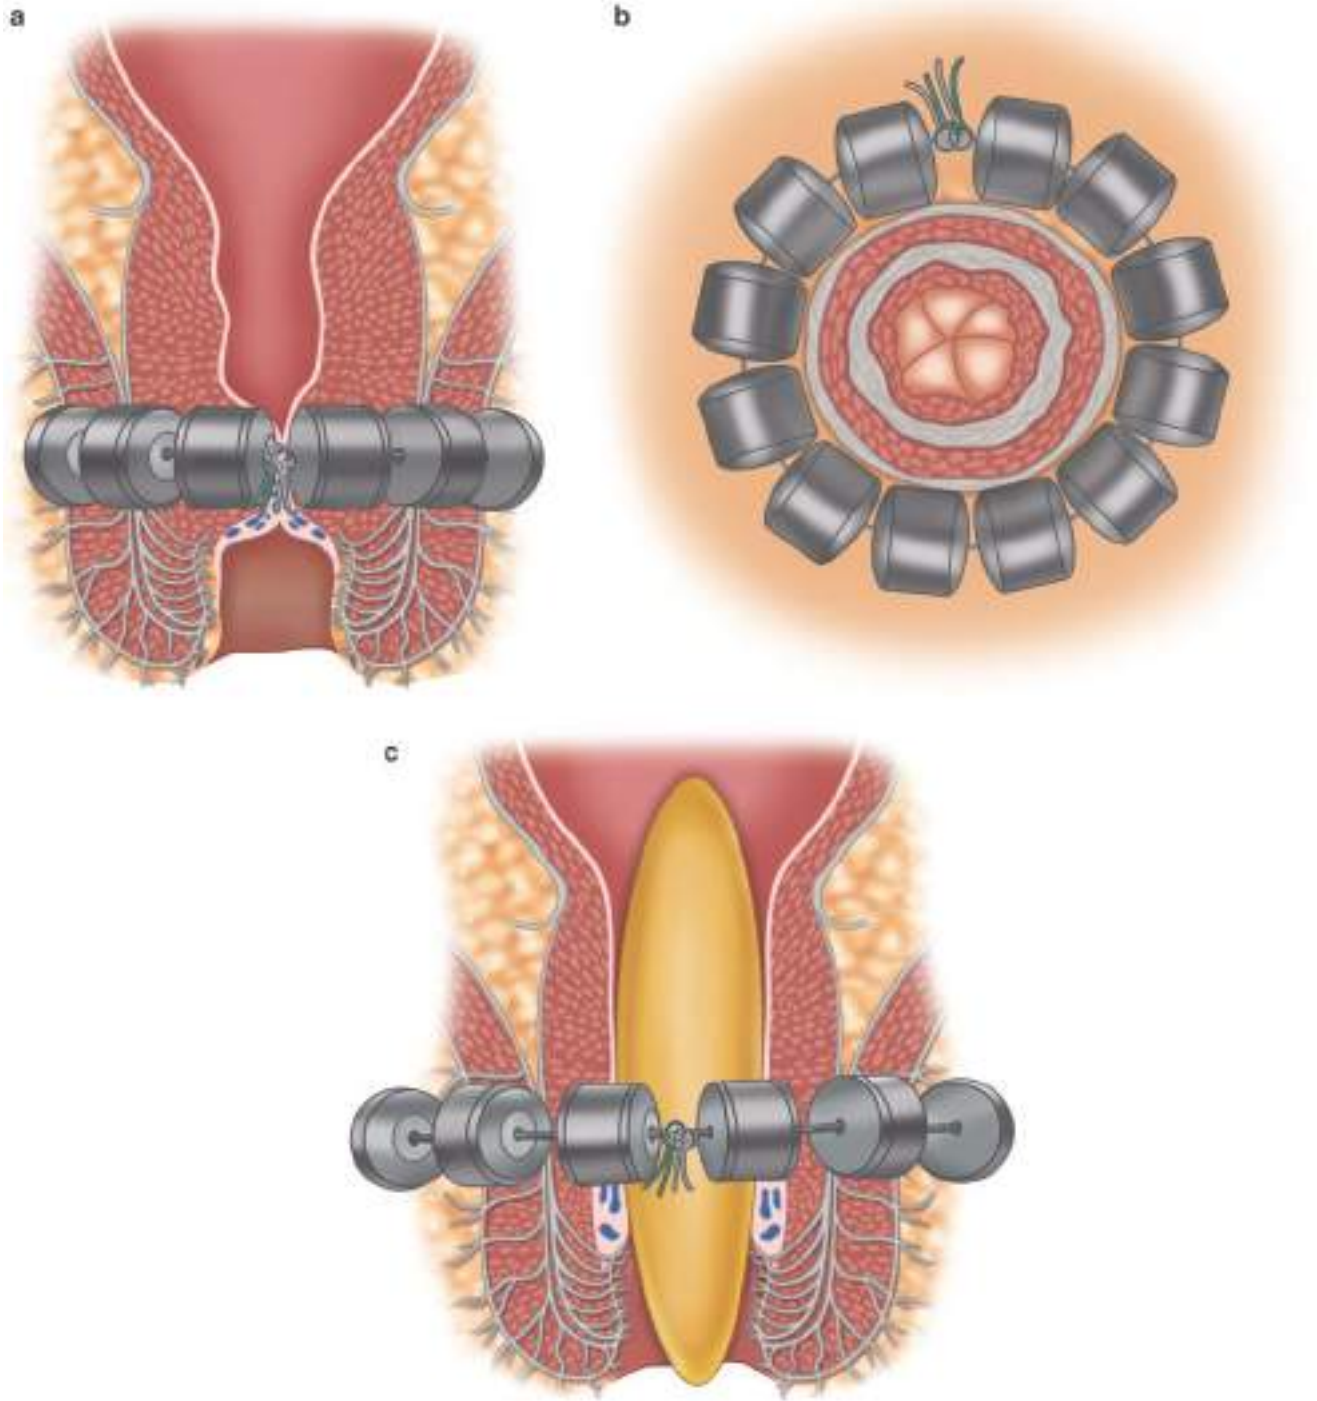

FIGURE 61-12. Magnetic anal sphincter. (**a**) In the resting state the magnets keep the anal canal closed. (**b**) Axial view to demonstrate placement of the magnetic sphincter outside the sphincter complex. (**c**) With bowel movements and Valsalva, the magnets expand to allow passage of stool.

plete occlusion of the anal canal when the magnets clump together (Figure 61-12a, b). During defecation, the magnets are forced apart by defecation and the device is allowed to expand in an "open position." Therefore, the string that contains these magnets has some redundancy to accommodate the fecal bolus and expand to the open position (Figure 61-12c). Thus, the natural position of the magnets leads to a closure of the anus which prevents anal leakage. Original studies describing MAS efficacy reported a promising improvement in patient continence as measured by a decrease in the Wexner Fecal Incontinence Severity Score and the Fecal Incontinence Quality of Life Scores [75, 76]. Complications at the time of

implantation appear comparable to those noted when placing the previously discussed fluid filled artificial bowel sphincter, with 29 % of patients reporting postoperative pain, temporary swelling and erythema in both gluteal regions after the implantation from low grade infections. Ultimately as many as 15 % require device explantation [75, 76]. A small randomized controlled study comparing initial 30 days complication rates and revision/explantation rates of MAS to ABS showed the two devices to be comparable in the short term, with comparable functional outcomes [77]. It is hoped, however, that this new device may require fewer long-term revisions following a successful implantation. While this is a reasonable supposition, long-term data on device function and device retention is still not available and a study reporting the satisfaction rates in the first 23 women in the world implanted with this device from 2008 to 2012 suggests the satisfaction rates may decrease over time [78]. As of this writing the company is in the process of obtaining FDA approval that allows this device to be implanted in patients who fail SNM therapy.

Stoma and Stoma Alternatives

Stoma creation remains a valid alternative for patients suffering from fecal incontinence. If all other treatments fail, patients receiving a well-constructed ostomy can expect an improved quality of life with a resumption of normal activities. When questioned, 84 % of patients undergoing ostomy creation to address fecal incontinence state that they would choose to have the stoma created again [79]. This being said, the observed quality of life is mainly in the domain of social functioning, while other quality of life domains measured by the SF-36 such as vitality, emotional health, etc. remain suppressed [80]. Furthermore, patients with a stoma are at risk for a separate set of stoma-related complications such as stricture, prolapse, peristomal inflammation, and retraction, among others (see Chap. 55). Therefore, given the numerous treatments available to ameliorate fecal incontinence severity, stoma creation should be an option of last resort.

In a small number of patients who failed other interventions and are seeking an alternative to a traditional stoma, a reverse appendicostomy [81] or a cecostomy tube placement can be considered. This provides a small opening from the skin into the colon for administration of an antegrade colonic enema (ACE) consisting of water, laxatives, or a combination of the two to clear the colon in a predictable fashion. The goal is to allow a patient to leave the house without fearing a major fecal accident. Patients interested in the ACE procedure are counseled to expect spending at least 1 hour emptying their bowels after each irrigation. Furthermore, many can expect persistent leakage of mucus and stool, skin difficulties from fluid leakage near the cecostomy tube or mini stoma, and in cases of native tissue conduits such as appendicostomies—stoma stenosis and stoma revisions. Furthermore, the majority of the data regarding short- and long-term efficacy of this approach is in children [82, 83], while the data in adults is mostly anecdotal.

Though other surgical options have been described such as injection of alternative bulking agents [66, 84–106], graciloplasty (stimulated and unstimulated) [107–115], pudendal nerve stimulation [116, 117], etc., these options are not available currently in the USA. For a full discussion of these options, please see the ASCRS FI task force review of all available options [118].

Conclusions

Fecal incontinence is a common, yet under recognized condition. Since the vast minority of patients seek medical care due to embarrassment, colorectal surgeons should feel comfortable in asking patients if they suffer from this debilitating problem. Recently many new treatment modalities with the potential to improve quality of life and symptoms have become available. Direct comparisons of these modalities with regard to cost and efficacy will help shape the treatment algorithms of the future.

Functional Bowel Disorders for the Colorectal Surgeon

Jennifer M. Ayscue and Anjali S. Kumar

Key Concepts

- Irritable bowel syndrome (IBS) may arise from motility disorders, visceral hypersensitivity, and/or dyssynergy of the brain-gut relationship.
- Treatment for IBS often involves a combination of diet and medications.
- Chronic pelvic pain has multiple names, causes, anatomic and physiologic features. Similarly treatment options are numerous, but algorithms can be followed.

Introduction

Functional syndromes like IBS and chronic pelvic pain are a set of disorders that have roots in physiologic causes, but often include a strong psychological component. Chronic conditions like these are labeled "functional" when organic or anatomic causes have been ruled out. Most syndromes like these are poorly understood by gastroenterologists and colorectal surgeons who are generally more comfortable treating visible disease with specific procedural interventions. It is paramount that colorectal surgeons understand the symptoms, diagnostic criteria, and treatment strategies of these disorders, especially with respect to the role of medical management and physical therapy. These conditions can be vague and unremitting, causing frustration for the provider to definitively treat and for the patient to find relief permanence.

Irritable Bowel Syndrome

Epidemiology

Although IBS is the most commonly diagnosed gastrointestinal (GI) disorder, most colorectal surgeons do not have a good grasp of the intricacies associated with this common problem. It affects approximately 3–22 % of the population [1–3] depending on which criteria is used for measurement. IBS is diagnosed based on clinical symptomatology and is 1.5–2 times more prevalent in women versus men with women having more complaints of abdominal pain and constipation and men complaining more of diarrhea [4].

Pathophysiology

The pathophysiology of IBS is not well understood. It was initially thought to correlate with psychiatric illnesses, but since that time, other potential relationships have emerged. These include motility disorders, visceral hypersensitivity, and the notion of the brain-gut syndrome. More recently, other concepts like immune activation, genetic predisposition, altered intestinal permeability, history of acute gastrointestinal infection, and the human microbiome have been potentially implicated in the cause of IBS [5, 6]. It is interesting to note that more than 60 % of the human fecal load consists of bacteria, and alterations in the body's bacteria quantitatively or qualitatively may either lead to or treat the symptoms of IBS. The natural history of IBS is generally one of a chronic, relapsing disease. A mere 2–5 % of patients are ultimately diagnosed with alternative organic GI disorders and only 12–38 % of cases improve over time [5]. However, it has been noted that in patients who develop symptoms of IBS after a gastrointestinal infection, their symptoms usually resolve after only 5–6 years [7]. It is most likely that IBS is caused by a combination of factors and may require a blend of therapeutic options.

Diagnosis and Symptoms

Patients with IBS are diagnosed using clinical symptoms after exclusion of specific organic causes. The first diagnostic criteria were provided by Manning et al. in 1979 [8], but these were subsequently revised by multinational groups into the Rome I, Rome II, and the most recent Rome III criteria [9]. The Rome III criteria includes recurrent abdominal pain or discomfort at least 3 days per month for the past 3

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_62

months, with symptom onset >6 months before diagnosis, associated with two or more of the following:

(1) *improvement with defecation*,
(2) *onset associated with a change in frequency of stool*,
(3) *onset associated with a change in stool form/appearance*.

In addition, guidelines published by the American College of Gastroenterology IBS Task Force recommend no additional testing with the possible exception of serum serology for celiac sprue, colonoscopy for patients over the age of 50 or in patients with specific alarm features which include rectal bleeding, unintended weight loss, iron deficiency anemia, nocturnal symptoms, and a family history of selected organic disease such as colorectal cancer, inflammatory bowel disease, and celiac sprue [10]. Celiac disease may be indistinguishable from IBS with abdominal pain, gas or bloating, and diarrhea, constipation, or both. It is an enteropathy resulting from an immune-mediated response to deamidated gliadin and is diagnosed by small intestinal biopsy demonstrating villous atrophy, crypt hyperplasia, and inflammation of the lamina propria or by serum test for specific elevated antibodies. In fact, 38 % of patients with celiac disease have been shown to have symptoms of IBS compared to control patients in a meta-analysis of four case–control studies [11]. Of the antibody tests, elevated Immunoglobulin A (IgA) anti-tissue transglutaminase antibody is the most diagnostic, followed by elevation of IgA endomysial and anti-tissue transglutaminase antibodies, and to a lesser degree, anti-gliadin antibody levels which are useful in monitoring the response to treatment of celiac disease. Other differential diagnoses for IBS include microscopic colitis, gastrointestinal infection, lactose maldigestion, inflammatory bowel disease, thyroid dysfunction, chronic constipation, and small intestinal bacterial overgrowth (SIBO) [12]. Although patients with IBS may present with symptoms of chronic constipation, IBS patients have abdominal pain or discomfort as a significant related symptom.

IBS may be classified into diarrhea-predominant (IBS-D) in which ≥25 % of bowel movements are classified as loose (not related to laxatives) according to the Bristol Stool Form Scale [13] or constipation-predominant (IBS-C) where ≥25 % of bowel movements are classified as hard or lumpy. Patients who have alternating features of at least 25 % of each type of stool are called IBS-mixed (IBS-M) [6]. Placing patients into these categories is important because many treatment strategies and recommendations are symptom-based (Table 62-1).

Treatment

Diets have long been implicated in the pathogenesis and symptomatology of IBS. Even though only about 1–10 % of Western society populations have true food allergies [14], patients with IBS often complain that the ingestion of food is a frequent precipitant of their symptoms with foods high in carbohydrates or fat being the most commonly implicated [15]. The relationship may represent a food intolerance, but many IBS patients commence dietary modifications occasionally leading to inadequate nutrition [16]. Recommended first line therapies have focused on specific dietary alterations such as gluten restriction. This may improve symptoms in patients with IBS, especially those who are diarrhea-predominant, according to controlled trials [17, 18]. However, a study by Biesiekierski et al. reported even better symptom relief in IBS patients with a diet restricting poorly absorbed carbohydrates unrelated to gluten intake [19]. A randomized, controlled trial by Halmos et al. demonstrated that reducing the intake of poorly absorbed short-chain carbohydrates, otherwise known as fermentable oligosaccharides, disaccharides, monosaccharides and polyols (FODMAPs), significantly improved the severity of symptoms of IBS [20]. Dietary FODMAPs are (1) fructose (fruits, honey, high fructose corn syrup (HFCS)), (2) lactose (dairy), (3) fructans (wheat, garlic, onion, inulin, etc.), (4) galactans (legumes), and (5) polyols (sweeteners, stone fruits). Examples of varying levels of FODMAP diets (low, moderate, high) are detailed in Table 62-2. A subsequent study by Staudacher et al. randomized 41 patients to either a FODMAP diet or their regular diet, and they noted that 68 % (13/19) of patients in the FODMAP diet reported adequate control of their symptoms as opposed to only 23 % (5/22) of patients eating their regular diet [21].

Fiber has long been recommended as first-line therapy for IBS, especially IBS-C, but overall results have been disappointing. A randomized, controlled trial of 275 patients showed that psyllium and soluble fiber improved symptoms of IBS over insoluble fiber (bran), followed by placebo. They reported early dropout of some patients due to reported worsening of symptoms especially in the bran group [22]. In a 2014 meta-analysis, a modest benefit for soluble fiber, but not for insoluble fiber was also noted in patients with IBS [23]. Thus, the American College of Gastroenterology Functional Bowel Disorders Task Force has recommended psyllium in the treatment of IBS [24]. However, use of insoluble fiber should be discouraged, especially in IBS-C patients. Table 62-3 details characteristics and examples of soluble and insoluble dietary fibers.

IBS has been shown to occur subsequent to episodes of bacterial gastroenteritis, leading to the implication that the gut biome may substantially relate to the pathogenesis of IBS [25]. SIBO has been studied as a possible cause of IBS. Unfortunately, definitive evidence that patients with IBS also have SIBO is variable, but it appears to be more common in IBS-D predominant patients [26–29]. Rifaximin is a poorly absorbed, broad spectrum antibiotic used for SIBO and is not

TABLE 62-1. Treatment options in irritable bowel syndrome

	Mixed IBS	Diarrhea-predominant IBS	Constipation-predominant IBS
Dietary modifications	Lactose free, gluten restriction, low FODMAP	Lactose free, gluten restriction, low FODMAP	Lactose free, gluten restriction
Fiber supplement	Trial (psyllium)	Trial (psyllium)	Trial (psyllium)
Antibiotic, probiotics	Consider trial of antibiotics if has SIBO, probiotics	Consider trial of antibiotics if has SIBO, probiotics	Consider trial of probiotics
Peppermint oil	Consider trial	Consider trial	Consider trial
Antidiarrheals/ Antispasmodics	Consider loperamide, diphenoxylate atropine	Consider loperamide, diphenoxylate atropine, hyoscyamine	Not recommended
Antidepressants	Consider trial of TCAs, SSRIs	Consider trial of TCAs, SSRIs	Consider SSRIs
Psychological therapies	May consider	May consider	May consider
5-HT3 antagonists	Alosetron (restricted)	Alosetron (restricted)	Not recommended
Prosecretory agents	Not recommended	Not recommended	Trial of linaclotide, lubiprostone
Osmotic laxatives	Not recommended	Not recommended	Trial of PEG, other non-stimulant laxatives

TABLE 62-2. Examples of foods by varying levels of FODMAP (Fermentable Oligo-Di-Monosaccharides and Polyols)

Food group	Low FODMAPs	Moderate FODMAPs (limit)	High FODMAPs (avoid)
Eggs, meats, poultry, fish	Meats, eggs, fish, shellfish		
Dairy	Lactose low dairy: cream cheese, half and half, hard cheeses (cheddar, colby, parmesan, swiss, etc.), soft cheeses (brie, feta, mozzarella, etc.), sherbet, yogurt (greek), whipped cream		High lactose dairy: buttermilk, chocolate, creamy/cheesy sauces, custard, ice cream, milk (cow's, goat's, sheep's, condensed, evaporated), soft cheeses (cottage, ricotta, etc.), sour cream
Meat, non-dairy alternatives	Non-dairy milks, nuts (walnut, macadamia, peanut, pecan, pine), nut butters, tempeh, tofu	<10 almonds <10 hazelnuts	Cashews, beans, black eyed peas, bulgur, lentils, miso, pistachios, soybeans, soybean milk
Grains	Made with gluten free/spelt grains		Made with wheat/barley/rye when it's the major ingredient
Fruits	Bananas, blueberries, cantaloupe, cranberries, grapes, honeydew, kiwi, lemon, lime, mandarin, orange, pineapple, raspberries, strawberries	¼ avocado, <3 cherries, ½ grapefruit, ½ pomegranate, <¼ cup shredded coconut, <10 dried banana chips	Apples, applesauce, apricots, blackberries, canned fruit, dates, dried fruits, mango, nectarines, papaya, peaches, pears, plums, prunes, watermelon, avocado
Vegetables	Alfalfa/bean sprouts, bell peppers, carrots, cabbage, cucumbers, eggplant, green beans, kale, lettuce, potatoes, radishes, spinach, squash, tomatoes, zucchini	¼ cup canned artichoke hearts, <3 asparagus spears, 4 beet slices, <½ cup broccoli, <½ cup brussel sprouts, <1 cup savoy cabbage, 1 celery stick, <½ cup green peas, 3 okra pods, <10 pods snow peas, ½ corn cob, <½ cup sweet potato	Artichokes, cauliflower, mushrooms, sugar snap peas
Beverages	Coffee, tea		Made with HFCS, fortified wines (sherry, port)
Seasonings, condiments	Jam/jelly/pickle/relish/salsa/sauce/maple syrup without HFCS, most spices and herbs, homemade broth, butter, chives, cooking oils, mustard, pepper, margarine, mayonnaise, green onion, olives, pesto, salt, seeds, sugar, soy sauce, vinegar		Products with HFCS, agave, garlic, garlic salt/powders, honey, hummus, molasses, onions (not green), onion salt/powders, tomato paste, artificial sweeteners (isomalt, mannitol, sorbitol, xylitol)

TABLE 62-3. Characteristics of soluble and insoluble fibers and dietary sources of each

Fiber type	Mechanism	Dietary sources
Soluble	1) retains water and turns to gel during digestion 2) slows digestion and nutrient absorption from the stomach and intestine	Oat bran, barley, nuts, seeds, beans, lentils, peas, and some fruits (citrus, apples, strawberries) Many vegetables
Insoluble	Speeds the passage of foods through the stomach and intestines and adds bulk to the stool	Wheat bran, vegetables and whole grains

specifically Food and Drug Administration (FDA) approved for IBS, but in a recent meta-analysis of five randomized trials, it was shown to improve symptoms in predominantly non-constipated IBS patients [30]. Probiotics, which contain live bacteria, have shown some potential in improving global symptoms such as bloating and flatulence in IBS [21]. In particular, preparations with a combination of probiotics may have the most overall effect on symptom improvement. Prebiotics, which are nutrients taken to encourage the growth of probiotic bacteria, and synbiotics, which are a combination of probiotics and prebiotics, have also been considered as potential added or alternative therapy. However, to date, studies on probiotics, prebiotics, and synbiotics are insufficient to make adequate recommendations on their use.

Other therapies, including exercise, psychological therapies and acupuncture may have variable benefit. Regular exercise has been shown to improve symptoms in IBS with a statistically significant difference in the IBS symptom severity score [31]. The effect of psychological therapies was evaluated in a recent meta-analysis of 32 varying trials on different psychological therapies including hypnotherapy. They reported overall improvement in IBS symptoms relative to control therapies [32], but access to therapists experienced in the management in patients with IBS may be challenging. In a controlled study of acupuncture, there was no demonstrated benefit in IBS patients compared to sham acupuncture [33].

Diarrhea-Predominant IBS (IBS-D)

Antispasmodics such as hyoscine, dicyclomine, otilonium, cimetropium, and pinaverium have been tried with some degree of success in IBS-D. A 2011 Cochrane review reported improvement in abdominal pain and global IBS symptoms over placebo [34], but use may be best for postprandial abdominal cramping and loose stools [5]. Anticholinergic side effects such as constipation, fatigue, dry mouth, dizziness, and blurred vision may limit use of antispasmodics, especially in the elderly.

Peppermint oil has also been used and may be effective through diminished visceral hypersensitivity and effect of pain sensation in the gut. A meta-analysis of nine studies showed a statistically significant improvement of global IBS symptoms with few side effects such as reflux [35].

Tricyclic antidepressants (TCA) and selective serotonin reuptake inhibitors (SSRIs) have also shown promising results for global symptom improvement and reduction of pain in IBS, although the side effect profile may limit patient tolerance [21]. Thus, these medications should be selected carefully with close physician follow-up. TCAs were studied as a part of a meta-analysis of 17 randomized controlled trials including 1084 patients [29]. Patients receiving TCAs were statistically less likely to remain symptomatic versus placebo. TCA side effects include dose-dependent constipation, drowsiness, weight gain, dry eyes and mouth, and QT-prolongation.

Serotonergic agents affect gastrointestinal secretion, motility, and sensation. Serotonin subtype 3 (5-HT_3) receptors affect visceral pain, and 5-HT_3 antagonists decrease painful gut sensations and slow intestinal transit [36]. Alosetron, a selective 5-HT_3 antagonist has shown efficacy in IBS-D [37]. However, reports of severe constipation and ischemic colitis initially led to its withdrawal by the United States FDA in 2001. It was subsequently reintroduced in 2002 under a risk management program, restricting its use to treatment only for women with severe IBS-D. Ondansetron, a less potent 5-HT_3 antagonist has been shown to significantly improve stool consistency, nausea, stool urgency and frequency, bloating, and global IBS symptoms [38].

Although loperamide is an effective antidiarrheal, it has not been shown to be effective and is not recommended in the treatment of symptoms of IBS except to decrease the frequency and increase the consistency of stool [21].

Constipation-Predominant IBS (IBS-C)

Tegaserod, a partial serotonin subtype 4 (5-HT4) receptor agonist, increases intestinal secretion, augments the peristaltic reflex, and accelerates gastrointestinal transit [39]. It was granted FDA approval for IBS-C patients in 2002 but was withdrawn by the FDA in 2007 for possible cardiovascular adverse effects and is not currently available in the USA. Prucalopride, another 5-HT4 agonist, is available in Canada and Europe, but data is lacking.

SSRIs have similar effects in the bowel as serotonin receptor agonists. As an antidepressant, SSRIs were also studied as part of the meta-analysis by Ford et al. and were noted to have similar results with significant improvement in symptoms of IBS over placebo [29]. However, side effects of this medication include sexual dysfunction, nausea, drowsiness, agitation, and diarrhea, so they are more appropriately considered for use in IBS-C patients.

Prosecretory agents have also shown promise in the treatment of IBS-C. Linaclotide is a hormone in the guanylin peptide family that activates guanylate cyclase-C receptors in the intestinal lumen. This leads to a cascade of events causing sodium and water secretion as well as modulation of afferent pain sensors [40]. In a 2013 meta-analysis of three controlled trials in patients with IBS-C, a statistically significant improvement of symptoms was noted with 290 μ linaclotide compared with placebo [41]. Lubiprostone, another prosecretory agent, works by activating chloride channels in the intestine, resulting in chloride and water secretion and faster intestinal transit. In two randomized controlled trials, lubiprostone was also shown to improve symptoms in 1171 IBS-C patients compared to placebo with a relatively low incidence of nausea and diarrhea [42].

Laxatives have also been tried in the treatment of IBS-C patients. PEG formulations have been studied, but overall results have been disappointing. Chapman et al. reported on the use of PEG in 139 patients noting an increase in the number of bowel movements to at least four per week with an increase of at least two or more from baseline, but there was no improvement in abdominal discomfort or pain [43]. No other known randomized controlled trials have been performed for other laxatives, and use has been limited due to cramping and increased pain concerns.

Chronic Functional Pelvic Pain

Like IBS, chronic functional anal pain is a set of disorders that has roots in physiologic causes, but can often have a strong psychological component. Chronic pain in the anal canal, rectum, or pelvis is labeled "functional pain" when organic or anatomic causes have been ruled out. Like IBS, these pain syndromes are typically poorly understood by gastroenterologists and colorectal surgeons who are generally more comfortable treating visible disease with specific procedural interventions. In addition, there is a paucity of research evidence available to guide the diagnosis and treatment of these conditions. Therefore, like IBS, chronic functional pelvic pain can be frustrating for the provider to definitely treat.

Chronic pelvic pain syndromes affect up to 7 % of the population, but are brought to the physician's attention in only a third of these cases. Patients often report significant impairment in quality of life, work absenteeism, and psychological distress due to chronic pelvic pain.

A challenge in caring for patients with anorectal and pelvic pain is that a number of structural and inflammatory etiologies must be considered. Absence of a visible anorectal abnormality as evidenced by anoscopy or proctoscopy is useful in completing this evaluation. The provider should keep an eye out for cryptitis, fissure, abscess, hemorrhoids, solitary rectal ulcer, inflammatory bowel disease, and rectal ischemia. Chronic prostatitis and pelvic endometriosis should also be considered as potential contributors to chronic pelvic pain. These disorders are difficult to elicit on physical exam, but symptoms of these disorders may be elicited in the history.

A limitation in achieving success in these patients is that there is little consensus on the usefulness of the various diagnostic modalities (imaging studies, defecography, manometry, pudendal nerve terminal motor latency, endoscopy, endoscopic ultrasound) used in evaluating such patients. There are also a wide variety of therapeutic options (including massage, dietary modifications, laxatives, antispasmodics, antidepressants, anxiolytics, topical agents, local anesthetic injections, steroid injections, botox injection, and surgery). Studies testing the effectiveness of these therapeutic modalities are difficult to conduct as many of these disorders are multifactorial and difficult to stratify. Typically, pelvic pain disorders are grouped into the following disease descriptions: chronic proctalgia, coccygodynia, and pudendal neuralgia.

Chronic Proctalgia

To improve consistency in the diagnosis of anorectal pain syndromes, the Rome III criteria has defined chronic proctalgia as: "chronic or recurrent rectal pain or aching lasting at least 20 min, in the absence of structural or systemic disease explanations for these symptoms." Duration of pain >20 min is a distinguishing feature, since shorter episodes of pain are classified as proctalgia fugax. Proctalgia fugax is sudden, severe pain in the anorectal region which lasts <20 min, and is usually described as disappearing completely, just as suddenly as its onset. Although proctalgia fugax can recur, the number of episodes is relatively few and is therefore not considered a chronic pain syndrome.

Chronic proctalgia is further divided by the Rome III criteria into two subtypes: (1) levator ani syndrome (LAS) is termed when traction on the pelvic floor produces tenderness and (2) unspecified functional anorectal pain where painful sensations are absent when the levator muscle is palpated during digital rectal examination.

Inflammation of the levator or arcus tendon of the levator ani muscle has been suggested as a cause of chronic proctalgia, since tenderness on palpation is most commonly found on the left side where the muscle inserts into the pubic ramus of the pelvis. This etiology has been called into question by investigators who have unsuccessfully attempted to relieve symptoms with local steroid injections to decrease inflammation [44, 45]. In addition to psychosocial factors such as anxiety disorders, depression, and stress, history of spinal surgery and childbirth are common features in patients presenting with this syndrome.

Anorectal physiology and imaging studies (defecography) are often undertaken but found to have little diagnostic or prognostic value. Increased anal canal resting pressures on anorectal manometry are inconsistently reported.

Treatment considerations include biofeedback, digital massage of the levator muscles, trigger point injection with a steroid or botulinum toxin, and electrogalvanic stimulation (EGS) (Figure 62-1).

In a prospective, randomized trial of 157 patients, Chiarioni et al. found that among patients meeting Rome III criteria for chronic proctalgia, those with dyssynergic defecation were more likely to report successful outcomes after pelvic floor rehabilitative therapy. The authors suggest that a simple balloon evacuation test performed in the office with a disposable Foley catheter filled with 50 mL of water enables providers to select patients that will be more likely to benefit from biofeedback [46].

Caudal block steroid injection and/or pelvic tender point injection with a mixture of triamcinolone acetonide and lidocaine resulted in no improvement of rectal pain, which discredits the inflammatory etiology of these syndromes [44, 45]. Temporary paralysis of the muscle has also been tested by injection of Botulinum Toxin A and resulted in prolonged balloon expulsion but no differences in rectal pain [47].

Digital massage of the puborectalis sling (Figure 62-2) can be undertaken with the intention of relaxing the tensed

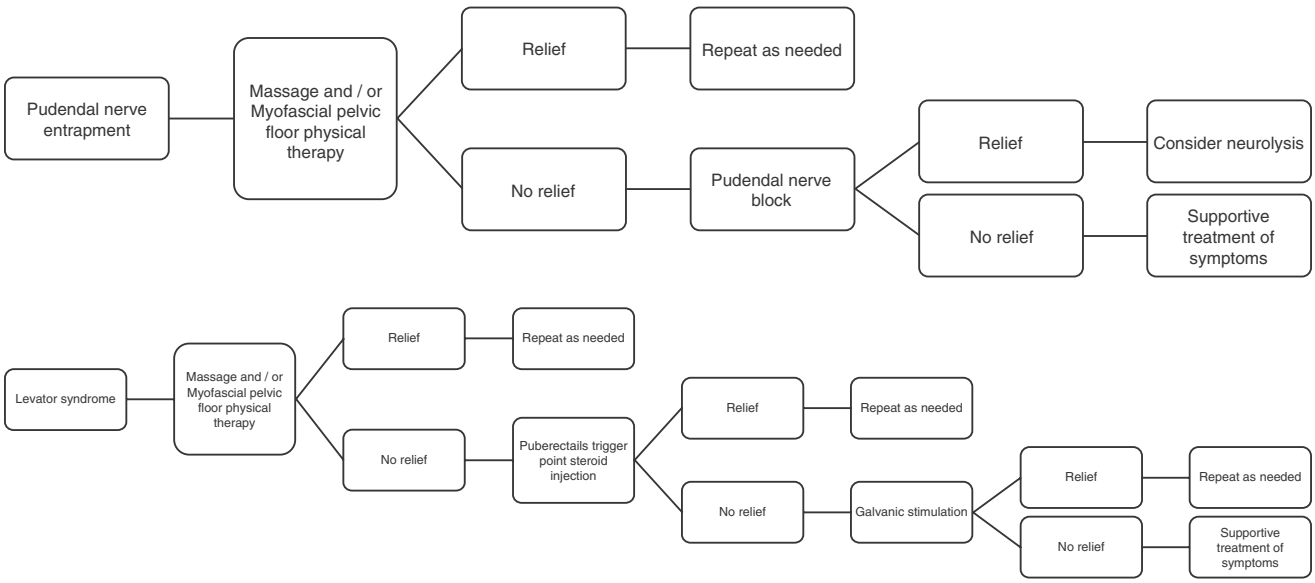

FIGURE 62-1. Algorithm for management of chronic proctalgia.

FIGURE 62-2. Massage with myofascial release via a vaginal approach.

muscles [48]. Therapists advise that massage should be performed firmly and repetitively (affected side massaged up to 50 times). Many believe that if the massage does not cause discomfort, it may not be effective [48]. It is important to note that massage of the levator ani muscle is seldom prescribed as sole therapy, and is often employed in conjunction with hot sitz baths or a short-term course of oral Diazepam, both of which are assumed to have myorelaxant properties. Success was as high as 68 % in a study of 316 chronic proctalgia patients [49].

As illustrated in the management algorithm (Figure 62-1), EGS can be considered when conservative measures have failed. In delivering EGS, a low frequency oscillating current (80 cycles per second) is applied to the pelvic floor muscles through an anal probe. This induces fasciculation which will cause prolonged fatigue. It is thought that this fatigue breaks the spastic cycle in order to provide sustained symptom relief. It is important to counsel patients that the side effect most commonly reported is mild worsening of pain on the first days of treatment. Studies have reported a success rate of 25–91 %. Sohn et al. reported the highest success rates among their 80 patients. They delivered EGS at gradually increasing voltages (0–300 V, per patient tolerance) for 1 h per day for three sessions in a 10-day period. These results were not able to be reproduced by other investigators who attempted the same protocols [50].

Coccygodynia

Pain arising in or around the coccyx is termed coccygodynia. It can be exacerbated by prolonged sitting on hard surfaces. When the pain lasts more than 2 months, it is considered chronic. Chronic spasm of the pelvic floor which exerts tension on a stiff coccyx may be an etiologic factor, with accidental trauma acting as a trigger. Traumatic childbirth and repetitive trauma (such in the case of truck drivers or horseback riders) can also factor into its cause. Lumbar disc degeneration, history of epidural injection, and previous spinal or rectal surgery are also commonly reported in the history of patients complaining of this condition.

Obesity and female gender may predispose patient to this condition, accounting for pelvic rotation which exposes the coccyx and makes it more vulnerable to traumatic injury. One study found that coccyx instability, defined as intermittent

FIG. 62.3. Patient positioning for coccygodynia injection (*top*). Sagittal view of intended tract and bony landmarks for injections for coccygodynea (*inset*).

subluxation or hypermobility seen on lateral dynamic radiographs when sitting, was associated with a high prevalence of symptom reporting [51]. Pre-existing spinal alterations may play a role in those complaining of post-traumatic coccygodynia [52]. Spicule (bone spur) or bursitis (inflammation of structures in close proximity to the coccyx) may also cause pain. Though magnetic resonance imaging (MRI) may be helpful to exclude tumors, disc disease, and identify anatomic risk factors, many believe that they do not add significant insight into the diagnosis of coccygodynia [53]. Depression and anxiety disorder have also been reported to amplify coccygeal pain symptoms in the absence of anatomic findings [54].

Trigger point injection with steroid (Figure 62-3) can be considered for transient relief of pain. Coccyx manipulation (Figure 62-4) has been found in a recent prospective, randomized, controlled study to be beneficial (22 % of patients in the manipulation group reported a significant pain decrement compared to only 12 % of patients in the placebo group) [55].

As outlined in the treatment algorithm (Figure 62-5), in selected patients with severe and unresponsive coccygodynia, surgery may be considered [56]. Wray et al. randomize a group of 120 patients between treatment with injections of methylprednisolone and bupivacaine alone or injections and manipulation of the coccyx under general anesthesia. Injections alone were successful in 60 % and injections plus manipulation was successful in 85 % of the patients in that arm of the study. The 23 patients who failed either of these two treatments came to coccygectomy. Nearly all had a good result, suggesting that this operation may be appropriate in those patients who have failed a trial of less invasive therapy [57].

FIGURE 62-4. Operative manipulation for chronic coccygeal pain. The *top figure* demonstrated digitation via the anus with the patient in the prone position. The *bottom illustration* demonstrates (from a sagittal view) the intended overall effect of changing the angle of the coccygeal structures.

Pudendal Neuralgia

Pudendal neuralgia is also called Alcock's canal syndrome, or pudendal canal syndrome. When chronic pain is reported in the perineal area in the absence of organic diseases that may explain this symptom, the provider could consider entrapment injury. The pudendal nerve travels through a musculo-osteo-aponeurotic tunnel between the sacrotuberal and sacrospinal ligaments as illustrated in Figure 62-6 (lateral view).

The pudendal nerve arises from S2, S3, and S4 of the sacral plexus. The nerve leaves the pelvis beneath the piriformis muscle through the greater sciatic foramen. It then passes on to the sacrospinous ligament medial to the ischial spine and reenters the pelvic cavity. While beneath the levator ani muscles, it runs ventrally through Alcock's canal, a thickening of the obturator internus fascia. In the ischiorectal fossa, it gives off an inferior rectal and a perineal branch. The two documented sites of pudendal nerve entrapment are between the sacrotuberous and sacrospinous ligament and in the pudendal (Alcock's) canal.

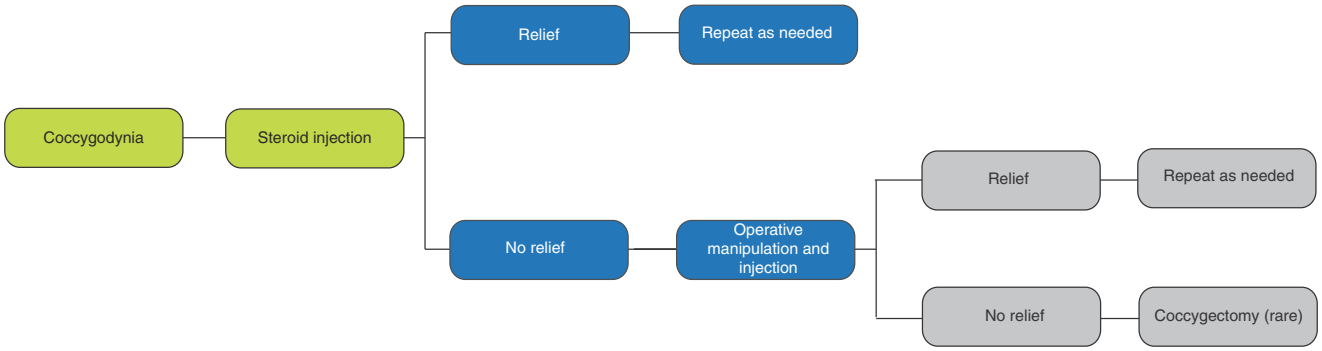

FIGURE 62-5. Algorithm for management of coccygodynia.

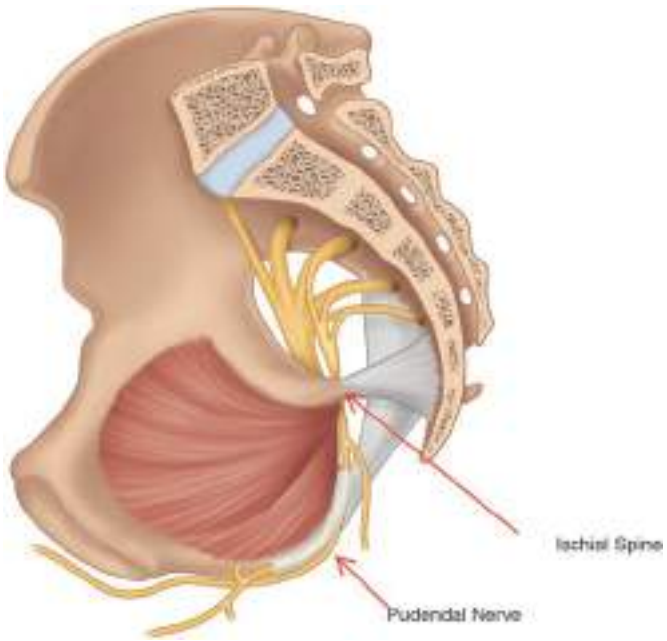

FIGURE 62-6. Demonstration of the anatomical course of the pudendal nerve from a posterolateral view of the bony and ligamentous structures.

Many patients with chronic pain have induced hypertrophy of the pelvic muscles caused by athletic activities in their youth, which has in turn caused remodeling of the ischial spine and rotation of the sacrospinous ligament and nerve compression.

Colorectal surgeons should keep in mind that although entrapment is the most common etiology, herpetic neuropathy, stretch neuropathy, and post-radiotherapy neuropathy can also be risk factors elicited by a careful history [58].

In 2006, a multidisciplinary working group on pudendal neuralgia held in Nantes, France [59], identified five requirements of essential diagnostic criteria for pudendal neuralgia:

(1) *Pain should be limited to the innervation territory of the pudendal nerve. This excludes any pain that is limited to the coccygeal, pelvic, or gluteal areas*;
(2) *Pain is predominantly experienced while sitting, in accordance with the nerve compression etiology hypothesis. In long-standing pudendal neuralgia, pain may become continuous, but it is still worsened by the sitting position*;
(3) *The pain rarely awakens the patient at night*;
(4) *On clinical examination, no objective sensory impairment can be found even in the presence of paresthesia. The presence of a sensory defect should prompt investigations to exclude diseases of the sacral nerve roots and the cauda equina; and*
(5) *Pain should be relieved by anesthetic infiltration of the pudendal nerve. This is an essential criterion, but it lacks specificity as pain related to any perineal disease may be relieved by pudendal nerve block.*

The experts cautioned that a negative block does not exclude pudendal neuralgia, as the block may have been confounded by technical errors.

The experts also listed the following as exclusion criteria for the condition: (a) pain in a territory unrelated to the pudendal nerve, (b) symptomatic pruritus instead of paresthesia, (c) exclusively paroxysmal pain, and (d) imaging abnormalities that could explain the symptom.

There are a number of treatment options that have been described in recent literature, ranging from operative or image-guided nerve injections, neuromodulation, and operative augmentation of the entrapment (i.e., release) (Figure 62-7).

Nerve Injection

Operatively, colorectal surgeons may consider taking the patient for an anal exam under anesthesia and either transanally or transvaginally, attempt to palpate the pudendal nerve for a directed block (Figure 62-8). Success rates are variable [60]. Therefore, image-guided therapy may be more precise than this blind approach.

Mamlouk et al. reported 52 CT-guided pudendal nerve blocks of anesthesia and steroid performed in 31 patients who suffered from chronic pelvic pain with a presumed diagnosis of pudendal neuralgia.

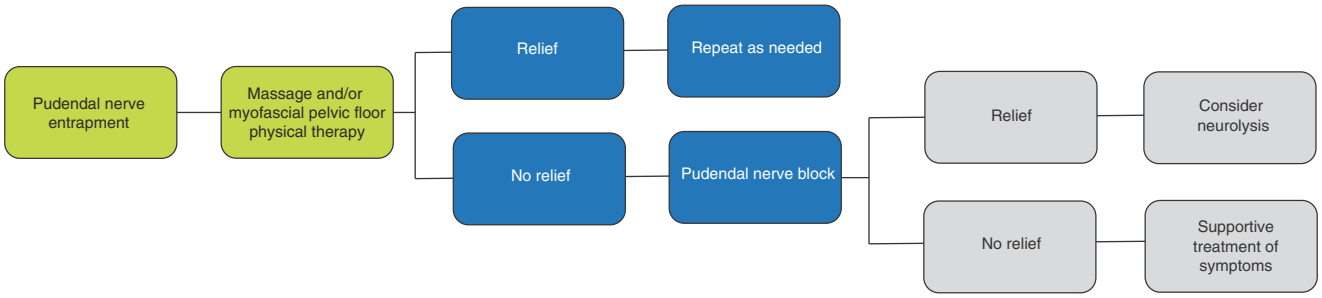

FIGURE 62-7. Algorithm for management of pudendal nerve entrapment.

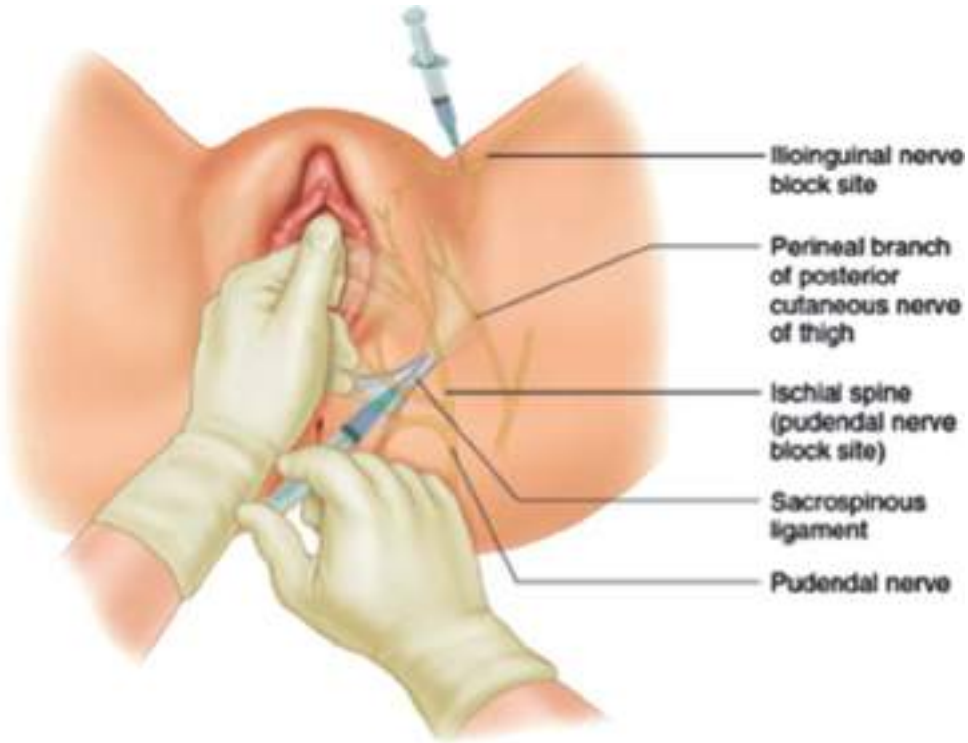
FIGURE 62-8. Demonstration of the administration of a pudendal nerve block with the patient in lithotomy position. Note that digitation for landmarks in this illustration is via the vagina, however, a transanal rectal approach can also be considered.



All procedures were successful technically, which was defined as contrast material filling the pudendal canal on CT. Of the 31 patients, two had long-term relief with pudendal nerve blocks alone. Fourteen had subsequent surgery based on initial improvement with block(s), and all 14 patients improved after surgical nerve release. The authors concluded that CT-guided pudendal nerve blocks were more valuable diagnostically than therapeutically [61].

Schelhorn et al. describe a case report of an MR guided perineural injection procedure in an athletic, young adult. A 20-guage MRI Chiba needle (100 mm, Somatex, Medical, Teltow, Germany) was advanced transgluteally and obliquely, aiming the needle position almost parallel to the obturator fascia. The needle tip was placed within the pudendal canal and position was verified with initial saline injection. Then a mixture of triamcinilone and bupicivaine was injected. The pain improved, but returned after 6 days post procedure, therefore the procedure was repeated until the patient reported complete relief. A total of six injections were undertaken in this manner over a period of 2 months, ultimately resulting in complete relief [62].

Neuromodulation

A neurosurgery group published a case report of a male patient with pudendal neuralgia who underwent lead placement with a 16-contact surgical lead at the level of conus medullaris which allowed for multicolumn stimulation. Using transverse combinations, these surgeons were able to obtain 100 % paresthesia over the perineal area without

unwanted dorsal root stimulation. They reported that this patient's perineal and radicular pain was successfully relieved for 12 months with an improvement in all quality of life domains and a reduction in drug consumption [63].

Sacral nerve stimulation (SNS) is a technique that many colorectal surgeons have experience with in the treatment of fecal incontinence. A case report by Valovska et al. suggested that SNS may prove to be beneficial in pudendal entrapment, although the device is not FDA approved for this indication. The authors showed improvement in a patient's symptoms after Interstim (Medtronic, Minneapolis, MN, USA) lead placement. The patient suffered from chronic pelvic pain due to a nerve injury as a result of hysterectomy. Initial implantation with test leads resulted in pain improvement, and a permanent implant was placed (4 tined Interstim leads, individually placed into the bilateral S3 and S4 foramina). The patient was followed for 4 years with good results [64].

Nerve Ablation

Destroying the nerve can result in symptom relief. This can be done by operative division as described below, or by image-guided techniques. Prologo et al. reported a case series of 11 patients with pudendal nerve entrapment who underwent CT-guided cryoablation of the nerve within Alcock's canal. They used a 17-gauge cryoablation probe (Ice Sphere, Galil Medical, Arden Hills, MN), and undertook two 8-minute-5-minute freeze–thaw cycles. The patients showed a significant reduction in their pain scales ($p < 0.005$) [65].

Operative Approaches

In terms of neurolysis, there are four described approaches to surgical decompression of the pudendal nerve. All surgical methods involve neurolysis to eliminate the possible source of compression: transperineal, transgluteal, transischiorectal, and laparoscopic. We have also included recent reports of other operative approaches to alter the anatomy of the canal.

Transperineal

With patients positioned in lithotomy position, a semicircular incision is undertaken on the side of the anus on which the nerve is affected. Identification of the inferior rectal nerve is performed and this nerve is followed blindly with a finger until the pudendal nerve is reached. Adhesions around the pudendal nerve are then bluntly reduced. The approach allows access to the rectal branch and should be limited to patients with only rectal involvement of pudendal neuralgia. However, it is a blind procedure that does not allow for extensive dissection of the nerve beyond the distal Alcock's canal.

Transgluteal

With the patient positioned in prone jackknife a transgluteal incision is made overlying the sacrotuberous ligament. When the ligament is reached, it is transected at its narrowest portion and edges of the ligament are reflected open. The pudendal nerve is found immediately below the ligament together with the pudendal vein and artery. In this manner, the nerve can be visualized from the subpiriformis fossa to the distal Alcock's canal. Neurolysis is performed and the sacrospinous ligament is transected. The nerve is then transposed anteriorly to decrease tension. Surgery is concluded by the closure of the subcutaneous fat and overlying skin.

Persistent nerve entrapment even after neurolysis procedures can be approached in a way described by Hibner et al. [66]. They recommend a transgluteal incision, identification of the nerve via a nerve monitoring system, followed by adhesiolysis from the piriformis muscle to the distal Alcock canal (a surgical microscope was employed). They enclosed the nerve in a NeuraWrap Nerve Protector (Integra, Plainsboro, NJ, USA) and coated it with an activated platelet-rich plasma. An ON-Q PainBuster (Halyard Health, Alpharetta, GA, USA) catheter was placed along the nerve into the Alcock canal, and 0.5 % bupivacaine was infused at 2 mL/h. The sacrotuberous ligament was repaired using an Achilles or gracilis cadaver ligament. The overlying subcutaneous tissue and skin were then closed. Eight of the nine patients followed reported global improvement, and using an 11-point numerical pain scale, scores improved from a mean of 7.2–4.0 ($p = 0.02$).

Transischiorectal

In this technique, an incision is made in the lateral wall of the vagina in women and between the rectum and the scrotum in men. Dissection is then directed to the ischiorectal fossa on the affected side. Electromyogram is used to direct the surgeon to the area of compression to limit the need of extensive dissection. Similarly to the transperinal approach, access to the pudendal nerve is limited. Recovery is difficult in men with painful incisions between the scrotum and rectum that are prone to infection.

Laparoscopic

This approach does not require transection of the sacrotuberous ligament and provides good visualization of the nerve's course, but long-term success rates have been poor. Perhaps with robotic surgery, which allows greater visualization and precision, this approach will be further improved.

Another option is to decompress the pudendal nerve, as described by Erdogru et al. (Figures 62-9 and 62-10) They undertook 27 laparoscopic pudendal nerve decompression/transposition procedures (Istanbul technique) and protected their release with an omental flap in an effort to prevent

refibrosis around the nerve long-term. The technique involves complete division of the sacrospinous ligament and splitting of the inner (caudal) side of the levator ani muscles until the fatty tissue in front of the entrance to Alcock's canal is reached. The aponeurosis of the internal obturator muscle is opened, thus opening the canal. With a 6-month follow-up, a >80 % reduction in the visual analog pain scale was noted in over 80 % of the patients [67]. Quality of life scores also improved and were maintained during the 12-month follow-up.

Augmentation of the Canal

Venturi et al. studied patients who underwent Alcock's canal augmentation via transperineal injections of autologous adipose tissue with stem cells along the canal to increase space for the nerve to travel and decrease compression. This was a pilot study undertaken in 15 women and initial results were promising. They followed pudendal nerve motor terminal latency (PNMTL) and there was a trend to better conduction, and improved pain scores in the short term [68].

Conclusion

In summary, although IBS and chronic functional pelvic pain represent a spectrum of disease entities that are difficult to diagnose, manage, and treat, a systematic approach with a multidisciplinary team is essential. While surgery is only occasionally necessary, the colorectal surgeon must remain knowledgeable about these life-altering problems.

Middle and Anterior Compartment: Issues for the Colorectal Surgeon

Cecile A. Unger and Marie Fidela R. Paraiso

Key Concepts

- Multi-compartment pelvic floor disorders are common and require a multi-disciplinary team approach to evaluation and management.
- The levator ani muscles and connective tissue structures of the pelvis provide the main supports to the pelvic floor and pelvic organs.
- Transvaginal repair of pelvic organ prolapse is commonly performed at the time of transperineal repair of rectal intussusception or prolapse.
- The most commonly performed abdominal procedure for pelvic organ prolapse is the sacral colpopexy, which can be performed concomitantly with ventral or other types of rectopexy.
- A transvaginal or transanal approach can be taken to repair a rectocele, but the transvaginal approach is more common and seems to have better outcomes with less morbidity.

Introduction

Many patients who complain of descensus in a single pelvic compartment may be affected by prolapse in multiple pelvic compartments [1] and several publications have described coexistence of rectal and pelvic organ prolapse [2–9]. In addition, there is a high incidence of anorectal dysfunction in women with genital prolapse. As a result, multi-compartment pelvic floor disorders are now increasingly being evaluated and managed together by female pelvic medicine and reconstructive surgery (FPMRS) surgeons and colorectal surgeons [10, 11].

It is imperative for specialists to recognize when consultation with the one another is indicated, as joint management may significantly improve patient outcomes. For instance, defecatory symptoms may not improve with transvaginal rectocele repair alone [12], as obstructive symptoms may be related to more extensive posterior compartment dysfunction. For example, studies have shown that an enterocele is not an uncommon finding in patients presenting with a rectocele, and may occur in up to 42 % of patients [13], and rectal intussusception may occur in up to 68 % of patients undergoing defecography for symptomatic rectocele [14].

The other posterior compartment conditions that may occur with anterior and middle compartment prolapse include sigmoidocele, anismus, perineal descent, and/or rectal prolapse. Peters et al. [15] showed that in 55 patients evaluated with rectal prolapse, 52 of the patients had other pelvic floor defects, and 39 were found to have occult rectal prolapse that simulated a rectocele or enterocele. Patients with the above-mentioned posterior defects often require radiographic evaluation for accurate diagnosis, as well as a multi-disciplinary team approach to management [16, 17].

In this chapter, we review the anatomy of the pelvic floor and the important relationships between its compartments, we describe the FPMRS surgeon's approach to the evaluation and management of pelvic organ prolapse, we provide an overview of the transvaginal and abdominal approaches to apical prolapse procedures that can be performed concomitantly with colorectal procedures, and we describe and compare the different approaches to the rectocele repair.

Anatomy of the Pelvic Floor

The levator ani muscles (puborectalis, iliococcygeus, and pubococcygeus) contribute to the main support of the pelvic organs and play an important role in the pelvic floor (Fig. 63-1). [18]. In their normal state, the levators maintain constant tone, which helps support the pelvic organs against fluctuating changes in intraabdominal pressures, and also keeps the urogenital hiatus closed, drawing the distal urethra, vagina and rectum up toward the pubic bone [19]. The muscles can also be voluntarily contracted (performance of a Kegel exercise) but can also be lengthened and relaxed, which is important for micturition and defecation.

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_63

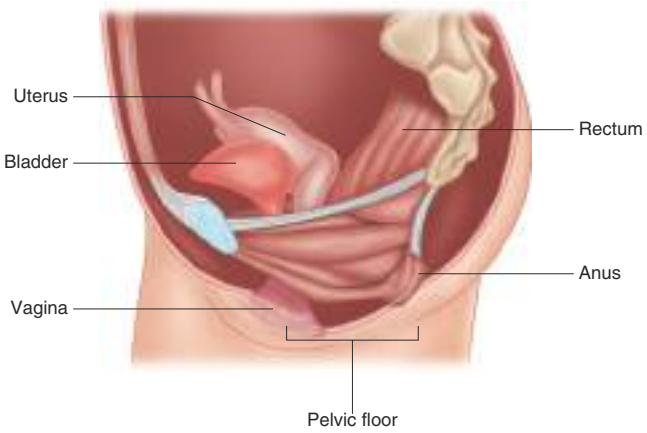

FIGURE 63-1. Interaction between the levator ani muscles and the pelvic organs. The levator ani muscles (puborectalis, iliococcygeus, and pubococcygeus) contribute to the main support of the pelvic organs and play an important role in the pelvic floor.

The *puborectalis* originates from the each side of the pubic bone and forms a U-shaped sling that courses above the external sphincter muscle and around the anorectal junction [19]. The *iliococcygeus* is the least bulky of the levator ani muscles and is located posteriorly, arising from the ischial spines and the *arcus tendineus levator ani* with its fibers meeting in the midline and inserting into the coccyx. The *iliococcygeal raphe* forms as a result of the converging iliococcygeal muscle fibers, and forms the *levator plate*, an anatomic shelf on which the rectum, proximal vagina, and uterus rest. In a woman with normal support, the levator plate lies almost parallel to the horizontal plane in the standing position [20]. The *pubococcygeus* originates from the inner surface of the pubic bone and contains three divisions that are named according to the attachments of the muscle fibers [21]. The *pubovaginalis* inserts into the lateral walls of the vagina and helps to maintain para-vaginal and urethral support and plays a role in urinary continence [22]. The pubococcygeus muscle fibers that attach to the perineal body are termed the *puboperinealis*, and in its contracted state, the muscle draws the perineal body toward the pubis. The *puboanalis* is comprised of muscle attachments to the anus at the level of the intersphincteric groove, and along with the puborectalis muscle, this muscle helps to elevate the anus, which also keeps the urogenital hiatus closed [23].

The *perineal membrane* (also referred to as the *urogenital membrane*) spans the opening of the ventral pelvic outlet [24] and is continuous with the *arcus tendineus fascia pelvis*, attaching the distal vagina and urethra to the distal pelvis, while the dorsal outlet is made up of dense connective tissue that attaches to the ischiopubic rami as well as the distal vagina and perineal body [23]. The *perineal body* is located between (and attaches to) the distal third of the posterior vagina and the external sphincter of the anus and is made up of a portion of the *bulbospongiosus* and *superficial transverse perineal muscles* as well as dense connective tissue [25]. This muscular structure supports the distal vagina and rectum, and these attachments can easily be disrupted during childbirth, necessitating proper reattachment and repair after delivery in order to restore the proper distal pelvic floor supports.

There are important relationships between the levator ani muscles and the connective tissue structures that attach the uterus, cervix, vagina, and rectum to the pelvic walls, and these interactions are also responsible for structural support in the pelvis. The supporting or *endopelvic fascia* is a more complex and controversial structure than the levator ani. Located between the visceral peritoneum and parietal fascia of the levator ani is fibroareolar tissue containing neurovascular bundles, smooth muscles, collagen, and elastin, which is often called the endopelvic or endovisceral fascia [26]. This structure fans out to envelop the pelvic organs and anchors them to the surrounding pelvic sidewall structures. DeLancey calls the endopelvic fascia the *viscero-fascial layer* because it is a combination of the pelvic viscera and endopelvic fascia and plays a key role in the support of the vagina and uterus [27, 28]. Norton [29] has described the interaction between levator ani and endopelvic fascia as the "boat in the dry dock." The levator ani is like the water in a dry dock that floats the boat, and the ligaments are like the mooring that holds the boat in place. When the water in the dock begins to recede, the moorings are strained to hold the boat in place. The term "ligament" is commonly used to describe pelvic floor connective tissue structures; however, it is important to recognize that these structures do not really meet the true definition of the term. In fact, there is great variation in the composition and function of these structures. Some consist of dense connective tissue bands that connect portions of the bony pelvis and are responsible for pelvic stability. These "ligaments" are often used as anchoring sites in pelvic organ prolapse surgery, and examples include the sacrospinous ligaments, uterosacral ligaments, and the anterior longitudinal ligament of the sacrum. Smooth muscle, fibrous, and areolar tissue also make up some of these connective tissue structures, and are more likely to play a role in the orientation and support of the pelvic organs inside the pelvis. Examples of these structures include the round and broad ligaments of the uterus.

The rectovaginal septum is a condensation of tissue that extends approximately 3 cm proximal to the perineal body but is not present above the rectovaginal pouch [30] and it is attached to the pelvic sidewalls by the *arcus tendineus fascia rectovaginalis* [31]. Surgically and histologically, it is hard to delineate this layer of tissue between the vagina and rectum, and the same has been described for the layers of tissue between the vagina and bladder in the anterior compartment [32]. These tissues have previously been referred to as the pubocervicovesical (anterior) and rectovaginal (posterior) fascial layers; however, histological studies cast doubt over the "fascial" nature of these layers [28], and surgically, the layer that can be separated between

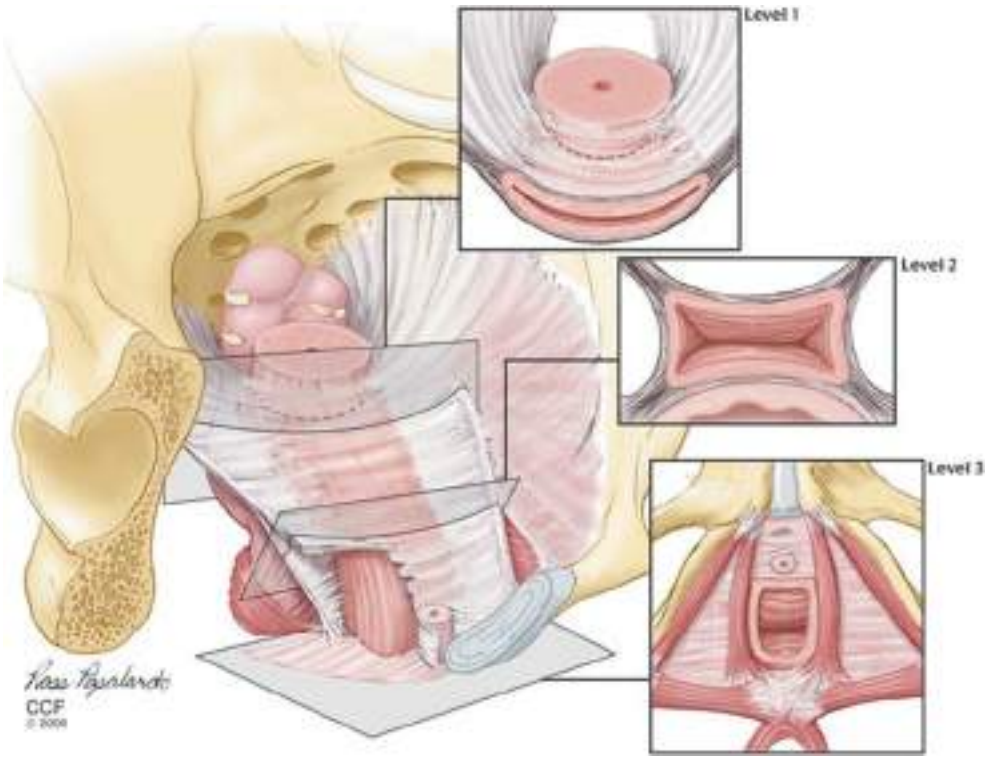

FIGURE 63-2. Illustration of the endopelvic fascia and the levels of support to the vagina. From Lee PYH. Pelvic Floor Disorders. In: Beck, D.E., Roberts, P.L., Saclarides, T.J., Senagore, A.J., Stamos, M.J., Nasseri, Y. (Eds.) ASCRS Textbook of Colon and Rectal Surgery, 2nd ed. Springer, New York, 2011. Meurette Reprinted with permission Ó Cleveland Clinic Center for Medical Art and Photography 2004–2009.

the vagina and the rectum and the vagina and the bladder appears to predominantly be made of vaginal muscularis. Therefore, when we describe repair of a cystocele and/or rectocele, we commonly refer to plication of the muscularis layer, rather than a separate fascial layer between the two structures.

DeLancey [33] has described three levels of vaginal connective tissue support that help us understand how and why pelvic floor support defects occur (Fig. 63-2). The parametria are the lateral supports to the uterus and cervix and are made up of perivascular connective tissue that contains the uterosacral and cardinal ligaments. These structures are known as Level I support and provide the apical support of the vagina to the pelvic sidewalls, keeping the vagina suspended vertically over the pelvic floor. Women with Level I support defects present with either uterine/cervical or post-hysterectomy vaginal apex prolapse. The mid portion of the vagina is suspended to the pelvic sidewalls via lateral connective tissue attachments to either the arcus tendineus fascia pelvis or the medial aspect of the levator ani muscles. These attachments are important for anterior vaginal wall and bladder neck support. Defects in these supports can manifest as anterior vaginal wall prolapse (a cystocele) or stress urinary incontinence symptoms. As previously mentioned, the distal vagina attaches to the perineal body posteriorly, and these attachments contribute to Level III support. Defects in these structures can present as distal posterior vaginal wall prolapse (a rectocele) as well as perineal detachment and descent.

The etiology of pelvic organ dysfunction is multifactorial but appreciating the relationships between the above-mentioned anatomic structures is an important part of understanding how pelvic floor dysfunction occurs. For example, mechanical disruption of the connective tissues or neuromuscular injury of the pelvic floor can lead to anatomic changes such as lengthening or widening of the genital hiatus as well as a change in the incline of the levator plate [34]. If the axis of the vagina becomes more vertical, the pelvic organs can become oriented directly over the larger hiatal opening, which can lead to descensus of the pelvic organs through the hiatus [35]. We also believe that there may be a genetic component to pelvic floor disorders. Recent histologic studies have demonstrated that the elastin and collagen content in the vaginal walls of women with pelvic organ prolapse and incontinence differs from women who do not suffer from these conditions [36]. It is not completely clear whether these women have a genetic predisposition to changes in collagen and elastin homeostasis, placing them at risk for pelvic floor dysfunction over time, whether the distension and mechanical disruption caused by the prolapse is responsible for the histologic changes reported, or if a combination of these factors are at play. There is currently

ongoing research examining these questions, but what remains clear is that the underlying etiology of pelvic floor disorders is complicated and likely involves multiple factors.

Evaluation of Pelvic Organ Prolapse

The diagnosis of pelvic organ prolapse is made using a combination of history and physical examination. Patients with symptomatic prolapse usually describe vaginal bulge, pressure, discomfort, as well as functional symptoms such as difficulty voiding or defecating, and sexual dysfunction. The physical examination for prolapse includes a general gynecology examination and should be conducted with the patient in the dorsal lithotomy position. If physical findings do not correspond with symptoms, or if the maximum extent of prolapse cannot be confirmed, the woman can be reexamined in the standing position.

The pelvic organ prolapse quantification (POP-Q) examination is a validated tool that is used to measure and report prolapse [37]. Using the hymen as a reference point, the POP-Q measures the genital hiatus length, the perineal body length, the total vaginal length, the amount of cervical or vaginal apex prolapse, and the presence/extent of prolapse of the anterior and posterior vaginal walls. All measurements are taken while the patient is performing a Valsalva maneuver with the exception of total vaginal length. The maximal amount of prolapse noted is used to assign a stage to the prolapse (Table 63-1).

Many women with pelvic organ prolapse also have urinary incontinence. Women who do not have symptoms of incontinence are at risk for de novo stress urinary incontinence when their prolapse is corrected because the previously obstructed urethrovesical junction is straightened by elevating the vaginal apex and anterior vaginal wall [38]. Adding an anti-incontinence procedure at the time of prolapse repair significantly reduces the incidence of stress urinary incontinence [39, 40], and as a result, it is important to screen patients for incontinence symptoms at the time of evaluation, and also to evaluate patients for occult incontinence before proceeding with surgery. During the pelvic examination, if the patient has a full bladder, she may be asked to cough or Valsalva, and her urethra is examined for leakage of urine. Alternatively, simple cystometry can be performed with placement of a catheter attached to a 60 cc syringe with the plunger removed placed approximately 15 cm above the level of the pubic symphysis. The bladder is filled with normal saline and the patient is then asked to cough, and the urethra is observed for any degree of leakage of urine. Otherwise, urodynamic testing is performed, and an overview of this office procedure is described below.

Based on current evidence, there is no role for routine imaging in the evaluation of pelvic organ prolapse, but it may be useful for diagnosis and management when rectal intussusception, occult rectal prolapse, sigmoidocele, or enterocele is suspected as the underlying cause of a patient's defecatory symptoms. For example, rectal prolapse frequently coexists with other pelvic floor defects and internal rectal prolapse may simulate a rectocele or enterocele and requires defecography to establish the diagnosis [15]. Anal manometry, defecating proctogram, dynamic MRI, and endoanal ultrasound may also have an important adjunctive role in assessing obstructive defecatory symptoms and/or fecal incontinence in patients presenting with pelvic floor disorders, and are often ordered and/or performed by the colorectal surgeon to help with assessment and treatment planning. Indications and interpretation of these tests has already been discussed in previous chapters, and not within the scope of this chapter.

Overview of Urodynamics

Urodynamic testing is an office-based procedure that is used to evaluate the function of the lower urinary tract system. Pelvic floor surgeons rely on urodynamic testing for several different indications; however, there are no agreed upon guidelines for when to perform the procedure, and testing is often based upon clinical history, presenting symptoms, previous pelvic floor surgeries, and upcoming planned procedures [41]. Table 63-2 lists common indications for urodynamic testing used by most FPMRS surgeons.

Urodynamics evaluates the pressures at which the detrusor muscle of the bladder is able to accommodate during bladder filling, how well a patient is able to suppress micturition at

Table 63-1. Pelvic organ prolapse stages

Stage 0	No prolapse; apex descends within 2 cm of the total vaginal length
Stage 1	Most distal portion of the prolapse descends to a point greater than 1 cm above the hymen
Stage 2	Most distal portion of the prolapse descends within 1 cm of the hymen (above or below)
Stage 3	Prolapse extends more than 1 cm beyond the hymen but no more than within 2 cm of total vaginal length
Stage 4	Complete eversion; extension within 2 cm of the total vaginal length

Table 63-2. Indications for urodynamics

Complicated lower urinary symptoms history
Pre-operative evaluation of stress incontinence
Urgency incontinence refractory to medical therapy
Recurrent urinary incontinence after anti-incontinence surgery
Frequency, urgency, and pain syndromes unresponsive to therapy
Nocturnal enuresis

various volumes, and how well the patient is able to initiate voiding which requires adequate detrusor muscle contraction with simultaneous relaxation of the urethra. The procedure is performed and recorded in a standard fashion in order to facilitate clear communication between providers, and the terminology used to report urodynamic findings is based on published guidelines by the International Continence Society (ICS). Figure 63-3 depicts the set-up and catheter placement for multi-channel urodynamics, which is the method most commonly used by practitioners. Patients are positioned comfortably on a urodynamics chair and disposable micro-transducer catheters are used. A catheter is placed inside of the bladder and measures *vesical pressures* (P_{ves}) and a catheter is placed inside of either the rectum or vagina and measures *abdominal pressures* (P_{abd}). *Detrusor pressure* (P_{det}) is determined by subtracting the abdominal and vesical pressures ($P_{abd} - P_{ves} = P_{det}$).

The first stage of urodynamics is referred to *filling cystometry*, which assesses the relationship between volume and detrusor pressure during bladder filling, also known as the *storage phase*. The bladder is then filled with normal saline and the patient is asked about bladder sensations: first sensation of filling, first desire to void, strong desire to void, symptoms of urge, and pain. The bladder is filled until *cystometric capacity* is reached and this volume is recorded. Detrusor contractions are also recorded during filling and are defined by rises in P_{det}, which represent *detrusor overactivity*, an abnormal finding on urodynamics that is indicative of overactive bladder disorder. Bladder *compliance* can be calculated by dividing the volume change by the change in P_{det}, which should remain low and constant during filling. Rises in P_{det} not associated with a detrusor contractions are a sign of poor bladder compliance and can be associated with neurogenic bladder disorders. In order to assess ability to suppress micturition during filling, patients are asked to perform provocative measures (Valsalva, cough, jumping) to simulate stresses on the bladder, and episodes of leakage with these maneuvers are indicative of stress urinary incontinence. Under normal physiologic conditions, as the bladder fills, urethral resistance should generate enough pressure to compensate for any abdominal or detrusor pressure that is experienced during normal activities. The *leak point pressure* measures the urethra's ability to prevent involuntary leakage of urine, and is defined as the lowest P_{det} or P_{ves} at which urine is expelled through the urethra. *Abdominal leak point pressure* is most commonly used to assess stress urinary incontinence as it assesses the ability of the urethra to resist increased abdominal pressure. This information is sometimes helpful to assess the severity of stress urinary incontinence.

The second stage of urodynamics is *uroflowmetry* and it involves assessment of bladder emptying, known as the *voiding phase*. After they undergo filling during the first phase of the study, patients are asked to void into an electronic volume detector and a graphical representation, or flow pattern, of the weight of the urine over time is created. Conditions that alter the uroflowmetric parameters include bladder neck obstruction, urethral resistance, and detrusor contractility. In addition to urine flow, post-void residual (PVR) is also assessed after passive or active filling of the bladder. Techniques to determine PVR include ultrasonographic assessment as well as catheterization.

Surgical Management of Middle and Anterior Compartment

Women presenting with bothersome pelvic organ prolapse have a number of treatment options, including observation, conservative treatment with a pessary and/or pelvic muscle exercises, and surgery [42]. Surgical management should be chosen after careful counseling, and if the patient no longer is improved by or does not desire conservative therapies. Surgical management should aim to address all of the segments of the vagina that are involved in the prolapse and an attempt should be made to improve related visceral function of the lower urinary tract, vagina, and anorectum [38].

There are important considerations to review with the patient before proceeding with prolapse surgery. These discussion points often help the surgeon and patient make a decision about appropriate route and approach to the surgery, and these important factors are listed in Table 63-3.

Transvaginal Repair

Transvaginal repair of pelvic organ prolapse is commonly performed at the time of transperineal repair of rectal intussusception or prolapse. In most cases, the FPMRS surgeon first performs the transvaginal prolapse repair, in order to operate in a clean-contaminated field, and the colorectal surgeon follows and performs his or her transperineal repair after the vaginal repair has been completed. However, the order of surgery can be coordinated based on surgeon preference and availability. Below we provide a brief overview of the surgeries performed.

Anterior compartment prolapse refers to prolapse of the bladder due to defects in the anterior vagina and is called a *cystocele*. This can be repaired performing a native tissue repair (anterior colporrhaphy) or with placement of a biologic or mesh graft. Cystocele repair is commonly performed at the time of transvaginal apical repair and confers very little additional morbidity to the overall procedure. The overall rate of anterior compartment recurrence has been estimated to be as high as 55 % [43], but depends on definitions used for recurrence. The rate of recurrence also appears to be higher in native tissue groups compared to mesh or graft augmentation groups: RR 1.39 (95 %CI 1.02–1.90) with a polyglactin mesh inlay and RR 2.72 (95 %CI 1.20–6.14) with a porcine dermis mesh inlay [44]. While the recurrence rate is higher after native tissue repair, it remains unclear if the higher adverse event rates associated with mesh augmentation (i.e., mesh erosion rate ~10 %) for repair of the anterior compartment outweigh the risk of recurrence, and at this time, most surgeons would argue that it does not.

Table 63-3. Preoperative considerations

Is hysterectomy indicated? Does the patient desire uterine preservation?
Is the patient sexually active? Does she desire to maintain sexual function?
Through which route should the surgery be performed—vaginally, abdominally, laparoscopically, robotically?
Should a native tissue repair be performed or is graft augmentation necessary?
Is the patient undergoing a concomitant colorectal procedure, and which route is best for that procedure?
Should a concomitant anti-incontinence procedure be performed, and if so, which one?

Middle compartment prolapse refers to apical prolapse and includes post-hysterectomy vaginal apex prolapse as well as uterovaginal prolapse. Uterine-sparing techniques, namely hysteropexy, exist for the repair of apical prolapse in patients who desire uterine preservation. In other patients, vaginal hysterectomy with apical suspension or post-hysterectomy apical suspension, are commonly performed procedures. Apical suspension can be performed through an extra or intraperitoneal approach. Intraperitoneal bilateral uterosacral colpopexy is often performed at the time of vaginal hysterectomy and is a popular surgery in the USA. It is most commonly performed vaginally, but can also be done abdominally or laparoscopically, with or without robotic assistance. Its biggest advantage is that it suspends the vaginal apex in such a way that it maintains the normal axis of the vagina [38]. During this procedure, the uterosacral ligaments are exposed bilaterally and two to three delayed absorbable and/or permanent sutures are placed through the ligament 1–2 cm above the level of the ischial spines. These sutures are then passed through the vaginal cuff, suspending the apex of the vagina to the ligaments once the sutures are tied down. Studies have shown that success rates after uterosacral colpopexy are high. In a systematic review by Margulies et al. [45] the pool rates for anatomic success by compartment (anterior, apical, posterior) were 81.2 %, 98.3 %, and 87.4 %, respectively. Interestingly, patients with more severe prolapse had significantly worse cure rates, which has been reported in other studies as well [46].

Extraperitoneal suspensions are usually performed for post-hysterectomy vaginal vault prolapse, but can also be done after hysterectomy once the peritoneum is closed. The vaginal apex can be suspended unilaterally to the sacrospinous ligament for moderate-to-severe prolapse, or to the bilateral iliococcygeus fascia just below the ischial spines, in cases of minor apical prolapse or if the vagina is not long enough to reach the sacrospinous ligament. A sacrospinous suspension can be performed via an anterior, apical, or posterior approach and requires careful extraperitoneal dissection of the pararectal space down to the ischial spine and the sacrospinous ligament. Suspension sutures made of either delayed absorbable and/or permanent material are then placed through the ligament with care taken to avoid the pudendal neurovascular structures through direct visualization using a standard needle driver, or through specialized ligature carrier instrument such as the Deschamps or the Miya hook. The Capio™ (Boston Scientific, Inc., Natick, MA) is a suture-carrier device that was developed in the last decade and is also commonly used by surgeons to perform this

procedure. Once two to four suspension sutures are placed through the ligament, the sutures are passed through the vagina, suspending the apex to the ligament once the sutures are tied down. Studies have shown that the sacrospinous colpopexy is effective in treating apical prolapse with recurrence rates as low as 8 %; however, anterior compartment recurrence is more common after sacrospinous suspension, with rates as high as 37 % 6–15 years after surgery [47]. The sacrospinous ligament suspension remains a popular approach for post-hysterectomy prolapse and concomitant cystocele repair at the time of suspension is recommended.

If patients are older and no longer desire sexual activity, a vaginal obliterative procedure can be performed instead of a reconstructive procedure. This is commonly performed at the time of transperineal colorectal procedures when patients present with concomitant advanced stage pelvic organ and rectal prolapse, especially if they are older and frailer and are determined to not be good candidates for a transabdominal repair. Obliterative procedures can be performed for post-hysterectomy vaginal prolapse as well as for uterovaginal prolapse, in which case either the uterus is left in situ (a Lefort procedure), or a vaginal hysterectomy is performed followed by a colpectomy and obliteration of the vagina (colpocleisis). The major advantage of the obliterative procedure is that is associated with a quick operative time and low morbidity, but most importantly, these procedures are associated with the lowest rates of recurrence and very high patient satisfaction [48].

Abdominal Repair

The most commonly performed abdominal procedure for pelvic organ prolapse is the sacral colpopexy, which can be performed through a laparotomy or by laparoscopy or robot-assisted laparoscopy. The procedure involves suspension of the vaginal apex to the anterior longitudinal ligament of the sacrum using a bridging synthetic or biologic graft. Synthetic grafts that have been used in the past include polypropylene mesh, polyester fiber mesh, polytetrafluoroethylene mesh, Dacron mesh, and silastic silicone rubber. Large-pore, light-weight polypropylene mesh is currently the most common type of synthetic mesh used, and we recommend using this mesh over the others, as it is associated with the least amount of complications. Biologic materials that have used for this procedure include fascia lata, rectus fascia, dura mater, porcine dermis, and porcine small intestinal submucosa. The data that exist comparing synthetic mesh and biologic materials have shown that anatomic outcomes with biologic materials such as fascia lata are inferior to those when synthetic mesh is used [49, 50]. We prefer to use mesh for routine sacral colpopexy procedures; however, we recommend using biologic materials, and most often use cadaveric fascia lata, for combined ventral rectopexy procedures when a sigmoid resection is performed. This recommendation is based on the theory that infection resulting from anastomotic leak would necessitate removal of the implanted prosthesis. The data supporting this recommendation are sparse.

To perform the procedure, the patient should be positioned in dorsal supine low lithotomy position. The bladder is drained continuously with a Foley catheter. A sponge stick or end-to-end anastomosis (EEA) sizers can be placed in the vagina and rectum for manipulation of the vaginal apex and delineation of the rectovaginal septum. A laparotomy is performed, or intraperitoneal access is gained laparoscopically with or without robotic assistance. The patient is positioned in steep Trendelenberg and the small bowel is placed or packed into the upper abdomen, and the sigmoid colon is deviated to the left pelvis as much as possible. Pertinent anatomy is identified, including the bilateral ureters, the bifurcation of the aorta, and the iliac vessels. A longitudinal incision is made in the peritoneum over the sacral promontory and the anterior longitudinal ligament is exposed. Care must be taken here to avoid injury to the presacral venous plexus and middle sacral artery. Next, either a subperitoneal tunnel is created or the peritoneum is opened from the sacrum down to the posterior cul-de-sac in order to cover the graft with peritoneum after it is attached to the sacrum. The vaginal EEA sizer or alternate probe is then used to elevate the vagina and the peritoneum over the anterior vagina is dissected sharply in order to create a 4 cm pocket between the vagina and bladder. The same technique is used posteriorly: the rectovaginal septum is identified by separating the vaginal and rectal EEA sizers, and the peritoneum is incised sharply so that a posterior 4–6 cm pocket can be created. The mesh is then secured to the anterior and posterior vagina in a "Y" configuration using 0 or 2-0 suture (our preference is monofilament delayed absorbable suture) and with the vagina placed in the right pararectal space, the stem of the mesh is secured to the sacrum using 0 or 2-0 suture (our preference is monofilament permanent). The peritoneum is then closed over the mesh with absorbable suture.

Sacral colpopexy or colpoperineopexy can also be performed in conjunction with ventral or other rectopexy and requires a multi-disciplinary team approach to the surgery (Fig. 63-4a, b). During the peritoneal dissection, the colorectal surgeon mobilizes the sigmoid and rectum and either the FPMRS surgeon or colorectal surgeon performs the posterior dissection of the rectovaginal septum down to the level of the perineum (in the case of perineopexy) so that the posterior mesh may be attached as caudal as possible. This is especially important for patients with outlet defecatory dysfunction and/or a perineocele on examination. As mentioned in the chapter on rectal prolapse, in cases of redundant sigmoid colon suspected on defecography or other preoperative studies and confirmed intraoperatively, the colorectal surgeon may choose to perform a partial sigmoid resection with EEA in conjunction with the prolapse repair. If this is the case, as we previously mentioned, we advocate for biologic graft placement to avoid the need for removal if postoperative

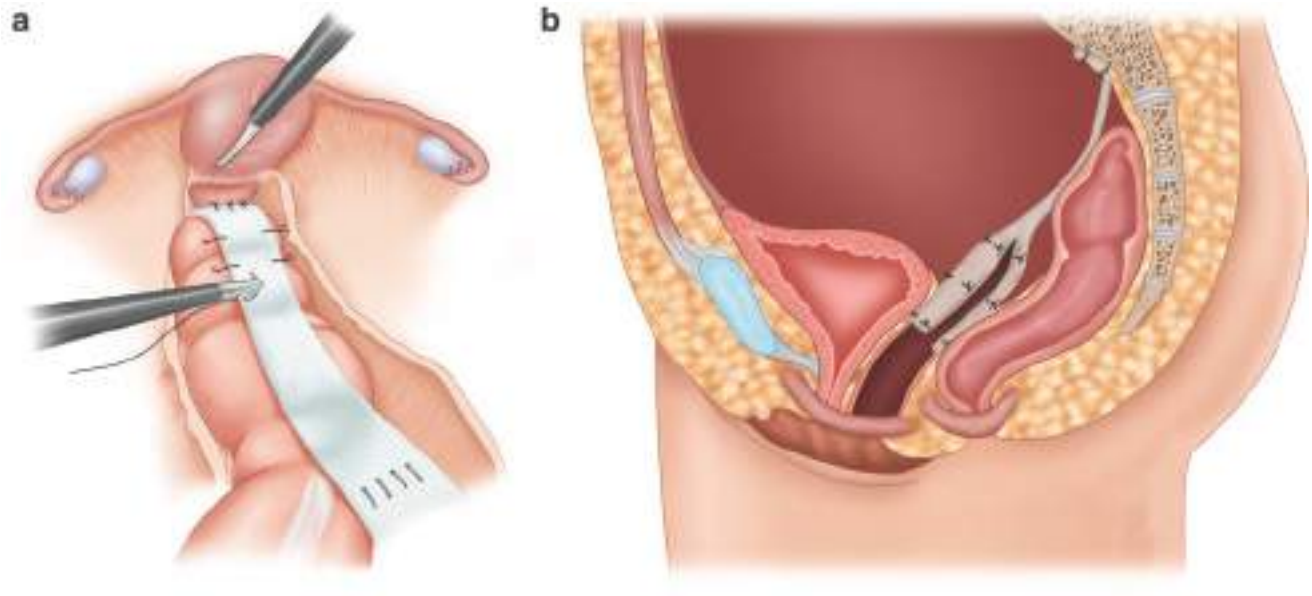

FIGURE 63-4. Combined sacro-colpo-rectopexy procedure. (**a**) The graft is secured to the anterior rectum. (**b**) Sagittal view of the procedure showing suspension of the vagina and rectum to the sacrum using a graft.

anastomotic leak occurs. In our practice, we use porcine small intestinal submucosa (6 or 8 ply) for this portion of the procedure. Instead of posterior vaginal placement, the posterior graft is attached to the fascia of the pubococcygeus and iliococcygeus muscles laterally, to the distal rectum, lateral rectal attachments, and to the perineum distally. The mesh is then secured to the sacrum by one of the surgeons while the other confirms that there is adequate suspension without too much tension of both the rectum and vagina. Restoration of normal anatomy is key during this portion of the surgery.

Pooled data show that sacral colpopexy has superior outcomes to a variety of vaginal procedures including sacrospinous colpopexy, uterosacral colpopexy, and transvaginal mesh [44]. However, the procedure is associated with longer operating time, longer time to return to daily activities of living, and increased cost if the open abdominal approach is performed. Therefore, care should be taken in choosing the appropriate patients for the procedure, and the risks and benefits of the procedure versus the other approaches should be discussed.

With regard to combined rectopexy and sacral colpopexy procedures, there are many published reports of successful outcomes showing that a multi-disciplinary transabdominal approach is both safe and effective with good symptomatic improvement for patients with combined genital and rectal prolapse [17, 51–58]. Review of the literature also reveals that adverse events related to combined rectopexy with sacral colpopexy appear to be low, and there does not seem to be significant added morbidity to performing the procedures together. In a single institution retrospective analysis, VanderPas et al. [59] looked at 133 patients who underwent sacral colpopexy alone, suture rectopexy alone with sigmoid resection, or combined sacral colpopexy with suture rectopexy with and without sigmoid resection. The authors found that the only difference in perioperative adverse events between the groups was the rate of postoperative ileus: the rate was much higher in the rectopexy alone group compared to the two sacral colpopexy groups (22.2 % vs. 3.8 % vs. 5.9 %, $p=0.004$). Otherwise, they reported that concomitant sacral colpopexy at the time of rectopexy did not increase the rate of intra- or postoperative complications.

The main concern is for spondylodiscitis, a condition that includes a spectrum of spinal infections such as discitis, osteomyelitis, epidural abscess, meningitis, subdural empyema, and spinal cord abscess [60]. Implanted prosthetic materials pose an ongoing risk during surgery and post-operatively because of the direct inoculation of bacteria at the time of graft and suture placement and because of the continued presence of a foreign body. As sacral colpopexy involves placement of a graft material over the sacrum, it represents a unique risk for spondylodiscitis, and there are reported case reports after this procedure [61, 62]. There are also reported cases of spondylodiscitis after combined rectopexy cases with and without sigmoid resection [63, 64]. More importantly, our group has found a significant increase in the risk of pelvic abscess formation after combined ventral rectopexy cases compared to sacral colpopexy alone (11.1 % vs. 0.8 %, $p<0.001$). In this cohort of patients, resection of the bowel did not seem to contribute to this increased risk, and rectopexy alone was sufficient for abscess formation.

Extra caution must be taken during these procedures to place the sacral sutures in the anterior longitudinal ligament of the sacrum and not inadvertently in the vertebral disc space, as this may increase the risk of bacterial inoculation

into the space, especially when the graft has been attached to the rectum. While there are documented reports of favorable outcomes using synthetic mesh, even with sigmoid resection is performed [59], our group attempts to minimize the risk of infection of prosthetic synthetic material by using a biologic graft when a bowel resection is indicated and by always using monofilament delayed absorbable sutures on the rectum and vagina and monofilament permanent sutures on the sacrum. We also have a low threshold to evaluate postoperative patients with either a CT scan or an MRI who complain of malaise and/or lower back pain or who have ongoing nondescript symptoms that cannot be explained by another cause of infection.

Surgical Management of the Posterior Compartment: Approach to the Rectocele Repair

Symptoms associated with a rectocele can often be managed effectively without surgery. Conservative management includes the initiation of a routine bowel regimen in order to avoid constipation and straining with bowel movements. A good regimen usually includes a high fiber diet, adequate water intake, and an over-the-counter stool softener. Pelvic floor physical therapy with or without biofeedback is also a conservative management strategy that can be offered to patients who are noted to have dysfunction of the pelvic floor muscles on examination. In addition, rectoceles protruding into the middle and upper vagina may also benefit from pessary placement.

Surgical management is an option for patients who fail conservative management. Surgeons differ in their opinion regarding when surgical management is indicated. Some surgeons (many colorectal surgeons) believe that dysfunctional fecal evacuation alone is not an indication and that patients should complain of needing to splint to defecate, or have vaginal protrusion of the rectocele beyond the hymen. In our urogynecology practice, we offer patients surgical treatment if they fail conservative measures, have any emptying/evacuation complaints and/or vaginal bulge or protrusion symptoms. Surgical management and planning are done after a thorough pelvic floor examination as mentioned above. Prolapse of the posterior vaginal wall can be isolated or can occur in conjunction with prolapse of the other compartments, and surgical planning is done accordingly. Concomitant enterocele and sigmoidocele can also be present with a rectocele, but there are no data describing how often this occurs, and whether or not the presence of one of these conditions affects surgical outcomes after rectocele repair.

Before proceeding with surgical management, an important thing to always consider is that constipation symptoms may be related to underlying physiologic dysfunction [65], and not the rectocele itself. In addition, while posterior compartment prolapse is commonly associated with symptoms of bowel dysfunction, it is unclear how related they are to the presence or severity of prolapse [66], which can make the decision to proceed with surgical management a challenge. There are data, however, that show significant improvement in anatomy of the posterior compartment as well as defectaory symptoms after rectocele repair [67], and therefore, there is reason to believe that posterior repair is beneficial for some patients. Patients should be well counseled about the possibility of persistent constipation or defecatory symptoms after rectocele repair, and conservative management of these symptoms may still be needed after surgery. Several approaches to rectocele repair exist. The transvaginal techniques used by pelvic floor surgeons will be discussed here. The transanal techniques will be discussed in Chap. 59.

Transvaginal Repair

Transvaginal repair is currently the most common approach to rectocele repair, and two techniques for transvaginal repair exist. The “traditional” or “midline plication” technique involves plication of the vaginal muscularis and rectovaginal tissues with or without the underlying levator muscles in the midline. A “site-specific” repair entails repair of discrete defects in the vaginal muscularis and rectovaginal tissues without plication of the levator muscles, usually with a finger inside of the rectum to discern repair of the defects.

Figure 63-5 provides an overview of how the transvaginal rectocele repair is performed. Patients are positioned in the dorsal lithotomy position. The posterior vaginal wall is injected with a local anesthetic with dilute epinephrine (our preference is 0.5 % lidocaine with 1:200,000 units epinephrine) and then incised in the midline from the most dependent portion of the rectocele proximally, (easily identified on rectovaginal examination), to the hymen. If there is detachment of the rectovaginal septum from the perineum, a gaping genital hiatus, and/or a perineocele, a perineorrhaphy should also be performed, and the perineal epithelium should also be incised. Once incision is made, clamps are placed on the incised vaginal epithelial edges, gentle traction is applied, and the fibromuscular layer of the vagina is dissected off of the epithelium, creating bilateral epithelial flaps. If an enterocele sac is encountered, it is usually opened, the small bowel contents are reduced and the sac is purse-stringed shut with either permanent or delayed absorbable No. 0 or 2-0 suture. Next, plication is performed either in the midline, or in a site-specific manner using either No. 0 or 2-0 absorbable or delayed absorbable suture until the rectocele is completely reduced. If a perineorrhaphy is performed, a 0 absorbable suture is used to reconstruct the perineum by plicating the inferior portion of the bulbospongiosus muscles and the superficial transverse perianal muscles and reattaching this complex to the rectovaginal septum if indicated. The epithelial edges are then trimmed bilaterally and reapproximated with 2-0 absorbable suture.

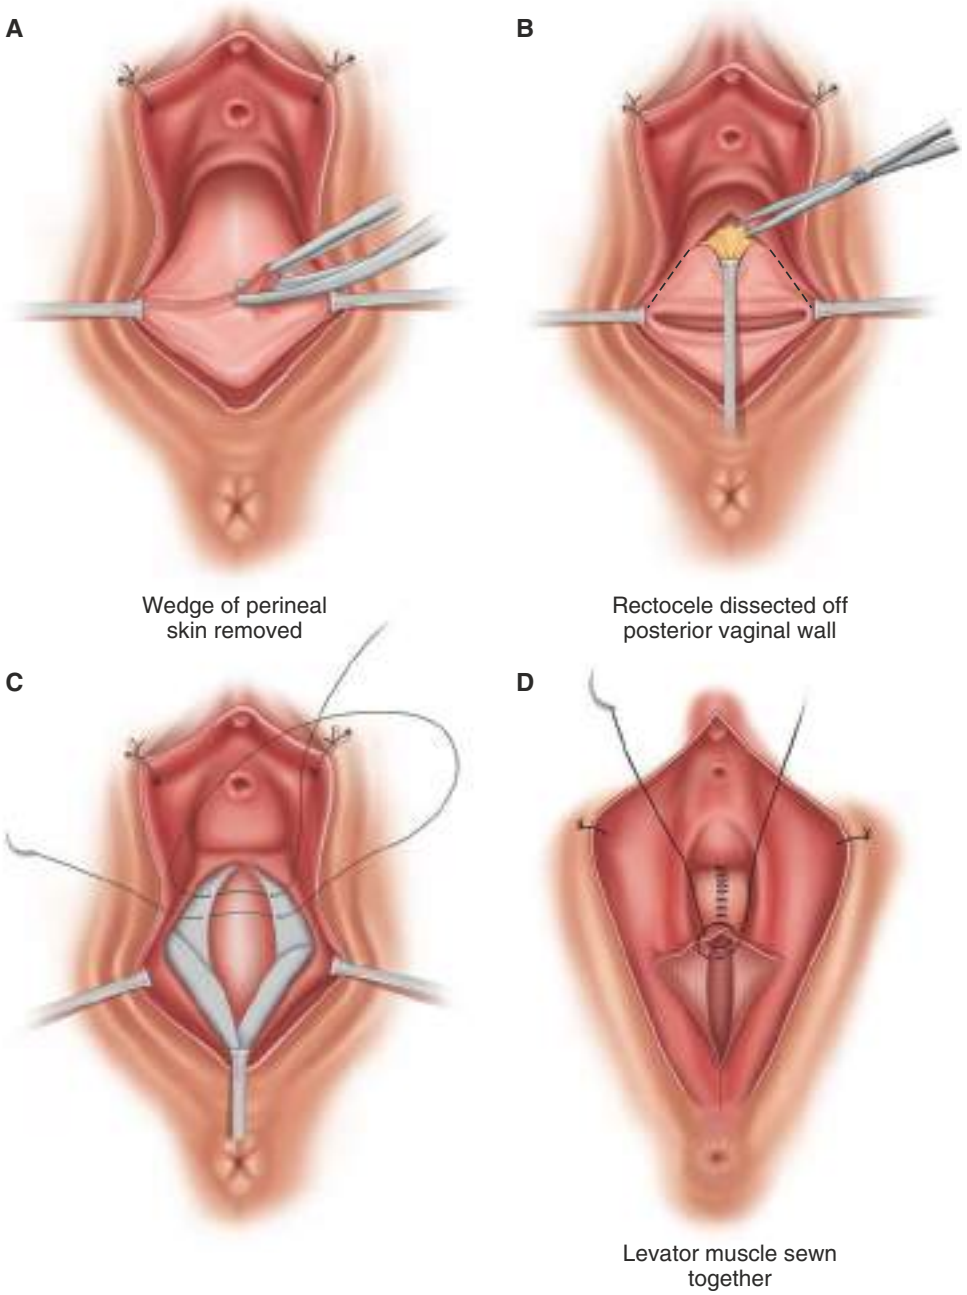

FIGURE 63-5. Transvaginal rectocele repair. (**a**) The posterior vagina and perineum are incised. (**b**) The epithelium is dissected off of the underlying vagina muscularis. (**c**) The muscularis and rectovaginal tissues with or without the underlying levator ani muscles are plicated. (**d**) The posterior vaginal epithelium is reapproximated.

The transvaginal rectocele repair can be further modified by augmenting the repair with either a synthetic or biologic graft. Synthetic graft materials can be either absorbable or permanent and are commonly made out of polyglactin or polypropylene, and the most commonly used biologic grafts are dermal or intestinal and are bovine or porcine in nature. The data that exist on posterior compartment repair with graft augmentation do not show significant benefit from its use. Altman et al. [68] prospectively looked at augmentation with a porcine dermal graft and reported a 40 % anatomic recurrence at 3 years and less than 50 % of patients had improvement in their defecatory symptoms. Sand et al. [69] compared rectocele repair with and without placement of a polyglactin mesh and found that recurrence was similar between the two groups.

In a review of posterior vaginal wall prolapse by Maher and Karram [70], midline plication and site-specific repair were found to both have a mean reported anatomic success

rate of 83 %. The authors also found that of the patients undergoing midline repair, 18 % complained of postoperative dyspareunia and 26 % complained of defecatory dysfunction with need to perform vaginal digitation to defecate, compared to 18 % for both problems in the site-specific groups. In their retrospective analysis, Abramov et al. [71] found that patients undergoing site-specific repair were more likely to experience recurrent rectocele compared to their midline plication cohort (32 % vs. 13 %, $p=0.015$). In a randomized trial by Paraiso et al. [72], patients with a stage II or greater rectocele were randomized to one of three rectocele repair arms: midline plication, site-specific repair, and augmented repair with porcine small intestinal submucosa graft. At 1 year, anatomic failure was found to be highest in the augmented group, followed by the site-specific repair group (46 % vs. 22 % v. 14 %, $p=0.02$). Interestingly, there was no statistical difference in defecatory and dyspareunia symptoms between the three groups. In a multicenter randomized trial, Sung et al. [73] also found no statistical difference in postoperative dyspareunia and resolution of defecatory symptoms in patients undergoing any type of native tissue repair (midline plication and site-specific) compared to a porcine small intestinal submucosa graft augmented repair; however, contrary to the above-mentioned studies, the authors also did not find a difference in objective and subjective success rates between the two groups.

Transanal Repair

In 1967, Marks [74] described the transanal rectocele repair procedure. While less commonly performed (compared to the transvaginal approach), it is still performed by some colorectal surgeons (see Chap. 59).

Several trials exist comparing the transvaginal and transanal approaches to rectocele repair. Kahn and Stanton [75] looked at women with symptomatic rectoceles with and without defecatory dysfunction who had impaired rectal evacuation on defecography but normal anorectal compliance on anal manometry. Transvaginal repair involved midline and levator plication and was performed by FPMRS surgeon, while the transanal colorectal surgeons performed a transanal repair. Nieminen et al. [76] performed a trial with broader inclusion criteria and included all women with symptomatic isolated rectoceles and intact anal sphincter function who did not respond to conservative management. Transvaginal repair was performed by FPMRS surgeons and involved midline plication only without levator plication and transanal repair was performed by colorectal surgeons. Both trials reported significant alleviation of symptoms by both operative techniques, but the transanal approach seemed to be associated with more clinically diagnosed rectocele recurrences and decreased incidence of dyspareunia.

In general, the transvaginal approach seems to be the more commonly performed operation for symptomatic rectocele particularly by FPMRS. The anatomic outcomes seem to be better, and it may be associated with less morbidity. However, the procedure is associated with higher rates of postoperative dyspareunia, especially if levator plication is performed, and it does not always resolve all defecatory symptoms.

Conclusions

Pelvic floor disorders are mostly a continuum of a disease process resulting from the loss of pelvic floor support. It is not uncommon to have multi-compartmental dysfunction, often requiring a multi-disciplinary team approach to evaluation and management. FPMRS surgeons and colorectal surgeons must strive to work together to offer their patients treatment strategies that are associated with the best outcomes but also with the lowest risk of morbidity. Understanding the anatomic relationships of the pelvic floor is the first step in achieving this. Second, is having a good grasp of each specialist's evaluation and management strategies, and working together to offer patients a comprehensive plan of care.

Pediatric Colorectal Disorders

Daniel H. Teitelbaum and Peter F. Ehrlich

Key Concepts

- **Cloacal anomalies**: These are among the most complex of pediatric colorectal conditions. Careful anatomic assessment must be done prior to surgical correction. Long-term follow-up is essential as future gynecological and genitourinary problems may arise that also need corrective action.
- **Anorectal atresias:** Imperforate anal anomalies are commonly associated with both genitourinary and spinal anomalies; both of which may complicate the long-term management and care of such patients. Life-long incontinence may be seen in up to 50 % of such patients.
- **Hirschsprung disease:** While surgical correction will result in a good stooling pattern. Many patients may suffer from recurrent enterocolitis after a pull-through, which requires immediate attention by a surgeon experienced in dealing with this secondary disorder. Children may also occasionally suffer from anorectal incontinence. In general, they need to be followed long-term for similar potential problems.
- **Necrotizing enterocolitis (NEC):** NEC may lead to full-thickness intestinal necrosis, resulting in the loss of a considerable amount of small and/or large intestine. Even without intestinal loss, an ischemic-associated stricture may occur, which is typically in the splenic flexure region, and may require dilation or resection of this portion of the colon.
- **Inflammatory bowel disease:** Diagnosis and the treatment are quite similar to adults. A key consideration is the need to ensure adequate growth and maturation through adolescence. Often this plays directly into the timing and decision for surgery.
- **Constipation:** Constipation can be challenging and typically can be initially approached with medical management. It is important to rule out Hirschsprung disease and anatomic obstruction. For the most intransigent of cases, some will benefit from an appendicostomy.

Introduction

Pediatric colorectal disease processes range from complex congenital developmental disorders to a wide range of acquired disorders. This chapter, while not trying to be a comprehensive review, will discuss some of the key colorectal disorders that are commonly cared for in childhood, and often carry with them life-long issues that colorectal surgeons may often encounter. Thus, familiarization with both of these types of disorders, and the management of potential complications, is paramount.

Congenital Anomalies

Cloacal Anomalies

Cloacal anomalies are the most severe and complex form of anorectal malformation (ARM) and occur in ~1:20,000 live-births [1]. Embryologically, the cloaca is a transient organ that becomes divided to separate the gastrointestinal tract from the genitourinary tract [1].

Clinically, a cloaca describes the condition in which the urethra, vagina, and rectum empty into a single channel with a single perineal orifice, located on the anterior perineum at the expected site of the urethra [2] (Figure 64-1). Typically, this is associated with a hypoplastic formation of the labial structures, and the perineal opening may be so small that adequate removal of secretions may be inhibited. This may lead to associated significant abdominal distension due to reflux of urine into the vaginal cavity, or excess secretions of the uterus due to maternal hormonal stimulation. This distension may worsen as the infant is unable to pass meconium and may require urgent decompression via a vaginostomy tube placement as well as colostomy (see section "Current Therapy").

Various cloacal malformations may present with similar prenatal imaging features, including dilation of the vaginal cavity [1]. The exact anatomic delineation will require

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_64

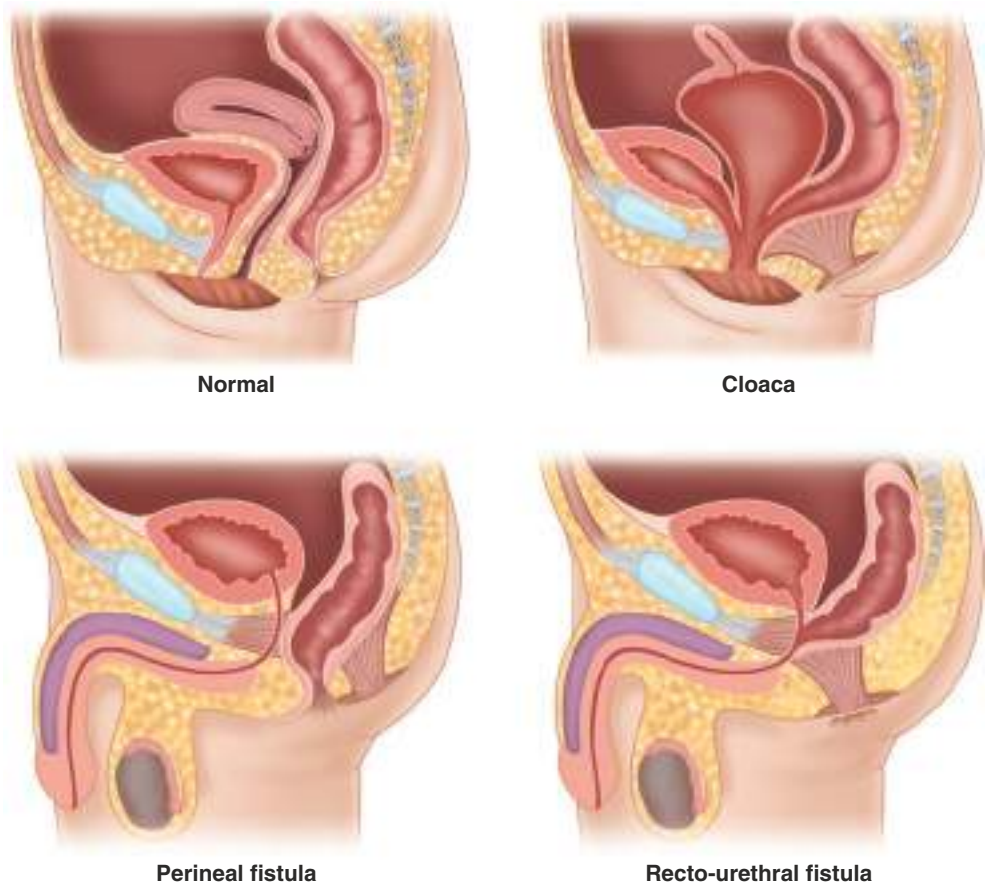

FIGURE 64-1. Classification of anorectal atresias. *Top left panel* Normal cross-sectional appearance of female anatomy. *Bottom left panel* Male with low imperforate anus (perineal fistula). Rectum is located within most of sphincter mechanism. *Top right panel* Female with cloaca. There is no plane of dissection between the rectum and urethra.

endoscopy and extensive radiologic work-up. One variant of cloacal malformation is a urogenital sinus, in which only the urethra and vagina form a common channel; the rectum is separate and in the appropriate anatomic location.

Mechanisms Underlying Cloacal Anomalies

Normally present in the 4–5-week old embryo, the cloaca is a derivative of hindgut endoderm [3]. A urorectal septum forms at the cranial aspect of the cloaca to divide it into the urogenital sinus ventrally and the anorectum dorsally [4]. Once the urorectal septum reaches the perineum, the cloacal membrane dissipates to open the urogenital sinus and, separately, the posterior anorectum. The urogenital sinus will mature to become the urinary bladder and urethra with a portion incorporated into the vagina and hymen [5].

The subtypes of ARM observed result from the timing of developmental arrest. The actual causes of the various stages of arrest are not known, but molecular models implicate Homeobox, bone morphogenetic proteins (BMPs), and Sonic hedgehog (SHH) signaling [6]. In addition, changes in sex hormone concentrations have been implicated, as evidenced by the association of urogenital sinus malformation variants with female virilization in congenital adrenal hyperplasia [1].

Current Therapy

The current therapy for cloacal anomalies is surgical. An initial prenatal work-up should determine the presence or absence of hydrocolpos (distended vagina filled with fluid). Failure to recognize and manage hydrocolpos can lead to serious complications, including vaginal rupture, hydronephrosis (distended and dilated kidney), and sepsis [7]. These complications are prevented with early vaginal decompression and drain placement when the colostomy is formed. We have recently described a minimally invasive approach via combined cystoscopy and vaginoscopy [8]. Occasionally, perforation of either the vagina or uterus may occur in utero; and this will be associated with significant abdominal distension, gastrointestinal dysfunction, and respiratory distress. In these latter cases, initial surgery will be considerably more challenging, and typically an open abdominal approach may be needed.

Definitive surgery is undertaken once the anatomy has been mapped out using radiologic imaging and endoscopy. Recent uses of 3-dimensional imaging using either fluoroscopy or MRI scanning requires the instillation of contrast into the vagina, bladder, and rectum, but dramatically increases the accuracy of the preoperative imaging [9]. The length of the common channel is a major factor when choosing a definitive surgery [10]. Short common channels (<3 cm) can be repaired with a perineal incision and have less associated morbidities [11]. Long common channels (>3 cm) require a more complicated repair with abdominal and perineal incisions [10]. Long-term outcomes depend upon associated anomalies. Measurement of the channel length is typically assessed with cystoscopy and vaginoscopy just prior to the definitive surgery.

Surgical management will require separation of the rectum from the cloacal channel, with implantation in the center of the remaining sphincter complex. The introital structures (i.e., vaginal and urethral) are then mobilized as a single unit and brought down to the perineal skin. For long channel anomalies, greater degrees of mobilization may be required, or a combined intra-abdominal and perineal mobilization may be needed. In almost half of the cases, a Didelphus system is found including vaginal septum or in more extensive cases, two complete hemi-uterine structures. These should be identified at the time of the initial surgery with some attempts to unify the two vaginal cavities.

Long-term follow-up is critical, as many of these children will have life-long urological and gynecological problems. Additionally, as with all patients with imperforate anus, the incidence of anorectal incontinence is at least 50 % (see below).

A distinct entity, cloacal exstrophy (i.e., bladder and cecum open onto the external abdominal wall), is associated with an omphalocele, imperforate anus, and ambiguous genitalia (typically absence of a phallus in males). In one review, 96 % of cloacal exstrophy patients had foreshortened colons and 13 % had short bowel syndrome, resulting in prolonged hospitalization and intravenous nutrition [12].

Anorectal Atresia

Anorectal atresia, or imperforate anus, is caused by abnormalities in hindgut development [10] that result in ectopic positioning of the anal opening in the cloaca due to anatomical and/or genetic factors. The extent of ARM directly relates to the degree of development in the posterior aspect of the cloaca (Figs. 64-1 and 64-2). Smaller defects have a more posterior phenotype, such as an anocutaneous fistula; while more extensive defects will lead to more anterior abnormalities, such as a recto-urethral fistula occurring above the levator muscular complex, and in very severe cases manifesting as a cloaca [13, 14].

Underlying Mechanisms

Animal models suggest that a disruption in endoderm development results in ARM. A mutation of fibroblast growth factor receptor 2IIIb (*Fgfr2IIIb*) or the gene encoding its ligand, fibroblast growth factor 10 (Fgf10), results in both colonic and duodenal atresias, suggesting a similar mechanism causes both defects [15]. *Fgfr2IIIb* encodes a membrane-bound tyrosine kinase receptor thought to be expressed only in the endoderm of the developing intestine [16]. Fgf10 is expressed in the rectum when anorectal continuity is established in mice [17]. Mutation of *Fgfr2IIIb* or Fgf10 [18], Hedgehog signaling [15, 19], Wnt5a [20], and *caudal type homeobox 2* (*Cdx2*) mutations have all been associated with ARM phenotype in mice [21]. Recent literature suggests familial inheritance patterns. For patients with a rectovestibular or rectoperineal fistula, almost 15 % had a positive family history for ARM [22]. Thus, genetic consultation is important.

ARMs are associated with the VACTERL complex, which encompasses: Vertebral defects (e.g., sacral anomalies or hemi-vertebra), Anal atresia, Cardiac defects (most commonly atrial septal or ventriculoseptal defects), Tracheo-Esophageal fistula, Renal anomalies, and Limb dysplasias (e.g., typically a

FIGURE 64-2. External appearance of perineum in various forms of imperforate anus.

poorly formed radial bone and/or absent thumb). The incidence is estimated to be 1:10,000–1:40,000 live-births [23].

Prior to surgical interventions a work-up for each of these anomalies should be undertaken. In general, this would include the following: plain films of the vertebral column (cervical to coccyx), ultrasound of spinal cord to rule out a tethered cord, cardiac echo—as the most common defects are atrial septal defects and/or ventricular septal defects, assurance that a decompressing tube may be passed from the mouth to the gastric lumen to help rule out most types of trachea-esophageal anomalies, and an ultrasonographic exam of the genitourinary system.

Current Therapies

The initial decision is whether to perform a primary repair or colostomy. To assist in this decision, the child should have a post-24-h prone lateral radiograph to visualize the terminal location of the rectum, which may be facilitated with ultrasonography. A primary pull-through is feasible if the rectum has descended below the pubo-coccygeal muscle complex. However, a colostomy should be performed if there is any question of rectal position or when atresias terminate above the pubo-coccygeal muscle complex. Placement of the ostomy should be as proximal as possible in the descending colon. This allows sufficient distal rectum to pull-through to the perineum.

Anatomic uncertainty increases the risk of injury to adjacent tissues [24]. Furthermore, the recto-urethral fistula often connects through the child's prostate or sphincter complex of the urinary bladder. To better define these connections, a radiologic contrast study through the colostomy should be performed [2].

The classic procedure is the posterior sagittal anorectoplasty [25]. In this procedure, a large midline incision is made on the perineum. The rectum is identified (typically just above the levator complex), and is opened to allow the identification of the recto-urethral fistula. Careful dissection of the fistula using a submucosal dissection is performed, followed by ligation of the fistula, and mobilization of the rectum to allow a pull-through without excess tension. Using a Pena muscle stimulator, careful placement of the rectum through the residual sphincter complex can be performed (Figure 64-3). More recently, a laparoscopic approach to the pull-through procedure has been advocated, which allows a far less extensive perineal dissection, with ligation of the recto-urethral fistula from above via the laparoscopic approach [26].

Long-Term Considerations

Children with anorectal atresia require long-term follow-up, as most will continue to have problems well into adulthood. In the few months following surgery, the child will require dilations of the anal canal. In general, a 12-month-old child will necessitate the easy passage of a #14 Hegar dilator before the protective colostomy may be closed.

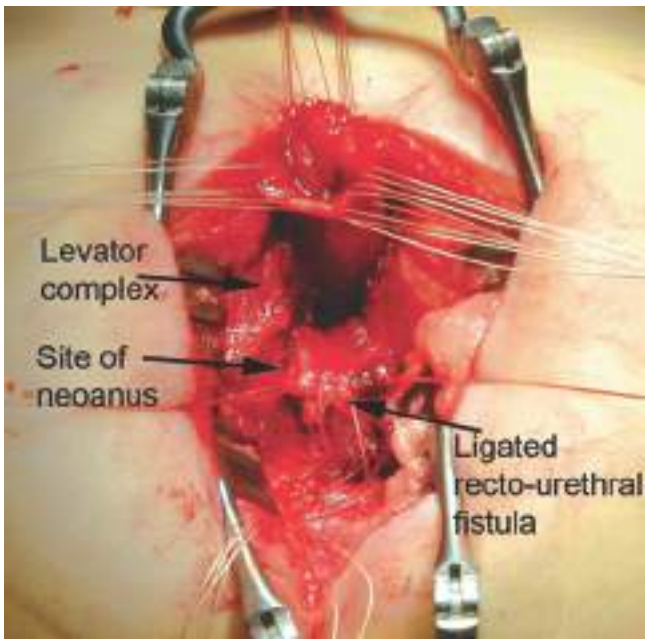

FIGURE 64-3. Intraoperative appearance of a posterior sagittal anorectoplasty (PSARP).

The most common long-term issues relate to the evacuation of a bowel movement. Functional outcomes are dependent upon the height of the fistula Lower lesions typically have issues with constipation, while higher fistulas have issues with incontinence [10]. Another strong predictor of anorectal continence is the integrity of the sacrum. Infants having more than three intact sacral vertebral bodies will typically have a reasonable chance for continence. For children with imperforate anus with a perineal fistula, the greatest issue is long-term constipation. Most of these children will require daily laxative therapy. In general, polyethylene glycol is the most commonly used agent initially, and can result in long-term success.

For infants with poorly formed sacral elements and/or imperforate anal anomalies with a more proximal fistula, incontinence may be at 50 % or higher. Strategies to deal with incontinence are dealt with below in this chapter.

Hirschsprung Disease

Hirschsprung disease (HD) is characterized by the absence of colonic ganglion cells, typically in the distal colon. The lack of a functional myenteric nervous system leads to a derangement of motility necessary for propagation of enteric contents, resulting in obstruction [27]. HD is estimated to occur at 1:5000 live-births with a male-to-female preponderance of 4:1 [28], except in total colonic aganglionosis, which has a stronger association with female patients.

Presentation and Underlying Mechanisms

Infants present with delayed passage of their first bowel movement (meconium), which typically occurs in the first 24 h of life. The diagnosis should also be considered in children suffering from difficult bowel movements, poor feeding, poor weight gain, and progressive abdominal distension. Figure 64-4 shows the most likely pathogenesis of aganglionosis. The aganglionic area lacks nitric oxide synthase (NOS) and cannot produce the smooth muscle relaxant nitric oxide, thus leading to colonic constriction. This is worsened by an increased number of stimulatory parasympathetic fibers that increase the constriction of the distal colon. A contrast enema will show a constricted distal rectum (Figure 64-5) with a more dilated proximal colon. It is important to again note that the dilated part is the *normal* segment of bowel. While this may demonstrate the transition zone, the extent of aganglionosis may be difficult to predict with accuracy on enema alone, particularly in newborns. Suction rectal biopsy (typically at the bedside), or full-thickness rectal biopsy in the operating room for older children, should be performed to detect hypertrophic nerve trunks and the absence of ganglion cells in the colonic submucosa to confirm the diagnosis.

The pathogenesis of HD is uncertain, but may involve failure of either neural crest cell migration or survival [29]. Multiple genetic markers have been identified as playing a crucial role in HD [28]. While less than half of HD cases have been traced to a specific genetic cause, mutations in the *RET* proto-oncogene pathway compromise nearly half of all familial cases and a smaller fraction of sporadic cases. At this time, it is unclear how

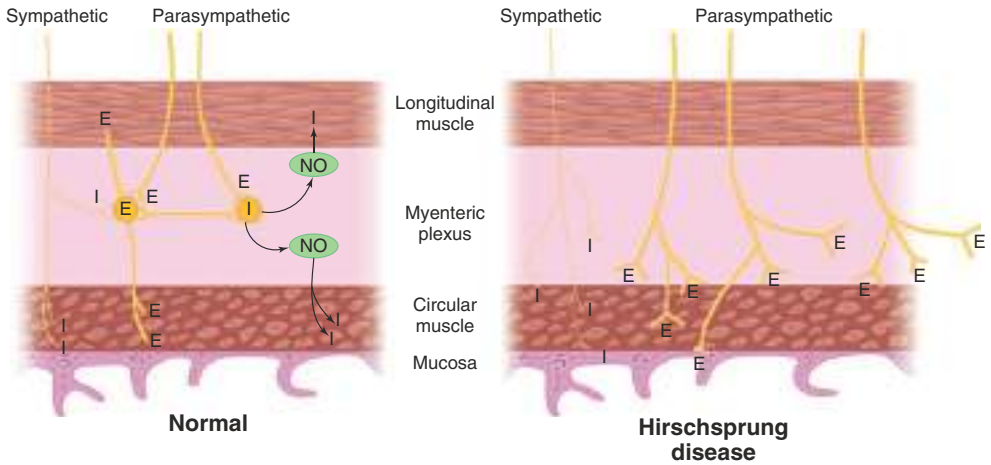

FIGURE 64-4. Diagram showing the pathophysiologic processes which drives functional obstruction in Hirschsprung disease. Note in Hirschsprung patients there is predominance of excitatory parasympathetic fibers (causing an increase histologically of hypertrophic nerves) with a loss of intrinsic ganglion cells and a loss of nitric oxide, which is critical for the relaxation of smooth muscle. E: excitatory; I: inhibitory; NO: nitric oxide

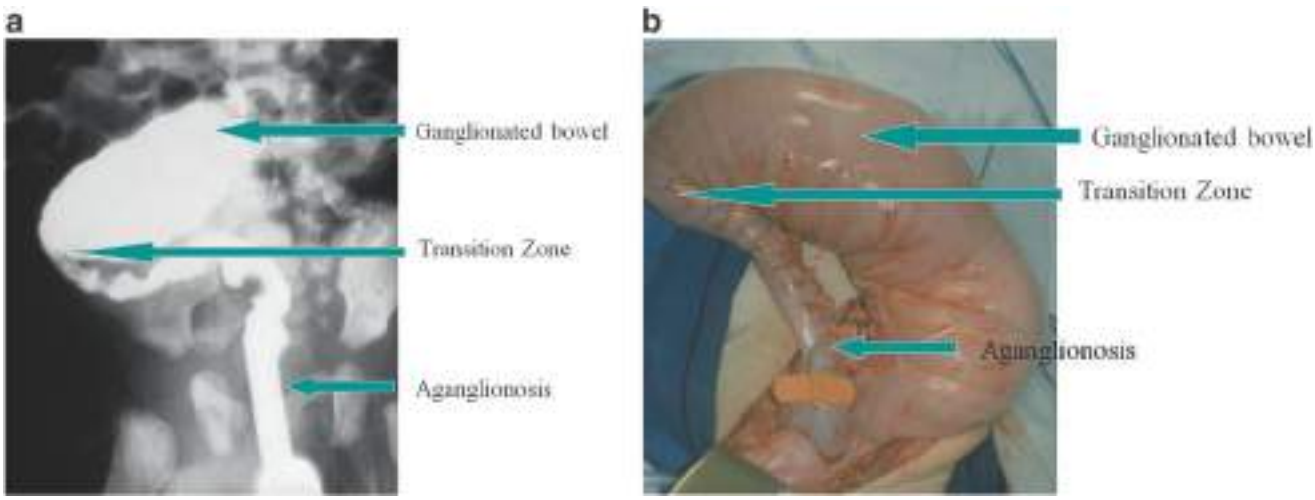

FIGURE 64-5. (**a**): Radiographic contrast enema in infant with Hirschsprung disease. Note constricted distal colon representing the aganglionic segment, with a transition zone and proximal, dilated ganglionated colon. (**b**): Operative image of same patient. Note constriction of aganglionic segment and dilation of proximal colon with a hypertrophy of the longitudinal muscle layer.

these mutations translate to aganglionosis, especially since not all family members of patients with HD who carry the same *RET* mutations will show a HD phenotype [30]. Loss of ganglion cells results in an absolute loss of NOS with resultant depletion of nitric oxide in the aganglionic portions of the bowel and failure of the smooth muscle to relax [31].

Molecular Markers

Over 30 genetic mutations have been identified in patients with HD, including mutations in *RET*, *EDN3*, or *EDNRB*. However, such mutations can also be found in non-affected family members. In addition, largely due to incomplete penetrance and variable expressivity, it is not possible to perform accurate prenatal diagnosis of HD at this time [30]. As specific genetic mutations are associated with other anomalies, however, genetic screening may still be valuable in these patients. For example, certain *RET* mutations can lead to medullary thyroid cancer, and genetic screening offers the ability to identify these mutations and prophylactically remove the thyroid prior to malignancy development.

Current Therapies

Swenson performed the successful surgical treatment of HD in 1948, consisting of a full-thickness perineal resection and colo-anal anastomosis, though there have been several advancements since then [32]. Today, the most common techniques involve an open, laparoscopic, or transanal approach with a retrorectal pull-through (Figure 64-5b) [33]. The Soave procedure involves a mucosal/submucosal resection distally and a full-thickness resection proximally of the diseased segment, followed by a pull-through procedure within the muscular cuff. Finally, the Duhamel procedure involves a resection of the proximal diseased bowel with a retrorectal mobilization (leaving the diseased rectum in-situ) and performing a retro-rectal anastomosis with the rectum and normally innervated bowel. Regardless of the approach, the concept is to remove or bypass the aganglionic segment with an anastomosis of proximal, ganglionic bowel. Many studies have attempted to tease out which technique is superior without a clear consensus [34–36], and most children do well regardless of the type of procedure [37–39].

After surgery, children may experience long-term postoperative complications including soiling/incontinence, constipation, and recurrent enterocolitis [40, 41]. This latter complication, enterocolitis, is a GI inflammatory condition that can lead to diarrhea and systemic septicemia, and has been reported in up to 40 % of children after a pull-through procedure. While the etiology is unknown, it may be a complex interaction between intestinal microbiome and still undefined abnormalities within the ganglionic intestinal segment. Medical management including broad spectrum antibiotics and/or minor procedures can aid in many situations to alleviate enterocolitis [42, 43].

Long-term incontinence has been reported in approximately 5 % of children after a pull-through [44]; however, a larger number may have a delay in successful toilet training or persistent stooling problems for several years after their pull-through. Although uncommon, an occasional patient with a successful pull-through may develop secondary problems including strictures, recurrent enterocolitis, or secondary loss of ganglion cells. These more uncommon conditions may require reoperation, including a posterior myomectomy (in the case of recurrent enterocolitis) [45], or redo-pull-through for strictures or aganglionic segments [46].

Acquired Diseases

Necrotizing Enterocolitis

NEC is an acquired disease affecting the intestine of newborns and is a leading cause of infant morbidity and mortality in neonatal intensive care units (NICUs). NEC is currently the most common premature newborn surgical emergency [47]. Infants born with a birth weight of <1000 g and/or <28 weeks gestation are at the greatest risk. The presence of pneumatosis intestinalis on radiographs or intraoperatively will be seen in most advanced cases; and at times this air may extend into the portal tree (Figure 64-6).

Underlying Mechanisms

Empiric and experimental data suggest that NEC occurs in a vulnerable host who has become further compromised at the level of the gastrointestinal tract, and whose main purposes of barrier function and immune modulation are disturbed or immature. This initiates an ischemic cascade that becomes unbalanced, resulting in loss of epithelial barrier function with subsequent progressive enteric mucosal and then full-thickness injury [47].

Gut colonization has been documented to involve both environmental and genetic factors, and bacterial colonization may be abnormal in infants with NEC [48]. The process appears to be driven by abnormal bacteria/TLR4 signaling pathway, leading to diminished nitric oxide production, decreased intestinal motility with subsequent bacterial overgrowth, and breakdown of barrier function [49].

Current Therapies

Prevention of NEC should be considered the primary treatment. Breast milk has been shown to significantly decrease the incidence of NEC [50]. This is believed to be due to the high concentrations of epidermal growth factor (EGF) and IgA in human breast milk [51]. As well, human milk provides a rich source of oligosaccharides which, while indigestible by humans, serves as a nutritional substrate for lactobacillus and other favorable strains of Firmacutes within the microbiome [52].

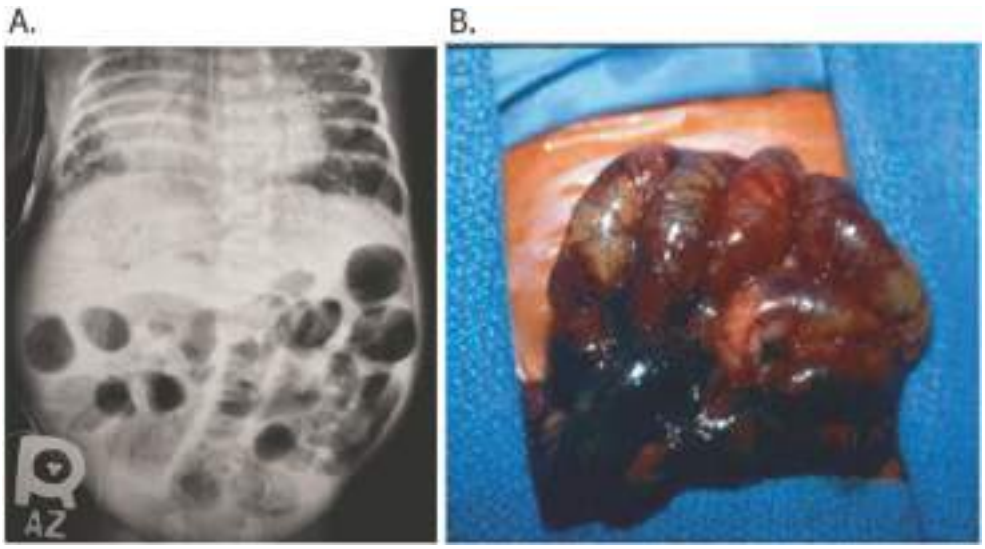

FIGURE 64-6. (**a**) Radiograph of a premature neonate with necrotizing enterocolitis. Note diffuse pneumotosis intestinalis, and air in the biliary tree. (**b**): Intraoperative appearance of the same neonate showing pneumotosis intestinalis and patchy ischemia/necrosis to the small bowel.

In the absence of a surgical emergency, supportive care is the basis of treatment. This consists of discontinuing enteral feedings, GI tract decompression, and administration of intravenous fluids/nutrition. Broad spectrum antibiotics should also be given [47]. Frequent abdominal examinations and radiographs are performed to monitor for disease progression/regression.

In general, surgery is indicated for clinical signs of perforation (e.g., pneumoperitoneum) or clinical deterioration despite maximum medical treatment. The goal of operative treatment is to remove necrotic intestine while preserving bowel length. Unfortunately, almost 50 % of neonates undergoing surgery do not survive, emphasizing the severity of NEC. Furthermore, infants may suffer from considerable loss of small and large bowel with resultant short bowel syndrome. As many neonates may be hemodynamically unstable, and may not tolerate a full laparotomy, performing a percutaneous drainage of the abdomen via a small right lower quadrant incision is an option for very small premature infants an alternative to surgery. Outcomes between open laparotomy and drainage have been shown to have somewhat equivalent outcomes [53].

Constipation and Anorectal Incontinence

Childhood constipation is a common problem, especially in Western societies [54]. Persistent constipation can lead to fecal retention, impaction, and overflow incontinence. Constipation can be classified as either organic or functional. Most children pass meconium in the first 48 h of life [55]. In the neonatal period, a child with "constipation" should be considered to have an organic cause of their constipation or a bowel obstruction until proven otherwise. In children outside of the neonatal time period, the vast majority of their constipation is functional [56]. Functional constipation is defined as constipation not associated with a congenital anomaly, acquired disease or medications. The Rome III criteria is considered the best method to make an accurate diagnosis of functional constipation [57, 58]. Management of functional constipation in childhood includes education especially around toilet training, dietary changes, and oral medications. The most commonly used medications are polyethylene glycol, or in more resistant cases, senna glycosides (sennosides). Our first step in all the children we evaluate with chronic constipation is to empty the colon of stool and begin a bowel management program. In children who have or should have been toilet trained, we have found behavioral pediatric therapy as a useful adjunct, although the evidence supporting this approach is mixed in the literature [59, 60]. Those children that are refractory to initial treatment need further work-up to rule out an organic cause. Motility assessment, colonic transit, and manometry are useful in guiding future therapy, especially if considering a more invasive intervention. In the few studies to date reporting long-term outcomes, cure rates for chronic constipation are reported between 50 and 70 % [61, 62]. Other non-surgical treatments that have been reported include abdominal wall transcutaneous electrical stimulation [63, 64], and more recently, the PERISTEEN™ (Coloplast, UK) enema program has also reported good results in some children with functional chronic constipation [65].

Surgical Treatment for Chronic Functional Constipation

In spite of the prevalence, the majority of children with functional chronic constipation can be managed without surgery. A few, however, fail and more aggressive interventions are needed. There are no controlled trials of surgical therapy for children with chronic functional constipation. Common

FIGURE 64-7. Example of a Chait tube showing the pigtail end which secures it in the cecum.

procedures used include the Malone anterograde continent enema (MACE) [66–68], or other anterograde continent enema procedures such as a cecostomy typically via a Chait® tube (Cook Medical Co.) [69, 70] (Figure 64-7). One advantage of these procedures are that they are reversible. Resection of a megarectum or colon in children has been reported with mixed results, as has a colostomy [71]. Perhaps the most recent approach to children with intractable constipation has been the use of sacral nerve stimulation (SNS). To date, when used in children with chronic constipation and or fecal incontinence, SNS has shown promising preliminary results [72–75], with series demonstrating up to an 80 % success. One limitation to the use of SNS is that in the USA the use is limited to children over 15 years; thus, its usage in younger patients is considered off-label.

Figure 64-8 shows a decision and management tree in the msanagement of functional constipation.

Constipation and Fecal Incontinence in Children with Hirschsprung Disease (HD) or Anorectal Malformations (ARM)

Constipation and/or fecal incontinence are considerably more challenging to treat in children with HD or ARM. In HD, bowel dysfunction has been reported by parents in up to 65 % of children [76]. Problems are more common in younger children and can have a significant impact on their social interactions and overall quality of life. While such problems may improve in adolescence, in some patients problems can be life-long [77]. In one long-term study, 42 % of patients reported occasional soiling, 12 % had frequent soiling, 46 % had no soiling, and constipation occurred in 9 % [78]. If a child has HD with an associated syndrome, the risk of bowel problems was significantly higher. The etiology of constipation or fecal incontinence in children with HD includes: enterocolitis, anastomotic issues (including stricture), sphincter dysfunction, and a retained/acquired aganglionic segment. As stated early, enterocolitis is one of the most devastating complications of Hirschsprung disease. Symptoms can occur acutely, be recurrent and low grade or chronic [40]. In either situation, this requires prompt treatment with rectal decompression of air and fecal contents, antibiotics, and if needed, intravenous fluids [79].

Strictures at the anastomotic site (often due to ischemia) may respond to dilatations, however, persistent strictures will require a repeat pull-through [80]. Sphincter dysfunction may also be due to excessive stretch of the sphincter complex or retention of an aganglionic rectal cuff, the latter of which may lead to obstructive symptoms due to a high-pressure zone in the anal canal after endorectal pull-through [45]. Constipation can also be the result of a retained or long aganglionic segment [80]. This latter problem may be due to the retention of a small segment of aganglionic bowel at the initial operation at the level of the sphincters to help with continence. As the child grows, this aganglionic segment may also grow, therefore creating a functional obstruction. Findings of an aganglionic segment may also be due to an anastomosis at the transition zone where there are fewer ganglion cells and some larger nerves.

Children with these disorders lack adequate sphincter complex musculature or innervation. Thus, constipation and fecal incontinence are even more prevalent in children with ARM [81–83]. Only one-third will have voluntary bowel movements and complete evacuation, while the remaining will require some interventions. ARMs comprise a wide variety of lesions and bowel problems that depend on the anatomic defect (i.e., where there are pelvic muscles and nerves), the quality of the surgical repair, and early aggressive treatment to avoid the development of a megacolon. With the use of a focused bowel management program, the majority can be expected to achieve social continence and improved quality of life [84].

Diagnostic Work-Up and Therapy

In children with HD and bowel dysfunction, a digital examination, contrast enema, stool studies, and endoscopy with biopsies (at 2, 4 and 6 cm) above the anastomosis are all critically important. The combined results will help determine if there is transitional zone or aganglionic tissue. In cases where it is uncertain as to whether there is fecal incontinence, anorectal manometry may prove useful. Defecography and motility studies may also be helpful. For enterocolitis, oral antibiotics (typically metronidazole, or intravenous if the child is sick) and a rectal decompression are the first-line treatment options [40, 85]. For sphincter dysfunction or aganglionic segments, the initial therapy is a bowel management program (see below). If those treatments

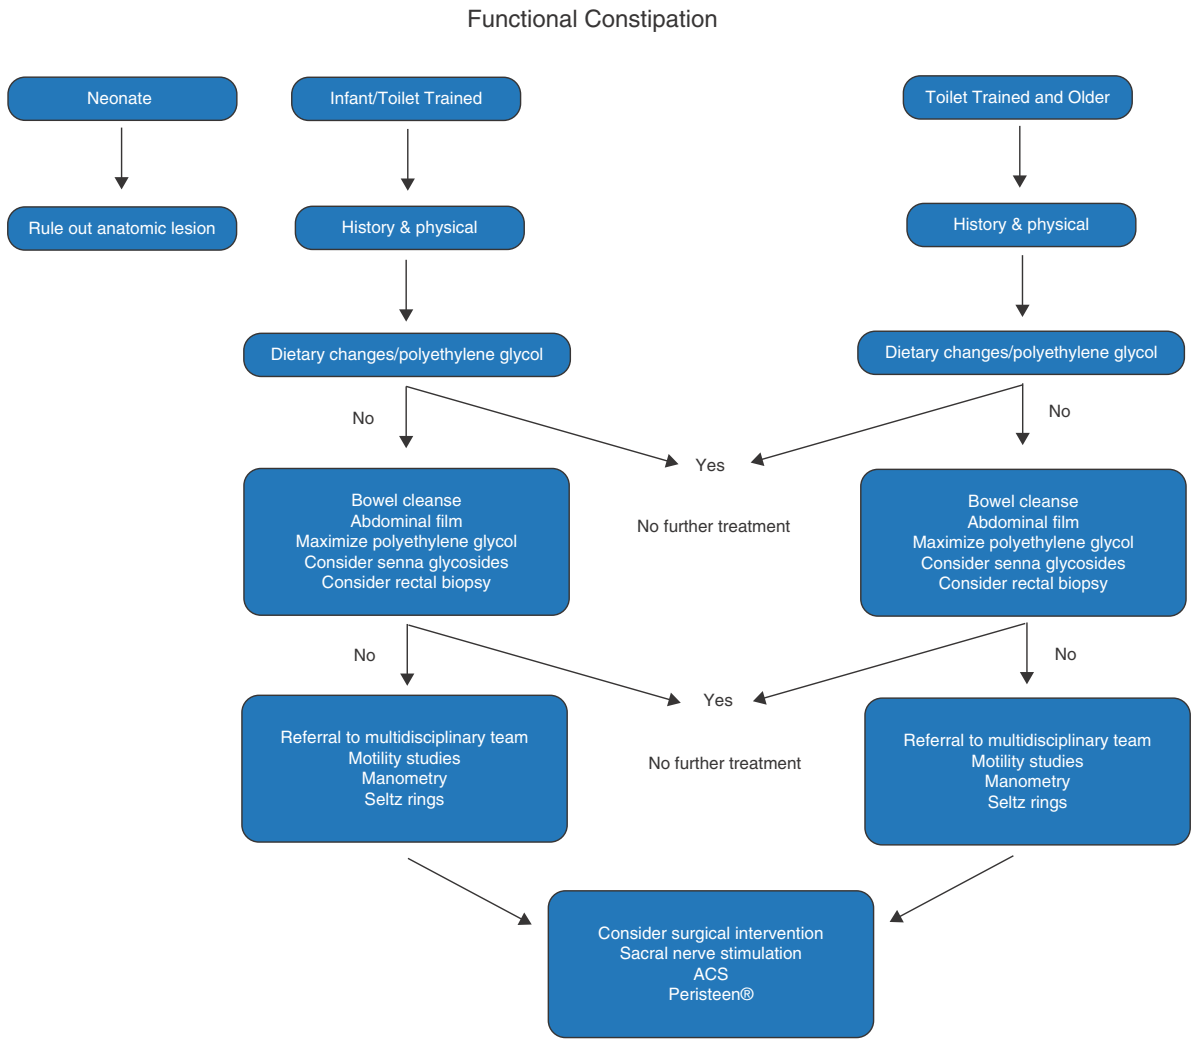

FIGURE 64-8. Decision tree in the management of functional constipation. Abbreviations: *ACE* antegrade continent enema.

fail, internal anal sphincter botulinum toxin injections can result in good long-term outcomes in up to 50 % of children who suffer from an outflow obstructive symptoms [86, 87]. Surgical therapy includes posterior myotomy, ACE procedures, and in cases that have failed other treatments, re-do pull-through [45, 80].

For constipation and fecal incontinence in children with ARM, it is important to realize that the loss of a sphincteric complex may result in both of these symptoms. As such, the initial investigations should also include a contrast enema to rule out retention of stool with overflow incontinence. Similar to HD motility studies, defecography and manometry can be helpful. In either case, the first-line of therapy consists of a bowel management program. While most often not necessary, surgical therapy includes an ACE procedures, or for severe cases, a colostomy. SNS in children with HD and ARM has been performed, but the data is preliminary, and no conclusions can be made whether incontinence is improved by this modality.

Inflammatory Bowel Disease in Children

Crohn's and Ulcerative Colitis (UC) are the most common forms of IBD encountered in childhood [88, 89]. In many aspects, both the medical and surgical therapy are similar to the adults and are detailed in other chapters. In children, Crohn's and UC can occur at any age, but the peak incidence is in late adolescence to early adulthood. In addition, there is a slight female predominance. Children with IBD tend to present differently than adults, as there is often a more prolonged course prior to definitive diagnosis. The initial symptoms are often systemic in nature without focal gastrointestinal manifestations. These include: fever of unknown origin, arthritis, and chronic microcytic anemia. Approximately 35 % of children present with delayed growth or development, which can precede the development of any other overt symptoms by months or even years, and for Crohn's patients in particular, significantly delay the recognition of disease [88, 89].

FIGURE 64-9. Pediatric perianal Crohn's disease.

Presentation

In Crohn's disease the most frequent distributions are the following: 33 % are limited to the small bowel alone, 45 % involve both the ileum and colon, 20 % have isolated colonic Crohn's, and 1/3 of patients have perianal disease (Figure 64-9), though this is rarely the sole location. Most patients have oral lesions, yet they are rarely severe [88, 89].

Ulcerative Colitis

Children with UC may present with extra-intestinal manifestations. The most common is a polyarthritis, involving large joints, but without joint destruction. In UC, the severity of inflammation largely parallels the severity of the intestinal component. Therefore, a colectomy is curative not only of the colitis, but also most other extra-intestinal manifestations—although (similar to adults) bile duct pathology is not prevented [88, 89].

Molecular Basis

With the exception of very early-onset IBD occurring before the age of 2 years, no overt differences in genetic susceptibility have been identified in children as compared to adults. In contrast, very early-onset IBD seems to be a genetic disease with defects in the IL-10 signaling pathway likely being involved [90].

Investigations

In children, the endoscopic appearance of the bowel is the same as in adults, as is the histopathology. Radiographically, magnetic resonance enterography is preferred to CT scan, especially with the concerns of radiation from repeated computed tomography scans CT over time [91, 92].

Medical Treatment

The drug choices to treat both Crohn's and UC in children are identical to adults. However, a unique consideration in the medical management of children with IBD is the long-term impact of treatment on growth, bone health and social development [88, 93]. On one hand, medical therapy exposes the child to years of toxic therapy. This should be compared to uncontrolled inflammation and the risk of disease-associated complications, such as fibrosis, fistulas, and cancer. Infliximab use has reduced the need for surgery in children for both Crohn's disease and UC [94]. For Crohn's disease, the multicenter REACH trial and the Scottish trial found that overall response rate was 88 %, and the 8-week remission rate was 59 % (REACH trial) and 47 % (Scottish trial), respectively [95–97]. For UC, infliximab induced a response in 73.3 % of patients and the overall remission rate at week 54 was 28.6 %.

Surgical Indications

The surgical indications in the pediatric population are similar to adults, with the exception of growth retardation. For children with Crohn's disease, acute indications include exsanguinating hemorrhage, perforation, suspected cancer, unresponsive disease, growth retardation, systemic complications, and steroid dependency. In children with UC, they classically include toxic megacolon, perforation, uncontrolled bleeding, and obstruction. On a more chronic basis, indications include refractive disease, steroid dependency, failure to thrive, and impaired psychosocial development. The principles of surgery for children with IBD are identical to those in adults. For CD, it is important to remember that only the diseased segment is removed, as the need for future surgery is high.

In patients with UC, when a restorative total proctocolectomy is required, most surgeons are performing the ileal pouch-anal anastomosis (i.e., J-pouch). A recent review from the Cleveland Clinic compared outcomes in children and adults in children who underwent a restorative proctocolectomy. Although patients who had the surgery at a pediatric age tended to have a higher incidence of postoperative pouch complications, the long-term rates of pouch retention were comparable [98]. Interestingly, a multicenter review between straight and J-pouch reconstructions demonstrated less frequency of bowel movements in the J-pouch group, but this benefit was lost by 3 years of age, suggesting that both approaches may be quite successful in children [99].

Summary

While in many pa0rts of the world, pediatric patients are managed by pediatric specialists including pediatric surgeons. Yet, common colorectal problems will still be referred to general surgeons and colorectal surgeons. As such, it is important that surgeons of all backgrounds have a generalized awareness for the more common clinical conditions that are encountered, their treatment, and what may require modification in this population to account for growth, development, or a different natural history of disease in this population.

Considerations for Geriatric Patients Undergoing Colorectal Surgery

Kevin R. Kasten and Todd D. Francone

Key Concepts

- The geriatric population is diverse, with varying levels of health status including physiologic reserve and cognitive function. As such, chronological age is a poor marker of functional, physical, and cognitive decline in the elderly.
- Fit elderly patients, those without significant comorbidities or cognitive decline, can be managed similar to that of younger patients. Frail patients are associated with higher morbidity and mortality in both elective and emergent operations.
- Elderly patients undergoing emergent procedures are at high risk (17–31 %) for post-operative mortality.
- Minimally invasive surgery is safe and appropriate in the elderly population, allowing them to benefit from decreased post-operative morbidity, faster return of bowel function, decreased length of stay, and less pain.
- While some assessment models identify age as an independent risk factor for adverse outcomes, a focus on chronologic age substantially limits effective management of the geriatric patient.
- Frailty is used to represent a global limited reserve in the elder population. As such, abnormalities in frailty domains are a potentially useful tool for predicting poor outcomes.

Introduction

Today's elderly population is steadily growing, due in part to improvements in general medical care, enhanced screening protocols, and advances in anesthesia. In fact, the average life expectancy for a 75-year-old man and woman is now 10.7 and 12.8 years, respectively [1]. Life expectancy is further predicated on level of fitness (Figure 65-1). Recent projections suggest over half of all current operations in the USA are performed on patients older than 65 years of age, with estimates of surgical volume increasing from 14 to 47 % between 2000 and 2020, due to more elderly patients [2]. This steadily increasing volume of elderly patients underscores the importance of defining, and applying appropriate treatment in this population.

Unfortunately, considerable evidence suggests elderly patients with cancer are less likely to be offered standard of care treatment. This is particularly evident in clinical cancer trials, where elders comprise only 25 % of participants [3]. Exclusion of older patients is not limited to clinical trials, but also extends to chemotherapy, radiation therapy, and surgical intervention [4, 5]. For decades, advanced chronological age has been considered the main factor for determining surgical intervention in older patients. Non-operative bias stems from outdated reports demonstrating higher risk of mortality and morbidity. Recent, but inconsistent, data suggests elective surgery may be safe in the elderly with mortality rates as low as 4.7 % [6–10]. However, post-operative mortality and morbidity in the older population remain variable, with post-operative morbidity reported as high as 60 % [6, 9, 10]. The discrepancy in data may reflect the absence of a consistent definition of "elderly" in the literature, as well as incomplete information concerning common risk factors unique to the elder population.

Several studies have attempted to identify risk factors predictive of adverse peri-operative outcomes in the elderly (e.g., emergency surgery, ASA, pre-operative comorbidities, and advancing age); however, the evidence is inconsistent and surgical decision algorithms remain unclear [11]. Current risk stratification models, such as Colorectal Physiologic and Operative Severity Score for enumeration or Mortality and Morbidity (CR-POSSUM) [12, 13] and National Surgery Quality Improvement Program (NSQIP) Morbidity and Mortality Risk Calculator [14], employ chronological age as a variant predictor of adverse peri-operative outcomes. Despite this, chronologic age does not accurately reflect functional, physical, and cognitive decline.

In this chapter, we will elucidate current outcomes in the geriatric population, highlighting standard and alternative endpoints across a range of diagnoses treated electively and

emergently. We will also review the importance of a thorough pre-operative evaluation in elder patients with a focus on current and future risk assessment models to help predict outcomes. Recognition of pre-operative markers depicting the unique variability of the geriatric patient may provide additional insight in predicting poor outcomes, and thus aide pre-operative decision-making.

Current Outcomes in the Geriatric Population

The challenge with evaluating and comparing outcomes among the elderly is population heterogeneity due to diverse health status. The elderly exhibit significantly higher rates of comorbidities ranging from cardiovascular disease to cognitive decline. Congestive heart failure, hypertension, and other chronic comorbidities are relatively higher in elderly cohorts, with those over 85 years significantly worse off than their 71- to 75-year-old counterparts [15, 16]. Similarly, cognitive impairment affects 6 % of patients in the 75–79 age cohort, increasing to 10 % in 80–84 year olds, and more than 18 % in patients 85–89 [16].

The incidence of colorectal pathology is seemingly linked to increasing age, and as such, elderly individuals are increasingly evaluated for surgical care of cancer, bowel obstruction, rectal prolapse, and volvulus [17]. The difficulty for a surgeon lies in determination of appropriate treatment options, each guided by underlying comorbidities and desired patient endpoints. To assist in patient education, the surgeon should understand how different pathologic states and presentations lead to wide-ranging outcomes in this unique population.

Mortality

Key Point: Elderly colorectal patients undergoing emergent procedures are high risk for post-operative mortality, ranging between 14 and 31 %.

Modern health care continues to favor longevity as a central outcome measure. As such, in-hospital and 30-day mortality statistics are the most universally reported surgical outcomes in elderly colorectal patients. Historically, a 29–33 % overall mortality was reported for patients over 75 and 80 years undergoing colorectal surgery from 1955 to 1982, respectively. This has steadily declined over the ensuing years. Patients above 80 demonstrated a 16.2 % overall mortality (14.2 % emergent; 2.1 % elective) in 1985–1991. For patients older than 70, overall 30-day mortality decreased from 29.7 % during 1955–1982, to 18.2 % in 1977–1987, 9.8 % in 1988–1990, and 6.2 % in 1997–2004 [6]. Other studies show similar acceptable mortality rates in the geriatric population, including a 9.6 % 30-day mortality in POSSUM-matched patients over aged 75 [18], and 8.7 % in-hospital mortality in octogenarians undergoing lower gastrointestinal procedures [17].

Emergency surgery poses less favorable outcomes for patients of all ages. The elder population is no different. In fact, mortality rates may diverge by a factor of 7 between elective and emergent procedures. In studies of octogenarians undergoing lower gastrointestinal procedures, in-hospital mortality was reported to be at least 28–32.3 % following emergent cases, compared with 1.7–4.7 % in elective cases [17, 19]. On multivariate analysis, an emergent procedure was independently associated with increased mortality [17]. When all emergent colon resections by age group were analyzed between 2001 and 2008 in the NHS system, overall 30-day mortality for patients older than 70 was 24.1 %. When divided by age cohort, mortality was 17 % in those aged 70–75, 23.3 % in 76–80, and 31 % in those over 80 years of age [20]. Thus, elderly colorectal patients undergoing emergent procedures are high-risk for post-operative mortality.

Mortality rates are also higher in patients admitted from a long-term care facility or nursing home (47.6 %) [19]. The elevated rates are likely related to an increasing number of synchronous comorbidities and lower performance status for this particular subset of the elderly. Moreover, patients discharged to institutions following surgery demonstrated 6-month mortality rates of 40 %, compared to 17 % of those who were discharged home [19]. Additionally, elderly patients with DNR orders undergoing emergent exploration also demonstrated higher mortality rates. Those undergoing surgery for bowel obstruction demonstrated a 30-day mortality of 30 %. Further analysis suggested mortality of 40 % when the patient sustained a post-operative complication, versus 20 % without a complication. As DNR was independently associated with mortality, it is possible DNR patients receive less intensive post-operative care when a complication occurs, thereby leading to worsened outcomes [21]. Thus, physicians caring for an elder in the emergent setting should carefully discuss goals and expectations of treatment with patients and their family members as expected outcomes after surgery may not be fully realized.

Given these poor results, the utility of 30-day and in-hospital mortality time points in the elderly has been questioned. The physiologic reserve of the elderly is clearly less than that of the younger population; therefore, it is not surprising to see a greater impact on their long-term post-discharge survival. Several groups have begun studying longitudinal time points including 90-day, 180-day, and 1-year post-operative mortality. Predictably, 90-day outcomes for patients over 80 years are worse, demonstrating mortality of 13–19 % [22]. In elderly colorectal patients, those aged 70–75 showed 34.7 % 1-year mortality, versus 41.6 % in 76–80 year olds, and 51.2 % in those over 80. Overall, a 15–20 times higher rate of death was seen in each cohort when compared to age-matched general population [20]. Similarly, an analysis of NHS colorectal procedures involving 29,000 patients aged 75 and older undergoing elective colectomy demonstrated a 30-day in-hospital mortality of 5.4 %. One-year mortality ranged from 15.6 % in 75–79 to 18.8 % in 80–84 and 23.3 % in 85–89 age groups [22]. Differences in short- and long-term outcomes suggest a focus on the wrong endpoints in the elderly.

Morbidity

Key Point: Understanding the relationship between age and comorbidity allows surgeons to stratify appropriate surgical intervention without relying on age alone.

The elderly experience increased complication rates following surgery. It is unclear whether age itself serves as a risk factor, or simply a marker of higher morbidity patients. A NSQIP analysis of surgical patients over 70 years old demonstrated a linear relationship between age and complications, increasing 0.71 % per year of age [6]. Octogenarians undergoing lower GI procedures demonstrated a 53.5 % overall rate of morbidity, with 38.4 % requiring post-operative surgical intensive care unit (SICU) admission. Common major complications included pneumonia (25 %), respiratory failure (15 %), and MI (13 %), followed by ileus and delayed extubation as common minor complications. Not surprisingly, pulmonary comorbidities have been linked with an increased risk of complications [17, 23].

As one would expect, increased complication rates parallel increased rates of mortality in elder patients undergoing emergent operations. In fact, certain analyses have shown a 17 times higher risk of complication following emergent surgery in the elderly, whereby 87.9 % of emergent elderly patients demonstrated a complication, of which 62 % were major. Furthermore, patients undergoing emergent procedures are rarely sent home independently (6.5 %), especially compared to elderly patients undergoing elective procedures (69.2 %) [17].

In addition to specific organ-based complications, elders are prone to delays in functional recovery. The return to functional baseline status is often prolonged and may occur as follows: mental status (3 weeks), timed up and go (6 weeks), activities of daily living (ADL) (6–12 weeks), and grip strength (>24 weeks). For clarification, "Timed up and Go" is a simple test used to measure an individual's mobility which requires the individual to rise from a chair, walk a small distance, turn around, and sit back down. Interestingly, the majority of patients over age 60 years may not return to functional baseline for at least 6 months post-operatively, signifying the potential impact of surgery on this patient population. Considering this data represents patients without post-operative complications, it's no surprise that recovery times further worsen in patients experiencing complications [24].

Disease-Specific Outcomes

Mortality and morbidity rates vary with elective and emergent operations, as well as with various procedures and pathologic states. This section reviews outcomes associated with several procedures and pathologies commonly encountered in the geriatric.

Ostomy Closure

Key Point: Age alone should not preclude one's decision to restore intestinal continuity. Creation of a stoma is not without risk and may be more detrimental in the elderly population.

Colostomy closure is a high-risk procedure in most patients regardless of age and comorbidity. Consequently, often it is not offered to elderly patients due to concern over poor outcomes. With historical mortality rates ranging between 0 and 4.5 %, and morbidity rates as high as 50 %, surgical trepidation is understandable. Yet, data suggests elderly patients may tolerate stoma reversal just fine with no differences in complications rates, despite increased comorbidities. In an analysis of surgical outcomes, Bosshardt et al. demonstrated a reversal rate of 78.6 %, with a 6.1 % morbidity and no mortality among patients greater than 70 years [25]. In a study of 84 colostomy closures from 1987 to 1993, those patients older than 70 years demonstrated no difference in complication rates when compared to younger patients, despite having significantly higher ASA scores [26].

Creating a stoma avoids certain peri-operative risk, in particular that associated with anastomotic leak, which is notorious for substantial mortality and morbidity in the elderly population [27, 28]. In fact, studies show the elderly are more likely to undergo stoma formation even when fit for restoring intestinal continuity. In a retrospective analysis from 1992 to 2002 of patients over 70 years old ($n=103$) compared to younger patients ($n=280$), rates of stoma formation and overall outcomes were evaluated. Elderly patients were more likely to undergo stoma formation for cancer (75 % vs. 45 %) and obstruction (6.8 % vs. 2.9 %), but less likely in IBD cases (2.9 % vs. 28.9 %) and diverticulitis (11.7 % vs. 16.1 %). Furthermore, elderly patients were less likely to undergo closure of stoma even when considered fit for surgery (78.6 % vs. 95.2 %) [25].

Nevertheless, creating a stoma is not without its own misfortune. Quality of life and social impairments associated with an ostomy must be considered. Older patients have difficulties in properly managing a stoma bag, and the bag affects their psychological well-being. Independent maintenance of the stoma may not be attainable [28]. In addition, several studies have demonstrated older age (>65) to be linked independently to major stoma complications [25, 29].

Given the potential for higher rates of complications from stoma formation, difficulties related to long-term stoma management in elderly, and the lower likelihood of closure for this population, primary anastomosis should be considered. The risk associated with restoring intestinal continuity should be weighed against the patient's underlying pre-disposing risks factors; however, for elderly patients desiring closure of a stoma, age alone should not rule out performance of this procedure.

Fecal Incontinence

Key Point: Treatment of fecal incontinence greatly improves quality of life in elderly patients, and often is successful with management of constipation and biofeedback.

Rates of fecal incontinence in elderly patients are high, especially within an institutional environment, so early diagnosis and management may benefit a large number of colorectal patients. Prevalence of fecal incontinence is currently estimated between 2 and 5 % in patients over 65 years of age, increasing to 3–17 % in patients over 85 years old. Non-institutionalized patients over 65 years old are 5-times more likely to have gross incontinence compared to younger patients. This leads to embarrassment, depression, and reclusivity. Fecal impaction was noted as the most common predisposing process to fecal incontinence, reported in up to 42 % of geriatric patients in treatment units [30]. Constipation often leads to fecal incontinence in the elderly population, with heavy laxative use producing liquid stool and subsequent overflow incontinence around partial or complete impaction [31]. Other factors independently associated with fecal incontinence include prior bowel resection, prior hemorrhoidectomy, loose/liquid stool, and constant fecal urgency [32]. Fecal incontinence is increasingly prevalent in institutionalized elders with rates reported over 50 %. Risk factors in institutionalized patients include neurologic disease, psychiatric disease, poor mobility, age over 70 years, and dementia [30].

Successful management of fecal incontinence depends upon underlying etiology. For constipation, appropriate bowel regimens are highly successful. Other etiologies require appropriate workup with defecography, anal manometry, and endorectal ultrasound to determine management options. Biofeedback is a well-described conservative management option for fecal incontinence, with high rates of success in elderly patients [33, 34].

Diverticulosis/Diverticulitis

Key Point: Management in the elderly remains controversial, with worse outcomes following elective surgery providing support for non-operative management in patients without complicated disease. In those requiring surgery, early intervention is advocated.

Diverticular disease is quite common among the elderly population, with incidence steadily increasing with age. In fact, greater than 65 % of patients 80 years or older demonstrate some degree of diverticulosis, and 10–25 % of patients develop symptoms consistent with diverticulitis. Unfortunately, significantly higher rates of comorbidities may preclude the elder population from standard surgical treatment, including restoration of intestinal continuity. A study specifically comparing management and outcomes of young patients vs. elderly (over 70 years) treated for perforated diverticulitis demonstrated elderly patients underwent fewer primary anastomoses (25 % vs. 46 %). Worse, only 43 % of Hartmann's procedures were subsequently closed, disproportionately impacting the elderly population. Although 30-day mortality was significantly higher in elderly patients (14 % vs. 4 %), there was no difference in rate of complications (32 % vs. 33 %), and no factors were independently associated with worsened outcomes [35]. Other studies have identified certain factors placing the elderly population at particularly high risk for increased complications risk in the setting of diverticulitis. Specifically worth mentioning is end-stage renal disease (ESRD). In an analysis of elderly patients (>65 years) with ESRD undergoing surgical management of diverticulitis, ESRD was associated with more emergent surgery, higher rates of complications, and increased ostomy creation [36].

Several other studies have demonstrated worse outcomes in elder patients undergoing emergent operations for diverticulitis, with mortality rates of 10.4–12.4 % in emergent and 2.4–3.1 % in elective cases [37, 38]. A study utilizing the Medicare Provider Analysis and Review (MEDPAR) inpatient file evaluated in hospital mortality of over 23,000 patients older than 65 years with a primary admission diagnosis of diverticulitis. The study demonstrated an increase in the adjusted odds of in-hospital mortality with age: OR 1.3 (70–74 years), OR 2 (75–79 years), OR 3 (80–84 years), and OR 5.4 (85 years and up). Additionally, in-hospital mortality was higher in emergently treated patients (8 % vs. 1.4 %), and in particular those older than 85 years (15 %). In fact, emergently treated patients older than 85 years had a 5-times increased risk of mortality compared with 65- to 69-year-old patients [39].

Similarly, a study utilizing ACS-NSQIP from 2005 to 2009 demonstrated mortality increased with age with rates as high as 18 % in patients greater than 70 years old undergoing emergent management of diverticulitis [40]. Despite these findings, the likelihood of requiring emergent operation for diverticulitis is low in the elderly. Furthermore, various studies have shown the probability of perforation decreases with age, even in patients with repeated attacks [40, 41]. In fact, more than half of emergently treated patients are younger than age 65, while only 15 % are over 79 years of age [40].

Thus, although diverticulitis is commonly encountered in the elderly population and appears to have a lower risk of perforation in this age group, this must be balanced against the potential impact and higher mortality associated with emergency surgery and sepsis on this population. As such, early intervention should be considered in certain circumstances given the significant rise in complications associated with urgent/emergent procedures in the elderly population.

Rectal Prolapse

Key Point: Surgical management is safe, effective, and indicated in the elderly to prevent suffering and reduced quality of life.

Rectal prolapse can be quite debilitating at any age, causing a significant decline in quality of life. For this reason, surgery should be considered in most cases. The choice of operation will depend upon goals of care, patient comorbidities, and surgeon comfort with treatment options. Outcomes for both transabdominal and perineal approaches have been shown similar among young and old groups. In an 18-year retrospective study from the University of Minnesota, patients undergoing perineal proctectomy for rectal prolapse were grouped into the following age cohorts: <70 years, 70–79 years, 80–89 years, >89 years. There were no differences between groups in post-operative length of stay, early complications, or late complications. The overall complication rate was 5.6 %, with an acceptable 8.3 % rate in patients >89 years old. Interestingly, late complications decreased as patient age increased, possibly due to death from other causes or patients not seeking care due to age. Overall recurrence rate was calculated at 22.6 %, with the lowest rate seen in eldest adults [42].

Historically, transabdominal approaches have been avoided in the elderly patients due to concern for patient comorbidities and inability to tolerate general anesthesia. More recent data suggests otherwise, demonstrating improved outcomes with transabdominal repair. The shift toward a transabdominal repair may in part be related to a

shift in technique with minimally invasive approaches gaining favor over the past two decades. A recent study using the ACS-NSQIP 2006–2009 dataset compared laparoscopic, open, and perineal procedures for rectal prolapse. When grouped by age, 33 % of patients were 70–79 years, 53 % 80–89 years, and 15 % >89 years old. From a demographic standpoint, higher ASA level and mean age of patients were seen in perineal procedures, but no other significant differences occurred between groups. Laparoscopic procedures demonstrated the lowest complication rate at 2.2 %, compared with 8.7 % perineal and 12.3 % open. On adjusted analysis, undergoing open procedure was the only independently associated risk factor for complication development (OR 6.3). Overall mortality was quite low at 1.7 %, with no difference between treatment groups. While similar hospital length of stay was shown between perineal and laparoscopic procedures, open rectopexy patients spent an average of 2 days longer in the hospital. Interestingly, although most surgeons choose perineal procedures due to concern for patient comorbidities and inability to tolerate general anesthesia, this study demonstrated over 83 % of patients underwent general anesthesia, regardless of procedure, ASA, or underlying comorbidities [43].

It is not the goal of this chapter to compare outcomes of minimally invasive and perineal techniques. Nonetheless, it should be stated that current data suggest minimally invasive approaches are safe and effective in the elder population, with lower complication rates, a potentially more durable repair and mortality similar to that of a perineal repair. As such, surgeons should consider laparoscopic or robotic-assisted rectopexy [44] for elderly patients with or without underlying comorbidities.

Colonic Volvulus

Colonic volvulus is more common in the geriatric patient. While cecal volvulus usually presents in the 5th and 6th decades of life, sigmoid volvulus has a mean age at presentation of 68 years and a peak incidence in the 8th decade. Historically, mortality rates are less than 12 % in urgent cases with viable bowel and 30 % in urgent cases with non-viable bowel [45, 46]. Spontaneous reduction of cecal volvulus occurs in less than 2 % of patients and is not considered a viable treatment option. More than 90 % of sigmoid volvulus patients are successfully decompressed with endoscopy. Management almost exclusively involves resection due to the low risk of this procedure in most settings, and high risk of recurrence when non-resectional procedures are performed. Surgical management of sigmoid volvulus is suggested within 2–5 days of decompression.

Data shows elderly patients more likely to undergo Hartmann's procedure for management of sigmoid volvulus. The surgeon should consider the higher 30-day mortality in elderly patients undergoing Hartmann's resection (25–50 %) compared with primary anastomosis (8–13 %) [47–49]. Additionally, consider laparoscopic resection when possible to further decrease risk of complications. In patients not fit for operative intervention, percutaneous endoscopic colonic (PEC) tube placement is associated with 75 % decompression. However, a 4 % mortality and 30 % complication rate limit its use in all but the most comorbid patients. For a disease almost exclusively confined to the elderly, data supports resection and anastomosis in most patients following endoscopic reduction.

Inflammatory Bowel Disease

Key Point: Restorative proctocolectomy may be safe in select elders; however, careful consideration should be given to the risk of fecal incontinence and decline in quality of life.

Inflammatory bowel disease (IBD) is often felt to be a disease of younger patients; however, it has a second mode of incidence at 55–70 years. Reports suggest IBD in the elderly carries an altered phenotype from younger patients, including involvement of different gastrointestinal sections, poorer response to therapy, higher complications, and higher mortality. However, worsened outcomes may simply be related to misdiagnosis and mismanagement in older patients. A retrospective evaluation of all IBD patients surgically treated from 1989 to 1999 compared elderly patients over age 60 years to a younger cohort using 30 total matched clusters in an SAS statistical algorithm. As seen in other disease processes, elderly patients underwent significantly higher percentage of emergent procedures. Despite this, no difference in 30-day mortality was seen between groups. Complication rates were significantly higher in the elderly cohort (47 % vs. 20 %), with subsequent adjusted analysis demonstrating OR 3.5 for age alone in development of a post-operative complication [50].

When operating on the elderly in an elective fashion for IBD, controversy exists regarding performance of high-risk procedures such as ileo-pouch anal anastomosis (IPAA). Despite the obvious unease in regards to higher morbidity and mortality associated with a restorative proctocolectomy in the elder population, the majority of concern lies with the risk for fecal incontinence and decline in quality of life. Remarkably, the majority of the literature supports similar rates of morbidity (29.4 %) and mortality (5.9 %) in patients younger and older than 65 years of age, except for higher rates of dehydration from ileostomy in elderly patients [51–53]. While some degree of incontinence is also not unexpected in the elderly population, anal sphincter function can be severely impaired after undergoing IPAA, producing a significant impact on one's QoL. That being said, current data suggest that select elderly patients can achieve adequate function after an IPAA. At the Cleveland Clinic, 17 of 1911 patients undergoing IPAA for ulcerative colitis (UC) were over 70 years of age at time of surgery. Thirty-eight percent reported complete

continence, 12 % reported rare incontinence, and 50 % reported some incontinence. Using quality of life instruments, 82 % of elderly patients stated they would undergo pouch surgery again, and 89 % recommended it to others [53].

Pellino and colleagues reported similar results in 27 patients over 70 years of age undergoing IPAA for UC. When compared to 81 younger controls, long-term follow up showed similar outcomes between groups in bowel control and health-related quality of life at 1 and 3 years post-ileostomy closure, but elderly patents still had higher rates of partial incontinence. Further, elderly were more likely to be taking anti-diarrheals at 1 year, with no difference between groups at 3 years [54]. Similar results were seen following IPAA in patients older than 80 years for UC. At 6 months, elderly patients reported higher rates of nocturnal seepage and use of anti-diarrheals. At 12 months, only nocturnal seepage was different between groups. Despite these long-term difficulties, 100 % of patients were happy with IPAA and would undergo surgery again [55].

Despite multiple factors contributing to pouch failure rates, age has not been implicated. In a study by the Mayo Clinic looking at patients over 55 years, a 1.6 % pouch failure rate was determined at 10 years for patients older than 70 with a mean follow-up of 8 years. While incontinence was reported more often in elderly patients, no difference was demonstrated in post-operative complications (e.g., pouchitis, stricture, fistula, obstruction), quality of life, or pouch failure rates between young and old cohorts. On average, elderly patients had two nightly stools compared with 0–1 for younger patients. Rates of severe sexual restriction were more common in elderly patients, measured as 15 % incidence at 5 years and 22 % at 10 years [56].

As with any patient, multiple factors should be considered when discussing surgery for IBD. Data suggests no difference in patient need for surgical resection based upon age at presentation, and no difference in rates of surgery for hospitalized IBD patients [57]. As such, surgical management of IBD is safe for elderly patients and should be considered in select individuals but not in the absence of serious thought for the risk of fecal incontinence and decline in quality of life.

Colon Cancer

Key Point: Although chronologic age alone should not be an exclusion criterion, more work is needed to establish an optimal and efficient strategy for choosing who would benefit most from not only surgical resection but potential adjuvant therapy after surgical intervention.

Colon cancer is largely a disease of old age, disproportionately affecting the elderly, with prevalence and incidence increasing significantly into the 8th decade of life (Figure. 65-2) [58]. In those older than 75, colon cancer is the most common primary neoplasm [59]. Unfortunately, clear guidelines for the management of elderly patients are lacking due to exclusion of this population from most studies of colon cancer. Inclusion of the elderly in outcomes studies produces mixed results due to confounding variables such as underlying comorbidities and different rates of emergent operations compared to younger patients. Additionally, published outcomes may demonstrate selection bias linked to global location and time period of diagnosis [60].

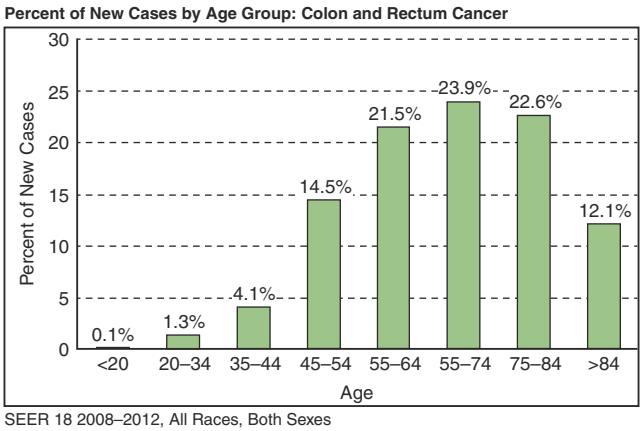

FIGURE 65-2. Colon cancer is largely a disease of old age with prevalence and incidence increasing significantly into the 8th decade of life. Colon and rectum cancer represents 8.0 % of all new cancer cases in the USA [58]. Available at http://seer.cancer.gov/statfacts/html/colorect.html.

The skepticism regarding oncologic resection in the elderly is not entirely unsubstantiated. When matched for stage and histology, numerous studies have demonstrated higher 30-day mortality rates of 8–22 %, along with higher complications rates that are almost double that seen in younger populations [60–62]. As you would expect, mortality and post-operative complication rates were increased after oncologic resection in elders undergoing emergent resection. Reported mortality rates for patients over 70 undergoing emergent colectomy are between 6.1 and 38 % [60, 63]. In a mult-icenter German trial of colectomy for cancer, overall complication rates increased from 32 % for elective procedures in the elderly to 50 % in emergent cases. Of note, while numerous studies have demonstrated increases in peri-operative complication rates among elders, anastomotic leak rates have not been among them [60, 61].

Numerous studies have demonstrated that select elders will benefit from standard oncologic treatment including surgical resection with or without adjuvant chemotherapy. Neuman and colleagues utilized the SEER database from 1992 to 2005 to evaluate patients over 80 years of age who underwent colectomy for stages I–III colon cancer. Ninety-day mortality was reported at 6.6 % and 1-year mortality at 14.3 % [15]. Sixteen percent of patients over age 80 years demonstrated metastatic disease at surgery. When broken out by stage of disease: Stage I median survival calculated as 69 months, with a 5-year survival of 77 %; Stage II median surgical calculated as 54 months, with a 5-year survival of

35 %; Stage III median survival calculated as 33 months, with a 24 % 5-year survival; and Stage IV median survival was 24 months, with a 0 % 5-year survival [64]. In fact, based on available data, if elderly patients survive initial post-operative period and any complications, 5-year survival has been shown to be similar to younger patients [60].

Likewise, older persons with Stage III disease have been shown to derive the same benefit from adjuvant therapy as their younger counterparts. In a systematic review of Stage III patients from 4 randomized controlled trials (XELOXA, AVANT, X-ACT, NSABP C-08), oxaliplatin demonstrated improved disease free survival (DFS) in all study groups and all ages. While effect was attenuated in patients over age 70, adjusted analysis did not show age as independently associated with DFS [65]. These findings are consistent with reports of patients over 75 years demonstrating no difference in cancer-specific survival (CSS) when compared to younger patients [66].

Reluctance to treat elders with colorectal cancer is not limited to surgical resection. Numerous studies demonstrate the exclusion of patients over 75 from participating in oncologic clinical trials. As a result, a disparity persists in the administration of standard adjuvant therapy between younger and older patients despite a meaningful survival advantage for most patients. In fact, recent studies suggest only 14 % of all patients over age 80 diagnosed with colon cancer received chemotherapy [15], with less than 20 and 60 % receiving chemotherapy for Stages II and III disease, respectively [64]. The discrepancy in management is, in part, related to concern the elderly cannot tolerate chemotherapy. However, based on current literature, this is not the case. Pooled analyses of adjuvant chemotherapy trials have not reported increased side effects in older patients except for myelosuppression [67, 68] and fatigue [68].

In a systematic review of Stage III patients from 4 RCTs, higher rates of grades III and IV toxicity were noted in elderly patients receiving oxaliplatin, although neuropathy was no different between groups [65]. The MOSAIC trial, which compared the use of adjuvant 5-FU-based chemotherapy with and without oxaliplatin (Eloxatin), also demonstrated no difference in dose intensity between patients younger than 70 and ≥70 years old for either 5-FU or oxaliplatin. Nonetheless, fewer than 5 % of elder patients completed all 12 cycles compared with the younger group, but the study also excluded patients over 75 years old, which suggests the elderly may have been underrepresented in this trial [69].

FOLFOX is well tolerated by the elderly. However, they may not see the same survival benefits of FOLFOX compared to younger patients, so consider infusional 5-FU or capecitabine alone. It is important to note that patients over 80 years had more minor complications from capecitabine, but adjusted analysis did not demonstrate an association with age [70]. This treatment plan is usually beneficial for the elderly, as they are more susceptible to toxicity from oxaliplatin. Palliative chemotherapy is controversial due to limited data, as most studies excluded patients older than 65 years of age from treatment. Recent work demonstrates little benefit of palliative therapy on overall survival in the elder population. Yet as discussed above, select elders will tolerate therapy similar to that of a younger population. In a recent single-institution study looking at patients over 70, no difference in response rate to palliative therapy was found versus younger patients (24 % vs. 21 %). However, there was a significant increase in median OS from 8 to 11.7 months when elderly received chemotherapy. Additionally, progression-free survival doubled from 4 to 10 months. When comparing regimens, fewer side effects were seen with capecitabine compared to 5-FU, and bolus 5-FU produced more side effects than infusional therapy. Of note, in patients over 65 receiving bevacizumab, higher rates of arterial thrombotic events were seen. Based on these findings, the authors recommended continuing with standard regiments for both curative and palliative protocols for all patients, regardless of age, with continued tailoring based upon toxicity and response to regimen [71, 72].

Rectal Cancer

Key Points:

- *For the elderly population, the surgeon should be particularly aware of pre-operative fecal incontinence and decreased mobility as restoration of an intestinal continuity with a low anastomosis may worsen the predisposing condition leading to a debilitating and degraded quality of life.*
- *In the elderly patient population with rectal cancer, fit elders have been shown to tolerate chemoradiotherapy (CRT) similar to that of younger patients.*

Advancements in the treatment of rectal cancer including minimally invasive techniques, developments in organ-sparing procedures with local treatment, sphincter-sparing techniques, neoadjuvant CRT, and adjuvant chemotherapy regiments have all benefited patients. However, determining the optimal treatment for rectal cancer for patients at any age requires a complex decision-making process. As colorectal surgeons, it is our responsibility to understand and coordinate the wide variety of modalities available to optimize survival, minimize morbidity, and maximize quality of life. Although always critical, strong considerations should be given to intent of surgery, possible functional outcomes, and preservation of anal continence and genitourinary function when treating rectal cancer in the elderly population.

As in other disease processes, elders with rectal cancer present with an increased number of comorbidities [73]. As such, numerous studies demonstrate a direct correlation

between comorbidity and surgical complication rates. This is certainly not surprising given the increased morbidity associated with a pelvic dissection. Remarkably, despite the increased morbidity with a pelvic dissection, operative mortality has not been shown to be significantly different among older and younger populations. In patients over 75 years of age treated at a tertiary referral center for cancer, operative mortality was under 2 % for both groups [73]. In a similar study of open cases for rectal cancer in patients over 75 years old, higher rates of emergency procedures (5 % vs. 3 %) and multiple comorbidities (26 % vs. 13 %) were seen in the elderly; however, overall post-operative mortality was similar between the two groups (3.5 % in elderly vs. 0.5 % in younger individuals) [74].

Consistent with findings in colon cancer, overall survival for older patients with rectal cancer is worse. This is to be expected given the added complexity associated with the increasing comorbidities of the elderly population. Nonetheless, as was also demonstrated in colon cancer, disease-specific survival has not been shown to be worse in elder patients [73, 74]. The study from Memorial Sloan-Kettering Institute in 2000 collected prospective data on 157 patients over the age of 75 undergoing pelvic surgery. Overall survival was significantly lower in elderly patients (51 % vs. 66 %) while disease-specific survival was identical, especially when compared stage for stage [73]. Additionally, in an analysis of the DOD military database and central tumor registry, a lower 5-year survival rate occurred following curative resection in elderly (43 % vs. 65 %), but cancer-specific survival was no different between elderly (60 %) and younger patients (70 %). DFS was also similar at 60 % vs. 69 % in elderly and young, respectively [74].

Common to all generations, functional outcomes following pelvic surgery remain of utmost importance. For the elderly population, the surgeon should be particularly aware of pre-operative fecal incontinence and decreased mobility as restoration of an intestinal continuity with a low anastomosis may worsen the predisposing condition, leading to a debilitating and degraded quality of life. When a linked Medicare dataset was analyzed for functional outcomes in elderly patients over 80 years old from nursing facilities who underwent sphincter-sparing procedure or stoma creation, no differences were seen in demographics, pre-operative incontinence (23 % vs. 28 %), or operative mortality (13 % vs. 18 %). On multivariate analysis, pre-operative incontinence was a risk factor for post-operative incontinence [75].

Low anterior syndrome results in increased bowel function, erratic bowel movements, urgency, obstructed defecation, and minor fecal leakage. Following LAR, complete recovery of bowel function to a "new normal" typically occurs at 6–7 months, although some patients may spontaneously improve at 12–18 months. Surprisingly, current data suggest no difference in functional outcomes among elderly patients. Almost 85 % of elderly patients report minor, or no, issues with incontinence [76]. Hida and colleagues evaluated a 107 patients undergoing low anterior resection (LAR) with colonic pouch anastomosis within 4 cm of the anal verge. The cohort was grouped in three categories: age <60, 60–74, and >74 years old. Functional outcomes were no different amongst groups and, as expected, improved in all groups when the anastomosis was 5–8 cm from the anal verge (Table 65-1) [77]. Thus, in well-selected patients with intact sphincter mechanisms, procedures that spare a stoma are perfectly reasonable in the elderly.

Table 65-1. Outcomes by age cohort in rectal cancer following ultra-low colon J-pouch reconstruction [77]

Outcome	<60 years old (%)	60–74 years old (%)	>74 years old (%)
Urgency	10	14	20
Incomplete evacuation	3.3	7	0
Anti-diarrheals	77	71	80
Garment soiling	30	36	20
Protective pad	57	57	40
Gross incontinence	13	7	20
Fear releasing flatus	50	43	60
Avoid social activity	50	57	60
Dissatisfaction with function	27	29	0

Functional outcomes after low anterior resection were no different amongst the elderly when compared to younger candidates; thus procedures that spare a stoma are perfectly reasonable in select elderly

In contrast to colon cancer, neoadjuvant CRT is often employed to down-size and perhaps even down-stage a rectal cancer. In the revised Dutch TME trial, the effects of pre-operative radiotherapy (5×5Gy) were compared in those 75 or older with rectal cancer to those younger. The proportion of patients receiving pre-operative radiotherapy in the TME study did not differ between the young and elderly (50 % vs. 49 %, $p=0.70$). Although peri-operative complications had a greater impact on the elderly with a mortality of 50 % vs. 7.1 % in younger patients, radiotherapy was not an independent risk factor leading to more complications. In fact, elder patients appeared to respond better to therapy than younger patients. Those receiving pre-operative radiotherapy not only demonstrated lower recurrence rates (5.4 % vs. 14 %), but distant metastases survival (81 % vs. 69 %) and cancer-free survival (81 % vs. 66 %) were both greater; a phenomena not seen in the younger population [78].

Multi-modality neoadjuvant therapy with the addition of capecitabine also appears to be well tolerated by select elderly. In a recent multicenter retrospective analysis, 125 elders between 70 and 90 years of age underwent neoadjuvant CRT. Of those patients, adverse effects ≥grade 2 were observed in 32 % of the patients while only 15 % observed adverse effects ≥ grade 3. Dose reduction for toxicity was only performed in 18 % of the patients and CRT discontinuation was necessary in just 9 % of patients [79]. These results are comparable to younger patients as reported in a recent RCT with grade 2 adverse events observed in 22–38 % of participants, and grade 3 or 4 in 14–29 % [80–82].

Some data have revealed increased toxicity with the addition of chemotherapy to radiotherapy. A retrospective study in 2013 looked at 126 patients aged 70 or older who underwent RT or CRT for rectal cancer. The overall rate of grade 3 toxicity was 34.9 %; with a rate of 8.7 % in RT only group and 26.2 % in the CRT group (P=0.004) [83]. Although toxicities may be slightly more frequent in the elderly, data show patients can tolerate chemotherapy and radiation with limited modifications of the planning treatment. Older patients with rectal cancer of varied stages can be safely treated with careful monitoring and frequent modification of treatment.

Amongst colon, breast, and lung cancer, recruitment of elderly patients in clinical trials for rectal cancer is sparse [73]. As a consequence, our judgment of the appropriateness of therapeutic strategy is severely inadequate. Modern oncologic principles may require tailoring for elderly patients. Radical surgery for rectal cancer is not always the best option, and should be compared against risk of mortality and patient goals for functional life. To illustrate this, Neuman et al. utilized a Markov analysis to demonstrate non-operative "watch and wait" management of rectal cancer as superior to operative management with radical surgery. The study demonstrated that observation was preferred to surgery if the ability to correctly identify patients with true complete responses exceeded 58 %, if quality of life after surgery was poor (utility <0.81), or if the relative reduction in recurrence risk with surgery was <43 % when compared with observation. Overall, the conclusion was surgery benefits the average healthy 65-year-old patient [84].

The impact of surgery extends beyond the peri-operative 30-day period. Long-term consequences on a patient's overall health status, quality of life, and survival must be considered, especially in the elderly. Given the lack of adequate management algorithms in the elderly population, oncologic management of the elderly should be tailored to the individual with an adequate understanding of the patient's underlying functional, physical, or cognitive impairments.

Laparoscopic Surgery in the Elderly

Key Concept: Minimally invasive surgery is safe and appropriate in the elderly.

The benefits of laparoscopy are well established with decreased pain, better cosmesis, early return of bowel function and shorter hospitalization. These benefits extend to the elder population in both benign and oncologic disease with numerous studies validating the benefit of minimally invasive surgery in this group. In one of the largest studies comparing open and laparoscopic colorectal surgery, Frasson and colleagues looked at a cohort of 535 patients, 37.6 % of which were over the age of 70 [85]. Laparoscopy was shown to reduce post-operative morbidity in the laparoscopic group when compared to open resections (20.2 % vs. 37.5 %) as well as length of stay (9.5 vs 13 days). Additionally, the impact of laparoscopy was more pronounced in the older cohort when the two groups were compared highlighting the potential advantage in this population. Other studies have shown similar results demonstrating that laparoscopic is safe in the elderly and its benefits are not exclusive to the younger [86].

Reoperative Evaluation in the Geriatric Patient

There is a consistent data throughout the literature suggesting 30-day mortality significantly increases for each decade through age over 90 years [6, 87]. Yet it is clear that one's age is a poor representation of physiologic reserve and multiple other factors play a significant role in the assessment of an elder individual. In fact, a patient's physiologic age, rather than one's chronological age has been shown to be a more precise indicator of one's ability to tolerate surgery. Because elderly patients are more susceptible to surgical complications, the surgeon must optimize modifiable risk factors when possible. For instance, it has been estimated that the prevalence of cardiovascular disease in women is 12 and 19 % of men 75–84 years old. That risk may be mitigated by following established management guidelines in the administration of appropriate aspirin, statins, and beta-blockade in the peri-operative period. Unfortunately, adherence is notoriously poor, despite data indicating that 3-year mortality may be decreased in peri-operative patients. Thus, it is mandatory for the surgeon to properly assess the patient in the pre-operative setting to improve peri-operative outcomes and patient safety (Table 65-2).

In general, surgical risk groups are based on type of surgery and defined as "low," "medium," and "high-risk," with 30-day cardiac event rates (MI and death) of <1, 1–5, and >5 %, respectively. All abdominal procedures involving the colon and rectum are included within the "medium" risk group (at a minimum). Laparoscopic cases are treated similarly to open cases regarding cardiac risk. In addition, functional capacity is utilized for pre-operative risk assessment. It is estimated based on patient daily activity, or measured with exercise testing. As a reference, 1 metabolic equivalent of task (MET) is an expended metabolic equivalent at rest, 4 METs is equivalent to climbing 2 flights of stairs, and 10 METs represents strenuous sports activities (Table 65-3). Anything less than 4 METs is considered poor functional capacity, but is not strongly associated with worsened cardiac outcomes in abdominal surgery. That being said, current guidelines recommend patients with poor functional capacity to undergo further cardiac evaluation and risk-benefit analysis. Patients with greater than 4 METs do not require further cardiac workup, regardless of risk factors [88, 89]. Use of functional capacity, or other cardiac risk indices such as the Lee index, identify patients requiring further pre-operative cardiac testing.

Table 65-2. Preoperative workup for geriatric patients undergoing colorectal surgery

Cardiac assessment
1. Patients with active cardiac conditions require cardiology assessment and workup
2. Patients with over two clinical risk factors require heart rate management, but do not need cardiac testing unless results will change operative management
3. Patients undergoing low risk surgery, more than 3 METs, or fewer than 3 clinical risk factors may proceed with surgery
Pulmonary assessment
4. Encourage smoking patients to quit more than 8 weeks pre-op, although 4 weeks may be long enough in some studies
5. Aggressive management of COPD and asthma
6. Routine CXR and PFTs not indicated
Diabetes and glucose assessment
7. Obtain baseline glucose level
8. Obtain baseline BUN and creatinine
Nutritional assessment
9. Patients with BMI <18 or unintentional weight loss over 10 % in 6 months require evaluation by a registered dietician
10. Pre-operative nutritional assessment labs not otherwise indicated
Anemia and hematologic assessment
11. Obtain baseline hemoglobin and hematocrit
Cognitive assessment
– All patients require adequate history from patient and family member
– All patients require cognitive assessment (Mini-Cog)
– All patients require anxiety/depression assessment
– All patients require assessment of alcohol use, identification of possible abuse
– All patients require evaluation of decision-making capacity to ensure informed consent
– Any new findings, or worsening of existing findings, requires further evaluation by appropriate geriatrician or mental health care provider
Laboratory and non-invasive testing
– Unless previously indicated above, routine CBC, BMP, PT/PTT, EKG, CXR are not required

Adapted from Chow et al. [118]

Table 65-3. Metabolic equivalents of task—table derived using values from Tudor-Locke C et al. website companion, http://appliedresearch.cancer.gov/atus-met/ (*Source*: 19564664)

Activity performed	METs
Low intensity activities	*<3*
– Sleeping	0.9
– Reading/writing	1.6
– Washing, dressing, grooming self; grocery shopping	2.1
– Bowling	3.0
Moderate intensity activities	*3–6*
– Walking (3.0 mph)	3.3
– Home exercise, light to moderate effort	3.5
– Bicycling, leisure, light effort	4.0
– Dancing	4.5
– Playing volleyball, softball	5.5
High intensity activities	*>6*
– Hiking, fencing, wrestling	6.0
– Soccer, snowboarding	7.0
– Basketball, jogging	8.0
– Tennis, racket sports	8.5
– Jumping rope	10.0

Metabolic equivalents are used to measure functional capacity and are often utilized for pre-operative risk assessment in surgical candidates of all ages

Cardiac Evaluation

Keynote: Overall, the risk of a peri-operative cardiac event for patients undergoing a procedure of 'medium" risk is less than 1 % compared to a 4 % risk in patients with known CAD.

Current studies advocate that the risk of a cardiac event or death in the elder population is no greater than younger patients; hence the application of recommendations is universal. Overall, the risk of a peri-operative cardiac event for patients undergoing a procedure of 'medium" risk, which includes all intra-abdominal cases, is less than 1 % compared to a 4 % risk in patients with known CAD. Clinical cardiac risk factors include angina, prior MI, heart failure, stroke/TIA, renal dysfunction, and IDDM. Additionally, exercise tolerance, ambulatory EKG changes, echo changes demonstrating prior MI, valvular disease or left ventricular diastolic dysfunction, and positive stress test have also been associated with increased risk of peri-operative cardiac event [90]. As such, an EKG is required for patients with presence of cardiac risk factors prior to any surgical intervention. Patients undergoing medium risk surgery (i.e., abdominal) without risk factors should be considered for at minimum an EKG evaluation. Echocardiography is not required in patients free of cardiac symptoms, but should be considered in patients undergoing high-risk surgery [89, 90]. Interestingly, there is minimal evidence to suggest pre-operative revascularization reduces risk in non-cardiac surgery. Instead of cardiac catheterization, beta-blockade, and statins pre- and peri-operatively are strongly recommended [90]. For patients with recent MI, risk of recurrent MI in all comers is over 30 % when surgery performed within first month. Thirty-day mortality related to surgery is 14 % during first month, dropping to 10 % after 3 months, and to normal risk when more than 6 months from date of MI [91]. The take-home point is that unless surgical

intervention is urgent or emergent, patients with recent myocardial infarction should be delayed at least 6 months.

Pulmonary Evaluation

Key Points:

- *Chronic obstructive pulmonary disease (COPD) is the single most important risk factor for development of post-operative pulmonary failure.*
- *In patients with history of tobacco abuse, smoking cessation for more than 6–8 weeks is recommended.*

Studies of post-operative complications in elderly colorectal patients have consistently demonstrated higher risk of respiratory failure, pneumonia, and failure to extubate. The surgeon should identify patients with pre-existing lung conditions and recent functional decline. In such patients, it is prudent to refer to pulmonary specialists for optimization through inhalers, incentive spirometry, mobilization, and other indicated treatments [90]. Risk factors requiring further work up include abnormal CXR, high ASA, abnormal respiratory exam, elevated Goldman Cardiac Risk Index [92] (Figure 65-3), and elevated Charlson comorbidity index [93]. (Table 65-4) Interestingly, obesity is not a pertinent risk factor [89]. In contrast, COPD is the single most important risk factor for development of post-operative pulmonary failure. Up to 25 % of elderly patients with COPD have an operative pulmonary complication, with mortality approaching 7 % [89]. In patients with history of tobacco abuse, smoking cessation for more than 6–8 weeks is recommended [90]. If patients pursue smoking cessation, duration needs to be greater than 2 months, otherwise risk of pulmonary complications is significantly increased. This includes patients who cut down before surgery, with relative risk 6.7 for individuals undergoing major non-cardiac surgery [94].

Surgical site is the most significant non-modifiable risk factor for pulmonary complication, with risk increasing as surgical site moves closer to diaphragm. This is illustrated by rates of upper and lower abdominal complication between 13–33 % and 0–16 %, respectively. Minimally invasive surgery greatly mitigates the risk of pulmonary complication based on surgical site. Anesthesia type also plays a role, with rigorous systematic review demonstrating epidural anesthesia superior to general anesthesia, producing lower mortality (3.1 % vs. 2.1 %), rates of pneumonia, and rates of respiratory depression. As such, some strongly advocate for spinal/epidural anesthesia in patients at high risk for post-operative pulmonary complications [94]. Unfortunately, there are no general pulmonary guidelines or recommendations for surgical optimization in the elderly [89]. Therefore, routine consultation with the anesthesia team, or pulmonary medicine, will greatly enhance management.

Goldman Cardiac Risk Index (9 risks)	Points
1. Age > 70 years	5
2. Cardiac History	
Preoperative MI < 6 months	10
3-4. Physical Examination	
3. S_3 Gallop or HJR > 12 cm H_2O	11
4. Significant aortic stenosis	3
5-6. Electrocardiogram	
5. Rhythm other than NSR or atrial ectopy	7
6. VPBs > 5/min	7
7. General Medical Status: one or more of these factors	3
a. pO_2 < 60 or pCO_2 > 50 mmHg	
b. Serum K < 3.0 or HCO_3 < 20 meg/mL	
c. BUN > 50 or creatinine > 3.0 mg/dL	
d. Chronic liver disease or delibitation	
8-9. Type of Surgery	
8. Intrathoracic, intraperitoneal, or aorta	3
9. Emergency	4
Possible total points and complications rate	**53**
Class I: 0.7% cardiac complications & 0.2% mortality	0–5
Class II: 5% cardiac complications & 2% mortality	6–12
Class III: 11% cardiac complications & 2% mortality	13–25
Class IV: 78% cardiac complications & 56% mortality	≥ 26

Multifactorial index of cardiac risk in noncardiac surgical procedures. *N Engl J Med.* Oct 1977;297(16):845–850 [92].

Diabetes and Glucose Management

Key Point: Current research indicates that elderly patients may greatly benefit from strict control of glucose levels below 180 mg/dL.

Surgical stress is associated with insulin resistance, and this effect has been shown to be more pronounced in elderly patients. As such, reducing insulin resistance is of potential benefit in improving peri-operative outcomes. Multiple studies have advocated drinking a high carbohydrate drink 2 h before surgical intervention to help prevent insulin resistance. Reduction in resistance might lead to decreased infectious complications, decreased ileus, less anxiety, and less peri-operative discomfort and hunger [95]. Without these drinks, 66.7 % of non-diabetic patients had at least one episode of hyperglycemia within 72 h of surgical intervention. On adjusted analysis, hyperglycemia was independently associated with increased rates of sepsis, surgical site infection, reoperation, and increased LOS [96]. Allowing clear liquids

TABLE 65-4. Charlson comorbidity index—summation of score for given patient provides index

Clinical comorbidity	Item score
Myocardial infarct	1
Congestive heart disease	
Peripheral vascular disease	
Dementia	
Cerebrovascular disease	
Chronic pulmonary disease	
Connective tissue disorder	
Diabetes, without complications	
Peptic ulcer disease	
Chronic liver disease (no portal hypertension)	
Each decade over 40 years	
Hemiplegia	2
Moderate, severe renal disease	
Diabetes, with complications	
Solid organ tumors, cancer	
Leukemia	
Lymphoma	
Moderate/severe liver disease, cirrhosis	3
Malignant tumor with metastases	6
AIDS	

Charlson comorbidity index is the most widely used comorbidity index which was developed to predict the 1-year mortality. Adapted from Charlson 1987 [93]

until 2 h before a procedure, then providing a carbohydrate drink, has been associated with reducing the risk of insulin resistance, decreasing the likelihood of complications from hyperglycemia, and limiting significant fluid shifts that are so prevalent in dehydrated elderly colorectal patients [90].

Strict glucose management has been well established to improve peri-operative outcomes in surgical patients. It is particularly important in the elderly population when you consider that over 27 % of patients older than 65 carry the diagnosis of diabetes, and another 50 % are at risk for development [97]. In fact, poor glycemic control (defined as any episode >150 mg/dL) has been independently associated with worsened mortality (OR 11.5) and increased risk of surgical site infections in elderly patients over 70 years undergoing abdominal surgery [98]. Recent studies have shown that elderly patients may greatly benefit from strict control of glucose levels below 200 mg/dL [96, 97, 99]. Caveats include an increased risk of hypoglycemia in elderly patients attributable to impaired counter-regulatory mechanisms, renal insufficiency, or delay in diagnosis related to delirium and altered mental status which are common in the elder population [96, 97].

Nutritional Assessment

Keynote: Malnourishment in the elderly has been shown to increase the risk of peri-operative complications by 6-fold. Optimization of nutritional status is highly recommended including the employment of registered dieticians or nutritionists.

Malnourishment affects between 2 and 32 % of elderly, and that's among the "healthy" geriatric population. In hospitalized elderly patients, prevalence of malnourishment is between 1 and 83 % [100, 101]. There is a sixfold increased risk of complications in malnourished elderly patients [89]. Further, poor pre-operative nutritional status was independently associated with post-operative delirium and mortality in elderly patients. Therefore, optimization of nutritional status and enhancement of protein metabolism is paramount [98]. In fact, enlisting the assistance of a registered dietician or nutritionist increases the rate of improving pre-operative nutritional status [90].

Using BMI or albumin alone to evaluate elderly patients is neither robust nor accurate, and is a poor indicator in clinically ill patients [90]. Prealbumin, transferrin, and retinol-binding protein provide a more accurate picture of patient nutrition. Abnormal vitamin A, B, or C levels indicate a high-risk for complications post-operatively. Clinically, obtain any history of recent weight loss, any chewing/swallow difficulties, any physical limitation/disability, underlying mental confusion, or ethanol consumption. If time permits, screening tools include Subjective global assessment (SGA) or Mini nutritional assessment (MNA) are also helpful and may provide further insight. [100] Evaluation and proactive management of malnutrition in the elderly improves surgical outcomes and should be performed on at-risk patients.

Anemia and Hematologic Disorder Evaluation

Key Point: For patients over age 65, pre-operative transfusion to treat hematocrit levels <24 % is associated with decreased 30-day mortality.

Anemia prevalence increases with age. Over 20 % of patients >85 years carrying the diagnosis, while 16 % of men and 10 % of women over age 75 are anemic. Underlying causes of anemia are split in thirds between malnutrition (iron deficiency accounts for 50 %), renal dysfunction, and unexplained anemia. Anemia in the elderly is subtle, with less than 3 % of patients having a hemoglobin level below 11 g/dL. However, it should not go overlooked, as it is associated with worsened mortality, morbidity, and functional status [102]. A NSQIP study evaluating anemia demonstrated a 0.8 % increased risk of 30-day surgical mortality for every 1 % point below "normal," defined as hematocrit of 39 [103]. In a propensity-score matched analysis of NSQIP patients over age 65, pre-operative transfusion for hematocrit levels <24 % was associated with decreased 30-day mortality. In patients with HCT >30 %, transfusion was associated with decreased mortality only when blood loss was significant (500–999 ml) [104].

A pre-operative CBC provides a baseline and allows the surgeon and anesthesiologist to discuss triggers for operative

blood transfusion. Because of anemia's correlation with nutrition, testing can be completed simultaneously [105]. For major elective surgeries, consider treatment with iron supplementation, folate supplementation, erythropoietin, or transfusion. Discussions regarding immunosuppressive effects and transfusion-related acute lung injury (TRALI) should be thoroughly covered during the informed consent process [103].

Dementia and Mental Status Evaluation

Cognitive dysfunction is common in elderly patients, with rates between 5 and 15 % in the general population and increasing to >60 % in high-risk groups. Although delirium and dementia in the elderly surgical patient have been shown to be significant risk factors for adverse outcomes, it is rare for a surgeon to perform an in-depth cognitive assessment either due to lack of time or knowledge base. In either case, pre-operative cognitive assessment may prove invaluable in improving peri-operative outcomes in the elderly population.

Delirium is the one of the most common post-operative complications in the elderly. It has been defined as a documented change in mental status characterized by reduced environmental awareness and attention disturbance. In a prospective analysis of patients aged over 70, undergoing abdominal surgery, the overall incidence of delirium was 60 % with a 30-day mortality of 20 % in those patients. In fact, 40 % of patients had 3 or 4 risk factors for delirium [98]. Recent studies have implicated dementia as the single biggest risk factor for post-operative delirium, although multiple additional factors have also been implicated (Table 65-5).

Table 65-5. Risk factors for delirium

Pre-operative
Dementia
Age [90]
Malnutrition [98]
Cognitive impairment [101]
Visual impairment [101]
Dehydration [90]
Immobilization [90]
Polypharmacy [90]
Severe illness [101]
Peri-operative
Poor fluid status [98]
Poor glycemic control >150 mg/dL
Metabolic derangements [90, 98]
Uncontrolled pain (PCA necessary to improve delirium in elderly patients [101])
Addition of more than four new medications [98]
Bladder catheters [98]
Serum urea nitrogen to creatinine ratio >17 [101]
Prolonged bed rest
Physical restraints [98]

Pre-operative prevention is possible in patients, with studies showing simple geriatric consultation decreases post-operative delirium. In the Hospital Elder Life Program, focus and management of six factors reduced delirium: visual and hearing impairment, cognitive impairment, sleep deprivation, immobility, and dehydration. Treatment should not utilize medications as first-line therapy. Instead, avoidance of triggers, reorientation, massage, relaxing music, 1 on 1 care with family are recommended. If medication is required, haldol should be initially considered and the clinician should refrain from restraints except in the most severe cases [106].

Current Risk Assessment

Commonly used predictors of post-operative complications are, for the most part, not tailored to the geriatric population. For example, the popular American Society of Anesthesiology is determined by a subjective estimate of organ system disease and likelihood of survival while the Lee and Eagle Criteria account for cardiac function only. Even recent pre-operative risk models such as the CR–possum take only age into account. As we've discussed, chronological age is a poor marker of functional, physical, and cognitive decline in the elderly. Several risk models have attempted to include markers for physiologic status such as the National Surgical Quality Improvement Program (NSQIP). Among other physiologic variables, the model includes age (<65, 65–74,75–84, 85 or greater) and functional health status (defined as independent, partially dependent, and totally dependent), both of which may help account for elder patients who are frail and reside in nursing homes or assisted living facilities. While these models identify age as an independent risk factor and are validated estimates of pre-operative risk, they are substantially limited in the evaluation of the geriatric patient. They fail to pre-operatively discriminate between the geriatric patients who should be considered for surgery, to identify those unfit individuals who should be excluded from radical therapy, and most importantly, those patients with modifiable health risks which can be optimized peri-operatively and perhaps improve outcome.

Frailty

The older population is a heterogeneous group with varying levels of health status. The current models for predicting peri-operative risk do not account for the diverse levels of physiologic reserves in the older surgical patients. The term "frailty" has been increasingly recognized as a surrogate for decreased physiologic reserve in the elder population. It has been described as a phenotype associated with the dysregulation of multiple physiologic systems such as the immune, adrenal, hormonal, and cardiovascular systems [107] In 2001, Fried et al. characterized frailty as an age-associated decline in five domains (Table 65-6): shrinking, weakness,

Table 65-6. Frailty score

Domain	Definition
Shrinking	Unintentional weight loss ≥10 pounds in the last year
Decreased grip strength	Patient squeezed a hand-held dynamometer (strength measurement was adjusted for BMI and gender)
Exhaustion	Response to questions about effort and motivation
Low physical activity	Survey about leisure time activities
Slowed walking speed	Speed at which patient could walk 15 ft.

Chart adapted from Makary 2010 [10]
Frailty score has been described as an age-associated decline in 5 domains: shrinking, weakness, exhaustion, low physical activity, and slow walking speed [107]

Table 65-7. Geriatric assessment domains

Domain	Measures
Functional status	1. Activities of daily living (Subscale of MOS Physical Health) [119] 2. Instrumental activities of daily living (Subscale of the OARS) [120] 3. Karnofsky Performance [121] 4. Timed Up and Go [122] 5. Number of Falls in Last 6 Months [123]
Comorbidity	Physical health section (OARS Subscale) [120]
Cognition	Blessed orientation-memory-concentration test [124]
Psychological	Hospital Anxiety and Depression Scale [125–127]
Social functioning	MOS social activity limitations measure [119]
Social support	MOS social support survey: Emotional/information and tangible subscales [119, 128]
Nutrition	1. Body mass index [128] 2. % Unintentional weight loss in last 6 months [129, 130]

A comprehensive geriatric assessment (CGA) should be a key part of the treatment approach for all older cancer patients [108, 109]

exhaustion, low physical activity, and slow walking speed. The definition was instrumental in providing the framework to help define this challenging population. In nonsurgical patients, frailty has been shown to identify those patients at risk for increase falls, disability, hospitalizations, institutionalization, and mortality [107].

In 2010, Makary and colleagues used the Fried criteria to establish the Hopkins' Frailty Score, which demonstrated that the frailty was a potentially useful tool in predicting poor outcomes in the elderly surgical population. Frailty was prospectively measured in 594 patents (aged 65 years or older who presented for elective major and minor surgery). Patients scoring 4–5 were classified as frail, 2–3 were intermediately frail, and 0–1 were non-frail. Utilizing multiple logistic regression, frailty was shown to be independently associated with the development of post-operative complications (OR 2.54; 95% CI 1.12-5.77), length of stay (OR 1.69; 95 % CI 1.28-2.23), and discharge to a skilled or assisted living facility after previously living at home (20.48; 95 % CI 5.54-75.68). In addition, when combined with other current risk assessment models such as ASA, Lee and Eagle scores, assessing frailty improved their predictive power [10].

The proposed standardized definition of the frailty score is a step in the right direction, laying the framework for decision-making algorithms in this challenging population. Yet the proposed five characteristics of the Fried frailty are still only several pieces of the puzzle. The term frailty is used to represent a global limited reserve in the elder population and as such other abnormalities in frailty domains have been used to describe or define frailty. Numerous studies have linked nutrition, cognition, and geriatric syndromes to poor outcomes in the elderly population—none of which are components of current surgical risk models.

Comprehensive Geriatric Assessment (CGA)

According to the National Cancer Comprehensive Network guidelines, a multidimensional comprehensive geriatric assessment (CGA) should be a key part of the treatment approach for all older patients [108, 109]. The CGA generally includes a compilation of validated tools to assess comorbidity, functional status (including ability to live at home), physical performance, cognitive impairment, psychological status, nutritional status, medication review, and social support (Table 65-7). In general, the benefits of geriatric assessment in older patients include prolongation of life and prevention of hospitalizations and admissions to adult living facilities [1, 110–112], prevention of geriatric syndromes such as delirium and falls [113, 114], prevention of cognitive decline [115], and detection of unsuspected conditions that may affect cancer treatment in more than 50 % of patients aged 70 or over [116].

To date, only a few studies have incorporated CGA as a pre-operative assessment tool, although it has been found useful in predicting morbidity and mortality. In the European Pre-operative Assessment of Cancer in the Elderly (PACE) pilot study [9], elements from CGA were found to be associated with an increased risk of poor surgical outcomes and increased length of stay. The study included 460 patients greater than 70 years of age undergoing elective cancer surgery for solid tumors, of which 32 % were gastrointestinal in origin. The presence of dependent instrumental activities of daily living (IADL), abnormal performance status, or a moderate-to-severe brief fatigue inventory (BFI) score prior to surgery was associated with a 50 % increase in the risk of post-operative complications. In a recent Norway study by Kristjansson et al. [7], the CGA was predictive of surgical morbidity in 178 elderly colorectal cancer patients with a median age of 80. This study is consistent with previous work identifying frailty as a predictor of surgical outcomes [10, 117]. More recently, Robinson and colleagues used seven frailty characteristics (Time Up and Go, Katz score, Mini-Cog, Charleston Index, anemia, poor nutrition, and the geriatric syndrome of falls) to define frail, pre-frail, and non-frail individuals. Of 201 patients who underwent

Table 65-8. 2012 American College of Surgeons NSQIP and American Geriatric Society proposed checklist

In addition to conducting a complete history and physical examination of the patient, the following assessments are strongly recommended:
Assess the patient's **cognitive ability** and **capacity** to understand the anticipated surgery.
Screen the patient for **depression**.
Identify the patient's risk factors for developing post-operative **delirium**.
Screen for **alcohol** and other **substance abuse/dependence**.
Perform a pre-operative **cardiac** evaluation according to the American College of Cardiology/American Heart Association algorithm for patients undergoing non-cardiac surgery.
Identify the patient's risk factors for post-operative **pulmonary** complications and implement appropriate strategies for prevention.
Document **functional status** and history of **falls.**
Determine baseline **frailty** score.
Assess patient's **nutritional status** and consider pre-operative interventions if the patient is at severe nutritional risk.
Take an accurate and detailed **medication history** and consider appropriate peri-operative adjustments. Monitor for **polypharmacy**.
Determine the patient's **treatment goals** and **expectations** in the context of the possible treatment outcomes.
Determine patient's **family** and **social support system**.
Order appropriate pre-operative **diagnostic tests** focused on elderly patients.

Adapted from Chow et al. [118]
American College of Surgeons 2012 best practices guidelines for the peri-operative care of the geriatric surgical patient

major cardiac or colorectal procedures, frailty was independently associated with increased post-operative complications, prolonged hospital stay, and higher 30-day readmission rates [117].

Current Recommendations

In 2012, the American College of Surgeons NSQIP and American Geriatric Society collaborated to create best practices guidelines for the peri-operative care of the geriatric surgical patient. In addition to conducting a complete history and physical, the authors recommended evaluations of pre-operative domains which included problems specific to elderly individuals. These domains are very similar if not the same domains included in the CGA discussed above and include cognitive impairment, frailty, poly-pharmacy, risk of malnutrition, and lack of family or social support. A proposed checklist was drafted for surgeons across all specialties to utilize in the evaluation of a surgical geriatric patient (Table 65-8) [118].

Improving Outcomes

Defining the elderly is the first step in improving outcomes and the frailty score has laid the foundation. Given the multiple domains involved in defining this complex population, it is not surprising that a multidisciplinary approach is likely required to improve outcomes. Pre-operative assessments should be designed at early detection and treatment of surgical and medical complications, in addition to early mobilization, pain management, and discharge planning. Assessments pre- and post-operatively should be performed by a team of providers including a consultant geriatrician, nurse specialist in geriatrics, occupational therapist, physiotherapist, and social worker in order to help identify discharge needs as well as education in optimizing post-operative recovery. Several orthopedic geriatric units have successfully incorporated pre-operative CGA to identify at-risk individuals and apply targeted therapy to help reduce post-operative adverse outcomes, as well as length of stay. The use of CGA may provide a systematic approach to identifying elders classified as frail and the opportunity to optimize these patients peri-operatively. When a specific multidisciplinary system was implemented for the management of demographic and POSSUM-matched patients over 75 years undergoing major colorectal resection, post-operative major complications were reduced to 17.2 % from 30.8 %. This lead to reduced costs, shorter hospital length of stay, and better quality of life for patients who returned home instead of being placed in a nursing home [18].

Conclusion

In summary, as a result of the growing population of frail older persons with chronic disease courses, surgeons will increasingly be faced with the challenge of managing various disease states in this population. Because surgery in the elderly is traditionally circumvented, it is a crucial first step to develop valid tools within surgery to assess comorbid illness, disability, and geriatric syndromes, and to understand how patterns of care and surgical outcomes of elderly persons relate to these underlying conditions. Once these steps are taken, evaluation of interventions to improve overall outcomes can focus not only on survival, but also to maintain function, improve quality of life, and prevent geriatric syndromes in the context of post-operative care for elders.

VBM	Value-based modifier
wRVU	Work-relative value unit

Key Concepts

- In 1965 President Lyndon B. Johnson signed Medicare and Medicaid Amendments (Titles XVIII and XIX) in to law.
- In 1987 the Resource-Based Relative Value Scale was instituted as the basis for Medicare Physician-Fee-Schedule.
- All congressional attempts at controlling the rising cost of health care in America failed.
- The Patient Protection and Affordable Care Act of 2010 mandated Alternative Payment Models.
- These alternative payment models require clinical integration to be successful in decreasing costs, increasing efficiency and quality in the delivery of health care to patients.

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_66

- Surgeons will have to understand these new alternative payment models in order to continue to deliver quality cost-effective care to their patients.
- The Resource-Based Relative Value Scale in combination with Quality Metrics will be the foundation of total compensation for surgeons within these new alternative payment models.

Introduction

Health Care Reform has become one of the most important social movements since Franklin Delano Roosevelt signed the Social Security Tax Act (SSTA) of 1935. He was the first President to advocate federal assistance to the elderly; the SSTA was a social welfare legislative act. It included insurance for older aged individuals (Title I), unemployment compensation (Title III), aid to families with dependent children (Title IV), maternal and child health (Title V), public health services (Title VI), and aid to the blind (Title X) [1]. President Roosevelt wanted to include national health insurance (NHI) in the bill, however his advisors at the time of development of the bill were concerned that attaching NHI as an amendment to the bill would prevent passage of the act [2]. President Roosevelt was under tremendous pressure from the American Medical Association (AMA) not to include NHI in his Tax Act, and he ultimately did yield to that pressure [1, 2].

Over the next 30 years there were continued federal discussions on the development of some form of NHI. President Harry Truman was a staunch supporter of NHI, but he did not have the political support in Congress to pass such a bill while he was President. It wasn't until July 30th, 1965 when President Lyndon B. Johnson signed Medicare and Medicaid Amendments (Titles XVIII and XIX) of the Social Security Act that instituted a national health program in the USA [3]. At the signing ceremony in 1965, President Johnson's speech was dedicated to past President Truman (who was in attendance), thanking him for his efforts and influence during the development and the passage of these amendments. The reality of the cost of Medicare became evident very quickly: first year Medicare costs were $2.4 billion for hospital payments and $640 million for physician payments. Since 1965 the cost of Medicare and Medicaid has continued to rise and to this date has never been reformed.

Today the cost of health care in America is staggering. A 2014 headline on the *Forbes* website exclaimed, **"Annual U.S. Healthcare Spending Hits $3.8 Trillion"—**the title of an article written by Dan Munro and appeared in Pharma & Healthcare 2014 [4]. Health care expenditures in the USA are currently about 18 % of the Gross Domestic Product (GDP) and it is projected to rise sharply. If health care costs continue to grow at the current "historical" rates by 2040 it will be 34 % of the GDP, while Medicare and Medicaid spending will rise to 15 % of the GDP. So today, it's no surprise that the American people, federal and state governments, and commercial payers are pushing for Health Care Reform.

President Barack Obama had "National Healthcare Reform (NHR)" as part of his electorate campaign for President in 2006, and on March 23rd, 2010, he signed into law the Patient Protection and Affordable Care Act [5].

Health Care Reform in America is "happening now" and it is moving at an unprecedented speed. Health Care Reform is not a new topic, but the previous paragraphs point out a very important premise: that the Delivery of Health Care in America is expensive and this cost cannot continue at the current rate of increase. One of the main targets of Health Care Reform is the current method of physician reimbursement, Fee-For-Service.

Physician Reimbursement

Fee-For-Service: Resource-Based Relative Value Scale

> Fee-For-Service (FFS) *is defined as payment to a provider, usually a physician, who receives a set fee for a particular service-such as performing a physical exam or administering an inoculation-either directly from the patient or from an insurer or other payer. Fee-for-service thus generates payments driven by the volume of services performed.* [6]

After passage in 1965, the Medicare and Medicaid Amendment to the Social Tax Act deemed that physician payments from 1966 to 1992 were based on a system of "customary, prevailing and reasonable" (CPR) charges. This was based on the "usual, customary and reasonable" (UCR) system used by the private health insurers. The CPR method of reimbursement was included in the original amendments in 1965. The UCR system was suppose to achieve two goals: (1) to limit doctors' fees within the fiscal capacity of an organized and tax-supported insurance scheme; and (2) to allow each doctor to continue his or her unique pattern of charging, without a standardized fee schedule [7].

Physicians submitted claims to Medicare with the charges they would "like" to collect. The reimbursement was based on each physician's profile of median charges (customary or usual) for all procedures, which were generated by a computation from the claims submitted the year prior. The prevailing charge was calculated each year for each procedure, by computer screening among all individual doctors' as "customary" charges in a particular region. Medicare would then pay the doctor the actual charge on the current bill that was based on the "customary" charge over the past year or the local medical profession's "prevailing" charge over the past year, whichever was the lowest [8]. Even physicians didn't know what the reimbursement would be after submission of the bill. By the 1980s it was clear that the UCR payment system was not working and was becoming more contentious over time.

The government tried to limit costs by means of economic controls, which were a mixture of inducements and price ceilings. They also tried to protect patients from the excessive balanced billing, which at that time was permitted. It was becoming clear that reform in physician payments was necessary and that a standard fee schedule may be required. The Department of Health and Human Services (HHS) and the Health Care Financing Administration (HCFA) at that time were devoted to free competition and market forces as a means of controlling the cost of physician services, including Medicare.

They were hopeful that the Medicare beneficiary, and other people would join Health Maintenance Organizations (HMOs) there by inducing the market to become dispersed to HMOs and individual patient doctor transactions. HCFA and HHS were very supportive of independent practitioners and did not want to suppress the "free enterprise" that existed in the medical profession. At that time the medical profession in general had tremendous impact in Washington. Unfortunately because of the rising costs in health care and inaction of HHS and HCFA, the task of physician payment reform became the problem of Congress. In 1985, Congress created the Physician Payment Review Commission (PPRC) with the intent of reforming Medicare physician reimbursement. At the same time Congress commissioned a research project to develop a Relative Value Scale (RVS) as the best basis for a new payment system. A research team at the Harvard School of Public Health was given a large grant in 1985 to devise a resource-based RVS for Congress to enact in the future.

With the threat of Congress instituting a completely unacceptable method of reimbursement for physicians, the AMA and several specialty societies agreed to supply expert advice to a Harvard research team. The Harvard team had been designing relative value scales for over a decade, attempting to reward work and other inputs of resources, and correcting biases from historical charges.

The Harvard team did produce an RVS in 1979 that was based on that research project [9]. The American College of Surgeons (ACS) at first would not cooperate with the Harvard project and created a rival research staff in order to develop its own fee schedule. The Harvard team tried to develop a uniform methodology, identifying the dimensions of complexity based on judgment, skill, physical effort, and stress due to risk of the service. The team inferred the roles of each of these in dozens of procedures from interviews with doctors, and then developed a relative weight of each of these dimensions for each procedure and time by means of a psychometric method.

To this day the methodology is questioned for reasons including the fact that it benefits cognitive over the surgical (procedural) specialties [8]. Originally, the Harvard team used telephone interview surveys of a small sample of physicians in order to gather their judgments on the relative amount of time required for different procedure (intraservice time). Then the Harvard team had the data and conclusions evaluated by committees of medical specialists (specialty panel) [10].

The criticism of the "original" methodology is that it was felt to be impossible to accumulate complete and reliable data to construct a stable measure of relative "resource-based" weights among procedures based, in large part, solely on "telephone" interviews and physicians' attitudes to this type of survey (physician compliance, and the thousands of procedures to be surveyed).

By 1987 the Resource-Based Relative Value Scale (RBRVS) was recognized as an alternative basis for establishing a payment rate for services and procedures of physicians in the medical and surgical specialties. The RBRVS would be measured by

(1) Time of procedure
(2) Pre- and post-service times
(3) Intensity of the procedure
(4) Practice costs, including malpractice premiums, and
(5) The cost of specialty training

The time and intensity would be based on a national survey of physicians who performed these procedures. A panel of multiple stakeholders would then be convened, including members of the medical profession, third-party payers, consumers, and other interested parties to evaluate and construct recommendations for policy purposes [11].

After several years and several new research grants, Congress was assured that a scientifically designed RBRVS would be phased in by 1993. The finished RBRVS was incorporated into new Medicare legislation by several acts of Congress: The Consolidated Omnibus Budget Reconciliation Act (COBRA) of 1985, which specified delivery by 1987; and the Omnibus Budget Reconciliation Act (OBRA) of 1986, which delayed the completion date until July 1, 1989 and specified implementation by December 31, 1989.

Part of the problem was due to the fact that since the enactment in 1965 of Medicare, Part B (physician payment) contained no administrative structure or cost controls. The reason for the lack of control of Part B was Washington was more concerned with Part A (hospital payment), and Part B was at that time voluntary for physicians. Washington was also concerned if there were strong cost containment controls it would have triggered protests from the medical profession and physicians would not support Medicare Part B.

The federal government attempted to control the increasing costs of the Medicare program by instituting "budget neutrality" and "expenditure caps." In the 1980s, the federal government mandated that if there was to be any restructuring of Medicare reimbursement policy it would not result in higher total costs (i.e., budget neutrality). In addition, spending would be "capped" at a particular level, for example, Medicare Volume Performance Standards (MVPS) (please see the next section Fee-for-Service). These two methods of controlling costs were controversial and also did not change

the continued increasing cost of the Medicare program. The federal government eventually decided to develop a "fee schedule" based on a conversion factor that was decided by Congress. *Washington realized then that with "the creation, monitoring, and updating of such a fee schedule it would require the full participation-and even the leadership-of the medical profession*" [8].

So the development of Joint committees, a permanent confederation of the AMA, specialty societies, and economic representatives who specialize in contracts and reimbursement, along with national negotiators who would develop agreements on the fee schedule and pass them on to Congress for review and approval.

In 1991, the initial meeting of the AMA Specialty Society Relative Value Update Committee (RUC) took place. The RUC is an expert panel of physicians that makes recommendations to the government on the resources required to provide medical services and maintain each service's "relativity" to a family of codes and to the entire RBRVS.

Charter documents were constructed, and the formation of three committees was outlined to help in this venture: RUC Research Committee, RUC Advisory Committee, and the Health Care Professionals Advisory Committee. Finally, in January 1992 the Medicare RBRVS was implemented. By May of 1992, the RUC had considered the first relative value recommendation from the American College of Obstetricians and Gynecologists (CPT code 58435: Transcervical introduction of fallopian tube catheter), and HCFA accepted the first RUC recommendation [12].

In July of 1992, the RUC submitted the first set of recommendations to HCFA for 253 new and revised CPT 1993 codes. This progressed relatively rapidly over the next few years, and by January 1997, the RUC had performed the first 5-Year-Review of the RBRVS, and there were already over 1000 CPT codes. At that time HCFA accepted 95 % of the RUC's recommendation. Shortly thereafter, two very important additions occurred; first, in January 1998, the Practice Expense Advisory Committee (PEAC) was created, which developed values for physician practice expense and were now resource based rather than a percentage of the wRVU (ultimately in 2003, the RUC submitted recommendations for the PEAC on direct practice expense). Second, in January 2000, the implementation of Resource-Based Professional Liability Insurance (PLI) was formed. Neither of these issues were part of the early original determination of the CPT codes. To put this all into perspective, to date there are over 8000 CPT codes listed in the Current Procedural Terminology (CPT) manual.

Today the RUC represents the entire medical profession; however, voting members of the RUC Committee are appointed by their national medical specialty societies, and usually represent those recognized by the American Board of Medical Specialties or are those that represent a large percentage of physicians in patient care and those that account for a high percentage of Medicare expenditures.

Table 66-1. Composition of the AMA RVS update committee (RUC) 2015–2017

RUC representative/society member	Appointment approval by
Chairperson currently cardiothoracic surgeon	AMA board of trustees

[a]Indicates a rotating seat

Four seats rotate on a 2-year basis, with two reserved for internal medicine subspecialty, one for primary care and another for any other specialty. Currently, there are 29 voting members of the RUC and over 100 medical specialties are represented at the three meetings per year [12]. Table 66-1 indicates the current composition of the RUC panel.

The methodology used to evaluate the services (CPT codes) presently is the online survey, and while it is much more sophisticated than the "phone surveys" used by Hsiao in the 1980s, it still does include many of his early recommendations [9]. These surveys are sent to practicing physicians or the specialty society who are the predominant providers of the procedure or family of procedures. An expert panel of the providers, which in many cases is composed of multiple specialty representatives, discusses the results of the survey, the new or revised "CPT Code" is then presented to the RUC, and finally the Work-Relative Value Unit (wRVU) is determined. There is a lot of discussion among the RUC voting members prior to arriving at the wRVU, assuring that the principles of the RBRVS are maintained.

The PEACs review the practice expense for each of the codes and sends its recommendation to the RUC for approval. Next, the wRVUs and the Practice Expense RVUs (PE-RVUs) for each code are submitted to the Center for Medicare and Medicaid (CMS). CMS then may accept the given RUC value or modify the value. That wRVU value is then published in the Federal Registrar, released annually in November, as the Final Rule. CMS then takes in to consideration regional variations of cost and the final total value is presented:

$$\begin{aligned}&\text{The General Formula :}\\&\text{Total RVU} = (\text{work RVU} \times \text{work GPCI})\\&\quad + (\text{practice expense RVU} \times \text{practice expense GPCI})\\&\quad + (\text{malpractice RVU} \times \text{malpractice GPCI}).\\&\quad \text{Payment Total RVU} \times \text{Conversion Factor}\\&\quad (\text{current value } 35.8013)\end{aligned}$$

The Conversion Factor (CF) calculation is a scaling factor that converts the geographically adjusted number of RVUs for each service in the Medicare physician fee schedule into a dollar payment amount. The CF is based on the (1) Medical Economic Index, which measures the weighted average annual price changes in the inputs needed to produce physician services; (2) the Sustainable Growth Rate (SGR); and (3) the updated adjustment factor (UAF). Table 66-2 has examples of three common CPT codes utilized by colon and rectal surgeons with all components and approximate reimbursement utilizing the current conversion factor.

This can also be looked at by the percentage of RVS value of the CPT code. For a typical CPT code, the average breakdown is as follows:

(a) Physician work, 50.9 %
(b) Practice expense, 44.8 %
(c) Professional liability insurance, 4.3 %

While this may seem a bit confusing, it really boils down into a few key aspects. Since 1992, the RBRVS has been the main payment system for Part B and is the basis for the Medicare Physician Fee Schedule. Second, the principle of the Physician Fee Schedule (PFS) is that Medicare will pay a standardized "approved amount" for each service regardless of the physician's fee for the service. Third, the CMS physician fee schedule remains the basis for commercial insurance company fee schedules throughout America. Finally, the work-RVU is the current value method of reimbursement for most "employed" physicians today. We will discuss this in much more depth later on in this chapter. It is quite evident that the Medicare PFS is the economic engine that runs the health care reimbursement and delivery of medical care in the USA.

Fee-For-Service: Why Did It Fail?

William R. Roper MD, CMS Administrator 1988

> …We face substantial problems in controlling the overall growth in expenditures for physicians. A fee schedule based on a relative value scale, no matter how carefully constructed, cannot be expected to address the growth in the volume and intensity of services. Whatever their merits, fee-for-service systems do not provide physicians with incentives to control this growth.

This is a quote from Dr. William R. Roper MD, who was the administrator of HCFA in the mid-1980s during the development of the Resourced Based Relative Value System [13].

As I mentioned in the previous section, the federal government attempted "expenditure caps" to try and control the rising Medicare costs. One example was the Omnibus Budget Reconciliation Act of 1989 (OBRA-89) that established the MVPS, which began in 1990. Under the MVPS policy, payment update for physicians' fees depended on the difference between the actual rate of growth in expenditures for physicians' services and a performance standard established for the year [14]. In reality, OBRA-89 also failed to slow rising Medicare costs. In response, the federal government passed the most controversial method of adjusting physicians' fee schedule based on the comparison of actual expenditures to target expenditures: the SGR. While the SGR is now of historical discussion, until April 2015 it was the most hotly contested approach of adjusting the physician's fee schedule. For that reason I will discuss the evolution and eventual repeal of the SGR method of controlling the rising costs of Medicare PFS.

On August 5th, 1997, the Balanced Budget Act (BBA) was enacted, and Section 1848(f) of the Act, as amended by section 4503, replaced the Medicare Volume Performance Standard (MVPS) with the SGR provision. Section 1848(f)(2) specified a formula for establishing SGR targets for physicians' services under Medicare [14]. Under the MVPS policy, payment update for physicians' fees depended on the

Table 66-2. Common current procedural terminology (CPT) codes billed by colon and rectal surgeons

CPT code	Descriptor	W RVU[a]	PE RVU[b]	PLI RVU[c]	Total RVU	Medicare payment $
44140	Colectomy partial with anastomosis	22.59	12.42	4.64	39.65	1370.58
44204	Laparoscopy, surgical; colectomy, partial, with anastomosis	26.42	12.59	5.53	44.54	1592.51
46260	Hemorrhoidectomy, internal, external, 2 or more columns/groups;	6.73	5.65	1.33	13.71	490.20

[a]Work-RVU
[b]Practice expense RVU
[c]Practice liability insurance RVU

difference between the actual rate of growth in expenditures for physicians' services and a performance standard established for the year [15].

The formula to calculate the SGR was based on an estimate of percentage change in each of four factors:

1. Fees for physicians' services
2. The average number of Medicare fee-for-service beneficiaries
3. The 10-year average annual percentage change in the real GDP per capita
4. Expenditures due to changes in law or regulations

The SGR was a failed mechanism intended to constrain Medicare PFS (Part B) spending by adjusting annual physician fee updates. The mechanism has been criticized as both ineffective and inequitable. Since 2003, Congress has averted formula-adjusted physician fee cuts by overriding the SGR. Every time Congress had to override the SGR there was a cost—one that required payment, except Congress could not find the funds due to budget restrictions. In a "catch-22" proposition, each year the scheduled cuts to Medicare PFS reimbursements were listed at or above 20 %. While this may lower federal expenditures, such large Medicare cuts would actually jeopardize beneficiaries' access to physicians because many physicians would stop seeing Medicare beneficiaries [16].

This all led to the Medicare Provider Payment Modernization Act of 2014 (H.R. 4015 and S. 2000), also called the "2014 SGR fix." This bill actually had bipartisan and bicameral support, except the legislation never left the congressional committee stage because Republicans and Democrats could not agree on how to pay for it. The Congressional Budget Office estimates the cost in 2015 as $174.5 billion [17, 18]. Since 2003, Congress had been trying to repair and/or repeal the SGR in order to stop the rising costs of Medicare spending and all have failed to change the trend. The 2014 SGR fix presented for the first time the Eligible Professionals (EP) definition, which includes physicians (73 %), physician assistants, nurse practitioners, clinical nurse specialist, and therapists with two payment pathways: one Fee-for-Service reimbursement and one for physicians involved in value-based alternative payment models: including the Accountable Care Organizations (ACO), bundled payments, and patient-centered medical homes [17, 18]. The proposed fee cut was scheduled to take effect on April 1, 2015, and would have instituted a 21.1 % decrease in physician fees. However, with overwhelming bipartisan and bicameral support, on April 15, 2015, Congress passed the Medicare Access and Children Health Insurance Payment Reauthorization Act, which repealed the SGR payment formula and guaranteed the Medicare PFS a 0.5 % increase in reimbursements to physician through 2019. President Barack Obama signed the Medicare Access and Children's Health Insurance Program (CHIP) Reauthorization Act of 2015 into law on Thursday, April 16th, 2015.

Since the inception of the PFS and the continued increase in health care costs, Congress, and CMS have focused on disassembling the current fee-for-service system and replacing it with Alternate Payment Models (APM). The Patient Protection and Affordable Care Act of 2010 mandated many of these changes in the delivery of health care in America. I will discuss some of the key portions of the law that will influence how physicians are reimbursed and deliver care.

The Patient Protection and Affordable Care Act of 2010 (P.L. 111–148)

In June 2009, the Executive Report of the President by the Council of Economic Advisers (CEA) entitled *The Economic Case for Health Care Reform* was released. This was one of the most influential "white papers" that stimulated health care reform, in general, and ultimately played a large part in development of the Affordable Care Act of 2010. At its roots, the report stated that the American health care system had substantial inefficiencies that have contributed to the spiraling health care costs.

The CEA pointed to key elements as the cause of these inefficiencies in the health care system:

1. Tremendous variation across states in Medicare spending per enrollee, with no evidence of corresponding variations in either medical needs or outcomes
2. Payment systems that reward medical inputs rather than outcomes
3. High administrative costs
4. Inadequate focus on disease prevention.

The CEA also implicated market imperfections in the health insurance market that create incentives for socially inefficient levels of coverage [5]. The CEA focused on two key components for health care reform:

1. Containment of the growth rate of healthcare costs, and
2. The expansion of insurance coverage.

As a very brief summary of the ACA 2010, it is an approach to expanding access to health care coverage and it;

> Requires most U.S. citizens and legal residents to have health insurance. Creates state-based American Health Benefit Exchanges through which individuals can purchase coverage, with premium and cost-sharing credits available to individuals/families with income between 133-400 % of Federal Poverty Level (FPL) ($19,530 for a family of three) and in (2013) creates separate Exchanges through which small businesses can purchase coverage. Require employers to pay penalties for employees who receive tax credits for health insurance through an Exchange, with exceptions for small employers. Impose new regulations on health plans in the Exchanges and in the individual and small group markets. Expand Medicaid to 133 % of the FPL. [19]

The ACA 2010 is about individual mandates, employer requirements, expanding public programs such as Medicaid and the CHIP, premium and cost-sharing subsidies to individuals and employers, tax changes related to health insurance or financing health reform, instituting health insurance exchanges, developing benefit guidelines, influencing private insurance with rules and regulations to increase participation with all levels of insured patients, mandating the "role" of states in insurance market regulations, administration of health plans and cost containment, and mandating quality improvement and health system performance measures that include prevention, wellness, and long-term care. It is the most inclusive and comprehensive reform in the history of the USA. This law affects all Americans, but the areas that are or will "directly affect" our participation and reimbursement in the health care delivery system are under the categories of Cost Containment, and Improving Quality/Improving Health System Performance. I will expand on these two areas of the law with a series of tables and discussion points.

ACA: Cost Containment Changes

Under the category of Cost Containment the law mandates many "Administrative" changes to health insurance companies: i.e., commercial payers must enact certain provisions in order to simplify delivery and relieve obstructions to the care to their beneficiaries (Table 66-3). The law also institutes sweeping changes within Medicare, which mandate the restructuring of payments to all providers (Tables 66-4 and 66-5). Medicaid is also affected by restricting payments for drugs. Of more concern, it dramatically decreases funding to Disproportionate Share Hospitals (DSH/Safety Net Hospitals) by $17.6 billion (2014–2020), and changing the methodology for distributing the "reductions" to these critical hospitals (Table 66-6). Of note, the vast majority of these DHS are major academic teaching centers, and this could negatively affect residency programs throughout the USA.

The final section of Cost Containment is Waste, Fraud and Abuse—where the overriding principle involves decreasing the cost of fraud by expanding over site, increasing the penalties for submitting false claims and augmenting funding for anti-fraud activities (Table 66-7). It is estimated by the Federal Bureau of Investigation that 3–10 % of all healthcare billings are fraudulent. To put this in context, every year Medicare pays over $566 billion for more than 50 million beneficiaries and Medicaid pays $428 billion for 70 million people [20].

Improving Quality/Health System Performance

Under the heading of Improving Quality/Health System Performance the law affects several areas that are important to physicians: Comparative Effectiveness Research (CER), Medical Malpractice, Medicare, Medicaid, and National Quality Strategy.

Table 66-3. Cost containment of ACA 2010: administrative simplification

Simplify health insurance administration by	Rules adoption date	Effective date
A single set of rules for eligibility verification & claims status	July 1, 2011	January 1, 2013
Simpler electronic funds transfer, health care payment & remittance	July 1, 2012	January 1, 2014
Simpler health claims/equivalent encounter information, enrollment & disenrollment in health plan premium payments, referral certification & authorization	July 1, 2012	January 1, 2016
Health plans must document compliance with these standards ($1 penalty per covered life)		April 1, 2014

Table 66-4. Cost containment: Medicare advantage (MA) plans restructure payments

MA	Restructure payments based on % of FFS[a] those with high % of FFS decrease their payments and increase those with a lower % of FFS	Phase in revised payments over 3 years beginning in 2011 for most areas For some areas phase in over 4–6 years beginning in 2011
MA	Bonus for those plans receiving four or more stars based on the current five star quality rating system for MA as much as a double bonus	Beginning 2012
MA	Modify rebate system based on quality rating	Phased in by 2019
MA	Phase in adjustments to plan payments or coding practices related to health status of enrollees (equaling 5.7 %)	Phased in by 2019
MA	Require MA plans to submit to Secretary of Health partial payments if ML ratio is less than 85 %	2014
MA	Require Secretary to suspend enrollment to MA plan if ML ratio[b] is less than 85 % for 2 consecutive years or terminate plan contract if ML ratio is less than 85 % for 5 consecutive years	2014
MA	Cap total payments, including bonuses at current payment levels	2014

[b]Medical loss ratio

Table 66-5. Cost containment: Medicare

Change	Effective date
Reduce annual market basket updates to inpatient hospital, home health, skilled nursing facility, hospice & other Medicare providers & adjust for productivity	Effective varying dates
Freeze the threshold for income-related Medicare Part B premiums	For 2011 through 2019
Establish a Payment Advisory Board of 15 members (no physicians) to submit legislative proposals containing recommendations to reduce the per capita rate of growth in Medicare spending if spending exceeds a target growth rate	Beginning in April 2013
Reduce Medicare Disproportionate Share Hospital (DSH)[a] payments initially by 75 % then subsequently increase payments based on % of uninsured population and the amount of uncompensated care	Effective January 1, 2015
Eliminate Medicare improvement fund	Effective upon enactment
Allow ACOs that voluntarily meet quality thresholds to share in cost savings they achieve for the Medicare program.	January 1, 2012
Create an Innovation Center (with in CMS) to test, evaluate, and expand Medicare, Medicaid, and CHIP (different payment structures & methodologies to decrease expenditures and/or improve quality)	January 1, 2011
Reduce payments by specified percentages to account for preventable readmissions	Effective October 1, 2012
Reduce payments to certain hospitals-acquired conditions by 1 %	Effective fiscal year 2015

[a]DSH—Hospitals that treat indigent patients receive at least partial compensation

Table 66-6. Cost containment: Medicaid

Change	Effective date
Increase Medicaid rebate for drugs: brand name 23.1 %, multiple source drugs 13 % on average manufacture average price	Effective on enactment
Reduce aggregate Medicaid DSH allotments	$0.5 billion 2014 $0.6 billion 2015 $0.6 billion 2016 $1.8 billion 2017 $5.0 billion 2018 $5.6 billion 2019 $4.0 billion 2012 $17.6 billion total reductions
Reduce aggregate Medicaid to DSH[a] allotments by developing a methodology to distribute the DSH reductions in a manner that imposes the largest reduction in DSH allotments for states with the lowest percentage of uninsured or those that do not target DSH payments, imposes smaller reductions for low-DSH states and accounts DSH allotments for 1115 Waivers[b]	Effective October 1, 2015
Prohibit federal payments to states for Medicaid services related to healthcare acquired conditions	Effective July 1, 2011

[a]DSH—Disproportionate Share Hospitals "safety net hospitals"

[b]1115 Waiver Section 1115 of the Social Security Act that gives the Secretary of Health and Human Services authority to approve experimental, pilot, or demonstration projects that promote objective of the Medicaid and CHIP programs. As long as these programs: expand eligibility, provide services not typically covered, or use innovative service delivery systems that improve care, increase efficiency, and reduce costs for Medicaid or CHIP programs

Table 66-7. Cost containment: waste fraud and abuse reduction

Change	Effective date
Provider screening	Dates vary
Enhanced oversight periods for new providers and suppliers initial claims (including enhanced oversight for 90 days)	Dates vary
Moratorium in areas identified as being at elevated risk of fraud in all public programs	Dates vary
Require Medicare & Medicaid providers and suppliers to establish compliance programs	Dates vary
Develop a data base to capture and share data across federal and state programs	Dates vary
Increase penalties for submitting false claims	Dates vary
Increase funding for anti-fraud activities	Dates vary

The ACA of 2010 supports CER by establishing a non-Profit Patient-Centered Outcomes Research Institute to conduct research that compares clinical effectiveness of medical treatments. This institute will be overseen by an appointed multi-stakeholder Board of Governors and with assistance of expert advisory panels. The law does state that the CER findings may not be construed as mandates, guidelines, or recommendations for payment, coverage, or treatment or used to deny coverage. The funding for this project was available at the beginning of the fiscal year 2010. The law mandates the funding by imposing a "fee" on issuers of specified health insurance policies and sponsors of self-insured health plans. It is a once-a-year fee based on the average number of lives covered under the policy or plan.

The law also mandates that medical malpractice "reform" is an important issue and awards 5-year "grants" to states in

order to develop, implement, and evaluate alternatives to current tort litigations, only if the proposals are likely to enhance patient safety by reducing medical errors and adverse events that are likely to improve access to liability insurance (5-year-funding began in fiscal year 2011). Unfortunately, I don't believe this is what physicians have in mind for Medical Malpractice Reform.

The Improving Quality/Health System Performance reference to Medicare for alternative payment models to providers is shown in Table 66-8. These changes to Medicare reimbursement are definitely one of the most important issues facing physicians today. This indicates the direction of the ACA of 2010 is toward the elimination of the fee-for-service method of payments to physicians. This method *is and will* continue to force physicians into Clinically Integrated Networks, and in addition, places some of the economic risks on the providers. The changes to Medicaid payments are just as onerous and are reviewed in Table 66-9.

National Quality Strategy

The National Quality Strategy was a mandate to "define quality" and also to incorporate quality measures into physician payments as incentives or penalties (Table 66-10). From this aspect, multiple "quality measures" have developed and are utilized today.

This brief overview suggests that the ACA of 2010 is forcing the initiation of alternative payment models and the formation of health care networks, which in turn forces physicians into clinically integrated networks. There are several methods of "physician integration" such as employment by the integrated network, physician hospital organizations, or independent practitioner organizations, or join a multispecialty practice. Whichever mechanism of integration the surgeon decides, one the following Alternative Payment Models or a combination of them will be the method of reimbursement.

TABLE 66-8. Improving quality/health system performance: Medicare

Change	Effective date
Establish a national Medicare pilot program to develop and evaluate paying a "Bundled Payment" for acute inpatient hospital/outpatient services, physician services, and post-acute-care services for an episode of care that begins 3 days prior to hospitalization and spans 30 days following discharge.	Establish pilot program by January 1, 2013 and expand program, if appropriate, by January 1, 2016
Create home demonstration program to provide high-need Medicare beneficiaries with primary care services in their home and allow health professional to share in any savings if they: reduce preventable hospitalizations, prevent hospital readmissions, improve health outcomes, improve the efficiency of care, reduce the cost of health care services, and achieve patient satisfaction	Effective January 1, 2012
Establish a hospital Value-Based Purchasing Program in Medicare to pay hospitals on performance on quality measures. Also extend physician quality reporting initiative beyond 2010	Effective October 1, 2012
Develop plans to implement Value-Based Purchasing Programs for skilled nursing facilities, home health agencies, and ambulatory surgical centers	Report to Congress due January 1, 2011

TABLE 66-9. Improving quality/health system performance: Medicaid

Change	Effective Date
Demonstrations projects in Medicaid to pay "Bundled Payments" for episodes of care that include hospitalizations	January 1, 2012 through December 31, 2016
Global capitated payments to safety net hospital systems	Effective fiscal years 2010 through 2012
Organize ACOs[a] for pediatric medical providers and allow them to share in cost savings	Effective January 1, 2012 through December 31, 2016

[a]Accountable care organizations

TABLE 66-10. Improving quality/health system performance: national quality strategy

Change	Effective date
Develop a National Quality Improvement Strategy (NQIS) that includes improving the delivery of health care services, patient health outcomes, and population health	Due to Congress by January 1, 2011
Create processes for development of quality measures involving input from multiple stakeholders for selecting quality measures to be used in reporting to and payment under federal health programs	Due to Congress by January 1, 2011

Alternative Payment Models

As mentioned in the previous section, the ACA of 2010 created the Center for Medicare and Medicaid Innovation (CMMI) and provided it with $11 billion for developing pilot projects and demonstration programs, all of which are currently underway, and each with the goal of developing different ways to organize and/or reimburse physicians other than the current fee-for-service method [21].

The Patient-Centered Medical Home

Medical home projects focus on providing comprehensive primary care that is patient-centric through better coordination of the care patients receive from all providers. This model may include a single payer or multiple payers, and may include Medicare beneficiaries as well. It is based on a risk-adjusted comprehensive per member per month payment or initially the private payers pay an enhanced fee-for-service evaluation and management payment to physicians who add processes of care. These include tools that organize clinical information or adoption of evidenced-based guidelines, as well a bonus payment for improved outcomes such as a decrease in hospital bed admissions or emergency department visits. Of note, the payment is still based on the fee-for-service model under the umbrella of the Medical Home Model.

These Medical Home pilot projects have demonstrated very modest savings up until now. UnitedHealthcare reported savings of about 4 % over a 2-year period and WellPoint reported 3 % in its first year in New Hampshire [21, 22]. Both systems continue to pay physicians on an FFS basis, along with some incentives for coordination of care.

The Michigan Blue Cross Blue Shield (BCBS) Medical Home pilot is utilizing an FFS model, but physicians receive higher fees for certain evaluation and management office codes and preventive care visits. The higher fees are based on quality measures adopted, the performance achieved, and also reflect the outcome results of all patients in the area, not just those who are BCBS of Michigan. In 2012 and 2013, BCBS of Michigan included added payments to specialists for the use of evaluation and management codes. In 2014, specialists received added payment based on the quality and efficiency of care provided to the population [23].

Accountable Care Organizations

The ACO model is authorized in Title III, section 3022 of the ACA and is under the Medicare Shared Savings Program. The ACOs comprise of groups of physicians, other health care professionals, and facilities that agree to work together to provide high-quality, coordinated care to their patients at measureable levels of savings. This model reimburses physicians on an FFS basis, but in order to control the increase in volume, they pay more to physicians who coordinate care and employ information technologies. The CMMI developed an alternative model, the Pioneer ACO, which is for organizations that have experience in offering high-quality, coordinated care to patients. These organizations must be willing to share losses and savings with CMS as long as they generate a minimum of 2 % savings. The ACO must have at least 5000 patients, have no enrollment process, but instead is based on where patients receive their primary care. The initial results of the Pioneer ACOs, reported in 2013, were not impressive, as all 32 met quality performance metrics, but only 13 produced savings large enough to share with CMS. The outcomes resulted in nine leaving the program, seven going onto regular Medicare Savings Programs, and two ceasing to function as an ACO [23].

Bundled Payment Pilot Projects

The CMS Innovation also developed the Bundled Payment for Care Improvement (BPCI) initiative, which was launched in January 2013. The BPCI is a new payment model that allows participating hospitals to enroll in bundled payment agreements with CMS for up to 48 predefined clinical conditions aggregated from Medicare Severity Diagnosis-Related Groups (MS-DRGs). While there are four different models of bundling, the *hospital* is the focal point of the bundle, and the bundle is based on an episode of care. The bundle includes physician services, post-acute providers, related readmissions, and any ancillary services provided during this episode of care. The providers indicate which conditions they want to bundle and propose a discounted price to CMS, based on historical reimbursements for a similar set of services [21].

These three payment models described above are *primary care driven* and *specialists* have historically shown little interest in trying or supporting alterative payment models because of the current FFS model. However, CMS and Congress are actively working to force specialists into alternative payment and delivery models.

Some of the early results of these models have been variable, including a recent independent study of the Michigan Blue Cross Blue Shield Physician Group Incentive Program that does support the FFS method of payment, but is now evolving into Fee-For-Value (FFV) model. They looked at the impact on quality and spending from 2008 to 2011 for over 3 million beneficiaries in over 11,000 physician practices. This statewide model has been evolving over a decade and includes independent practice associations, physician hospital organizations, and large multispecialty group practices. These groups provide clinical leadership, administrative structure, and technical infrastructure. Overall, there are more than 19,000 physicians, involving 68 % of active primary care physicians and 49 % of all active specialists. These physician organizations serve as intermediaries between BCBS of

TABLE 66-11. Center for Medicare and Medicaid Innovation: bundled payments for care improvements (BPCI) payment models

Model	Description	Phase 1	Phase 2	Payment type
1	Involves hospital payments for inpatient stays for most Medicare FFS discharges	Nonrisk bearing	Risk bearing	Retrospective
2	Includes all Medicare Parts A and B payments for the 48 selected clinical conditions	Nonrisk bearing	Risk bearing	Retrospective
3	Includes payments only for post-acute claims for participating skilled nursing facility, inpatient rehabilitation facility, long-term care hospital, home health agency, or physician practices	Nonrisk bearing	Risk bearing	Retrospective
4	Initial hospitalization, health care provider fees during the hospitalization, and payments for readmission	Nonrisk bearing	Risk bearing	Prospective "lump sum" payment to the participating hospital, which then pays the physicians and other provider groups

Michigan and practices participating in the Physician Group Incentive Program. These physician practices have established over 1400 patient-centered medical homes. Since it is primary care-based, the physicians who participate are eligible for up to a 20 % increase in reimbursement in their office evaluation and management fees. They may also bill for care coordination and care management services provided by ancillary providers. They also have an opportunity to earn an additional 15 % on evaluation and management fees for high performance on quality measures. The study did show that participation in the incentive program was associated with an ~1.1 % lower total spending for adults and 5.1 % lower spending for children, along with improved performance in 11 of 14 quality measures over time [24].

Unfortunately, the Patient-Centered Medical Home model, when utilized with the Medicaid population, found little to no impact on acute care use and only modest support for reduced costs and primary care use among patients with higher proportions of chronically ill patients [25].

Basically, the principle of the bundled payment model provides a payment for all of the care a patient needs over the course of a defined clinical episode of care. Its intent is to decrease healthcare spending and improve quality by financial incentives for providers for the elimination of services that are clinically ineffective or duplicative. Also, a shared payment encourages the coordination of care by holding multiple providers jointly accountable, and is designed to decrease the cost of the bundle of services.

In 2008, the PROMETHEUS Bundled Payment model was developed. This experiment was based on multiple services that were anticipated to be required under a particular episode of care: for a patient diagnosed with a specific medical condition or receiving a specific medical procedure. The payment rates are called "evidence-informed case rates." It is a risk-stratified model based on both the probability risk and technical risk. Probability risk is the classic risk used by insurance companies to predict the event will or won't happen, and the technical risk is related to "care production." The providers are expected to control technical risk or potentially avoidable complications through planning and training. So the PROMETHEUS model is designed to transfer the financial responsibility/risk for events related to technical risk (i.e., the providers), and the insurers retain the risk for probability. Three pilot sites were originally included: two chose chronic medical conditions and one chose a procedure.

Yet multiple challenges existed in implementing a bundle, including: defining the bundles, defining the payment method, implementing quality measurement, determining accountability, engaging the providers, and redesigning the care. As of May 2011, none of the pilot sites had been able to utilize PROMETHEUS as a payment method or had executed bundled payment contracts between payers and providers. However, even with the early poor results the participants did see promise and value in the bundled payment model [26].

Without a definitive way forward, the CMMI/BPCI initiatives for Medicare beneficiaries developed four models of payment (Table 66-11). Some highlights include:

The Risk-Bearing Phase (Model 2) has been the main type of bundle payment utilized because it represents the most comprehensive bundled payment by including all services following an index hospitalization. What was found was that the hospitals that enrolled in the BPCI initiative were large, nonprofit, teaching hospitals in the Northeast that have existing affiliations with post-acute-care providers. The few that enrolled in the risk-bearing model chose to focus on three or fewer conditions. The study did find that the most opportunity for savings was in the post-acute-care services such as skilled nursing facilities, rehabilitation facilities, and home health agencies. These services accounted for the highest amount of the variation in total episode-based care spending and are thus targets to reduce healthcare spending [27].

The reality of this section is that multiple stakeholders, especially CMS and the commercial payers, are spending a lot of money on alternative payment models. Much of the data discussed is weak, but what we are seeing today is that the "fee-for-service" method of reimbursement as is known today is going to be re-invented or discarded.

An important point to consider, as it pertains to the payment reform models as discussed in the previous sections, is that the current FFS method will be replaced "broadly" by new incentives that will reward appropriate quality care and value.

Even with payment reform, clinically integrated organizations such as ACOs will pay physicians a substantial amount by the FFS payment model. The hybrid FFS method of payment will include volume (wRVU), quality, and efficiency metrics for the provider who delivers care within these integrated delivery systems. The FFS payment model will remain the basis for determining the bundled payment (i.e., episode of care) amount and the method of reimbursement to the providers who deliver the care under the bundle. So at least for now the "Relative Value Scales," which is the measure of physician inputs by time and intensity of effort, will remain an integral part of payment reform.

Any reform to the Medicare PFS has broader provider payment reform because it directly influences private third-party payer's method of physician reimbursement. The Affordable Care Act section 3007 created a type of payment reform, a "Value-Based Modifier" (VBM) under the Medicare PFS. As required by law Medicare is "budget neutral"; however, the VBM will increase or decrease payment rates to each physician on the basis of CMS' assessment of value, which is based on various indicators of quality and efficiency [6, 28].

Clinical Integration

These alternative payment models ultimately rely on Clinical Integration, and there are many factors that are driving established physicians and physicians coming out of residency into integrated networks. Physicians are migrating to employment because of both healthcare market dynamics and physician's preferences. There is continued concern about the long-term economic effects of healthcare reform and decreasing reimbursement. Many small and medium-sized private practices are having difficulty managing their overhead costs. They also can't compete against the larger organizations, so they give in and or become absorbed/purchased by some of these integrated networks. Young physicians finishing residency are more interested in daily practice than on operating a business, especially because the economics of traditional private practice are so uncertain.

Hospitals and Health Care Networks are hiring physicians for several reasons: better clinical alignment with physicians to reduce the variation in care; increase in cost; and because government and commercial payers are pushing for better outcomes and reduced costs or face financial penalties. Since ACOs are mostly *hospital-centered*, hiring physicians can assist them accrue more patients more rapidly and these networks may influence the care delivered to the community. Integration of physicians into health care networks can have ongoing programs to evaluate and modify individual practice patterns because of the high degree of interdependence and cooperation among the physicians within the networks, which in turn will control costs and ensure quality.

Clinical integration facilitates the coordination of patient care across the "Continuum of Care" in order to achieve Quality Care; these integrated networks must include six goals of integration. The integrated system must be

1. Patient-focused
2. Safe
3. Timely
4. Effective
5. Efficient
6. Equitable

Physician payment reform must achieve a change in physician behavior by their delivery of care to patients within the clinically integrated networks. The current method of modification of physician behavior is through the use of financial incentives or disincentives. In theory, a "change" in physician behavior should reduce the marginal costs and thus the cost-benefit ratio by delivering high-quality healthcare.

In 1990, the Institute of Medicine (IOM) published *Medicare: A Strategy of Quality Assurance*, and defined quality of care as the "degree to which health care services for individuals and populations increase the likelihood of desired outcomes and are consistent with current knowledge." This definition is widely accepted and has proven to be a practical reference to quality assessment and improvement [29].

In the 2011 Report to Congress, the *National Strategy for Quality Improvement in Health Care (NQS)* was included in the ACA of 2010. The NQS pursued three broad aims:

1. Better Care: Improve the overall quality of care by making healthcare more patient-centered, reliable, accessible, and safe.
2. Healthy People/Healthy Communities: Improve the health of the US population by supporting proven interventions to address behavioral, social, and environmental determinants of health in addition to delivering higher quality care.
3. Affordable Care: Reduce the cost of quality healthcare for individuals, families, employers, and government.

The NQS has set six priorities to advance these quality goals. These priorities are based on the latest research, input from multiple stakeholders, and examples from around the country. NQS feels that these priorities have great potential to rapidly improve health outcomes and increase the effectiveness of care for all populations [29].

Table 66-12 describes the basis of what is happening right now with quality measures. Understand that these measures in one form or another are being instituted throughout American healthcare system.

TABLE 66-12. National quality strategy priorities and goals

Priority	Goal	Opportunities	Measures
Safer care	Eliminate preventable health care-acquired conditions	1. Eliminate hospital-acquired infections 2. Reduce the number of serious adverse medication events	Standardized infection ratio for central line-associated blood stream infection as reported by CDC's National Healthcare Safety Network
Effective care coordination	Create a delivery system that is less fragmented and more coordinated, where handoffs are clear, and patients and clinicians have the information they need to optimize the patient–client stewardship	1. Reduce hospital admission and readmissions 2. Prevent and manage chronic illness and disability 3. Ensure secure information exchange to facilitate efficient care delivery	All-cause readmissions within 30 days of discharge Percentage of providers who provide a summary record of care for transitions and referrals
Person and family-centered care	Build a system that has the capacity to capture and act on patient-reported information including preferences, desired outcomes, and experiences with health care	1. Integrate patient feedback on preferences, functional outcomes, and experiences of care into all care settings and care delivery 2. Increase use of EHRs that capture the voice of the patient by integrating patient-generated data in EHRs 3. Routinely measure patient engagement and self-management, shared decision-making, and patient-reported outcomes	Percentage of patients asked for feedback
Prevention and treatment of leading causes of mortality	Prevent and reduce the harm caused by cardiovascular disease	1. Increase blood pressure control in adults 2. Reduce high cholesterol levels in adults 3. Increase the use of aspirin to prevent cardiovascular disease 4. Decrease smoking among adults and adolescents	Percentage of patients 18 years or older with ischemic vascular disease whose most recent blood pressure during the measurement year is <140/90 mmHg Percentage of patients with ischemic vascular disease whose most recent low-density cholesterol is <100 Percentage of patients with ischemic vascular diseases who have documentation of use of aspirin or other antithrombotic during the 12-month measurement period Percentage of patients who receive evidence-based smoking cessation services (e.g., medications)
Supporting better heath in communities	Support every US community as it pursues its local health priorities	1. Increase the provision of clinical preventive services for children and adults 2. Increase the adoption of evidence-based interventions to improve health	Percentage of children and adults screened for depression and receiving a documented follow-up plan Percentage of adults screened for risky alcohol use and if positive, received brief counseling Percentage of children and adults who use the oral health care system each year Proportion of the US population served by community water systems with optimally fluoridated water
Making care more affordable	Identify and apply measures that can serve as effective indicators of progress in reducing cost	1. Build cost and resource use measurement into payment reforms 2. Establish common measures to assess the cost impacts of new programs and payment systems 3. Reduce the amoutn of health care spending that goes to undue administrative burden 4. Make costs and quality more transparent to consumers	To be determined

Clinical Integration and the Employed Physician: What About Contracting?

Physician Payment Reform Models are not "mutually" exclusive and can often be applied in combination with one another. Currently there is no certain understanding regarding which model works best, under what circumstances, and with what methods of implementation. One important point that I want to impress upon the reader is that the RBRVS system is and will be a part of the reimbursement to physicians in these alternative payment models.

I will discuss the different types of reimbursement models for surgeons that are being utilized in the market today. It will take into account economic definitions and models of payment. When surgeons decide on employment with a clinically integrated network, they are usually moving from a private practice environment. They will be negotiating an employment agreement and possibly sale of their practice. This section will discuss only the employment contract, and will include different models of reimbursement and other important aspects of these contracts.

If you are a trainee who has just finished residency or fellowship, you will be negotiating an employment contract that is not too dissimilar. So in most contracts there are a number of important categories that are usually included in the body of it, and one must consult an experienced attorney to assist in the legal interpretation and implications of these complex contracts (Table 66-13).

This section will concentrate on terms of agreement, signing bonus, compensation methods, incentive bonus, quality measures, and salary caps. A point for established surgeons moving into an employed position during negotiations: please realize that there is value to your seniority, "standing" in the community, board certification, and region of practice.

There are a number of compensation models utilized today to reach a total annual cash compensation package for a specified period of time including a fixed salary, base salary plus incentive bonus, treatment for an episode of care or specific services (FFS), capitation per member per month (patients or population), and performance-based pay with increases based on quality of care metrics. In this scenario, methods of payment can be defined as linear when a payment is made for each additional unit of service provided or non-linear when the payment is conditional on reaching a threshold/target or a series of thresholds/targets, or the amount of payment changes with each additional service provided.

The timing of the payments may also vary. One way is payment in advance, which includes a fixed overall budget, while the other is retrospective payment—after the service has taken place, with or without a cap on the total payments. The method of payment may also be reduced or withheld if "behavior" does not comply with what is required (e.g., financial penalty). These are basic principles of compensation models and are not mutually exclusive; therefore, before contract negotiations you should have an understanding of these models and just what your personal goal is. Usually, salary proposals are one of the few areas of these contracts that the surgeon may be able to modify during negotiations, so it is best to have a firm understanding of these concepts.

Many hospitals and healthcare networks utilize organizations like the Medical Group Management Association (MGMA) or American Medical Group Association (AMGA) that have been consulting with physicians, physician networks, hospitals, and integrated health care systems and have a vast data bank for recommendations that can give up-to-date national or regional physician salaries. Realize that most of employed physician salaries are based on a percentile of these national salaries represented by these organizations. The information that is available from these organizations is an invaluable resource for the surgeons during deliberations of salary. As was pointed out in this chapter the RBRVS, this becomes even more important when considering the wRVU is the basic component for valuing the compensation package. The Medicare conversion factor (currently at $35.082) is what the network will be utilizing as the bases for the value of the wRVU. Surgeons should make sure that the network conversion factor is a percentage greater than the Medicare conversion factor. The following models utilize many of the tenants of what has been discussed.

TABLE 66-13. Critical points to consider during contract negotiations

Employment agreements (non-academic)
Term of agreement
Duties and services
Performance standards
Location of services
Managed care contracts
Total annual cash compensation
Medical malpractice insurance/tail coverage
Salary caps
Compensation per wRVU (the conversion factor for Medicare is $35.082/RVU)
Signing bonus
Guaranteed base + Bonus
Pure production
Covenant noncompete clauses
Share of quality/utilization bonuses
Moving expense reimbursement

Fee-For-Service Model: Based on the Work-RVU

The physician reimbursement models that are being utilized today such as the guaranteed salary or the work-RVU based salary are very common and can be lucrative. However, the long-term outlook is not good, primarily because as the healthcare dollar reimbursement shifts to value-based purchasing and value-based modifiers, more and more employers will have to "adjust" physician reimbursement

according to these modifiers (Appendices 1–3). These models may be good for some surgeons who are looking for "short-time" employment, such as those planning on retirement soon or others working in an interim capacity.

In addition, all of these examples tend to have time limits for the "initial" contract. In some cases, it may be yearly, although 3–5 years should be the absolute minimum time frame. There will be changes in the compensation package after the initial contract comes to an end, and some contracts will utilize similar methods as the original contract and some may move to a "production only" method based on the wRVU and a conversion factor.

However, there are several models of reimbursement that have been shown to be successful that combine a base salary with an incentive bonus that is based on quality metrics that constructs a total annual compensation package that is competitive and fluid enough to modify as the economics continue to change. The two models that appear to have sustainable physician compensation models are the Geisinger Physician Compensation Model and the Massachusetts General Physicians Organization's Quality Incentive Program.

Geisinger Health System Physician Compensation Model

Geisinger Health System (GHS) of Pennsylvania believes that compensation systems can drive improvement in the value of care, and linking professional pride with improved performance. GHS ties employed physician salaries to the care they deliver and to patient outcomes. Most of the reimbursement is under a fee-for-service model. However 20 % of the total physician compensation (TPC) is based on performance incentives that are defined annually for each type of clinician. This is a "Fluid Model" allowing for modification from year-to-year, if necessary. The GHS compensation plan appears to be fair and reasonable because the organization is increasing the number of employed physicians with a low turnover rate (Table 66-14). A fundamental goal of the Geisinger Compensation Plan (GCP) is to maintain a total compensation package with an 80 % base salary paid monthly and 20 % variable (incentive) compensation that is directly dependent on both the annual performance of the individual and the group. The variable payment is given twice each year, once in March (reflecting July through December performance) and another in September (reflecting January through June performance) [30].

Base Salary

GCP defines the base component (80 % delivered in monthly paychecks) of each physician's compensation according to factors that describe his/her expected work effort (Table 66-15). Physicians within their specialty area are placed in quadrants based in relation to the 60th percentile (above or below) for both parameters (FFS production and compensation). Geisinger senior management, Geisinger's board management, and a compensation committee review all outliers with discordant performance and compensation data. As an example, physicians whose work production is high, but compensation is low according to national benchmark (or vice versa) will be reviewed under this policy [31].

Performance Incentives for Specialist Physicians

Geisinger's strategic vision of improving quality and efficiency through innovation and integration of care uses the variable portion of compensation (20 % of total) to incorporate that strategy into the work of every clinician. Each physician in a GHP service line has incentive goals that are developed by the service line members. These incentive goals are consistent with the system wide strategic aims of the GHP (Table 66-16).

The quality metrics are 40 % of the total incentive pool and 8 % of the total compensation. The financial metric is 25 % of the incentive pool, based on recent productivity of wRVUs at the 60th percentile of specialty-specific benchmarks, and thereby constitutes 5 % of the total compensation. In this formula this means extremely high levels of productivity do not necessarily translate directly into higher income.

Rather, innovation, legacy, and growth account for 35 % of the incentive compensation and ~7 % of total compensation (Table 66-17).

Overall it appears that Geisinger's compensation plan is successful, at least according to metrics that are also beneficial to the management of a delivery system. This is consistent with Geisinger Health System's national reputation as an integrated system that delivers high-quality, cost-effective

TABLE 66-14. Geisinger Health System of Pennsylvania composition

- Nonprofit integrated delivery system
- Tertiary/Community hospitals
- Outpatient facilities
- Sixty community practices
- Geisinger health plan (Insurance Company): 290,000 members/37,000 providers
- Employed physicians: 220 primary care/654 specialty physicians

TABLE 66-15. Geisinger compensation plan: base salary

- Work effort: includes teaching, research, and administrative activities measured in wRVUs[a]
- Increase or decrease depending on the physicians working above or below the expected ranges
- Depends on the physicians experience/specialty market rates
- GHS goal is for physician to exceed the 60 percentile for their specialty area in both FFS work unit production and compensation.

[a]Work-RVU metric is based on the relative value based upon time, skill, training, and intensity of the service delivered

Table 66-16. Geisinger compensation plan: performance incentives for specialists

Variable portion of compensation of 20 % of incentive payment:
Five general areas
Quality (40 %): Defined for each specialty through discussion with specialty leaders and senior management (average 4–5 measures)
Innovation (10 %): Development (example Wound Care Center)
Legacy (10 %): Under Geisinger's educational and research mission
Growth (15 %): Increase in Geisinger's patient population
Financial (25 %): Directly reflects wRVU recognized under FFS

Table 66-17. Geisinger compensation plan

Compensation plan	Basis/metric	Incentive pool (%)	Total compensation (%)
Base salary	FFS wRVUs		80
Performance incentives specialists			
	Quality	40	8
	Financial (wRVUs)	25	5
	Innovation	10	
	Legacy	10	
	Growth	15	
	Innovation/Legacy/ Growth	25	7

health care that has not based its productivity in FFS medicine. It also shows that integrated systems can be successful when the majority of reimbursement is provided by the FFS—at least for now.

When a compensation plan is based on work-RVUs, there is still a competitive tension that exists between individual incentives and unit-based incentives. This is especially true when measured under targets that depend on teamwork and collaboration among colleagues. This is a model that can and is utilized under bundled payments, and has the ability to be modified as health payment reform continues [30].

Massachusetts General Physicians Organization's Incentive Program

The Massachusetts General Physicians Organization (MGPO) incentive program was started in 2008 and was at the time an alternative method for the advancement of patient safety [31]. The MGPO is designed as an internal quality incentive program (QIP) based on several important features that keep physician acceptance and support (Table 66-18).

The MGPO employs almost 98 % of the physicians of the medical staff of the Massachusetts General Hospital, while simultaneously being a part of Partners Community Healthcare Inc. (PCHI). Over the years the PCHI network has evolved from the 1990s capitated payment model to a Pay-For-Performance (PFP) model of compensation in 2001. With the PFP model there was originally an income "withhold" based on a portion of payments due for services paid to hospitals and physicians. It was eventually paid to providers depending on meeting performance measures related to quality of care and efficiency that were prospectively negotiated.

Table 66-18. Massachusetts General Physicians Organization incentive program

Quality metrics are developed by the institutional management team and by quality leaders of each specialty
Competency in managing performance date and developing measures
Clear communication accompanied by consistent and accessible reporting
A fair process for adjudication appeals to performance decisions
Leaderships' commitment to setting priorities

Table 66-19. MGPO quality incentive program metrics

Tier	Physicians (%)	Work-RVU	Time lag measures[a]	Incentive payment $ (annual basis)
One	73	750 or >	Every 6 months	5000.00
Two	19	250–749	Every 6 months	2500.00
Three	8	50–249	Every 6 months	1000.00

[a]Three quality measures are identified: two measures are chosen by program leaders and apply to all physicians. One measure is specialty specific chosen by each clinical department or division

These original approaches evolved into the current model, because the targets were initially set at an aggregate level, and differed by major commercial payers within the region. In addition, the model was focused only on primary care (Table 66-18).

Another problem was with the data that was being captured to determine compensation. It was not current, and needed extensive review and adjustment in order measure incentives. This resulted in a long lag in subsequent incentive payments with the PFP model of up to 24 months. This delay in receiving payments reduced physicians' engagement and overall reduced the impact of the PFP model [32]. This does show the need for these networks to evolve from one model to another as the economics change or with changes in physician satisfaction.

Today the network has over 1700 clinically active physicians who have qualified for the program (Table 66-19). This program costs $3.0–3.5 million for each 6-month period. It requires four full-time equivalent employees (staff members) whose positions add ~7 % to the program overall cost per 6 months. The funding is from an already existing administrative fee that is a percentage of the practice expenses, and it covers all central MGPO management functions [32].

The MGPO incentive program measures 130 quality measures: though only 15 apply to all physicians, so the majority of these measures are specialty specific. The initial results of the MGPOs were reviewed and the percentage of program performance quality measures met in the 6-month time lag was 62 % over the first 13 terms, with over 90 % of the incentive dollars paid out.

Overall, the MGPO-QIP was felt to be successful in many ways, especially when looking at the program's affect on the organization's capacity to measure quality and improve the

collection and maintenance of data over time. The QIP led departments to develop protocols for the maintenance and review of performance data and allowed for changes in improvement priorities. Other benefits of the MGPO-QIP program included allowing physicians to become more accustomed to performance measures. By aligning the MGPO physician compliance with the federal governments meaningful-use-criteria for health information technology, this brought $15.5 million in incentive payments to the organization in 2013 [32].

These compensation packages are early models that are showing different levels of success. Yet, it is important to realize that these models are evolving and maturing along with the alternative payment models.

Summary

Health Care Reform has been moving at an incredible speed over the past several years and the main target of reform is the Fee-for-Service method of physician reimbursement. Over the last 3 decades there have been multiple attempts to modify or control the Medicare PFS, although all have been unsuccessful in containing the cost of healthcare in America. The Patient Protection and Affordable Care Act of 2010 has mandated and funded the application of Alternative Payment Models into the current Health Care Delivery System. The current models of physician reimbursement that are currently in the marketplace will evolve into the primary methods of reimbursement for the delivery of healthcare in the near future. These payment models require clinical integration in order to be successful in delivering care at a low cost, high-quality, efficient manner. The end result is that the majority of surgeons will have to integrate into these clinical networks in order to continue to deliver care and to financially survive.

Appendix 1: Physician Compensation: Model 1 Guaranteed Salary

One-year contract	$20,000 signing bonus
Base salary	$280.000/26 payments/40-hour workweek
Additional on call per diem	$500–750/day

Appendix 2: Physician Compensation Model 2

Work-RVU Based Compensation

Utilizing a dollar conversion factor: that is defined as the numeric factor which physicians multiply wRVUs to calculate physician compensation

Year 1: $40.00/wRVU
Year 2–5: $47/wRVU
Bi-weekly draws—approximately: $7000.00 (Year 1)
Reconciliations of draw: quarterly, semiannually "True Up Date"

These updates can mean an augmentation for increased production or a "reduction" at the next update for not covering overhead.

Appendix 3: Physician Compensation Model 3

Work-RVU Compensation with a Base Salary (Guaranteed)

Five-year contract	$20,000 signing bonus (returned if terminate employment before 24 months)
Base salary years 1–2	$300,000 which is approximately 6500 wRVUs at $45/wRVU
Base salary years 3–5	$300,000 but is subject to adjustment (calculated for a set time period) in advance of the first day of the next employment year and is based on a wRVU, over a period of time the preceding years.

Incentive bonus years 1–3

Work-RVU	Incentive compensation/wRVU
6501–7500	$51
7501–9000	$53
9001–10,500	$55
10,501 or >	$57

Incentive bonus years 4–5	is based on wRVUs generated by physician in excess of tier one baseline, which is multiplied by a "conversion factor" per wRVU which will be adjusted/based on an independent variable
Salary cap	approximately $600,000

Ethical Issues in Colorectal Surgery

Jason D. Keune

Key Concepts

- Ethics is a formal way of examining what one should do.
- The four principles approach emerged from a common morality of health care.
- A moral dilemma occurs when the moral intuitions of individuals disagree.
- Informed consent is a process that is rooted in respect for patient autonomy.
- Surrogate decision-making is necessary should a patient become incompetent.
- Futility is a concept that is in evolution and should be based on a local definition.
- Disparities in outcomes from colorectal operations vary based on race.
- Financial conflicts of interest are a contemporary problem that has been addressed at the level of the federal government.

Introduction

Ethics, at its most fundamental level, is a way to answer the question, "what should we do?" Since surgeons are, first and foremost, doers in the world, it seems apropos that ethics should be a part of our study. Surgeons have a unique relationship with humankind, and ethics is a way of exploring this relationship deeply.

In this chapter, I will discuss what ethical problems in surgery are, and what a good, reasoned way to approach them might be. I will then discuss several twenty-first century issues in colorectal surgical ethics. This chapter should not be regarded as an exhaustive review, but rather a sampling of some of the most difficult problems faced by colorectal surgeons today.

The Ethical Dilemma

Surgical practice is similar to the practice of all medicine, in that it is conducted against a background of historical ethical problems that have achieved a relatively stable solution. We do not think twice now, for example, about obtaining informed consent prior to operating on a patient or enrolling him or her in a clinical trial. Part of our reasons for doing this may have to do with the legal framework that surrounds us, but should that legal framework be stripped away, informed consent intuitively seems a good thing that we ought to do. The individual *moral intuition* that we each have seems to march in lock step in this regard—rarely does anyone bring up an ethical dispute with getting good informed consent.

Occasionally, however, our moral intuitions disagree. What one surgeon views as "right," another views as "wrong." More commonly, the surgical team views one choice as right and the patient, or patient's family, views the choice as wrong. The story of Jahi McMath is a recent example of such a disagreement. McMath was a 12-year-old girl who suffered an irreversible anoxic brain injury while undergoing a tonsillectomy for obstructive sleep apnea at a hospital in northern California in 2013. While she was pronounced dead by brain-death criteria by her physicians, her family protested, claiming that she was not, in fact, dead. The family obtained a restraining order against the hospital and physicians and was successful in transferring her body out of the hospital. She remains on ventilator and nutritional support to this day [1].

New ethical dilemmas arise against the relatively stable background of an ethical surgical practice for several reasons. First, the contemporary practice of surgery is rooted in technological advancement. As new developments in technology arrive, there is a push to use them, especially in situations where a group of patients were in a position in which no good option was available until the new technology was

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_67

invented. Second, we live in an increasingly plural society. The cultural, ethnic, and religious differences between a patient and physician can have a shrinking effect on the common moral ground between the two. Without some compensating effect, that contracted common ground can lead to the formation of an ethical dilemma.

Ethical dilemmas occur due to the time pressures inherent in surgical care as well. Leak, sepsis, and trauma may all invariably arise after hours. Not surprisingly (and not uncommonly), ethical dilemmas will accompany them, occurring in the middle of the night when ethics consultants are not available. In the case of an unstable patient, death may be imminent and there may not be enough time for an ethics consultant to arrive. Adding to this, communication can also be problematic when time is short. In many other situations, the meeting time is longer, but not by much: developing trust quickly is necessary, and there is little time to reflect on ethical common ground. Furthermore, dilemmas can be intensified, in part due to the fact that surgeons cannot easily "undo" their work. For these reasons, surgeons should have familiarity with the moral reasoning that is necessary to resolve ethical dilemmas.

Ethical Reasoning

Learning approaches to ethical reasoning can be daunting. The *four principles* approach puts forth what are known as "mid-level" principles: respect for autonomy, justice, beneficence, and nonmaleficence. These principles are valuable when trying to resolve ethical dilemmas, as they are general enough to be applicable to a wide range of situations, are commonly valued, and do not require much background or training in formal moral thought. The principles, which emerged from a common morality of healthcare, are defended by ethicists Tom Beauchamp and James Childress [2]. Moreover, they form the backbone of most clinical medical ethics discussions.

The principle of **respect for autonomy** states that clinicians ought to allow patients to make decisions about their medical care that is both free of coercion and fully informed. Obtaining informed consent, which I will discuss later in this chapter, is a good exemplar of the principle of the respect for autonomy. Of specific importance in granting autonomy to patients are the qualities of *liberty* and *agency.* Liberty emphasizes that patients should be given the opportunity to decide whether to undergo surgery and just what surgery that should be. Agency is the quality of granting the patient the knowledge necessary to make the decision and exercising that liberty.

"First do no harm" is an aphorism that describes the principle of **nonmaleficence** well. The obligation not to harm may arise in colorectal surgery practice in weighing the risks and benefits of a procedure, in end-of-life situations, and in drawing distinctions between killing and letting die. Harming should not be thought of only in the active sense, but passively as well, such as in cases of negligence or errors of omission.

Beneficence should be central to every colorectal surgeon's practice, since not harming is not enough. Beneficence implores physicians to do positive acts that benefit others. It exists on the same spectrum as nonmaleficence, but is distinct. Beneficence can come in conflict with respect for autonomy when a surgeon, intent on doing good, feels as though she should override a patient's wishes. When an act arises from beneficence, but violates respect for autonomy, it is called "paternalistic." Occasionally, a surgeon may ask, "how much beneficence?" If an act "goes beyond the call of duty," it is known as *supererogatory*, and is rarely morally required of a surgeon. The degree of beneficence required of a surgeon is therefore measured.

Justice is concerned with inequality. Colorectal surgeons should be cognizant of the fact that there are disparities in treatment outcomes, both in the baseline health and in the ability that patients have to access surgical care. Justice is prominent in the political debate about twenty-first century healthcare, especially considering the distribution of scarce resources, such as organs for transplantation, and determination about what rights individuals have to basic health care.

In the remainder of the chapter, I will review several prominent ethical problems that face colorectal surgeons. This should not be considered a comprehensive analysis, but rather a survey of some of the most common issues that may be encountered. My preference is to provide an in-depth analysis of several topics, rather than glossing over all of the ethical issues that a colorectal surgeon might face.

Informed Consent

Informed consent is a process, initiated by the surgeon, which enables the respect for patient's autonomy to be observed when a procedure is being planned, or another decision point is reached. Informed consent is also important in research. The general gestalt for the surgeon about informed consent is to describe the procedure in detail as well as the inherent risks, benefits, and alternatives. Tom Beauchamps and James Childress, in their classic text, *The Principles of Biomedical Ethics*, have done a more careful analysis of informed consent that can be useful for clinicians. Specifically, they have outlined seven elements in three categories for drafting an informed consent [2]:

Threshold Elements (Preconditions)

- Competence (to understand and decide)
- Voluntariness (in deciding)

Transformation Elements

- Disclosure (of material information)
- Recommendation (of a plan)
- Understanding (of 3 and 4)

Consent Elements

- Decision (in favor of a plan)
- Authorization (of the chosen plan)

The process of informed consent can be thought of as being comprised of elements that are categorized according to their role. The threshold elements, which are essentially preconditions to informed consent, include *competence* and *voluntariness*. The notion of competence rests on an evaluation about whether the patient has the cognitive abilities to both understand information about the procedure and to consider the consequences of the choice to undergo the procedure. Surgeons often encounter patients who are not competent—in this case a surrogate decision maker should be sought. The case of the marginally competent patient can be very complex. Surgeons may benefit from ethics consultation in cases such as these, as there are no straight-forward rules, and individual decisions regarding competency may widely vary. Voluntariness is the threshold element that is concerned with freedom from coercion. Patients should be able to make decisions about their care that is free from outside coercive influence.

The transformation elements include disclosure of material information, recommendation of a plan, and a confirmation of patient understanding. The disclosure of information can be considered central to attaining proper informed consent, and it is notable that a high-quality informed consent rests heavily on a high-quality disclosure. Beauchamps and Childress also address what composes a high-quality information disclosure [2]. I paraphrase this below:

- The facts that patients or subjects usually consider material in making decisions about whether to consent to the procedure
- Information the surgeon feels is material
- The recommendation of the surgeon
- The purpose of seeking consent
- The nature and limits of informed consent.

No informed consent process would be complete without the recommendation of a plan, as patients tend to see surgeons not only for their technical expertise, but also for a reasoned opinion about what the best treatment strategy should be. Patients should also be asked if they have questions, and the surgeon should ensure that the patient has a reasonable understanding of the proposed procedure.

The consent elements comprise the active portion of the process. A decision needs to be made in favor of or in opposition to a plan. Ensuring again that the decision is indeed free of coercion at this point is encouraged. For the informed consent procedure to be complete, however, the patient must signify, usually by signing a document, his or her authorization that the procedure may be carried out.

Surrogate Decision-Making

Many of the ethical dilemmas that arise for surgeons occur near the end of a patient's life. One such problem arises when a patient, previously competent about his or her own care, becomes incompetent. When such a situation arises, it is necessary to make decisions about care without the patient's direct input, but still maximize the ability to respect the patient's autonomy. Someone other than the patient must now be sought to make decisions for the patient. Two main questions should be asked:

1. Who should make decisions for the patient?
2. How should the surrogate decision maker best decide?

Advanced directives are instructions that are provided by patients that give direction to caretakers about how decisions should be made if the patient were to become incompetent. As this is not an infrequent situation, surgeons should have a thorough understanding of determining competence, as well as encourage their patients to have advanced directives and the process of surrogate decision-making when this is not available.

The two common ways that patients can provide direction to caretakers (should they become impaired) are (a) creation of living wills, and (b) the appointment of a durable power of attorney. A living will is a document prepared by a patient while competent that details the patient's preferences should they become incapacitated. It has been demonstrated that patients' preferences show stability over time [3]. Living wills can take a spectrum of forms, from being simple documents that specify only a few things that a patient would or would not want, to complex documents that specify what to do under a plethora of circumstances. Patients can also promote a set of wishes to die a natural death and not be kept alive by heroic measures or to promote the fact that the patient wants everything possible to be done to keep him or her alive.

Another way to have one's preferences recognized after one becomes incompetent is to appoint a durable power of attorney for healthcare. The durable power of attorney is a person who is appointed in advance by the patient to act as a surrogate decision maker. The power of attorney is "durable" because the power lasts beyond the point at which the patient becomes incompetent.

Unfortunately, not every patient has a living will, or a durable power of attorney. When this is the case, it is necessary to find a surrogate decision maker. Laws differ from state to state about how this plays out, but there is typically a hierarchical list: spouse, adult children, siblings, and down the line. If no family member can be found, most states allow for a court-appointed conservator. In situations where a conservator cannot be found, most states will then allow the healthcare institution to make decisions.

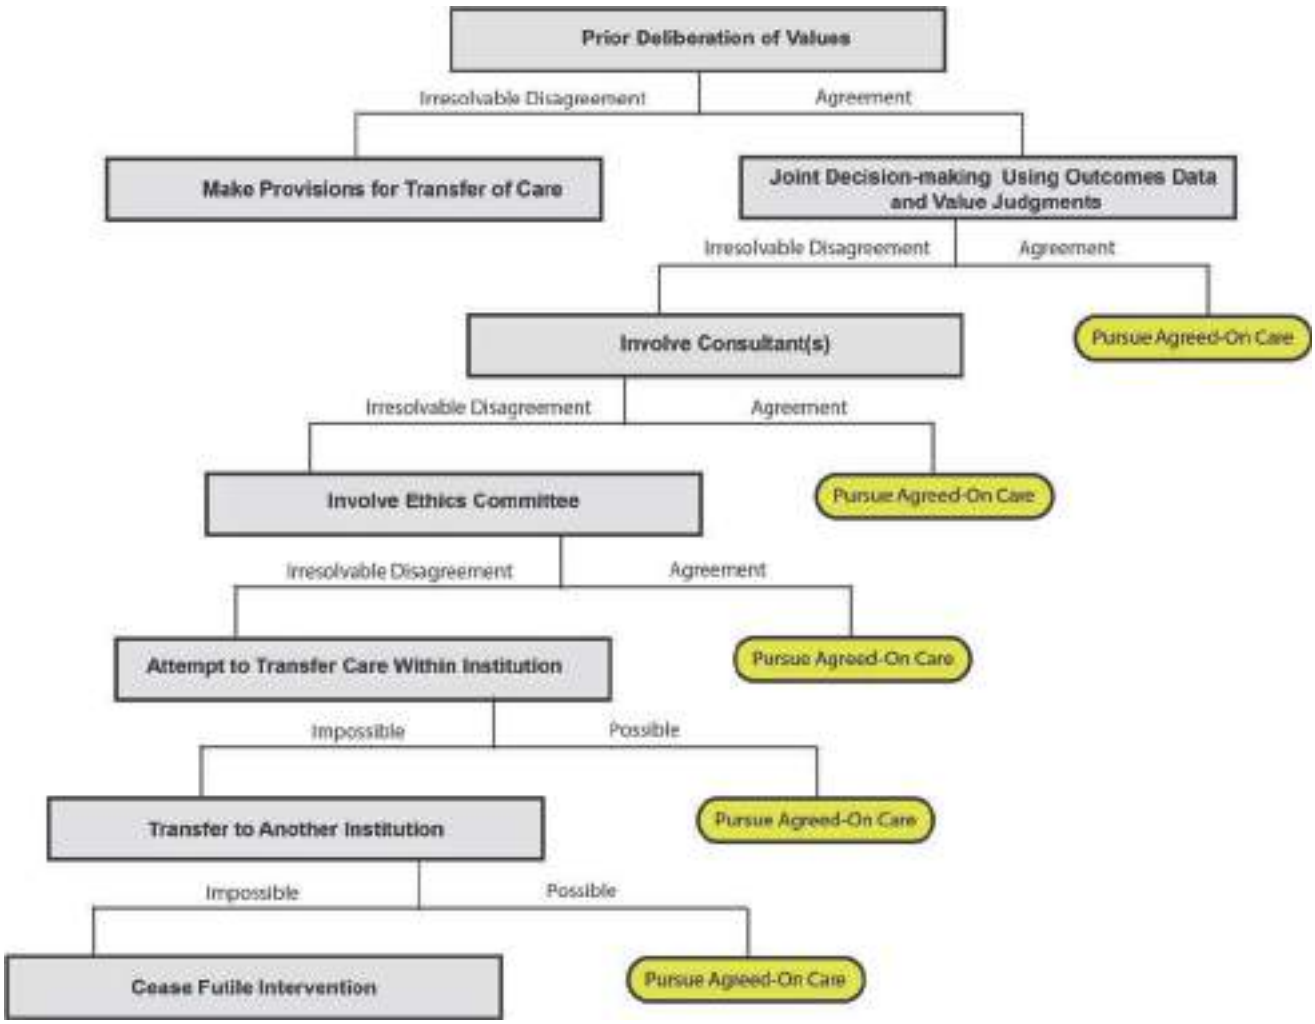

FIGURE 67-1. Fair process for considering futility cases. *Modified from Plows CW, et al. Medical futility in end-of-life care - report of the Council on Ethical and Judicial Affairs. JAMA. 1999;281:937–941* [5].

Simply designating a person is not enough, however, as the problem of how a decision maker ought to decide remains. The two most common standards involve: (1) the standard of substituted judgment, and (2) the best interest standard. In applying the standard of substituted judgment, the decision maker bases the decision on what he or she thinks the patient would want. This standard attempts to maintain respect for patient autonomy. In the best interest standard, which is rooted in beneficence, the decision maker makes choices based on what he or she thinks is best for the patient. This standard is best used when decision makers are not confident that they know what the patient would have wanted.

Futility

Colorectal surgeons are in the business of offering interventions to improve the health of patients. The problem of futility arises when the proposed treatment has such a small chance of being efficacious that the surgeon probably ought not perform it. The range of what is considered "futile" care tends to focus on lack of efficaciousness, lack of therapeutic "success," or care that is burdensome enough to outweigh any therapeutic benefit of the intervention. The concept of futility becomes especially important when one is discussing end-of-life care. Overall, there is a lack of a strict definition of futility that stems from a disagreement about what death is. Since some surgeons and families may have different views about death, the meaning of life-sustaining treatment may also differ.

Attempts to deal with the problem of futility have taken several forms over recent history. Initially, futility was defined in terms of specific *clinical* criteria, either by comparing one group to like patients in whom similar treatments have been useless or with the use of physiological goals. Yet, it was difficult to find consensus on such approaches because goal setting can be arbitrary and the definition of "useless" is by no means clear [4]. In response to the failure of such approaches, the American Medical Association Council on Ethical and Judicial Affairs recommended that a process-based approach to futility determinations should be taken [5] (Figure 67-1). This approach does not require a definition of

futility, but instead describes a process by which definitions might be agreed upon locally. The approach also does put a large amount of decisional power into the hands of ethics committees, which are often dominated by clinicians, and are of variable quality from organization to organization. Regrettably, the problem of futility is still relatively unsettled in the twenty-first century.

Refusal of Care

With sound mind and proper understanding, refusal of care is a patient's right. Yet, while the refusal may be "justified," this often leads to a dilemma when a treatment recommended by a surgeon is refused by a patient or their family. Especially if the treatment is considered standard of care, this can cause dissonance between surgeons and patients, as well as has the potential to alter outcomes. The refusal of blood products by Jehovah's Witnesses is one of the most common refusal scenarios encountered. On one hand, transfusion may be lifesaving in perioperative setting complicated by large volume blood loss. On the other hand, Jehovah's Witness patients that accept blood products are at risk of being shunned by his community. A policy put in place in 1945 by the Watchtower Society, the guiding organization of the church of Jehovah's Witnesses, required the "disfellowshipping" or expelling of members who willingly accept blood products. In 2000, though, the Watchtower Society changed the policy so that patients would not be "disfellowshipped" should they not comply with blood product refusal [6]. Though not official, the stigma on accepting blood products for this group seems to persist into the present era.

The respect for patient autonomy is prominent amongst the ethical principles in today's surgical practice. The strict observation of patient autonomy breaks down, though, when patients consent to a recommended procedure, but refuse to have certain elements of the care necessary to perform such procedures. Most surgeons standardize their practice in hopes of producing consistent surgical outcomes. Without being able to practice in the standardized way, however, surgeons are at risk of entering unfamiliar clinical territory. Most studies about death after low anterior resection, for example, assume that blood transfusion was available to the surgeons who performed the procedures. Calculating risks of doing such surgery without blood transfusion is therefore difficult.

It is necessary in such a situation to ensure that the patient who is refusing care or elements of care has full decisional capacity and is not being coerced. It should be pointed out that the ethics change as well when the patient is a minor and the patient's parents try to block certain aspects of care. Unless the decision is made in an emergency setting, parental consent is needed to perform a procedure on a child. The most common scenario for court intervention in such cases is when parents try to block the transfusion of blood products. The groundwork of a parent's right to make medical decisions can be found in a 1944 US Supreme Court case, in which the court ruled, "Parents may be free to become martyrs themselves. But it does not follow they are free, in identical circumstances to make martyrs of their children before they have reached the age of full and legal discretion when they can make that choice for themselves" [7].

Outcome Disparities in Colorectal Surgery

As John Rawls has put it, justice "is the first virtue of social institutions, as truth is of systems of thought." After reflection, one might recognize surgery to be as much of a social institution as it is a scientific one. One of the four "principles" of Beauchamps and Childress, justice can be thought of at its most fundamental roots as the ability "to be fair." Yet, when it comes to results following surgery, it follows that there is no moral justification for the outcome disparities that fall along racial lines. The statement by the American College of Surgeons that, "ethnic and racial health care disparities have no role in a humane and just society, and are ethically and morally antithetical to the practice of medicine and surgery," [8] highlights the problem, and makes it more mainstream. In addition, recent breakthroughs and public availability of large data management (e.g., SEER, NIS, NSQIP) have led to databases rich with racial and socioeconomic demographics, making comparisons between groups an obvious choice for study. Unfortunately, in many cases, no matter the question, distinct differences are detected along racial and socioeconomic lines.

In one example, Nestor Esnaola and colleagues identified 35,695 patients with non-metastatic rectal adenocarcinoma between 2003 and 2005 using the National Cancer Data Base [9]. They found that African American and Hispanic patients were more likely to present with advanced disease compared with white patients. They also found that only 85.1 % of tumors in African Americans were resected, compared with 90.7 % of whites, with a striking adjusted odds ratio of 0.62 (95 % confidence interval 0.54–0.71). The same group from the Medical University of South Carolina, when looking at the South Carolina Central Cancer Registry, noted the underuse of surgery for the black population [10].

Researchers at Mt. Sinai recently examined their own cohort of patients undergoing treatment for colon cancer, focusing specifically on racial and socioeconomic disparities as the complexity of the surgical options increases [11]. They found that patients undergoing the heated intraperitoneal chemotherapy for colorectal cancer (HIPEC) procedure were predominantly white, English speaking, privately insured, and had a higher mean income when compared to patients undergoing colectomy alone.

Another group from the Harvard Radiation Oncology Program analyzed over 1,000,000 patients in the SEER database who had diagnoses of lung, breast, prostate, or colorectal cancer. They found that the survival gap between black

and white patients (hazards ratio, 1.28; 95 % confidence interval 1.26–1.30 [$P<0.001$]) did not change over the period between 1988 and 2007. Interestingly, outcomes persisted independent of stage of disease and treatment, suggesting that efforts to improve screening and increase access to all parties may not solve the problem entirely [12].

Schootman and colleagues also recently examined colorectal cancer data from the SEER database from 1992 to 2005. They found that African Americans in high poverty neighborhoods had increased odds of an emergency diagnosis (AOR: 1.50, 95 % CI: 1.38–1.63). This may be a contributing factor to overall disparities that are seen in colorectal cancer outcomes by race [13].

Creatively designed research by Julie Freischlag and colleagues at the Johns Hopkins University tried to look for reasons behind these differences in outcomes that extended beyond the clinical realm. Their work revolved around the concept of the "unconscious biases" of medical students entering the Johns Hopkins School of Medicine. Using web-based clinical vignettes and the implicit association test to detect bias, they found that 69 % had implicit biases towards the white race and 89 % towards persons of the upper class [14]. These biases did not, however, impact the vignette-based clinical assessments, suggesting that the students did not allow this inherent bias to influence their clinical decision-making. A similar study was performed by the same group on 214 physicians at various stages in a surgical career. As with the previous report, bias was found, but clinical decision-making was not impacted [15].

The problem of disparities in surgical outcomes seems to be related to the problem of racial diversity in the surgical workforce. Diversity is a descriptive characteristic of a group of people that exhibit differences in their demographic makeup, cultural identities or ethnicity, training, and expertise [16]. Lee Bollinger, president of Columbia University, writing for a medical audience has remarked that developing an educational setting that is rich in diversity is the most important way to prepare students to work in a diverse society. Simply learning about ethnic and sociocultural diversity is not enough—students should be immersed in a learning environment that is rich with diversity itself [17]. There is a parallel here for surgeons: the more rich our diversity, the more prepared we will be to encounter a diverse patient population.

Unlike patient demographics, the demographics of surgeons working in the USA are poorly understood. The racial breakdown of the overall physician workforce is known, however, and it may be appropriately hypothesized that surgery parallels it. In 2008, Blacks, Hispanics, and Native American populations comprised 12.8 %, 15.4 %, and 1 % of the USA's population, respectively [18], but comprised only a mere 3.5 %, 4.8 %, and 0.1 % of the physician workforce [19]. Interestingly, while the American College of Surgeons does support a "Committee on Diversity Issues" [20], it does not collect racial demographics on its members. The American Board of Surgery likewise does not collect such demographics. How this data would ultimately affect future changes can only be speculated, yet could provide a baseline from which to launch future initiatives.

The vast amount of data that has been published to date regarding outcomes of surgery stratified by race and ethnography is due, in part, to the rich availability of demographic data that is available to researchers. It serves as a testament to the fact that surgeons care about this problem and want to focus on it. The situation will not change until researchers change their approach from observational studies to interventional ones, a change that will not happen until such studies are funded. One place to start would be the work of Lu Hong and Scott Page. They have shown in a modeling environment that a diverse group of intelligent agents will solve problems better than a group comprised of selected top performing intelligent agents [16]. It is time that such research is brought from "bench to bedside."

Physician Financial Conflicts of Interest

A conflict of interest exists in a state in which there is a dynamic interaction between two differing interests in the same person, such that one interest directly or indirectly impacts that person's ability to realize and possibly execute a pure motive in the other. As federal funding for research in colorectal surgery diminished through the 1990s, the need to fund research with funds from industry became much more prominent. Colorectal surgeons, too, have great decisional power with regard to resource use in their sphere, and therefore are often the targets of marking efforts by drug and device representatives. "Colorectal surgeon" was the most common profession amongst disclosures made from 2006 to 2009 given by presenters at the annual Clinical Congress of the American College of Surgeons [21].

The conflict of interest problem in the surgical profession comes about especially when one of the two interests is financial and the other is the well-being of the patient. The concern is that physicians will be unable to manage these potentially competing interests, leading to a diminished outcome for the patient. The high road of this dispute is to claim that surgeons ought not have any relationships that interfere with their interactions with patients, especially not ones of financial import. In reality, it would be hard to recognize an American healthcare system that was devoid of the for-profit pharmaceutical and device manufacturing companies that populate it. Though it is clear that surgeons should not let financial concerns impact decisions at the bedside, it is not clear that there should be a complete break in the relationship between surgeons and industry at the research and development level. In fact, this relationship can be beneficial. Safe and effective surgical innovation will not work without active surgeon input at every stage. This requires surgeons to interact with for-profit corporations, for the means of production of devices in the USA is in the private sector.

How to handle these potential conflicts is the major crux. At present, the management of financial conflicts of interest in the twenty-first century relies on the words of Justice Louis Brandies, who declared at the beginning of the twentieth century that "Sunlight is said to be the best of disinfectants" [22]. The Affordable Care Act, which became law in 2010, includes a section called the "Physician Payment Sunshine Provision," [23] which requires drug, biologics, and medical device companies to report all payments and transfers of value to physicians and teaching hospitals in excess of $10 per instance to the federal government. The payments are publically disclosed.

David Rothman hypothesizes that the result of such "Sunshine" will create a two-track career pathway for all physicians. One track is a "professional" one that is able to remain free from industry money to "simplify their clinical and organizational lives and allow their participation in various activities," while the other is an "entrepreneurial track for those who take pride in the size of their royalties" [24]. Such a black and white view may not be entirely appropriate for surgeons who want to participate in the evaluation and evolution of surgical devices. Working with industry also does not equate to an inability to make sound and non-bias judgments regarding patient care. Rothman's final statement of the commentary is spot on when he states, "It is too soon to chart the outcomes, but it would be surprising if physicians did not behave differently when watched." Only time will tell.

Conclusion

For those that have the power to make such significant change in the world, a study of what is right to do seems like a given. Ethics should be a part of every surgeon's training and ethical reasoning should be in every surgeon's toolkit, especially since surgeons are "doers." One never knows when an ethical dilemma will arise that will demand ethical reasoning. Who better than the surgeon to guide the resolution of the dilemma in a thoughtful reasoned manner.

Welcome to Litigation

Dennis K. Ames

Key Concepts

- In litigation, preparation is the key to a successful outcome.
- Preparation should begin as soon as you become aware of an adverse outcome likely to lead to litigation.
- Don't conduct an independent investigation.
- Never appear at a deposition without consulting an attorney.
- Meet with your attorney early.
- Communicate with your attorney regularly.
- Know what you can expect of your attorney, and when.
- Know what is expected of you, and when.
- Do your homework; and make yourself available.

The unfortunate reality for today's physician is that he or she will almost certainly be sued for medical malpractice in his or her career. According to data published in the *New England Journal of Medicine* in 2011, general surgeons (the publication does not include a cohort for colon and rectal surgeons) face a 15.3 % annual probability of facing a medical malpractice claim. Along with other "high risk" specialties, 80 % of general surgeons are projected to face a claim by the age of 45 years, and, by age 65, fully 99 % of those physicians in "high-risk" specialties such as general surgery are projected to face a claim [1].

The pertinent question for today's surgeon is not "What should I do *if* I get sued?"; rather, it is now, "What should I do *when* I get sued?"

If there is comfort to be taken in this data, it is that while physicians, depending on specialty, face a 5–20% probability of facing a malpractice claim in a given year, the probability of any such claim leading to an indemnity payment is substantially lower.

Portions of this chapter include material from Judicial Council of California Civil Jury Instructions (CACI), Nos. 200, 208, 219, 221, 501, 505, and 506. Permission to reprint CACI instructions in this publication has been expressly granted by the Judicial Council of California.

This chapter is designed to guide the physician-defendant toward achieving the ***best result*** the facts of the case allow. *Best result* is not measured only in the sense of winning or losing the case. As importantly, *best result* implies minimizing the human toll the process exacts on the physician-defendant, by reducing anxiety and frustration [2].

Anxiety is reduced by education and managing expectations. This chapter is organized to provide a general outline of each of the stages of the litigation process. It will describe each stage of the process, and define the role of the attorney and of the physician-defendant at each stage.

Frustration is reduced with preparation and being proactive in your defense. As a physician facing a malpractice claim, you have the right to expect your attorney to be well prepared at each stage of the litigation. As the physician-defendant you, too, have a significant role in the preparation of your own defense. To be prepared, you must know what to expect during the course of the litigation. You must understand the litigation process. You must understand what you have the right to expect from your attorney; and finally, you must understand what your attorney has the right to expect of you.

In an effort to minimize frustration, **TEACHING POINTS** are provided. These **TEACHING POINTS** include a list of things which the physician-defendant can do proactively at each stage of the litigation to assure himself or herself that everything which can be done in his or her defense is being done, and that his or her defense is not unwittingly being compromised.

Preparation: The Key to Success

The probability of a successful defense to any claim rests first on the underlying medical facts. Though relatively rare, true, "indefensible" surgical misadventures occur. Wrong-site surgery is one, for example. In such cases, the relevant medical facts may not be in dispute. If a claim arises from

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_68

the occurrence of a true surgical misadventure, it may be prudent to posture the matter toward settlement from the outset. But even in these situations, understanding the entirety of the process, and advance preparation for it, remain critical.

Even if the case involves an admitted surgical error, it remains important for the physician and the lawyer to be cognizant that the litigation process for the physician likely will not end with settlement of the claim with the patient—there is still the matter of a possible future investigation of the case by the state medical board. In such a case, the physician might appropriately ask whether or not the *best result*, when consideration is given for potential medical board investigation, wouldn't be a settlement before a formal complaint is filed, or, if the complaint is already filed, before the surgeon or hospital staff is deposed. Preparation in this setting would include an early consultation with counsel to discuss the ramifications to you personally and professionally of an early settlement versus proceeding to protracted litigation.

In the great majority of cases, however, the facts are disputed. The dispute may or may not involve what happened in surgery. The disputed facts may include the indications for surgery; the consent discussion; pre-operative knowledge of the patient's relevant medical history, laboratory values, medications, or other contra-indications; the substance of discussions with other medical providers, referring physicians, nurses, or radiologists; the existence of alternative therapies or surgical approaches; or the patient's post-operative course.

The reality of litigation is that the "facts" of a case are what the jury says the facts are on its verdict form. Until that moment, there are no facts, there is only evidence of facts. In coming to its verdict, the jury determines the facts after balancing the evidence presented at trial, giving weight to the evidence on either side of an issue as the members of the jury, individually and in their cumulative wisdom, see fit. Experience establishes that evidence which either side believes to be clearly decisive on an issue, nevertheless, may be marginalized or discarded in whole or in part by the jurors.

Effective litigation requires effective accumulation of evidence and effective presentation of that evidence. Effective accumulation and presentation of evidence requires thorough and focused preparation. That process begins at the initial meeting between the lawyer and the physician-defendant, if not sooner, and continues through the conclusion of the litigation process.

There are certainly many aspects of the process over which the physician-defendant may have little or no control, but it remains incumbent for the physician to recognize those aspects of his or her defense that he or she can affect, and to do whatever is necessary to achieve the *best result*.

Stages of the Litigation Process

The litigation process can be divided into three stages:

1. Initiation of the litigation process
   (a) Notice of an occurrence likely to lead to litigation;
   (b) Notice of events which suggests that litigation is imminent: Handling requests for medical records;
   (c) Service of the summons and complaint: Initial meeting with counsel;
2. The discovery process
   (a) Written Discovery;
   (b) Your deposition;
3. Trial

Initiation of the Litigation Process

Notice of an Occurrence Likely to Lead to Litigation

The litigation process may commence in a number of ways. First among them is the unexpected occurrence of something adverse to your patient.

Something happens during surgery or in the post-operative period which you believe may lead to a lawsuit. For example, at surgery, an adjacent organ or vessel is punctured; there is profound blood loss or spillage of bowel contents resulting in significant compromise; or there is even an unexpected patient death. In the immediate post-operative period, or even after discharge, the patient becomes septic and decompensates. Imaging demonstrates a previously unappreciated rent in the bowel. The patient is taken back to surgery at which time the rent is identified and repaired, but the patient has a rocky course. Or, several months or even years after bowel resection surgery you notice, for the first time, that the pathology report had identified a potentially malignant lesion for which no additional investigation was conducted.

In these instances the litigation process may be said to be initiated by you, in anticipation of litigation. When these adverse events occur, the important thing for you to recognize is that there are pre-existing protocols and procedures in place for you to access which have been established for just such events. The purposes of those protocols and procedures are twofold: (1) to accumulate and preserve the necessary evidence about the event in a timely manner, and, (2) as appropriate, to protect the evidence from undue disclosure to the opposition by veiling it within the cloak of one or more legal privileges.

Know the reporting procedures for significant clinical events of your hospital, your medical staff, your risk management department, and your malpractice insurance company. These will typically include voluntary or mandatory incident

reporting which are in place for purposes of quality assurance or for reporting of events which will likely lead to litigation.

Although evidentiary rules vary among state and federal jurisdictions, as a general proposition, when a hospital, medical staff, or even an insurance company has in place a pre-existing procedure for reporting such events for quality assurance purposes, any statement or disclosure made in furtherance of that purpose of quality assurance is privileged from disclosure as a matter of public policy [3]. Likewise, statements made to a risk management department or to an insurance company representative in anticipation of litigation are typically protected from disclosure by the attorney work-product privilege (which is different from the attorney-client privilege).

Whether either of these "pre-litigation" privileges will apply to a physician's disclosure depends on *why* the disclosure is being made. For example, the quality assurance privilege belongs to the hospital or its medical staff. The hospital or medical staff is deemed the "holder" of the privilege. It is the hospital and medical staff's obligation to conduct periodic and incident reviews of its staff's conduct and to investigate significant or "sentinel" events. To fulfill those duties, the hospital and its medical staff have procedures in place for these events to be reported. The goal of these procedures and the attendant privileges is to promote candid disclosure and discussion, which may be adversely affected if the participants are fearful that any statement made can or will be used against them later in litigation—thus the privilege. Therefore, *if the reason* the physician discusses or reports an event is pursuant to pre-existing hospital protocol to ensure that an adequate investigation of the event occurs, the physician's disclosure is deemed to be in furtherance of the quality assurance process; and, generally, that disclosure will be protected from later discovery. Application of the privilege depends on the physician's mindset when the statement is made.

Teaching Points

1. By knowing the hospital's or medical staff's quality assurance and reporting procedures a physician can tailor his disclosures, and, later, his deposition testimony to be consistent with those procedures. At deposition,

   Q. "Did you discuss what happened in surgery with anyone?"
   A. "Yes."
   Q. "With whom?"
   A. "I told the operating room supervisor and the chairman of the department."
   Q. "Why them?"
   A. "Because I understood that the hospital quality assurance department requires that these kinds of events be reported and investigated."
   Q. "What did you tell them?"

   By defense attorney:
   "Objection, quality assurance or peer review privilege."

Unless the physician understands that such procedures exist, and knows the reporting requirements of those procedures, the physician may not be prepared to provide the necessary foundation to invoke the privilege. The foundational question to establish the privilege is: "Why did you make the disclosure?" The foundation for the quality assurance privilege is established if the disclosure was made in furtherance of an existing and known hospital or medical staff policy.

Similarly, in anticipation of litigation, malpractice insurance organizations and risk management departments have procedures in place for the physician to report adverse occurrences so that an investigation into the matter can occur while memories are fresh and potential witnesses and other evidence is available. The purpose of these pre-litigation procedures is to accumulate reliable evidence which, if litigation does ensue, can then be produced to the assigned counsel to promote the physician's defense. The rationale of these pre-litigation reporting procedures is that it is anticipated that the physician's attorney will need, and therefore will request from his physician client, a *summary of the occurrence*. This request for a summary of the occurrence will be better served if the summary is prepared soon after the event. Memories fade. Reports made to the insurance company early, without waiting for a formal claim to be made, may be more reliable. Thus, insurance companies have established early reporting procedures in anticipation of the attorney's needs. It is recognized at law that the insurance company collects these pre-litigation reports in furtherance of the physician's defense as an ostensible agent for, and on behalf of, the attorney—even though the attorney has not yet been retained.

Because the pre-litigation reports are presumably being collected on behalf of the attorney, the collection of these reports by the insurance company is deemed to be the "work product" of the attorney. Although there are exceptions, generally, these reports are protected from disclosure by the attorney work-product privilege, much like disclosures made by the physician directly to the attorney are protected by the attorney-client privilege.

Summaries prepared by the physician on his own, outside of the medical chart, may be protected if, but only if, the summaries are being made in anticipation of a request from the malpractice insurance company, or in anticipation of a request directly from the attorney, and are kept confidential.

Teaching Points

1. To avoid question as to why you are preparing a summary of the events outside the medical chart, and thus to bolster your position that the summary is protected by the attorney work-product and attorney-client privileges, begin the summary with, "The following summary is being prepared in anticipation of litigation, to be provided to

my attorney when litigation commences." Ask your malpractice insurance company if it has forms for you to use for such a purpose.

Caveat

1. Privileges can be waived. Summaries prepared in anticipation of later disclosure to the attorney can only be protected if they are kept confidential. Disclosure of the summary to others who are not in the line of communication with the insurance company or attorney likely will waive the privilege. For example, placing the summary in the patient's hospital or office chart, where it is open to review by hospital or office staff, defeats the presumption of confidentiality. The summaries must be kept separate and apart from the chart and may not be disclosed to others.

Teaching Points

1. By knowing the malpractice insurance company's procedures for collecting statements from its physician insureds, the physician can anticipate that request, and prepare a summary in a timely manner. By knowing that the statement must be kept confidential, the physician can take appropriate steps to assure that the statement is not disclosed to others or placed in the patient's chart. At deposition,

   Q. "Did you prepare a summary of the events?"
   A. "Yes."
   Q. "When?"
   A. "The day after the surgery."
   Q. "Where is the summary?"
   A. "I gave it to my insurance company."
   Q. "Did you keep a copy?"
   A. "Yes."
   Q. "Have you shown it to anyone else?"
   A. "Yes."
   Q. "To whom?"
   A. "To my attorney."
   Q. "Have you shown it to anyone else?"
   A. "No."
   Q. "Where is your copy?"
   A. "It is in a locked drawer in my desk."
   Q. "Why did you prepare the summary?"
   A. "I was told by my insurance company that when unexpected adverse results occur I should prepare a summary of the events and maintain it confidentially for later use by my attorney."
   Q. "Show me a copy of the summary."

   By defense attorney:
   "Objection, attorney work-product and attorney-client privilege."

   The work-product privilege may also apply to discussions among the physicians in a group practice, if the statements are made in furtherance of an established (and preferably written) pre-existing policy of the group which provides that such events are to be reported to the president or general partner of the group, so that they can then be reported to the malpractice insurance company or the group's attorney.

Notice of Events Which Suggest That Litigation Is Imminent: Handling Requests for Medical Records

You may be placed on notice of ensuing litigation for the first time by the patient or her attorney requesting a copy of her medical records from you (as opposed to asking that a copy of the records be provided to another physician for future care), or by the patient asking that a copy of her records be sent to an attorney. These requests must be handled carefully and consistently. The response to the request should include everything that is being requested. If requested, this must include the entire record. Once litigation ensues, you will be asked again to produce your records. The record produced then will no doubt be compared to the record produced to the patient when first requested. Any difference will need to be explained. Additions or deletions to the record which are found in the later production can be devastating to your case.

The law allows the patient to obtain a copy of his medical record from his physician. This may seem to be a simple task; yet, the prevalence of electronic medical records (EMR) has made this task anything but simple. To respond to a request to produce the office patient chart from an EMR, the medical record is "created" by someone sitting at a terminal and choosing which screens to print. That person decides what is, or is not, part of the record. The terminal operator will decide whether to include clinical notes, referral, demographic, or insurance information; and, data imported from outside sources (e.g., operative reports or consult notes from referring physicians or hospital consultants). The terminal operator will decide whether to include billing information or scheduling information.

The operator will also decide whether or not to include metadata. Metadata, or "data about data," exists in the EMR at several levels. The clinical record reflects the substance of the medical record entry—a history taken or examination findings. The metadata will include an entry log for that data, including when it was entered and by whom. At another level the metadata may include a "comments" section for the entry. Consistent production of records requires a consistent definition of what is part of the patient's "medical record," as opposed to what is merely part of the office "administration" record. The production request and/or the laws of your jurisdiction will define the scope of the request and, therefore, will define the scope of the physician's obligation to search for, create, and produce the "medical record."

In the context of litigation, a party or his custodian of records will be asked to verify under penalty of perjury that the records produced in response to the request are a true and complete copy of the entire record as requested. That verification serves the formal evidentiary purpose of certifying that this is the complete record and that it may be used as such by any party to the litigation from that point forward, up to and including at trial. You or your staff may be questioned about the production or about any perceived inconsistencies or inadequacies of the production in deposition or trial. To be an effective witness, you and your staff must be able to rely on the production. Effective preparation to be an effective witness on this issue requires that consistent procedures be in place and followed.

It is also important that there be a process in place by which the physician is notified that a patient has requested her own records, or has requested that a copy of the records be provided to an attorney. In that case the physician should acquaint himself or herself with the patient to determine, at least preliminarily, whether this patient suffered an unexpected complication that could reasonably lead to litigation. If there is concern about litigation, it is prudent for the physician to contact his insurance company or attorney and ask for direction.

Teaching Points

1. Have a formal, written procedure in place which defines the scope of your medical record for purposes of responding consistently to medical records requests on a day-to-day basis. Speak with your attorney to learn exactly what you are obliged to produce in response before you respond to a medical records request made in the context of active or anticipated litigation.
2. Systematically check to confirm that your policy is being followed consistently.
3. Be sure that whoever verifies the response knows the office practices for "creating" the medical record, and can appropriately verify that the procedures have been followed.

Service of the Summons and Complaint: Initial Meeting with Counsel

The formal civil litigation process starts when the patient files a complaint, has a summons issued, and personally serves the summons and complaint on the physician, giving the physician notice that he has been sued. The procedural requirements relating to how specific the allegations of the complaint must be vary widely depending on the state or federal jurisdiction in which it is filed. Local rules may require that the complaint be specific and detailed, and that it be verified (sworn to under penalty of perjury). More often the procedural rules only require that the complaint be specific enough that it identify who the plaintiff is; who the defendants are; the relationship among the plaintiff and defendants that creates the duty or obligations among them out of which the claim arises; the manner in which the duty was breached or the obligations unsatisfied by the defendant(s); a statement relating to the classification of injuries suffered; and a statement, or prayer, at the conclusion of the complaint outlining the categories of damages sought.

In a medical malpractice case, the plaintiffs named will include the patient and/or affected family members. The defendants will include any one or more of the healthcare providers who attended to the patient's care, and typically will include the facilities where the care was provided. The healthcare providers may include the individual physicians, the physicians' corporate or partnership entities or groups, and the physicians' attendant staff, such as nurse practitioners or physician's assistants. In appropriate cases, defendants may include medical instrument manufacturers or suppliers.

The required statement of the relationship among the parties which creates the duty or obligation may be general ("The defendants and each of them undertook to provide the patient's medical care…"), or it may be specific ("On or about January 1, 2015, Dr. A performed a colectomy with anastomosis…").

The statement outlining the breach of that duty may also be general or specific. The statement must, however, provide the defendant with notice of the classification of wrongdoing which the plaintiff is alleging. The classification of wrongdoing is called a *cause of action*. In most cases the cause of action stated is medical negligence, or medical malpractice.

Extraordinary causes of action may also be alleged, and there may be subtle differences among the causes of action which are important to recognize. For example, in most jurisdictions, failure by the physician to obtain the patient's "informed" consent prior to surgery is a type or subcategory of negligence. The complaint may set out a separate cause of action for failure to obtain informed consent, but in reality, this is a specification of the allegation of negligence. The elements of the cause of action and recoverable damages mirror those of a medical negligence cause of action.

A claim for failure to obtain "informed" consent must be distinguished from an alleged failure to obtain the patient's consent to perform the surgery which was performed; or a claim that the surgery that was performed was substantially different from the surgery to which the patient consented. Performance of a surgery without actual consent is battery, an unconsented to touching. The allowable damages in a battery cause of action can be substantially different from the damages allowed in a negligence claim. Damages in a battery cause of action may include punitive damages, awarded to punish the defendant rather than to compensate the plaintiff.

In most jurisdictions, battery is considered an intentional tort. The claim of battery in the complaint may create significant insurance coverage issues, as your medical

malpractice insurance contract may contain an exclusion for intentional tort claims. The laws of your jurisdiction may not allow an insurance company to indemnify you for damages awarded for battery, or for any other cause of action for intentional torts.

Similar concerns arise relating to claims couched in terms of fraud, concealment, or intentional infliction of emotional distress. For example, a patient might allege that the physician fraudulently concealed from her the injury to the adjacent organ which occurred during the surgery. Is the plaintiff alleging mere medical negligence, or is she claiming fraud?

Usually, the caption of the complaint will list the causes of action which are contained within the body of the complaint, but this isn't always true.

The allegations of injury, likewise, may be specific or general, depending on the jurisdictional procedural requirements and the plaintiff's lawyer's preference. The categories of injuries suffered generally include general damages or non-economic damages for physical or emotional injuries (e.g., pain and suffering); and special damages or economic damages for calculable injuries for past and future medical expenses, and/or for past and future loss of earnings, earnings capacity, or financial support. In the appropriate case, future medical expenses may include the cost of medical monitoring; for example, when the claim is based upon a delayed diagnosis of cancer for which monitoring for recurrence is advised. Each of these categories of damages are classified as compensatory damages–damages awarded to compensate the plaintiff for actual loss.

The classification of damages is important, especially as between general/non-economic damages, such as pain and suffering, and special/economic damages for specific, calculable economic losses (medical expenses and loss of earnings). In several jurisdictions, the classification of damages will determine whether the plaintiff's recovery is "capped" or limited to a specific maximum number as a matter of statutory law. The statutory maximums usually apply only to general, non-economic losses. Likewise, a defendant's liability for damages may be limited to his or her proportionate fault for general, non-economic damages, so-called *several liability*; whereas each defendant who is held liable at all or in any proportion (even 1 %) for *all* of the damages awarded to the plaintiff for special, economic damages, so-called *joint liability*.

When extraordinary causes of action are included in the complaint (e.g., to include claims of willful misconduct such as battery or fraud), the categories of damages requested may be expanded to include punitive damages. Like criminal penalties, punitive damages are awarded to punish the defendant financially, with the secondary effect of deterrence of similar conduct in the future. To punish or deter, the damages must "hurt." Thus, the damages awarded must be in some proportion related to the defendant's wealth. The defendant's income and total financial assets become relevant; and, therefore, at some point during the trial the court may require the defendant to disclose his personal financial information to be used by the jury to calculate just how much must be awarded in punitive damages against that defendant to serve the purposes of punishment and deterrence. Moreover, it is because punitive damages are imposed to punish and deter *the defendant* that public policy precludes an insurance company from indemnifying the defendant from such damages.

The presence of extraordinary causes of action within the complaint creates insurance coverage issues and potential personal financial exposure for the defendant physician. The physician needs to be counseled early on in the litigation about these possible ramifications, so that the issues can be managed effectively.

Once the complaint is filed, a summons is issued. The right of the court to "summon" citizens to answer charges brought against them is rooted in the procedures of English common law. A defendant is deemed "summoned" to respond after proper service of the summons and complaint. The methods of effective service and the time and manner in which the served defendant must respond are established by the state's local procedural laws. The time in which to respond begins to run once the summons and complaint have been served on the defendant.

The complaint will identify each of the defendants who are being sued, but it is the summons which identifies who, among the defendants, is being served, and, therefore, who is obliged to respond. For example, the complaint may name as defendants an individual doctor, the doctor's personal corporation, and the doctor's practice group. That's three different defendants. To effect service on each of the three defendants, the plaintiff will have issued and served three different summonses.

If you practice as an individual doctor, and have established a personal corporation (e.g., Dr. Smith, Inc.), and practice as part of a group practice, and you are sued in each capacity, you may be served three different times. You will receive three summonses, which may appear identical, except that on one line, which identifies "person served," the wording will be slightly different. A separate copy of the complaint will be attached to each summons. Your attorney will need to obtain copies of all three sets of documents, even though they may appear identical to you. Keep all documents with which you are served, and forward each set of documents to your insurance company or attorney as soon as you receive them.

The time allowed for the defendant to file responsive pleadings is short, usually 30 days or fewer from the date of service of the summons and complaint. Before responding to the complaint, the defense attorney must analyze the complaint, and the relevant facts and law to determine, among other things:

- Who has been sued?
- Have the defendants been properly identified?
- Was the complaint timely filed, or is it potentially barred by the statute of limitations?

- Has the complaint been timely and properly served, and upon whom?
- Are the causes of action adequately pleaded?
- Does the complaint raise extraordinary causes of action, which require special handling or counseling?

Based on this analysis, the defense attorney will determine whether a routine response, an answer to the complaint, is appropriate, or whether a more involved pleading is necessary to challenge the scope or validity of the claims being made. This analysis and the preparation of a formal response by the attorney take time. The time allowed by law is short, so the process must begin as soon as possible. This requires that the physician notify his attorney or insurance company of the service of the complaint as soon as possible.

Teaching Points

1. You and your office need established procedures to handle legal documents and filings.
2. When a summons and complaint is received, keep the envelope in which it was served.
3. Make a notation of when specifically (date and time) it was received, and how it was received (by mail or in person).
4. Look on the summons to determine who has been served (the doctor, the doctor's corporation or the practice).
5. Notify your insurance company or attorney immediately, and provide a copy of the summons and of the complaint to them.
6. Review the complaint to determine whether any extraordinary causes of action (anything besides medical negligence or wrongful death) are listed on the first page of the complaint.
7. Look at the last paragraph of the complaint, the prayer, to determine which categories of damages are being requested.

If you haven't heard from an attorney within 10 days of providing a copy of the complaint to your insurance company, contact the insurance company to identify who has been retained on your behalf. Request that the attorney contact you immediately to discuss any concerns you may have about the timeliness of the complaint and the proposed response.

1. Confirm with the attorney that an appropriate and timely response has been or will be made on your behalf.
2. Confirm that an appointment with the attorney is made, and ask what you need to have available at that first meeting.
3. Create a file separate and apart from your medical chart, and keep a copy of the complaint and any other legal correspondence in that separate file. This is also where you should keep any summaries you may have created in anticipation of litigation.
4. Do not speak with anyone (including your partners or office staff) or do any independent research relating to the case, until you have received direction from your attorney.
5. Do not alter or supplement your records in any way; ***I repeat, do not alter or supplement your records in any way***.

The attorney's first task is to acquire a very basic understanding of the nature of the claim and to respond to the complaint. The procedural rules of the jurisdiction will dictate how specific the response or answer to the complaint must be, just as the rules define how specific the allegations of the complaint must be. The rules may require a point-by-point response admitting or denying each allegation contained in the complaint or it may require that the defendant merely file a general denial—a summary statement denying each and every allegation of the complaint without specification. Some jurisdictions require that the defendant verify the pleading by signing the answer under penalty of perjury, confirming that the admissions or denials contained in the answer are true.

A point-by-point response may be a time intensive process for the attorney and the physician-defendant, as each allegation is considered in light of the then-known information. It may require more than one conference and sifting through medical records. On the other hand, if only a general denial is required, the physician may play no role whatsoever in preparation of the responsive pleadings. The pleading requirements of the jurisdiction should be part of the initial contact between the attorney and the physician, so that the physician will know what is expected of him in this process.

In general, the responsive pleadings will serve to notify the court and opposing counsel that the defendant denies any wrongdoing, that the defendant disputes that anything he has done or failed to do has caused any injury to the plaintiff, and that the nature and extent of any injury alleged to have been suffered is disputed as well. In other circumstances, the responsive pleadings may set forth a legal challenge to the form of the complaint or the adequacy of its allegations to support the cause of action alleged. It may challenge the timeliness of the claim, with a contention that the allegations within the complaint itself establish that it is barred by the statute of limitations. It may challenge the right of the plaintiff to seek extraordinary damages such as attorney's fees or punitive damages, if the complaint contains prayers for these categories of damages.

Successful initial legal challenges to the complaint are rare. The overwhelming public policy is that all factual disputes between the parties are to be decided by a jury, in a trial, after the parties have had an adequate opportunity to conduct discovery in preparation for trial. Judges don't determine what the facts are, juries do. Judges decide what the law is and apply the law to the facts as determined by the jury. Therefore, in deciding whether to sustain or overrule an initial challenge to the complaint, the judge may not adjudicate any factual dispute. The judge must accept as true what is alleged in the complaint. A defendant's legal challenge is

sustained only if, "accepting everything alleged in the complaint as true," the defendant's challenge is still valid.

This legal standard is particularly frustrating to defendants when the complaint includes allegations which are patently false. The plaintiff alleges that the physician undertook the subject surgery without his informed consent, without discussing the risks, benefits or alternatives, and alleges further that if she had been told that there was a risk of injury to an adjacent organ she never would have consented to the surgery. You recall specifically speaking to the patient about the massive adhesions you expected to encounter and the attendant risks of injury to adjacent organs. You recall discussing the relative advantages of laparoscopic versus an open laparotomy approach, specifically as regards potential injury to adjacent structures. Your office medical record for the preoperative encounter includes a detailed note in your own hand outlining your discussion of these very risks and alternatives. Your chart includes a two-page detailed consent form which you and your partners have developed over the last 15 years, outlining the specific risks and alternatives, initialed by the patient in three different places, signed and dated by the patient and an office staff member. There is a similar document signed by the patient in the hospital. Yet, your lawyer tells you, and correctly so, that you have no right to bring this evidence to court at the pleading stage to challenge the complaint. She tells you that despite all existing evidence to the contrary, because the complaint says that you didn't obtain informed consent, the judge (as opposed to the jury) must accept as true that the issue of informed consent is in dispute, and this issue cannot be decided by the judge at the pleading stage.

Your patience will be similarly tested repeatedly throughout the litigation process. You will repeatedly inquire, "What's going on?"; "Why is this taking so long?"; and "Why hasn't this ridiculous case been dismissed already?" You will be told, "These things take time"; or, "It doesn't work that way"; or "There's nothing else we can do for now."

You've read in the complaint that you are being sued for unspecified amounts, based on what you know, or at least perceive, to be unfounded allegations, and now your lawyer is telling you that there is nothing you can do about it "for now." Rather, you must wait until the case or any issue in it is ripe for adjudication, and this may not be until trial. You are overcome by an overwhelming since of frustration, and justifiably so.

The frustration quotient establishes:

$$\textbf{FRUSTRATION} = \frac{\textbf{RESPONSIBILITY}}{\textbf{AUTHORITY TO ACT}}$$

To avoid frustration in any situation it is imperative that someone who bears the responsibility for an outcome should also have the authority to act as to effect a *best result*. The king was rarely frustrated. He could simply deny responsibility for anything while maintaining complete authority over the kingdom and his subjects. Surgeons undertake great responsibility for surgical outcomes and patient well-being. Their frustration level is manageable because, generally, the surgeon has the authority to act to effect a positive surgical result. That is the circumstance to which the surgeon has become accustomed. The duty and authority to act to fix the problem is ingrained in the very being of a surgeon, and is the only way to avoid intolerable frustration.

On the other hand, surgery and the healing process can be terribly frustrating for the patient, who perceives herself to be helpless and totally dependent on you for her care. To help reduce that frustration it is incumbent on the surgeon to educate the patient to manage expectations and to maximize her chance for a favorable outcome. The patient must be told in advance for how long she will be bedridden or unable to return to her activities of daily living, and what she can do to accelerate her healing process.

In litigation, the physician-defendant's authority to act is muted by the procedural processes. Initially, the physician-defendant may feel helpless and totally dependent on his attorney. Frustration abounds.

What can you do? Just as you educate your patients so that they can manage their anxiety and frustration, you must seek to educate yourself about the litigation process and manage your expectations and efforts accordingly. This can only be accomplished with an open dialogue between attorney and client. While you may not be able to run to court and protest your innocence, you don't need to sit by idly either. Speak with your attorney. Know what your role is; learn what will be expected of you and when; ask what can you do to best prepare yourself to succeed in your role; and, as importantly, ask what you should avoid doing so as not to inadvertently undermine your case.

There *are* things for you to do to achieve your *best result*. You have the authority to prepare yourself as directed, and to manage your own expectations within the parameters of the process. This can and will reduce your anxieties and frustration level.

Teaching Points

1. At the initiation of litigation learn what you can do affirmatively to achieve *your best result*.
2. Speak with your attorney early. Ask whether he intends to challenge the legal adequacy of the complaint. Ask what you need to do "now." What information and records need to be assembled? This not only includes medical records, but also increasingly includes fax, e-mail, and office telephone or cell phone billing records to establish the existence, date, time, and substance of communications between you and the patient or hospital staff.
3. Learn how long the process is expected to take. The estimate you receive may be broad, but it will provide you with some reasonable expectation. Tell your attorney how you would prefer to be contacted: office or personal cell

phone. Tell your attorney what mailing address to use: office or home. Tell your attorney whether there is someone in the office other than yourself who can be contacted regarding the case, e.g., an office manager, or if all communication should be with you only.

4. Ask when it will be necessary for you to be personally involved? Are there court hearing dates or deposition dates pending at which you must appear? Is a trial date set? If not, find out how much notice will be given to you when your personal attendance is necessary. Tell your attorney about any plans you have to be out of the area for any significant period of time for vacations or conferences. Update your attorney when new plans are made or when plans change.
5. Be patient! This will take time.

The Discovery Process

Written Discovery

In most jurisdictions, claims for medical malpractice are resolved in a jury trial. From the time the complaint is served on the defendant until jury selection is commenced, the parties to the lawsuit and their attorneys participate in a formalized accumulation and exchange of information which ultimately will be used at trial to educate the jurors about the relevant facts of the case. This is the discovery process.

To conduct discovery, the attorneys invoke legally sanctioned discovery procedures and the authority of the court to enforce those procedures, including the court's subpoena power. Basically, the law allows a party to subpoena or formally request relevant documents, such as medical records or employment records. The law allows parties to serve written inquiries to opposing parties, usually in the form of written questions called interrogatories. Most importantly, the law allows parties to interview opposing parties or witnesses under oath by way of deposition.

The procedural law of each jurisdiction sets forth in detail the manner in which parties may conduct this discovery. What the physician-defendant needs to know is that the discovery process is to be taken seriously as it has serious consequences.

Any party to a lawsuit may request information from any other party in the form of written interrogatories. The process is controlled by local rules of procedure. Some jurisdictions have created form interrogatories approved by the judicial council of that state. The form interrogatories cover a wide range of topics, which may or may not be relevant to the specific case. The attorney who propounds the interrogatories (i.e., asks the questions) simply checks the boxes on the form relating to the questions to be answered. The rest of the questions on the form can be ignored.

Other jurisdictions do not have judicially approved interrogatories, so that the attorney propounding the interrogatories must formulate the specific questions. Jurisdictions which use judicially approved interrogatories allow the propounding attorney to supplement the judicially approved interrogatories with special interrogatories, specifically drafted by the attorney, but maintain limitations and rules of procedure to do so.

By using judicially approved form interrogatories, the propounding party avoids objections as to the form of the question (e.g., vague, ambiguous, overbroad), which streamlines the process substantially.

The scope of the inquiry allowed by interrogatories is extremely broad. It includes personal and biographical data, insurance information, factual data relating to the underlying occurrence and medical care, information relating to potential witnesses, and to legal issues such as contentions of negligence, causation or damages, or affirmative legal defenses such as the statute of limitations.

Interrogatories are directed from one party to another. Although the interrogatories are directed to a party, the interrogatories are deemed to be directed to the party's attorney as well. The responding party is obliged to include within his response non-privileged information which is known or reasonably obtainable by the party "by inquiry to other natural persons or organizations, except where the information is equally available to the propounding party" [4]. Therefore the response must include information which the responding party may obtain by a reasonable inquiry to his office staff and his attorney. The responding party and his attorney are required to make a good faith search through the medical chart, the physician's personal files, and the attorney's files.

The local rules of procedure dictate the form of the questions and the timing and form of the response. Typically, the responding party must serve the responses within 30 days of his attorney's receipt of the questions. A party may request an extension of time within which to respond. The extension can be obtained by mutual agreement of the parties, or, if necessary, by the responding party's going to court and requesting a court order granting additional time by which to respond.

Within the time allotted to respond, much must be accomplished. The good faith inquiry necessary to respond should begin immediately. As the physician-client, you can expect your attorney to have in place office procedures to notify his clients immediately when interrogatories are served. That notification should include a copy of the interrogatories and clear instructions regarding the division of labor: which of the interrogatories the attorney is going to answer, and for which of the interrogatories the attorney is requesting assistance from the physician-defendant.

The notification from the attorney should also include a timetable for the response. Generally, the attorney's notification will include a date by which the physician's preliminary responses are due to him. The attorney may also ask the names of key office personnel who may be the source of additional information. There should be an agreement between the attorney and physician-defendant specifying who will be in contact with these additional personnel.

In each case, confidentiality must be maintained. Any person contacted must be told not to discuss the conversation or inquiry with anyone outside of the office management staff, the physician, the attorney or the attorney's staff.

The attorney will organize the information from each of the sources and will draft formal responses to the interrogatories. These responses may include both objections to the interrogatories and answers to the questions. Once the responses are prepared, the responses will be presented to the physician-defendant for verification.

A verification is a signature by the responding party, made under oath or penalty of perjury, which, depending on local rules, may or may not need to be notarized. The signature attests to the accuracy and completeness of the information contained in the response, at least to the best of his or her knowledge.

Once verified, the responses become affirmative statements of the responding party. The other parties to the litigation may justifiably, and legally, rely on the responses as being complete and accurate. The parties may use the responses for any relevant purpose in the litigation, up to and including trial. In some cases, the response to an interrogatory may be used as an admission against that party, and can be presented to the jury as such at trial.

One important purpose of interrogatories is for the propounding party to inquire about additional potential sources of information. This could include the names of potential witnesses or other sources of documents and records. The propounding party is entitled to rely on the response to include a complete list of these additional sources, to direct further discovery efforts.

Local rules of procedure provide sanctions and other consequences for a party's failure to provide timely and complete answers. For example, objections contained in the response may be deemed waived as a matter of law if the response was not served timely. Likewise, if the interrogatory has asked for the identity of witnesses (which could include office or operating room staff or assistants), and the responding party has failed to identify a specific potential witness, either out of inadvertence or because of a failure to conduct a good faith inquiry into the records, the responding party may be barred from producing that witness at trial.

It is rarely acceptable to simply respond that the requested information is equally available to the propounding party through alternative means (e.g., looking through the hospital records himself).

As with all aspects of the litigation process the interrogatory process may be time-consuming, and burdensome. But it must be taken seriously. Inadequate or inaccurate responses will be detrimental to your defense.

Teaching Points

1. Expect that you will be asked to answer interrogatories.
2. Expect that your responses will need to include biographical and personal data from you.
3. Expect that you will be asked to include the names of witnesses to the occurrence including relevant office staff, hospital staff, assistant surgeons, anesthesiologists, and consultants.
4. You don't need to wait until you are served with interrogatories, and the time period for responses starts to run, before you begin compiling the necessary information. At your initial meeting, ask your attorney if your jurisdiction has judicially approved form interrogatories which are used by attorneys in that area; or if there are other interrogatories which you likely will be asked to answer. Obtain a copy of the anticipated questions, and begin immediately to compile proposed responses. If the opposition will want this information, your attorney should have it as well, and soon.
5. Obtain assurance from your attorney that you will be notified as soon as interrogatories are served, and that the notification will include the date by when your preliminary responses will be expected. You also have the right to expect that your attorney will anticipate the need to respond to interrogatories, and will have begun a search of the relevant data sources in advance of the interrogatories being served. You also have the right to expect that your attorney will provide you with the proposed formal responses with sufficient time in advance of the deadline to respond so that you can go through the questions and answers with your attorney before you sign the verification.

You can expect that at deposition or trial your responses to the interrogatories will be presented to you. You will be asked to confirm that the verification includes your signature. You will be asked about the scope of your inquiry before providing the responses, and whether you read and considered the responses before verifying their accuracy under penalty of perjury. Therefore, conduct a good faith and thorough search in providing responses; and read and understand your responses before signing the verification.

There are other kinds of written discovery as well, such as requests for admissions, requests for production of documents (e.g., insurance policies, office protocols, licenses, and certifications), or requests for authentication of documents. In each case, the procedures are similar to responding to interrogatories. Be sure that you understand the time parameters for response and the scope of inquiry which is necessary, and that you have reviewed the proposed response before signing the verification.

Your Deposition

Unquestionably, the most important aspect of pre-trial discovery for the physician-defendant is the deposition. Giving an effective deposition requires effective preparation, and you have the right to expect that your attorney will aid you in that preparation. It is likely that your attorney attends depositions weekly, if not more frequently. He may have represented physicians at deposition hundreds of times or more.

He may be completely comfortable with the process. But this is *your* deposition.

The situation is analogous to taking a patient to surgery. As an experienced surgeon, you have taken part in hundreds, if not thousands, of surgeries before. You have a well-founded expectation concerning what you are about to undertake. However, this may be your patient's first surgery. As a surgeon you have the responsibility of educating your patient concerning what the patient must do to prepare herself in advance to maximize the likelihood of success at surgery. You must educate the patient regarding what is likely going to occur during surgery, including the risks associated with the process; and, you must provide the patient with a spectrum of potential outcomes so that the patient's expectations will be reasonable. You are the surgeon, but this is *the patient's* surgery.

The first step in preparing for a deposition is to know what a deposition is. A deposition is a recorded question and answer session during which the attorneys for all parties to the litigation, including the opposing party and all co-defendants, have the right to ask you questions. The scope of questioning is extremely broad. As a general rule the witness may be asked questions concerning any topic which might be directly relevant to the case, and concerning any topic which might be reasonably calculated to lead to the discovery of relevant evidence. In short, this is the one time that the parties are entitled to conduct a "fishing expedition." Be patient. The deposition may take hours, or even days. Your performance in the last one-half hour is every bit as important as your testimony in the first 1 h.

Your deposition may be a videotaped deposition. The party who schedules the deposition will give notice of whether he intends to videotape it. Be sure you know whether it will be videotaped and dress and present yourself accordingly. In your practice, you wear your lab coat, with physician designation. This may or may not be appropriate when presenting yourself for deposition. One issue you will want to discuss with your attorney in advance is what to wear.

The use of videotaped depositions is becoming more prevalent in recent years. I've never thought it necessary for a physician to wear a lab coat in deposition; however, my opinion on this is changing. Jurors are patients. Patients have an expectation of what physicians look like. The videotaping of depositions has two purposes: to intimidate the witness, and to present a video record to the jury at trial. You are a doctor. You have the extensive education, experience, and license to justify your use of the title, "Doctor." Wearing your lab coat at deposition provides an ongoing reminder to the audience or jury that you have earned and maintained that status, and that your testimony should be considered and weighed, accordingly. Being a doctor doesn't necessarily make you more believable; but it should add weight to your learned observations and opinions.

It is unlikely that you will be asked to wear your lab coat at trial. The stark difference between your appearance in a lab coat at deposition and in a suit and tie at trial may make your appearance at deposition seem staged. The decision whether to wear your lab coat, or any other questions regarding your presentation and attire, should be discussed with your attorney. In all cases, you should present yourself in business attire.

A deposition is a "legal," "formal" interview. The legality of the process is established by local rules of procedure. Foremost among them is that prior to beginning testimony, the court reporter, who is a designated officer of the court for this purpose, administers the oath. The words may vary, but the upshot is that you are being asked to swear or affirm that the answers you are about to give in deposition "are the truth, the whole truth, and nothing but the truth…" (Notably, the attorneys who are asking the questions aren't under oath. However, as the deposition is in the realm of judicial proceedings, rules of professional conduct oblige attorneys not to make material misrepresentations of fact or law at deposition.)

At the conclusion of the deposition, a transcript of the deposition will be prepared by the court reporter. It will look like a script. The questioner will be identified, and a verbatim transcript of the question will appear. The question will be followed on the page with your answer. You will be provided with a copy of the transcript. Within the parameters of your jurisdiction's procedural rules, you will have the opportunity to review the transcript and to make any changes to your answers which you believe are necessary to accurately reflect your testimony. (You may not make changes to the questions, although you may note typographical or transcription errors.) Your changes may be to form or substance.

The court reporter may have misunderstood or mistranscribed a word, or may have left out a word which you believe was spoken and which you believe is necessary for the transcript to accurately reflect your testimony. You may make those kinds of corrections.

You may also make substantive changes to your testimony. For example, you may have been asked at deposition whether, before proceeding to perform surgery, you took the opportunity to review the labs or consult notes. Consistent with your customary practices, you may have answered "Yes," to that question at deposition. Upon further review of the chart or upon further reflection after the deposition, it may become apparent to you that one of the consult notes didn't appear on the chart until after you began your surgery, so that, at least as to that consult note, your appropriate response should have been "No, it wasn't on the chart yet."

You may make that kind of substantive change to the testimony, but you must be cautioned that any substantive changes you make to the transcript can be commented upon by the opposing counsel at trial, and you may be asked why you gave a different answer at deposition. These kinds of changes can adversely affect your credibility at trial, and may have an adverse affect on your case. For that reason it is important that you give your best answers at deposition to minimize the need for changes later.

Because substantive changes can adversely affect your case, it is important that you consult your attorney before marking or making changes on the original transcript. A good practice is to make any proposed changes on a copy of the transcript or a different piece of paper and then to preview the proposed changes with your attorney before they are finalized.

Once you have reviewed the transcript, and made any changes you deem appropriate, you are asked to sign the deposition under penalty of perjury. Your signed deposition transcript becomes your testimony, for the trial and for any other subsequent legal proceedings. (In some jurisdictions, there are provisions for use of an uncorrected or unsigned certified copy of the deposition as if it were a signed and corrected original. These provisions may apply if you or your attorney have not notified the court reporter or the parties of any proposed changes within the time limitations provided by law, or, if the signed original hasn't been returned to the court reporter within the time frame allotted by law.)

Because the deposition is a legal proceeding, you have the right to have counsel present. Whether you are being deposed in a case in which you are a defendant, or simply as a witness, it is important that you be represented at the deposition by an attorney. If you are subpoenaed for deposition as a witness in which you are not a party, contact your attorney, risk manager, or insurance company and ask for representation. Too often, a non-defendant witness is lulled into a false sense of security, appears at deposition without an attorney, and, without proper preparation or representation, provides potentially incriminating testimony which provokes the patient's attorney to name the witness as a new defendant in the case. Depositions are too important to be taken lightly. You need proper representation.

It is your attorney's job to prepare you for the deposition and to represent you at the deposition. Preparation is imperative, but it is important that you be guided by counsel in that preparation. As with many aspects of the case, preparation for the deposition begins with the initial meeting. It is very important that you understand what is expected of you in anticipation of your deposition. Know what your counsel wants you to review in preparation for deposition, and what he doesn't want you to review. For example, the case may involve technical aspects of the patient's medical care, such as pulmonary issues or endocrine issues, which you, as a surgeon, may not have studied since medical school. You are familiar with the issues and general management, but not with the current state of knowledge regarding ventilation settings or esoteric thyroid stimulation medications. Before beginning a literature search on these or any issues, be sure that the attorney wants you to do so.

Typically, the attorney will want you to be familiar with the documentation which was available to you at the time of your treatment of the patient, as it would be this information which formed the basis of your differential diagnoses, and your treatment alternatives.

As discussed more fully below, the primary liability issue in a medical malpractice trial is whether the physician's care was negligent, i.e., was it below the applicable standard of care? Though language differs by jurisdiction, basically, the standard of care requires the surgeon to act as other duly competent and careful surgeons would act *under the same or similar circumstances.*

Though seemingly tautological, it remains true that *you* acted as you did under the circumstances which then-existed. Presuming that you are a reasonable and competent surgeon, and accepting that you acted as you did and intended to act, then your conduct under the circumstances that then-existed is, by definition, within the standard of care: You, a competent and careful surgeon, acted as you did, under the circumstances as they actually existed at the time.

It is your job at deposition to fill in the facts necessary for your lawyer to make this argument. You must be prepared to testify to your qualifications and experience, as to establish that you are a reasonable, competent, and careful surgeon. You must also be prepared to testify regarding your knowledge of the facts that existed at the time of your treatment of the patient.

The single most effective way to cross-examine a physician-defendant (or an expert) is to establish that the facts which the physician-defendant believed to be true at the time of his surgery, and which formed the basis of his actions or opinions, were not the facts as they truly existed. In that case, the physician was acting under the facts and circumstances as he *thought* them to exist, not as they, in fact, existed. In that case, the physician loses the value of the tautological argument. Knowledge of new or different facts may not have changed the conduct, but it infuses doubt.

The relevant facts would include the patient's recent and distant medical and surgical history; the existence of any peculiar risk factors, co-morbidities, or contra-indications; recent lab values, imaging studies, or consults; or even something as simple as whether blood had been typed and cross-matched before surgery, and was therefore available immediately, if needed.

By the time the deposition takes place, it is probable that you will have forgotten these details. With your attorney's assistance, refresh yourself, so that when questioned at deposition you can recount your knowledge of the relevant facts as they existed at the time, consistently and accurately. Ask your attorney to provide you with copies of the relevant records prior to the deposition so that you have the time and opportunity to refresh your recollection. But don't access additional records unless and until you are instructed to do so by your attorney. There are specific, strategic reasons for this advice.

In most instances the deposition of the physician-defendant occurs relatively early in the litigation process. The physician-defendant is being deposed as a percipient witness to the occurrences which form the basis of the case. As a percipient witness, the scope of inquiry generally includes exploration of all percipient observations. In the

litigation process, perception goes beyond the primary senses. In addition to what the doctor saw, heard, felt, smelled, or tasted, the physician is in the unique position of knowing and, therefore, to testify to *what he was thinking at the time of the events*.

Typically, inquiry into the physician's contemporaneous thoughts is fair game for deposition. Thus, he cannot only be questioned regarding what he saw or read before surgery, he can also be questioned regarding his decision-making and thought processes. This would normally include any percipient opinions, opinions *which he came to at the time of his care of the patient* concerning what may have caused or contributed to the patient's adverse outcome.

Opinions which are developed based upon supplemented or retrospective analysis of the facts are expert opinions. They differ from contemporaneous or percipient opinions. While inquiry into *contemporaneously developed* thoughts or opinions is considered appropriate during the physician's deposition as a percipient witness, opinions reached since the litigation ensued, or made retrospectively in reconsideration of the circumstances in anticipation of litigation, or in furtherance of the defense, may be handled differently. Again, this is dependent upon procedural differences among the various jurisdictions, but as a general rule, where a physician-defendant processes information in anticipation of litigation, which may include information obtained from the physician's attorney, the conclusions and opinions which are the product of those processes remain the work-product of the attorney, unless and until the physician's status as a witness changes from percipient witness to expert witness. This change in status usually occurs in one of two ways: (1) at the deposition, the attorney for the witness declares his intention to proffer the witness as an expert witness at trial; or (2) during the exchange of expert designations among the parties, the attorney for the physician formally discloses his intention to call his client as an expert. In that case, the plaintiff may have the right to depose the physician-defendant a second time to explore his expert opinions and the bases for those opinions.

Assuming, however, that it is not your attorney's intention to elicit expert testimony from you (or at least he is not in a position to declare his intention to do so on the day of your deposition), then the scope of your deposition will be limited to opinions you came to at the time of your care. In preparing for your deposition, understand the difference between percipient and expert opinions, and whether either or both are subject to inquiry at your upcoming deposition.

At deposition, you will be asked questions concerning your recollection of facts and occurrences. The party asking the questions is entitled to your best current recollection of those facts, even if that recollection is cloudy, vague, or non-specific. In addition, generally, the questioner is entitled to know what documents, if any, you have accessed or reviewed to refresh your recollection. And, he is entitled to question you regarding those documents. For example, you may be asked what the estimated blood loss was during the procedure. You may recall that there was nothing significant about the blood loss, but otherwise you can't provide a reasonable answer. Or, you may have recently reviewed the operative report in preparation for the deposition, and noted that the stated blood loss was actually substantial, and estimated to be 500 ml. Reading and being reminded by this note sparks a memory, and you now actually recall that there was an estimated blood loss of 500 ml.

Arguably, your present testimony of the facts is dependent upon what the operative note says. You may, therefore, also be asked, "If the note had referenced an estimated blood loss of 800 ml, would that have been your testimony?" In other words, did the entry in the chart actually spark a memory from which you are now testifying; or, are you merely accepting as true and accurate what is written in the chart? Are you testifying, or is the chart testifying?

If you are testifying from refreshed memory, you may be asked a series of questions about what it is about this entry that has sparked the memory. If you testify that you are merely accepting what is written in the chart, the follow-up questions may relate to how and when the document was prepared and stored, in an attempt to call into question the accuracy of the document, as opposed to the accuracy of your memory.

For these reasons, the questioner will almost certainly ask you to list all documents reviewed in preparation for the deposition, or documents reviewed to help refresh your recollection of the events. Your attorney is going to want to know in advance of the deposition what you are intending to review or have reviewed; he is going to want to control the universe of information to which you have had access in preparing for the deposition. By doing so, he will have some control over the scope of allowable inquiry.

For example, you may want to brush up on your infectious disease medicine before the deposition, out of fear that you will be asked something in that area of medicine. If you do so, you may be questioned about what you reviewed, and why. The implication may be that if you *now* believe that this information is important for you to know, why didn't you do your homework before the surgery? Don't conduct independent research before the deposition unless you are directed to do so by your attorney; or without first consulting your attorney.

Similarly, it may be that your attorney has provided you with a summary of the records or of the deposition testimony of other witnesses. As a general rule, that information from your attorney is privileged. It was provided to you in furtherance of your defense, not to prepare you for deposition. Know in advance whether you are to review your attorney's correspondence before the deposition; and tell your attorney that you have done so, so that he can be prepared with appropriate legal authorities to support and to invoke the attorney-client privilege in a timely manner.

At deposition, the questioner is entitled to your best estimate of anything that can be quantified. How many surgeries do you do in a year? How long does it typically take you to get to the hospital from your home? How many lap sponges

did you use in this case? How long did it take to perform this aspect of the case, or that aspect of the case?

The questioner is not entitled to your speculation, or to ask you to guess. Often the line between an estimate and a guess is difficult to define. Ultimately, at trial the judge is the arbiter of what information does or does not go to the jury. The first step toward admissibility is for the judge to determine whether the information is reliable. Speculation and guesses typically do not go to the jury because they aren't reliable. Therefore, fundamentally, the difference between an estimate and a guess is whether you have a reasonably reliable basis or evidentiary foundation for your answer. The foundation may include your observations and memory of the case; or, it can be based on your customary practices.

To demonstrate the distinction, a lawyer may ask you to estimate the length of the table in front of you. You don't have a tape measure, but based on your ability to observe the table, and your presumed fundamental knowledge of units of length, you can give an estimate. Your ability to see the table is the foundation necessary to provide your estimate. If you are then asked to estimate the length of the table in the attorney's private office, where you have never been, you lack the fundamental foundation to provide such an estimate. You may have knowledge about how long office tables usually are, but that is not the question. The question is, "How long is the table in this attorney's office?" You don't even know if there is a table in his office. Any answer you might give to that kind of question is pure speculation, and should not be offered. In that case, your answer should be a direct, "I don't know."

This same principle would apply to any question posed to you relating to events or conversations you did not witness. Likewise, you would rarely have a reliable answer to any question relating to the thought processes of other individuals. You may have knowledge of how nurses usually go about taking a history from a patient in the pre-op holding area. However, if asked whether a specific nurse asked a specific patient a specific question in this case, and you weren't there, the answer to that question is, "I don't know, I wasn't there." It is not, "Usually the nurse does ask that question." Let the nurse testify regarding what happened.

Similarly, you may have an understanding as to why a prior surgeon may have decided to do a direct repair of the colon rather than performing a diverting colostomy. Don't guess or presume what he was thinking; let him testify to his rationale. This will minimize the chance of inadvertent conflicts in testimony that could call into question the credibility of both witnesses.

The questions asked at deposition must be fair. To be fair, they must be relatively intelligible and unambiguous. You have the right to understand the question, and to ask the questioner to rephrase a question if you don't understand it. Exercise that right. If you don't understand a question, ask for it to be rephrased until you do understand it. If you answer a question, the presumption at deposition and at trial will be that you understood it before answering.

Ambiguous questions are troublesome. The trouble is that certain words are inherently ambiguous, such that they may have different meanings in ordinary speech as opposed to how they are used in medicine. One such word is "emergency." In ordinary parlance, "emergency" is used to describe a potentially dangerous situation for the patient which may require immediate (another word fraught with ambiguity) action. In surgical scheduling parlance, however, an emergency surgery is any surgery not otherwise scheduled as an elective surgery.

You may be asked whether the surgery you performed was an "emergency" surgery. In fact, the surgery was performed in the early evening after all scheduled surgeries were performed that day. It was performed after all appropriate preoperative testing was performed as to confirm the diagnosis and indications for surgery. It was performed by the operating room staff who were regularly on duty at that time. No one was called in. All typical time and care was taken in preparation of the patient for surgery. In anticipation of the potential need for the surgery the patient was kept NPO since the prior evening. From the standpoint of the surgeon, this was not an emergent situation and it was not an emergency surgery.

Yet, there on the intra-operative nursing records and on the anesthesia record the surgery is identified as "emergency surgery." Their designations are based not on patient acuity, but because it was not a scheduled surgery. However, if you answer the question, "Was this an emergency surgery?" with an emphatic "No," the plaintiff's attorney will no doubt challenge you at trial with the records prepared by the other practitioners who said it *was* an emergency surgery. This could lead to uncomfortable explanations, contradictions, and perceived back-pedaling.

There are two ways to avoid this kind of situation. In my experience one is much preferred. The first way to avoid this ambiguity is for the deponent (the person being deposed) to ask the questioner, "What do you mean by 'emergency?'" This kind of response may escalate the situation. The questioner responds, "Doctor, do you know what an emergency is?" To which the physician answers, "I know what an emergency is, but I'm not sure that you do…" This kind of dialogue is rarely productive, and may be affirmatively destructive if the jury believes the physician is being obstreperous or evasive.

The second way to handle the situation, and in my opinion the far better way, is for the deponent to answer the question as asked, but to include in that answer his or her definition of the potentially ambiguous word or phrase to clarify his or her answer. This avoids the ambiguity, the dialogue, and any suggestion that the physician is trying to avoid answering the question:

Q. "Doctor, was this an emergency surgery?"
A. "If, by emergency, you mean a surgery which needed to be performed that hour, or before thorough preparation could be made, no."

Or

Q. "Doctor, was this an emergency surgery?"

A. "If, by emergency, you mean a surgery which was not a surgery on the operating room's regular schedule, yes."

If the questioner wishes to reconstruct the question to define the word differently, he can do so, and you can answer the new question accordingly.

Adjectives and adverbs used by the questioner must always be considered for their potentially ambiguous usage. The usage may be innocent, but the usage of such words must be tempered with a thoughtful response.

The potential significance of the deposition process cannot be overstated. Once the deposition is completed and signed, it is your testimony. It can be used affirmatively by the opposition at trial to establish facts stated. It can be used by the opposition to contradict the testimony given at trial.

In most jurisdictions, the trial court will actually instruct the jury concerning the effect and significance of deposition testimony. The jury will be instructed in substance, as follows:

> A deposition is the testimony of a person taken before trial. At a deposition the person is sworn to tell the truth and is questioned by the attorneys. You must consider the deposition testimony that was presented to you in the same way as you consider testimony given in court. [5]

The opposing party may, therefore, literally begin his case against the physician-defendant by showing a videotape of portions of the deposition. The jury must consider that deposition presentation as if the same testimony was given by you live in court. The most common use of the deposition at trial is to emphasize possible contradictions or inconsistencies in your testimony as impeachment.

In addition, your deposition testimony can be used against you in virtually any future proceedings whether those proceedings relate to the same case, or if you are giving potentially conflicting testimony in some future case. For example, if there is an investigation of the occurrence by the state licensing board, they will typically request copies of any depositions taken in the case. Or, in the future, you may be retained as an expert in other cases. It is not uncommon for parties to a case to seek and obtain copies of past depositions given by the experts. Therefore, you could well be cross-examined concerning the testimony you are giving as an expert based upon the deposition testimony you gave in a case 5 years ago.

The deposition process is a "formal" interview. The process proceeds with question, answer, question, answer. The court reporter is obliged to report and transcribe the statements made at a deposition verbatim, in the exact order in which the statements are made. Thus, for example, if, in answering a question, you anticipate the end of the question and begin answering it before the questioner has completed the question, that is exactly how the transcript will read. This leads to broken, and potentially ineffective, testimony.

In addition, your attorney has a job to do at the deposition. That job is to assure that the questions asked are appropriate as to form (relatively clear, unambiguous, and not argumentative). The attorney must also assure that the question does not call for the disclosure of privileged information which would be subject to objection. The attorney cannot do his job if you do not allow some interval after the question is asked before you begin your response.

Wait until the questioner has completed his question. Think before answering. Respond to the question directly, and succinctly.

Answer the question which is asked. This would seem to be a simple instruction, easy to follow. In my experience, however, it is the instruction which my clients find most difficult to follow. The deposition process is in the form of an interrogation. It is not a conversation. In conversation, people often answer the question which they assume is being asked rather than literally answering the question which is asked. That is not the process of a deposition.

In conversation you are asked, "Do you know what time it is?" In response, you look at your watch, or your cell phone, note the time, and respond, "About 2:30." A perfectly appropriate course in conversation; but, a perfectly inappropriate course in deposition. The question was, "*Do you know* what time it is?" The answer to that question is "Yes," or "No." By answering the question in a conversational manner, you have not only not answered the question which was asked, you have potentially provided the questioner with invaluable information to which he was not entitled by asking the question he asked.

You have demonstrated that you use a watch as your timepiece; or, that you have a smart phone. Demonstrating that you have a smart phone could lead to a series of conversations concerning to what additional sources of information the smart phone is tied. Do you receive texts on the smart phone? Do you receive e-mails otherwise addressed to your office on the smart phone? Do you use the smart phone for your pages? This then could lead to additional discovery concerning your smart phone records, especially if the timing or duration of telephone calls ultimately becomes an issue.

This is not to say that the same information might not otherwise be gleaned if and when the appropriate questions are asked. It is to say that the opposition is not entitled to open that door by simply asking, "Do you know what time it is?" Don't invite him in.

Invariably, when cases go to trial, the physician-defendant reviews his deposition critically. As invariably, when reviewing the deposition the physician will note several potentially harmful answers which could have been avoided if he or she had simply answered the question asked.

The doctor is asked, "Did you examine the patient's abdomen?" The physician responds "I don't recall, but I usually do, and note my findings in the chart." A quick review of the chart by opposing counsel reflects no reference to an examination. Rightfully, or wrongfully, the implication based on

your expanded answer is that since no examination was recorded, no examination of the abdomen was made. All because the physician failed to restrict his answer to the question asked.

This is not to say that every answer should be "Yes," or "No." In fact, from time to time it may well be appropriate to provide a more comprehensive response to the question. For example, the question is: "Did you examine the patient's abdomen?" The physician responds, "I don't recall." The next question is: "When you examine the abdomen, do you chart your findings in the records?" The response is: "Sometimes I do; sometimes I don't." The physician would like to expand the answer to indicate that whether or not he charts his examination may be dependent upon his findings. He would chart any abnormal findings but would not necessarily chart the absence of significant findings. The proper way for a witness to expand his answer is not to simply continue to talk. A better way to expand the answer is to remark, "May I explain?" If the questioner responds, "Yes," the physician has the opportunity to expand his answer with notice of his intention to do so to his attorney. If the questioner says "No," thus restricting the doctor's opportunity to explain his answer, that can certainly be noted at trial by your attorney.

Finally, thanks to hours of television police shows we all know the basic Miranda warning, "You have the right to remain silent, anything you say can and will be used *against* you in a court of law." These Miranda rights relate to criminal proceedings. In a civil proceeding, such as a claim for medical malpractice, you don't have a right to remain silent, so you must appear and respond to questions at deposition. It remains appropriate, however, to know that everything you say at deposition, can be used *against* you at trial. The deposition is a tool for your opposition; rarely can it be used by your attorney. Every word spoken is potentially an arrow going straight from your mouth to the opponent's quiver, to be loaded in his bow and shot back at you if and when he sees fit to do so.

The foregoing is in no way intended to suggest that you should unduly limit or manipulate your answers. It is important that you answer the question which is asked, and not expand your answers unnecessarily. Yet, in all respects, you must feel free to answer all questions truthfully and, as necessary, to include within your response all information which you believe is required to give a thoughtful, complete, and meaningful response.

Teaching Points

1. Always consult with counsel before a deposition, and be represented by an attorney at a deposition, whether you are or you are not a party to the litigation.
2. Consult with your attorney sufficiently in advance of your deposition so that if additional record review or preparation is necessary you have the opportunity to do it.
3. Know what your attorney wants you to review prior to the deposition, and what she doesn't want you to review or access.
4. In every case you should be familiar with the details of your own care, including the substance of all records, consults, or notes which you had available to you at the time of your management of the patient, so that you can reiterate at deposition the basis of your management decisions.
5. Understand the difference between giving testimony based upon your memory being refreshed by review of documents, and giving testimony based strictly on your acceptance of what the document states. Are you testifying, or is the document testifying?
6. Understand in advance whether your attorney intends on your giving expert testimony based on a retrospective analysis, or whether you are giving testimony only as a percipient witness, in which case you will testify only regarding thoughts, conclusions, and opinions you actually came to while treating the patient.
7. Understand the difference between an estimate and a guess.
8. Don't give answers relating to conduct of others which you did not witness or the rationale for the conduct of another, unless that person told you why he did what he did. Knowing why someone might do something is not the same as knowing why this person did what they did on this occasion.
9. Have available at your deposition a list of the documents you reviewed in preparation for the deposition or to refresh your memory, and provide that list to your attorney in advance of the deposition.
10. Understand the question before you answer it. If a word used in the question is inherently ambiguous, define the word in your answer to clarify your response.
11. Wait until the questioner has completed his question. Think before answering. Respond to the question directly and succinctly.
12. Know if your deposition is going to be videotaped, and discuss your attire, accordingly.
13. Be prepared to give your best and most complete answers at the deposition so as to avoid the need to make substantive corrections when reviewing the transcript.
14. List proposed changes to your deposition on a separate piece of paper and discuss the proposed changes with your attorney before correcting the original transcript.

The Trial

As the process moves toward trial, your role in many respects changes. Up to the time of your deposition, you have acted primarily as a relatively silent party to the process. After the deposition, and as you move toward trial, however, you can become the most valuable and effective asset your team has. It is unlikely that any expert that your attorney retains will

have as much knowledge of the situation which you encountered as you do. Often, you will be as well educated and experienced as your expert. Frankly, there will be no one who is more invested in investigating and sorting out the pertinent records and testimony than you are. No one will have more at stake.

While the practices of attorneys vary, I believe that, after the deposition and as we proceed toward trial, it is important to provide my physician clients with everything which has been compiled during discovery. This includes the depositions of all of the parties, and all of the experts. It includes all of the records and literature.

At trial, the defense has one distinct advantage. Present at counsel table throughout the trial, defense counsel has a built in expert, knowledgeable of the facts and of the medicine, and fully invested in the defense of the case: You. It is my opinion that the defense lawyer should leverage the situation to his best advantage, by providing you with all relevant information.

In doing so, the attorney has the right to assume that you will read and analyze the information provided to you. This will be time-consuming. Often, the information fills two or three banker's boxes.

To facilitate this exercise, it is best for the information to be provided to the physician-client as it is accumulated, rather than delivering all the boxes to the doctor's doorstep the night before trial. Communicate with your lawyer. Know what he intends your role to be at trial. Know what he intends to provide to you, and ask that it be sent to you sooner rather than later.

You must make yourself available to meet with your attorney to prepare for trial. This may take as much as a day or two, or longer. It will mean time away from your practice and your family. But the work must be done.

It is very important that you be present at trial preferably throughout the trial, but certainly as often as you possibly can be.

The plaintiff will be there. The jury will quickly understand that the plaintiff believes in her case and that she considers the proceedings important enough to her that she has placed all other aspects of her life aside to be present in the courtroom.

The jury is ordered to be in the courtroom. They are told they must arrive on time, they must be present everyday, and they must be attentive throughout the day.

They will expect no less from you. If you are not present, your absence will be noticed. Even if it is assumed that you are literally in surgery saving lives, the jury will nevertheless resent the fact that their lives and the important things that they do have been ordered to be put on hold, while you apparently are free to conduct your personal and professional life. That is not the image the defense wishes to portray. It is far preferred to portray to the jury from the outset that these proceedings, the jury's time and attention, and the outcome of this case is as important to you as it is to the plaintiff.

During the course of the trial day, the jurors will be watching everything which occurs in the courtroom. Do not be disruptive or inattentive. Keep your cell phone turned off, or at least on vibrate. Do not answer texts in the courtroom. If it is absolutely necessary, alert your attorney to the situation, excuse yourself from the courtroom (assuming this is permitted by the court), conduct the necessary business, and return to the courtroom.

The trial itself will proceed pursuant to the local rules of the jurisdiction, including any particular courtroom rules of your particular judge. Trial schedules vary significantly. Rarely will a trial judge devote his entire courtroom day or week to a pending trial. There is other business to which the court must attend. Rarely will trials proceed all day, Monday through Friday.

More often, the trial court will not be in session for trial on one or more days during the week. The court's trial schedule will be made known at the outset. Most courts provide attorneys with advance notice of their trial schedules. Ask your attorney on what days the trial will be in session, when you are expected to be present, and on what days there will be no trial (days on which the court is "dark"). This will help you plan your schedule as well.

Alert your attorney as soon as possible to any vacations or schedule conflicts that might impede your ability to be present during the trial. The attorney may be able to have the trial schedule altered to accommodate your schedule, but the likelihood of her being able to do so will be greatly diminished without advance notice.

Although practices vary, trials are typically scheduled to begin on Mondays. Your attorney will appear at trial at the appointed date and time. Often, the court will have scheduled more than one trial to begin on the same day. Most cases don't go to trial; they settle or are otherwise disposed of. Still, the court may have two or more cases ready to begin on the same day, or his courtroom may be occupied with an ongoing trial. Ask your attorney what the likelihood is of your case actually starting on the date assigned, so that you can attempt to accommodate your professional schedule.

Once your case is assigned to a specific courtroom, the attorneys and judge typically proceed with pre-trial procedural matters. This may take a small portion of the day, or it may take the entire day. Your attorney should be able to provide you with some preview of whether your personal attendance will be necessary in the morning of the first day of trial, in the afternoon of the first day of trial, or not until the following day.

Once the preliminary matters are completed, the judge will typically call up a panel of jurors who will then be interviewed by the judge and the attorneys to determine their suitability for your trial.

The jury selection process, called *voir dire*, is often time-consuming. Nevertheless, your attendance during jury selection is extremely important.

First, it is within the jury selection process that the prospective jurors make their first impression of the case. You don't want the jury's first impression to be that you are absent from the courtroom.

Likewise, jury selection is the first opportunity you will have to form your first impressions concerning each of the jurors. Observe the jurors. Observe their mannerisms and their willingness to make eye contact. Listen to their comments. Listen to their concerns about their own experiences with the medical profession. Your "gut feeling" about the jurors is important.

In most jurisdictions, your attorney will have the opportunity to excuse jurors without specifying a reason. These peremptory challenges are exercised based as much on *gestalt* as on any science. Your ability to evaluate the perspective jurors' response to the parties, the attorneys, the court, and the process is likely just as valuable as your attorney's. At the appropriate time, share your observations and thoughts. They might be important to the attorney.

Once the jury is selected, and this could take an entire day or longer, the attorneys for each party are invited to make an opening statement. The opening statement is not an argument. Rather, it is merely a summation of what the attorney believes the evidence will establish. Some attorneys use a broad approach. Other attorneys provide a detailed analysis of what they believe the evidence will show.

Listen to the opening statements. The plaintiff's attorney may well expose his intentions, which may provide you with additional information concerning what aspects of your testimony need to be better prepared. Do not comment or gesture or react to the statements. To do so is inappropriate and disruptive, and you likely will be admonished by the court.

Your attorney's opening statement will include what she expects the evidence to prove. Implicitly, she is telling the jury what she expects you to tell them when you testify. Listen to what she says. If there have been mistakes made by your attorney about the facts or the medicine, point it out *after* she completes her opening statement so that the errors won't be perpetuated.

The parties then begin presentation of the evidence. The plaintiff has the burden of proof and therefore goes first. The plaintiff's attorney may or may not call you in his case in chief (i.e., the legal term for the initial portion of the trial in which the plaintiff puts on his case).

If you are called to testify by the opposing attorney, he will be questioning you as an adverse witness. This will entitle him to ask you leading questions. Be respectful of the process. Answer the question which is asked. Do not insist on attempting to expand or explain your answers, except, as in deposition, by asking, "May I explain?" Direct your comments to the questioner, not to the judge. By asking the questioner if you can explain, you have once again placed him on the horns of a dilemma. If he answers, "Yes," he's inviting a narrative which will no doubt be adverse to his case. If he answers "No," the jury will infer that the lawyer is trying to hide the true facts from them.

The most common derogatory comment made by jurors about any witness is that the witness was evasive, argumentative, and non-responsive. Don't be.

If your attorney believes that additional testimony from you is necessary on any topic, she will be prepared to ask you those questions herself. Trust her to do so.

During the course of the questioning, the opposing counsel may read from your deposition. Do not try to object to this; it is his right to do so. Do not comment about the passage read by saying that it was taken out of context, etc. Rather, patiently and confidently await your opportunity to explain the answers when asked to do so by your attorney.

During the course of the testimony always direct your answers to the questioner, unless asked to do otherwise. Unduly directing your comments to the jury may appear patronizing and unduly solicitous. Looking to your own counsel during your answer may appear to be a sign of weakness, as if you are looking for help.

There are other specifics concerning how to present yourself as the best possible witness, which you should discuss with your attorney.

While other witnesses are testifying, be respectful of them as well. Do not gesture as if in disbelief. Do not be dramatic. Present yourself always as the respectful professional that you are. Ultimately, most cases are greatly influenced by the testimony of the physician-defendant. Direct, confident, and responsive answers are always appreciated.

The roles of the judge and jury in a trial are different. It is the jury's duty to determine the facts of the case. The judge determines the law of the case. The jury hears the relevant evidence, deliberates amongst themselves, and then responds collectively to the questions on the verdict form. Although the questions on the verdict form may have several variations or subparts, there are really three inquiries:

(1) Was the defendant negligent in the medical diagnosis or treatment of the plaintiff?; if so,
(2) Was the negligence of the physician a legal cause of injury to the plaintiff?; and, if so,
(3) What dollar amount of damages do you award to compensate the plaintiff for the injuries, which you have determined were caused by the defendant's negligence?

Most often, the case turns on question No. 1:

Was the doctor negligent in the diagnosis or treatment of the patient?

The plaintiff has the burden of proof with respect to each of these questions. Generally, this means that in order to prevail, the plaintiff must persuade the jury, by the evidence presented in court, that what he or she is required to prove is "more likely to be true than not true." The jury will also be instructed that "if, after weighing all of the evidence,… you cannot decide that something is more likely to be true than not true, you *must* conclude that the party did not prove it." (Emphasis added.) If the plaintiff has not proven that you were negligent (if, for example, the jury determines

that the evidence on this issue is evenly balanced), the jury must decide the issue of negligence in the favor of the defendant [6].

How then can jurors, who are not doctors, decide whether a doctor was or was not negligent?

The jury will be given jury instructions by the judge, which outlines their task and how they are to go about satisfying that task.

The court will instruct the jury on the doctor's duty to conduct himself or herself in accordance with the standard of care, and on what evidence the jury should consider in coming to this conclusion.

The basic standard may be expressed as follows:

> A surgeon is negligent if he or she fails to use the level of skill, knowledge, and care in diagnosis and treatment that other reasonably careful surgeons would use in similar circumstances. This … is sometimes referred to as "the standard of care." [7]

In directing the jury as to what evidence the jurors may consider when deciding whether the doctor did or did not act as other reasonably careful doctors would act under similar circumstances, a basic instruction is as follows:

> You must determine the level of skill, knowledge, and care that other reasonably careful surgeons would use in the same or similar circumstances, based *only* on the testimony of the expert witnesses [including the defendant] who have testified in this case. (Emphasis added.) [7]

In most circumstances, the standard of care is defined as a standard of conduct, not a standard of result. The fact that a patient has suffered an unexpected or unintended adverse consequence is not, in and of itself, evidence of negligence. Again, while the verbiage of any instruction on this issue to the jury may vary depending on the jurisdiction, a basic statement of the applicable standards is as follows:

> A surgeon is not necessarily negligent just because his efforts are unsuccessful or he makes an error that was reasonable under the circumstances. A surgeon is negligent only if he was not as skillful, knowledgeable, or careful as other reasonable surgeons would have been in similar circumstances. [8]

The jury typically also will be instructed that simply because the experts on either side differ on what their personal preference is concerning proper management of the situation or that reasonable alternative methods for diagnosis or treatment were available, does not necessarily mean that the physician's choice of one approved method over another, even if the defendant's choice, in retrospect, proved to be the wrong choice, was negligent. This tenet of the law can be expressed as follows:

> A surgeon is not necessarily negligent just because he chooses one medically accepted method of treatment or diagnosis and it turns out that another medically accepted method would have been a better choice. [9]

"A difference of medical opinion concerning the desirability of one particular medical procedure over another does not… establish that the determination to use one of the procedures was negligent" [10]. Likewise, "[m]edicine is not a field of absolutes. There is not ordinarily one correct route to be followed at any given time. There is always the need for professional judgment as to what course of conduct would be most appropriate with regard to the patient's condition" [11].

It is important for the physician-defendant to understand these various legal propositions and the significance of each of them.

In deciding whether or not the physician-defendant was negligent, the jury is to consider only the testimony of the experts. Ultimately, the jury's decision will come down to which party's experts were more persuasive. The court may also instruct the jury concerning how they might go about weighing the conflicting testimony of the experts. One such instruction is as follows:

> … [I]t is up to you to decide whether you believe the experts' testimony and choose to use it as a basis for your decision. You may believe all, part, or none of an expert's testimony. In deciding whether to believe an expert's testimony, you should consider:
> (1) the expert's training and experience;
> (2) the facts the expert relied on; and
> (3) the reasons for the expert's opinion. [12]

Additionally,

> If the expert witnesses disagreed with one another, you should weigh each opinion against the others. You should examine the reasons given for each opinion and the facts or other matters that each witness relied on. You may also compare the experts' qualifications. [13]

In short, the weight to be given an expert's opinion is to be determined not only by the qualification of the experts, but more specifically, by considering the reasons given for each opinion and the facts or other matters relied on.

The fundamental question is whether the physician-defendant acted reasonably under the established circumstances. The fundamental method used to invalidate an expert's opinion is to establish that the facts stated as the basis for the opinion are inaccurate, or incomplete. An opinion is of no greater value than the facts upon which it is based. An opinion without proper factual foundation must, necessarily, collapse.

In preparation for trial, therefore, as your own advocate in the case, you should be well acquainted with the identities and opinions of the experts on either side. You must likewise be acquainted with the factual basis for each of those opinions. And, you should be prepared to guide your attorney to the records which you believe discredits the factual basis of the opinions of your opposing expert and to the records which confirm and support the factual basis of the opinions of your own experts.

In addition, you should be prepared to tailor your own testimony, mindful of the value of testimony you give which contradicts the factual basis of the opposing expert and supports the basis of your own expert. Knowing the bases of the

opinions of the experts on both sides, and tailoring your efforts and testimony to contradict the plaintiff's expert and to support your own expert, is the best way that you can contribute toward a successful defense of your case.

In the proper situation, as noted above, it is not fatal to your case to recognize that alternative methods and diagnosis also existed. In fact, it may be beneficial for you to explain that you were aware of these alternative methods, and considered them, but ultimately selected your method for reasons on which you are prepared to elaborate. By being prepared to discuss (both in deposition and trial) your knowledge of alternative treatments and the rationale for choosing the course you chose after discussing the options with your patient, you are potentially providing your defense with the factual foundation necessary to promote the "alternative methods of treatment" defense.

Familiarize yourselves with the applicable legal standards and instructions used in your local jurisdiction. Doing so immediately before trial, and at trial, is valuable. Doing so at the commencement of the case, as early as your first meeting with your counsel, is far more valuable.

At the conclusion of the evidence, the attorneys will proceed with their summation of the case or final argument. Because the plaintiff bears the burden of proof, traditionally the plaintiff goes first, the defense attorney then makes his argument, and the plaintiff's attorney makes the rebuttal and final comments to the jury. It is within the court's discretion to instruct the jury either before or after final argument.

Once the evidence has been completed, and the jury has received the final arguments of counsel and instructions from the court, the jurors will then proceed into the jury deliberation room. The documentary evidence will be delivered to them for their consideration.

During the course of deliberation, the jury may ask questions which will be considered by the court and counsel and responded to. The jury may also request that the testimony of one or more witnesses be read back to them. In that case, depending on the jurisdiction, either the jury will be brought into the courtroom, at which time the court reporter will recite the testimony; or, the court reporter will proceed into the jury deliberation room and read the requested passages to them.

Some jurisdictions require that the jury decide the cases unanimously. Other jurisdictions require a so-called super majority, typically 3/4 of the jurors must agree to decide any single question. Once the requisite number of jurors have come to a conclusion, the jury is then returned into the courtroom and their verdict is announced.

Based on the factual findings, or verdict, by the jury, the judge then will enter judgment in favor of one side or the other. The jury decides the fact of whether or not the physician-defendant was negligent and records that decision on the verdict. With that factual question answered, the judge then decides the legal effect of that answer (decides who wins), and incorporates that decision into his decision in the form of a judgment.

After the jury returns its verdict, either party to the case may ask that the jury be "polled." In that case, each individual juror will be asked his or her response to each of the questions. In this way, it will be confirmed that the requisite number of jurors have responded and agreed on the answer to each question so that it is a competent verdict.

Even if the case is won at trial, it will undoubtedly exact a huge toll on you personally and professionally. Jury trials are extremely expensive in terms of time, effort, and money. The jury system is not perfect, but in my experience, far more often than not, the jury gets it right.

Teaching Points

1. At trial, you are your attorney's best technical asset.
2. In preparation for trial, obtain copies of all relevant records and depositions, especially your deposition and all expert depositions.
3. Analyze the data with a focus on knowing the circumstances as they existed when you treated the patient; point out where the plaintiff's expert is wrong in his assumption of the facts, and be prepared to support the factual basis of your expert's opinion.
4. Know the basic legal standards that will be applied to define "medical negligence," so that you can tailor your testimony to meet that standard.
5. Understand the significance of "alternative methods" of treatment.
6. Alert your attorney to any schedule conflicts as soon as possible.
7. Consult your attorney regarding when exactly the trial is set to begin and when your personal presence is necessary.
8. Be present at trial, including jury selection.
9. Be cognizant of the opening statements of both sides; it will provide you with valuable insights relating to the proposed testimony.
10. Do not react to testimony with gestures or speech. Don't be disruptive of the proceedings or of your attorney's efforts.
11. When testifying, direct your responses to the questioner, not to the jury, the judge or your own counsel.
12. Do not expand your answers beyond the question asked, unless you have asked to do so, e.g., "May I explain?"
13. Recognize that preparation at each stage requires knowledge of the process and the respective roles of attorney and client; and that preparation is the key to achieving your personal *best result*.

Concluding Remarks

It has been the goal of this work to provide a primer for those not acquainted with the litigation process. It is intended as a guide to facilitate timely and effective communication

between physician-defendants and their attorneys. It is further hoped that by affording the physician-defendants a better understanding of the process, they can come to a better understanding of what is expected of them as clients, of what they can expect from their attorneys, and of how the attorney and client can work together toward managing expectations, minimizing anxiety and frustration, and formulating a strategy to achieve the *best result* available under the circumstances.

Communication is the key. Meet early. Discuss the case regularly. Know what is expected of you, and when. Know when your personal presence is likely to be necessary. Do your homework; and make yourself available.

If you prepare to succeed, the likelihood of achieving your *best result* will improve exponentially.

Surgical Education

Bradley J. Champagne and Helen M. MacRae

Key Concepts

- The dramatic changes in healthcare and surgical training have forced educators to adopt a new approach with an emphasis on outcomes and competence.
- A major impediment to surgical education is the lack of hospital or administrative support. The fiscal solvency of most academic institutions is more dependent on a high volume, cost-effective, and efficient department of surgery than ever before.
- Work hour restrictions are another major impediment to training. Residents must now make the most of all learning opportunities, as learners no longer have the "luxury" of unlimited clinical immersion.
- Simulation and surgical skills laboratories will, over time, have an increasing role in training for general technical skills, such as knot tying and procedure-specific skills. The successful application for procedure-specific training with virtual reality systems has recently been demonstrated in several trials.
- Competency-based medical education (CBME) is "an approach to preparing physicians for practice that is fundamentally oriented to graduated outcome abilities and organized around competencies derived from an analysis of societal and patient needs."
- To meet ACGME requirements, multiple assessments will be required to ensure milestone progression along all of the competencies. Assessments that are commonly used include the In-Training Evaluation Report (ITER), 360-Degree evaluations (including patient surveys), chart stimulated recall, oral examinations, multiple choice examinations, portfolios, and simulations and models.
- Post-graduate medical education now demands an increase in support at a time of waning resource allocation and protected time. In this climate, education often takes a backseat.

Introduction

Major changes in the way we train surgeons are occurring in several areas. One of the developments in medical education over the past decade which will have the largest impact on graduate education has been a shift in the focus from the processes of education to the outcomes of education, or development of competencies and attainment of milestones [1, 2]. This focus on outcome assessment and milestone achievement will require that training programs make better use of other advances in surgical education, such as simulation. Simulation-based training has also been used to help accelerate learners' growth in knowledge, skills, and attitudes, prior to entering the clinical arena, and the literature evaluating the use of simulation-based learning will be examined. As well, a competency-based framework requires that multiple formative and summative assessments be used to ensure that the required outcomes are achieved. To help in assessing the outcomes of training, practical methods that are available to assess learners in the six broad competencies of the Accreditation Council for Graduate Medical Education (ACGME) outcome project will be discussed. Finally, we will use examples from the Colorectal Surgery Milestones from the American Board of Colorectal Surgery and ACGME milestones project to demonstrate how one can integrate simulation and evaluation into a colorectal residency to help ensure all residents achieve milestones in a timely fashion.

Challenges to Surgical Education

Surgical education has seen many challenges over the past 2 decades. Surgical care is in an era of increased emphasis on accountability and outcomes [3]. Physicians need to be better trained to weigh the cost and value of diagnostic and therapeutic interventions, as there is more focus on cost

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_69

containment [4]. At the same time, there is a stress on patient safety and error mitigation [5]. Work hour restrictions require that residents must make the most of all learning opportunities, as learners no longer have the "luxury" of unlimited clinical immersion [6]. With fewer duty hours, some learning has moved away from the clinical environment to simulated environments to ensure learning objectives are met, and so that residents can make the most of learning opportunities presented to them in the limited hours available [7]. All of these factors impact on the ability to rely on the traditional Halstedian model of graduate medical education, whereby learners would iteratively learn to deal with most surgical problems through stepwise progression in training, enhanced by a large volume of exposure. Although this model served surgical education quite well for the past century, many would argue that it led to deficits in knowledge for practitioners, with "lacunae" of knowledge, or skills deficits. Because passing through the system was based on meeting an overall minimum standard, surgeons could graduate without adequate exposure or expertise in some clinical areas. Furthermore, insufficient attention to areas such as quality improvement, the use of new technologies, and ability to respond to shifting patient expectations, patient demographics, and health care delivery systems led to practitioners potentially unable to adequately serve the needs of the population [3].

These challenges have created a monumental task for trainees and educators that must be supported from the top down. Contemporary post-graduate medical education demands an increase in support at a time of waning resource allocation and protected time. As we move away from a Halstedian model, and try to make more of each teaching hour available, the teaching demands on faculty increase. Administration must recognize this when allocating resources, or resident teaching will suffer. At each academic institution, the vision of education imparted from the department chair and or administration must be articulated and clearly outlined. Unfortunately, allocating additional time for surgeons to teach residents, both inside and outside the operating room, has not been a major priority for administration, but rather, almost a foreign concept. This is, and will continue to be, a major impediment to training the surgeons of the future. More recently, several institutions have also exchanged their salary-based system for faculty with an incentive-driven compensation plan for increased volumes. This alteration may further impact on resident training. In essence, academic surgeons are being asked to do more with less clinically, while maintaining their research interests and training responsibilities. These changes have the potential to foster a pessimistic and apathetic attitude amongst academic surgeons in regards to training, however, we must recognize the critical role that our residents play in patient care. Without residents, patient volumes would diminish, our academic aspirations would wane as we would have even less protected time, and our lifestyles would dramatically change. Academic surgeons should ideally have their clinical volumes evaluated as a 90 % FTE (Full Time Employee) with 10 % allotted for teaching. This argument can be strengthened by numerous publications demonstrating that cases with trainees take significantly longer [8]. Without this fundamental change, many may argue that they are not being paid to teach. This may be true in principle, but faculty who feel they derive no benefit from residents should take their own patient calls on the floor, do consults in the emergency room, enter orders on patients, and take over all of the other duties residents perform. Irrespective of the frustrations that exist with administration, the relationship of the trainer and trainee is give and take. Trainees are also often frustrated with the system, and in general, are trying to become the best surgeons possible. Remembering that the deficiencies in reimbursement, time commitment, and resources allocation lie more with the system than with the residents can help faculty to deal with some of the frustrations inherent in teaching.

Competency-Based Medical Education

A fundamental change in residency may be required to deal with many of the changes that have evolved. A major focus of new models in post-graduate medical education is a focus on demonstration of attainment of competency, with a shift away from time and objective-based training to a competency-based framework. Examples of this change in culture can be appreciated in different Health Care Systems. The Outcome Project of the ACGME in the USA [1] and CanMEDS Competency by Design in Canada [2] focus on outcomes and abilities of the learner, with explicit competencies as the organizing principle of curricular design. With the Next Accreditation System (NAS) of the ACGME, and Competency by Design within the Royal College, the focus of accreditation will move away from assessing the objectives and processes of education, and towards assessing the outcomes of education. Programs will have to demonstrate that their trainees have acquired the knowledge, skills, and attitudes of the competencies required for safe and effective practice. Three concepts that have been forwarded in this move towards competency-based education are competencies, milestones, and entrustable professional activities (EPAs). These build upon each other.

Competency-based medical education (CBME) is "an approach to preparing physicians for practice that is fundamentally oriented to graduate outcome abilities and organized around competencies derived from an analysis of societal and patient needs. It de-emphasizes time-based training and promises greater accountability, flexibility and learner-centeredness" [9].

Competencies integrate knowledge, skills, and attitudes. They are observable and can be measured. Ideally, learners will demonstrate progressive attainment of competencies as they move from novice to expert, assembling competencies like building blocks as they develop knowledge, skills, and attitudes. These building blocks are the stepping stones to

milestone attainment. By explicitly identifying milestones that learners should achieve, competency-based education helps move learners along the pathway to excellence. A milestone is a defined, observable marker of an individual's ability along a developmental continuum [1]. Milestones are useful for planning and teaching, as frequent assessment of the milestone attainment of residents allows the program to assess where the learner is, where deficits might be, and plan learning opportunities accordingly. Although a competency-based curriculum is generally planned in terms of milestones, the eventual goal of a post-graduate training program is to ensure that graduates can carry out the essential tasks of the specialty. An Entrustable Professional Activity (EPA) is an essential task of a "discipline" that an individual can be trusted to perform independently in a given context [10]. Based on the demonstration of sufficient competence, the supervisor feels the resident is able to do the task independently. EPAs can be used for overall assessment and decisions as to when residents are ready for independent practice. Typically an EPA integrates multiple milestones. EPAs are the tasks or activities that must be accomplished (for example, manage a patient with rectal cancer), whereas milestones are the abilities of the individual on a continuum (for example, able to "assess imaging information and justify a TNM-based treatment strategy").

A central tenet of CBME is that learners must assume greater responsibility for their own learning and the assessment of their learning than in traditional approaches. Learners become responsible for developing a learning portfolio, and collecting formative and summative assessments to demonstrate they have achieved the desired outcomes. Thus, the competency-based framework places more onus for ownership of learning on the trainee, who must ensure they are actively seeking experiences to enable them to achieve milestones. They must also demonstrate, through assessment tools, their achievement. By putting more onus on the learner to take charge of their own development during post-graduate medical education, and focusing on the need to seek out learning opportunities and ensure milestones are reached, the hope is that competency-based education will better ensure that learners have the skills needed for lifelong self-directed learning and continuing professional development as they move along the medical education continuum into independent practice.

Strategies Outside of the Operating Room

In addition to increased accountability, the current paradigm of surgical education also advocates non-clinical, or ex-vivo, methods of training to improve clinical performance by providing practice opportunity in a safe environment. Surgical educators uniformly agree that technical skills exercises and training in the surgical skills center, designed specifically to allow the resident to optimize their operative learning and experience, will play a critical role. The American Board of Surgeons Resident Review Committee has made it mandatory that all surgical training programs have a means of training outside the operating room [11]. Therefore, simulation and surgical skills laboratories will, over time, have an increasing role in training for general technical skills, such as knot tying and procedure-specific skills (Figure 69-1). In its broadest terms, simulation is defined as the act of imitating the behavior of some situation or some process by means of something suitably analogous. Therefore, the majority of non-clinical technical skill exercises, regardless of the model, qualify as "simulation." Current platforms vary considerably in level of fidelity, from box trainers to technologically advanced Virtual Reality (VR) programs.

FIGURE 69-1. Pelvic Pouch Skills Lab Station at the Institute for Surgery and Innovation at Case Medical Center, Cleveland, OH.

Simple box trainers for laparoscopic skills such as the validated MISTELS (McGill Inanimate System for Training and Evaluation of Laparoscopic Skills) are effective at the junior trainee level and should be readily incorporated into any laboratory curricula. VR platforms have also been shown to improve performance in the operating room. More specifically, dedicated practice with VR simulators have correlated with improved operative times, and efficiency of movement for clinical laparoscopic cholecystectomy. Seymour et al. evaluated 16 residents of varying levels and compared clinical laparoscopic cholecystectomy outcomes between residents who received training on a VR system versus those who did not. They found no difference in baseline assessments between the two groups, but found that residents who trained on the simulator were faster, made fewer errors, and were less likely to injure the gallbladder in the operating room [12]. Grantcharov et al. also evaluated 16 residents and compared training on a VR simulator to a control group. They found improved economy of movements and fewer errors in residents who were trained on a VR simulator [13].

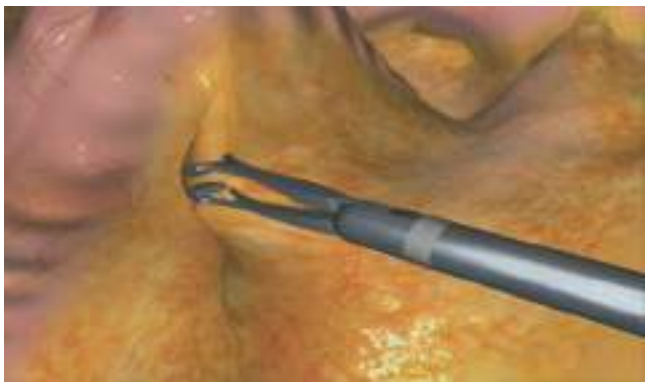

FIGURE 69-2. Virtual reality laparoscopic sigmoid module (Simbionix, Cleveland, OH).

Beyer and colleagues evaluated transfer of skills from simulators to the operating room using the Global Operative Assessment of Laparoscopic Skills (GOALS), a validated laparoscopic skills assessment model [14]. Their prospective trial involving 19 residents found improved GOAL scores in residents who were trained on a simulator when compared to those who were not.

Simbionix (Cleveland, OH) offers a VR (LAP Mentor) model for laparoscopic sigmoid colectomy that more accurately portrays resection in the operating room than previous hybrid systems [15] (Figure 69-2). Evidence of face, content, and construct validity have been established for general procedures with the LAP Mentor VR system [16]. More recently, evidence of construct validity was established for certain metrics, specifically with the laparoscopic sigmoid model [17]. In this study, the metrics assessing the instrument path length, the accuracy of the medial peritoneal mobilization, and the quality of the IMA dissection demonstrated the strongest ability to discriminate between general surgeons and expert colorectal surgeons. However, construct validity was not established for technical errors, as the model could not differentiate between experts and novice surgeons using this metric.

The successful application for procedure-specific training with VR systems has recently been demonstrated in several trials. Calatayud et al. tested "warm up" with a VR system prior to laparoscopic cholecystectomy and found that Objective Structured Assessment of Technical Skill (OSATS) global rating scales were better after practice [18]. Palter and Grantcharov developed a comprehensive ex-vivo preoperative training curriculum that improved performance for LC [19]. This study involved preparation with simulation, cognitive training, and participation in a cadaver lab. In this study, residents were PGY-2 through 4, having previously completed FLS and possessing some advanced laparoscopic experience. Using an entire curriculum that addressed multiple aspects of performance, which included procedure-specific simulation, overall laparoscopic colectomy skills were enhanced. While this impressive approach was successful, having all trainees perform this labor intense program prior to operative procedures may not be practical. The cost and time requirements of this model are likely not likely sustainable in most training programs outside of a trial. However, this well-designed trial most importantly demonstrates that preparation can improve performance for laparoscopic colon resection. More recently, Singh et al. [20] utilized a validated virtual reality laparoscopic cholecystectomy curriculum to study the role of video-based coaching in teaching laparoscopic skills. The authors found that video-based coaching enhanced the quality of laparoscopic performance on both virtual reality and porcine models. Simulation curriculums for endoscopic procedures have also been studied and found to be effective. Williams et al. compared general surgery residents to gastroenterologists in their ability to perform colonoscopy after the trainees completed an endoscopic simulation-training curriculum. They discovered that the trainees were capable of achieving quality measures equivalent to faculty gastroenterologists [21]. Furthermore, Iordache et al. recently validated a cadaver model with simulated training to place endoscopic colonic stents. They found that the model had reliability and evidence for construct validity [22].

Each academic institution may choose to incorporate one of these preparation models or a variation on this theme. The VR studies for basic laparoscopic skills training have routinely incorporated a proficiency-based model, whereby trainees have proficiency targets to meet, rather than time on task as a training goal [23].

Understanding Competency-Based Medical Education

Traditionally, residency has been primarily time-based, with time spent on rotations used as a surrogate for competence. In a pure CBME model, demonstration of defined competence in a time-free model would be used. This time-free approach is usually not practical, as rotations need to be somewhat structured, and learners gain competencies at very different rates. Thus, a hybrid model, in which learners move through rotations and other structured learning approaches (such as simulation-based learning), but only graduate once milestones are met, is advocated. Summative assessments are used to ensure competencies are attained, and residents are progressing satisfactorily with milestone achievement. Teachers ensure learners have the necessary learning opportunities, and use real time direct observation to evaluate achievement.

Carraccio [24] has compared traditional time-dependent models of curriculum development to pure competency-based curricula, which are time free (Table 69-1). In a time-dependent model, the main organizing structure would be time spent on rotations, as opposed to progression of competence. Rotations, with academic half days and formal teaching

TABLE 69-1. Comparison of competency-based education and traditional curricular models

Variable	Traditional model	Competency based
Goal of educational encounter	Acquisition of knowledge	Application of knowledge
Responsible for driving process	Teacher	Learner
Assessment	Emphasis on summative	Emphasis on formative with ongoing feedback
Assessment tools	Indirect, proxy assessment	Direct assessment, observation of real tasks of profession
Evaluation standards	Norm referenced (in relation to peers)	Criterion referenced (in relation to objective measures)
Rotations and program completion	Fixed time	Variable time based on demonstration of competence

Adapted from Carraccio C, Wolfsthal SD, Englander R, Ferentz K, Martin C. Shifting paradigms: from Flexner to competencies. *Acad Med*. 2002;77:361–7 [24]

are the main structures of this type of curriculum, with the learning goals being predefined objectives of training. In-training assessments are used to ensure that rotations are passed, but are usually completed at the end of a pre-defined time. Teacher's roles are primarily supervision and teaching, and learners provide service, attend academic sessions, and study for exams. In a time-free model, progression of competence, rather than rotations is the main organizing structure, with rotations seen as one of many resources to aid learning. Milestones are the learning goals, and the role of timed rotations is irrelevant. Assessment is focused on documentation of milestone achievement, with summative assessment used to ensure attainment of competencies. Teachers supervise, teach and also directly observe in clinical settings to ensure competencies are achieved. Learners must take ownership of their learning, plotting a course for progression of competence through a variety of learning activities. Once the competencies have been demonstrated to have been met, learners move on. Realistically, most programs will use a hybrid of these extremes, as development of a pure competency-based model is difficult to structure and monitor.

Some of the major challenges when thinking of implementing CBME are similar across specialties. In Internal Medicine, three of the major challenges identified were: incorporating practice-based learning and improvement and systems-based practice into the curriculum; evaluating residents across the competencies; and ensuring advancement based on competence, rather than time [25]. All of these will be major challenges for colorectal programs, which are short compared to most residencies, especially as the incoming residents may already require some degree of remediation [26]. However, practice-based learning and improvement can be incorporated into the everyday clinical context. For example, residents can be involved in quality initiatives, identifying and pursuing improvement processes, structured morbidity and mortality conferences, and provided with opportunities to identify gaps or improve measures. Furthermore, systems-based practice can be best addressed during transitions in patient care, from inpatient to outpatient and other settings.

Evaluating residents across all of the competencies is also challenging. A discussion of assessment modalities follows, but in general, direct observation in the clinical setting will likely be the most feasible method of assessment for a small program, as more structured assessment tools, such as standardized patient encounters, and performance-based assessments can be expensive and difficult to administer for only a few residents. The challenge for programs is to ensure they are documenting enough evaluative feedback to ensure milestone assessment is reliable and valid.

Assessment of Performance

Assessment of performance during post-graduate training can be either formative (meant to give feedback, or direction to learners) or summative (high stakes, end-of-training, such as certification decisions). Within a CBME framework, assessment of learning becomes vital to the entire process, and the assessment framework must be robust enough to ensure that developmental milestones are accurately assessed. Formative assessment is done frequently, to enhance reliability and validity, and is based around real clinical work. This allows for performance to be assessed across all of the competencies.

In a CBME model, the assessment process must become "more learner driven, learner focused and formative" [26]. Multiple types of assessment tools are available to help the Clinical Competency Committee (CCC) [27] make valid judgments about the milestone progress of their learners. To meet ACGME requirements, multiple assessments will be required to ensure milestone progression along all of the competencies. Programs will have to use a variety of assessments to provide their CCC with robust data.

Assessments that are commonly used include the In-Training Evaluation Report (ITER), 360-Degree evaluations (including patient surveys), chart stimulated recall, oral examinations, multiple choice examinations, portfolios, and simulations and models. Table 69-2 outlines these commonly used tools, and what competencies are best evaluated through their use. Evaluations used specifically for technical skill assessment in colorectal surgery include Performance Based Assessments (PBAs), operation-specific rating scales (e.g., those used for laparoscopic colectomy), outcome measures (e.g., cecal intubation rates), and final summative assessments [e.g., the Colorectal Objective Structured Assessment of Technical Skills (COSATS)]. Each of these evaluation tools will be briefly discussed.

TABLE 69-2. Evaluating outcomes in the core competencies

Core competency	Competency based
Patient care	Direct observation forms, oral examination, chart-stimulated recall, ITERs, 360-degree evaluation, procedure/case logs with reflection, PBAs, OSATS global ratings, portfolios (OSCEs)
Medical knowledge	MCQs, oral examinations, written examinations, chart stimulated recall, direct observations, portfolios
Practice-based learning and improvement	Portfolios, QI project, 360-degree ratings, MCQs, oral examinations, direct observations
Interpersonal and communication skills	360-degree, patient surveys, direct observations, ITERs
Professionalism	360-degree rating, patient surveys, oral examination, direct observation, ITERs
Systems-based practice	360-degree evaluation, direct observations at care transitions, patient surveys, portfolios

ITER in-training evaluation report, *OSCE* objective standardized certification examination, *MCQ* multiple choice questions, *PBA* performance based assessments

In-Training Evaluation Report

Assessment during post-graduate training has traditionally relied on the ITER. The ITER has the positive attributes of theoretically being comprehensive, being able to assess across all of the competencies, and being relatively easy to use, even in small programs, such as colorectal surgery. However, although in theory ITERs have the potential to give feedback on real world performance, the way in which they are operationalized in many programs make them suboptimal. Often, they are completed long after the training period, when recall may not be ideal. Assessors often use the "above average" portion of the form almost exclusively, and are reluctant to fail residents. Because of the failure to use the range of marks, the reliability of ITERs has been poor. As well, as a formative tool, the ITER often does not provide trainees with meaningful data on their own strengths and weaknesses. However, in terms of utility as an assessment tool, ITERs have many positive characteristics. They can be reliable, especially if multiple assessors are used to complete the ITER [28]. Qualitative and narrative components on an ITER, if based on specific traits with formative feedback, rather than generalities, can be very useful, and have been shown to be a predictor of overall and long-term competence [28]. Unfortunately, the educational impact on the learner is poor, especially if ITERs are completed long after the fact, without the opportunity for learners to discuss and reflect on areas needing improvement, however, if done on a more frequent basis, with formative feedback, while residents can still act on the results, ITERs have the potential to have a positive educational impact. They are cost effective, and have good acceptability to learners and assessors, as they theoretically are based on actual clinical performance. The challenge, then, is how to improve the ITER as an assessment tool to ensure all of the theoretical positive attributes are achieved.

ITER report quality can be improved with structured feedback to faculty on their ITER completion. Faculty overall feel that ITERs are worthwhile, however, in a study on faculty perspectives on the ITER, Watling et al.[29] found that evaluators felt their ability to produce a meaningful approach to ITERs was compromised by time constraints, lack of continuity between educational assignments, and the challenge of giving negative feedback. These areas need to be addressed in order to improve ratings. Engagement of faculty and residents in the ITER process is a critical factor in ensuring the ratings are improved. Thus, overall ITERs have many of the attributes required for a useful assessment tool, but programs must ensure faculty and residents are engaged in the process in order to get the most useful ratings. They likely will remain an important component of the evaluation system, but perhaps will become a committee-driven evaluation, and may better employ milestones and their assessment in the future.

Mini-CEX

The mini-CEX was developed by the American Board of Internal Medicine as a workplace-based assessment tool that would be feasible to implement in the real clinical setting, be useful for feedback, and give reliable data [30]. In the mini-CEX, the trainee is responsible for selecting a clinical encounter, where they will ask an assessor to observe them in the real patient setting. Thus, a snapshot of the doctor–patient interaction is observed. The assessor collects information on the encounter on a structured evaluation form, with immediate feedback to the resident on their performance. Trainees are responsible for selecting from a range of problem groups and assessors, so over time, they have a collection of assessments in their learning portfolio, leading to more stable (reliable) ratings. History and physical examination skills, communication, professionalism, organization, and efficiency, as well as overall clinical care are covered on the mini-CEX.

An instrument for assessment of surgical skills, with many aspects similar to the mini-CEX, was developed by a group in Ottawa [31]. This tool can be used by surgical programs to help evaluate many of the items important for surgical management.

360-Degree Evaluation

The 360-Degree evaluation is a measurement tool completed by multiple people, with different perspectives, who each interact with the resident. Patients, nurses, allied health personnel, peers, subordinates, and other related specialists might all complete surveys. Generally, these are best used for evaluation of competencies such as interpersonal and

communication skills, as well as professionalism. Practical considerations involve the logistics of distributing and collecting the forms (though online programs exist), and ensuring the evaluators are providing reliable data and not simply using this as a "gripe" session. It is important to assess how many of the evaluations being used are needed for the data to be reliable in order to keep the administrative burden acceptable. Usually, 10–20 completed forms are needed for reliable data. Studies in different domains suggest that 360-Degree forms correlate reasonably well with preceptor as well as self-reports of performance [32].

Oral Examinations

The oral examination has traditionally been used to assess clinical judgment. A structured oral examination is likely best to ensure reasonable reliability for formative or summative assessment. Medical knowledge, patient care, interpersonal and communication skills, and to an extent, professionalism can be assessed on an oral examination if it is well structured. As the structured oral remains an important component of board examinations, it is useful to provide residents the experience of participating in this type of assessment. In terms of utility, a structured oral has reasonable reliability and validity, is educational and acceptable to learners and other stakeholders, and is cost effective. Many of these properties will likely ensure it continues to be used for high stakes evaluation for the foreseeable future, thus, it should remain a part of the assessment toolbox for residency programs.

Portfolios

A learning portfolio is an important assessment tool in a competency or outcome-based learning framework [33]. The learner is responsible for developing the portfolio, and providing evidence of learning and achievement related to the competencies that have been mastered. A learning portfolio might include items such as self-evaluations, articles related to specific outcomes, presentations they have made around a topic, and results of both formative and summative assessments such as the mini-CEX, CARSITE examination, or oral examinations, all helping to support promotion decisions. Ideally, this learning portfolio would follow the individual into independent practice, and become part of maintenance of certification.

Technical Skills Assessment

Logbooks and Case Numbers

Logbook numbers can be seen as a surrogate for technical skill assessment. Although increased numbers of cases are associated with improved outcomes, the learning curve varies greatly between trainees, as does the number of cases required for proficiency [34]. Case numbers, other than identifying deficiencies, do not give meaningful feedback to residents on where they need to improve. However, they are useful for training programs to assess the operative experience provided to their residents, and to identify potential deficits.

Procedure-Based Assessment

Procedure-based assessments (PBAs) are completed via direct observations of entire operations [35]. The assessment covers consent, the preoperative planning, preoperative preparation, exposure/closure, intraoperative technique, and postoperative management. The United Kingdom has the most experience with using PBAs, where they are required for many technical specialties. For colorectal surgery, the Operative Competency Committee of the ASCRS has developed PBAs for several technical areas, which are available on the program director's website.

Because the PBA captures performance in a "real-life" environment, it is an ideal form of evaluation to demonstrate milestone achievement. However, the feasibility of its use as a high stakes assessment is questionable, as residents cannot be left to "fail" the examination. Within a competence-based curriculum, however, PBAs used formatively could help provide evidence of milestone achievement.

Simulation/Virtual Reality in Technical Skill Assessment

Simulation-based assessment can be used to assess many areas of competence, including professionalism [36], team-based skills [37], patient communication and interpersonal skills [38], and technical skills [39], Realistically, the use of these types of simulations will likely be in primary residency programs, where the larger number of residents justify the infrastructure and development costs required.

Simulation of technical procedures can include non-live animal models, synthetic tissue, computer-based models, cadaveric tissue, live animal, and hybrid platforms. An example of a simple model for basic technical skill assessment is the MISTELS system used in the Fundamentals of Laparoscopic Surgery program [40]. Virtual reality simulators have also been used for more complex skills, notably, simulators for colonoscopy and for laparoscopic colectomy. A recent Cochrane review [41] found that VR simulation led to improvements in operative time and "performance," but the impact on patient outcome was unclear.

GAS and LCAT of the National Training Programme in England

The National Training Programme (NTP) for Laparoscopic Colorectal Surgery in England used the global assessment scale (GAS) for feedback [42] as part of the training program.

Once a trainee within the program was deemed proficient, DVD recordings of two independently performed cases were submitted and reviewed by two blinded accredited assessors, using the laparoscopic competency assessment tool (L-CAT) [43]. The L-CAT is comprised of a 16-item marking sheet (4 task components for each of the 4 domains), incorporating 22 items identified. The tool was shown to perform well, with excellent reliability and evidence of validity. However, the examinees were surgeons in practice who performed their cases independently, thus the tool might not be suitable for a residency training program where intervention must occur for poor performance.

Colorectal Objective Structured Assessment of Technical Skills

The COSATS [44] exam is an assessment tool developed for summative assessment of colorectal technical skills. It is a derivation of the OSATS examination [39], which has been used in many specialties. In the COSATS, the candidate performs tasks specific to colorectal surgery, using a combination of virtual reality and bench models to simulate the selected skills.

Performance is assessed at each station using a task-specific checklist and a global rating scale, and pass–fail decisions are made based on the performance across eight stations. To date, reliability and evidence of validity are very good to excellent for a high stakes assessment. However, the COSATS is best seen as a summative assessment, as the feasibility of individual programs developing and setting up this examination for a few residents at a time is questionable.

Global Rating Forms

The global rating scale of the OSATS, and modifications of it, such as the GOALS [45] and the GAGES [46] to assess endoscopic skills, have been used to assess residents' technical skill in the operating room and in endoscopy, and to assess surgeons in practice [47], all with good evidence of reliability and validity. The global rating form is a relatively straightforward tool to use to collect a series of assessments on the operative skills of residents.

In summary, programs will need a variety of assessments to gather the evidence required by a clinical competence committee to make decisions on milestone attainment by their residents. Resident portfolios will likely become an important component of resident assessment, and shift some of the onus for collecting and collating evidence of competence attainment on the learner. These portfolios could then be carried into practice to aid in the maintenance of certification.

How Can CBME Be Applied to Colorectal Residency Training?

Colorectal milestones have been developed by the American Board of Colorectal Surgery and the ACGME. Residents are coming into programs with varying degrees of experience and competence, thus it is likely important to assess their starting point (along the milestones early in their residency) to ensure there is time to address areas of deficiency within a short training period. Deficits in technical or other skill sets need to be diagnosed as soon as possible within the training program to ensure adequate progression along the milestones occur.

An example of a Colon and Rectal Surgery Milestone is the Patient Care for Rectal Cancer. Multiple competencies related to rectal cancer care are included in the milestones, including imaging, choice of operating, surgery, and postoperative management and surveillance. For one of the components of competence, an entry level resident would be expected to list some imaging options for TNM staging. This competency would be relatively easy to assess with a quick written or oral examination. As residents progress, they are expected to be able to formulate strategies for imaging the rectal cancer patient and interpret the results. This likely would be taught in the program in several ways, including seminars or readings on imaging of rectal cancer, coupled with multidisciplinary rectal cancer rounds, where imaging is reviewed with radiologists, and other strategies for imaging might be discussed. In contrast, Level 4 (graduating resident) would expect that the resident is able to assess imaging information and justify a TNM-based treatment strategy. Again, this is currently done to an extent in multidisciplinary rectal cancer rounds; however, for a competency-based curriculum, the resident would have to gather data to show that they had been assessed on this competence. A direct observation of the resident's performance in cancer rounds, an oral examination, or a case write-up in which imaging is used to justify a TNM-based treatment strategy could all be used to assess the resident, and demonstrate competence in this area. The technical components of competence could be assessed with the COSATS global rating scale, or with a PBA for low anterior resection. Multiple components of the patient care competencies would be taught on the oncology rotation, or in the clinical setting, in rounds and during direct patient care. Overall, a move to a competency-based curriculum requires assessment to demonstrate that the resident is mastering the component pieces of rectal cancer patient care, and ensuring they move along the milestone progression expected of them. Assessment in a patient care setting would be expected for many of the components.

As the milestone committee meets, the evidence of competence assessment would be reviewed, and the milestone achievement marked for the resident. If there are competencies that are following below expected, targeted learning interventions towards these areas would be implemented.

For example, if a resident is noted to be deficient in some of the operative components, they could spend time in the simulation center practicing enabling skills for the procedures. The program would then try to ensure they have increased exposure to rectal cancer cases, preferably with known strong clinical teachers, allowing them to use their clinical time for refinement and milestone progression. Medical knowledge deficits identified early might lead to a structured reading program, or use of resources such as CARSEP or CREST.

Residents should develop a learning portfolio, which would include, among other things, direct observation assessments, self and other identified areas for improvement, quality improvement initiatives, and their case log information. Reflection on cases, especially in areas of difficulty, might also be helpful. The learning portfolio allows for the clinical competence committee to have multiple sources of information on the resident, enabling more accurate milestone assessments. For the resident, it allows them to see areas for improvement, enhancing self-reflection, and movement towards excellence.

Conclusions

CBME has arrived and will be an integral part of surgical training. As surgeon educators, we must strive to implement these measures in the most effective way possible and resist the urge to "check the boxes." Furthermore, we must take responsibility to make trainees understand the importance of both maximizing their learning experience for each case and becoming immersed in the learning environment outside of the operating room. Lastly, we must resist some of our own selfish interests and decide where the education of trainees falls on our priority list. In his essay on leadership [48]. John Maxwell recites, "The Law of the Big Picture" as "People do What People See." Therefore, it is unlikely for residents to prepare for cases well if they are not receiving instruction during the case or feedback after from disinterested faculty. Trainees must know and perceive that their trainers have a sincere interest in their education, or they will question the sincerity of the feedback and evaluative comments they receive. Although a move to a focus on the outcomes of education in many ways seems daunting, it is educationally sound, and, by moving some of the onus for improvement onto the learner, will hopefully improve lifelong learning in the profession.

Maintenance of Certification: Current Status and Future Considerations

Jan Rakinic and W. Donald Buie

Key Concepts

- Approximately 6–12 % of physicians "fail to meet professional standards of practice" as defined by deficits in knowledge, disruptive behavior, systems problems impeding physicians' care of patients, increasing physician age, problems unrelated to medical care (i.e., licensure issues or allegations of insurance fraud), physical illness, psychiatric illness, and substance abuse.
- The American Board of Colon and Rectal Surgery (ABCRS) ended time-unlimited certificates in 1989, and began issuing certificates that required diplomates in Colon and Rectal Surgery to pass a secure "recertification" examination every 10 years intended to demonstrate continued mastery of content sufficient for specialty practice.
- Parts I (maintenance of unrestricted license and good professional standing), II (lifelong learning and self-assessment), and IV (practice performance assessment and improvement) of the Maintenance of Certification (MOC) were designed to run concurrently in repeating 3 to 5 year cycles, with successful performance on the Part III secure specialty examination required at or about every 10 years to maintain specialty certification.
- Part II and Part IV of MOC continue to evolve, with Part II requiring a defined number of CME credits that incorporate a self-assessment activity, which physicians have to pass with a 75 % correct grade.
- ABCRS' Part II of MOC self-assessment requirement may be satisfied with, among other activities, completion of the Colon and Rectal Self-Assessment Program (CARSEP) every 3 years, or completion of the Surgical Education and Self-Assessment Program (SESAP), a product of the American Board of Surgery (ABS).
- Part III of MOC consists of the secure high stakes examination designed to assess broad knowledge of the specialty (previously the "recertification" exam).
- ABMS and member Boards continue to receive criticism regarding the financial and time burden of MOC requirements, redundancy with other professional and regulatory requirements, and most especially lack of relevance to physicians' practices and an absence of proof that MOC produces improved patient outcomes.

Introduction: How We Came To Be Here

Evaluation of the literature dealing with medical error shows three major potential sources: healthcare delivery systems, insurer practices, and individual practitioners at various levels—physicians, nurses, pharmacists, and other healthcare workers [1]. The physician remains the single most identifiable individual in the healthcare system—the individual who directs and coordinates the activities of nurses, pharmacists, and other healthcare workers according to the plan of care. However, exponential growth of innovation in technology, pharmacology, and new scientific knowledge has produced a medical care system that is far more complex than ever before, and many discrete parts of the whole must interact smoothly to deliver healthcare that is safe, timely, and cost-effective. Within the complexity of the modern healthcare system, physicians have recognized a gradual but progressive diffusion of autonomy affecting decisions regarding patient care. At the same time, physicians are increasingly required to accept responsibility for an ever-expanding volume of practices and regulations that take time away from patient care activities, are often frustratingly redundant, and produce little or no demonstrated improvement in healthcare delivery or patient outcomes.

In general, physicians are highly educated individuals who are well used to self-directed learning as well as assessment of their knowledge and performance, having successfully

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_70

progressed through college, medical school, residency, and often fellowship training—mastering the high stakes examinations at each level. The vast majority go on to perform successfully on the rigorous secure cognitive Board certification examination in their chosen specialty. Some boards have additional requirements for certification, such as oral examinations, medical record audits or case log reviews, or observation of the candidate's performance with standardized or real patients [2]. As physicians progress through their professional careers, each has pursued ongoing educational activities guided by personal assessment of his or her own relative deficits or needs related to individual practice patterns. Over time, documentation of continuing medical education (CME) credit accrual has been increasingly required by the hospital or health system at which each physician practices.

Board certification initially had no expiration date. In the 1980s, the American Board of Medical Specialties (ABMS), the umbrella organization for the 24 member specialty boards that certify physicians trained in ACGME-approved training programs, signaled that lifelong certification without demonstration of ongoing mastery was no longer sufficient to assure the public that physicians were maintaining clinical competence and continuing to provide high quality care throughout their career. Specialty boards responded in part by no longer issuing certificates without expiration dates. The American Board of Colon and Rectal Surgery (ABCRS) ended the process of issuing time-unlimited certificates in 1989, and began issuing certificates that required diplomates in Colon and Rectal Surgery to pass a secure "recertification" examination every 10 years intended to demonstrate continued mastery of content sufficient for specialty practice. Ongoing self-directed learning continued as before, with individual physicians selecting learning activities based on their assessment of their own needs.

In 2000, ABMS adopted Maintenance of Certification (MOC) as a policy with general standards for its member Boards (Table 70-1). Parts I, II, and IV were designed to run concurrently in repeating 3-year cycles, with successful performance on the Part III secure specialty examination required at or about every 10 years to maintain specialty certification. Institution of MOC was based on empiric data interpreted to determine that such a program was necessary for physicians to prove to the public that they maintained mastery of specialty content [3]. Between 2000 and 2009, ABMS and its member Boards had many discussions regarding the shape that Part II, Lifelong Learning and Self-Assessment, and Part IV, Practice Performance Assessment and Improvement, might take. Some stakeholders encouraged immediate increased rigor with regard to MOC standards and proof of physician engagement in MOC. However, few additional requirements were presented to individual diplomates for maintaining board certification at that time.

In 2009, the pace of MOC accelerated, with the process intended to be more continuous than episodic, with participation required on a more regular basis. The American Board of Emergency Medicine (ABEM), American Board of Internal Medicine (ABIM), and the American Board of Pediatrics (ABP) moved toward requiring active MOC participation every 2 years [4]. It was made clear that ABMS expected Part II of MOC to include a defined number of CME credits that incorporated a self-assessment activity, which the physician had to pass with a 75 % correct grade. Importantly, while the concepts contained in the four parts of the MOC program were not new to physicians, the specificity set forth by ABMS raised a new set of challenges for practicing physicians and member Boards.

Table 70-1. ABMS MOC program

The ABMS program for maintenance of certification has four separate parts
• Part 1: Licensure and professional standing. Diplomates are required to hold a valid unrestricted medical license in at least one state or jurisdiction in the USA, its territories, or Canada
• Part 2: Lifelong learning and self-assessment. Physicians participate in educational programs that meet specialty-specific standards set by their certifying board and that include a self-assessment component
• Part 3: Cognitive expertise. Physicians must pass a high stakes exam to show they possess fundamental practice related knowledge to provide quality care in their specialty
• Part 4: Practice performance assessment and improvement. Physicians compare their outcomes with peers and national benchmarks

ABMS American Board of Medical Specialties

The Reasoning and Evidence for Institution of the ABMS MOC Program

Hawkins et al. authored a monograph explaining the theory and evidence that supported the concept and framework for the ABMS MOC program [3], stating that development of the evidence base in support of MOC is "conceptually similar to validation of an assessment method and involves two related, sequential processes". First, empiric data should determine that such a program is necessary; second, developers of the program should collect evidence to see if the program is performing as it should, and use this evidence to guide continued improvement. The next several sections discuss the MOC program in its current iteration and the data considered to support its institution. However, evidence regarding whether the program is exerting the desired effect remains controversial.

Central to the data cited in support of the need for the MOC program are estimates that 6–12 % of physicians "fail to meet professional standards of practice" [5]. These include deficits in knowledge [6], disruptive behavior (though this data suffers from a low survey response rate) [5], systems problems impeding physicians' care of patients [7], increasing physician age [6], problems unrelated to medical care (such as licensure issues or allegations of insurance fraud) [8], physical illness, psychiatric illness [9], and substance abuse [10]. A 2009 study which used surveys, focus groups,

and in-depth interviews with physicians in practice and licensing authorities, along with analysis of Federation of State Medical Boards Action Data Bank records, to find areas of concern in physician performance, identified five themes including communication, economics, ethics/behavior, knowledge and skills, and competency and assessment. Underlying causes common to these themes included increasing complexity of health care systems, decreasing insurance reimbursement, inadequate staffing, physicians practicing in isolation, problems with documentation and record-keeping skills, failure of teaching team approaches to medical care, and the general punitive approach to physician performance problems [11]. Another concern is the finding that physicians seem not to be very good at assessing their own areas of relative strengths and weaknesses [12, 13], supporting the concept of activities with scored assessment that can then be used to guide further learning activities. Taken together, these studies suggest that at any given time, a minority of practicing physicians experience challenges regarding professional standards of practice. Also acknowledged is the fact that many of the underlying causes for concerns in physician performance have roots in dysfunctional systems issues. Regardless, this data was seen to indicate a need for a more narrowly defined national program applicable to physicians in all specialties, overseeing aspects of physician professional standing, lifelong learning, and practice patterns and outcomes. This became the current MOC program of ABMS, designed "to assure the public that individual physicians maintain good professional standing as well as mastery of specialty content," though evidence suggested that the vast majority of board-certified physicians were already doing so. There has been no comparable national attempt to address the dysfunctional systems issues identified in many of these studies discussed above.

Hospitals, health care systems, and third party payers clearly value board certification, as evidenced by the increasing requirement of certification to gain privileges, to the point where non-board-certified physicians have lower earnings and have found it difficult to practice in many markets within the USA [14]. However, methodology used to assess how consumers value certification-accreditation processes has provided an unclear answer, perhaps in part because patients do not understand the processes [15]. Patients of a family medicine clinic were surveyed in 1998, and agreed that board certification was the most valued attribute for their physician [16]. Parents of pediatric patients who responded to a web-based survey in 2010 noted that recommendation from friends or family was equally as important as board certification in choosing their child's physician; 77 % also agreed they would be likely to change physicians if the physician did not maintain certification [17]. In an unpublished Gallup poll commissioned by ABIM in 2003 and subsequently reported by Brennan et al., general public respondents agreed that they valued certification and MOC, and agreed that physicians should be evaluated more frequently than required at the time [18]. Respondents also agreed they would change their physician if s/he failed to maintain certification, and agreed that they would choose a board-certified physician over a non-certified physician recommended by a family member or friend [18]. It is important to recognize the design limitations of these studies; participants are constrained in their responses by the necessity of choosing among statements to "agree" or "disagree" with.

Is the MOC Program Performing as It Should?

Part I, maintenance of unrestricted license and good professional standing, is familiar to every physician as a routine part of maintaining standing at the hospitals and/or healthcare systems one works within. On a regular basis, each physician must submit proof of valid unrestricted licensure and details of medical and specialty training, including board certification in most cases, to secure privileges to practice within most hospitals, healthcare systems, and third party payer systems. The MOC program, however, was not constructed with the thought of capturing this information from any existing database. As a result, each diplomate is required to supply for the MOC program the same information already submitted to various other bodies for licensure and hospital/surgery center privileges. Member Boards have been tasked with collecting and storing this information for ABMS; this and other burdens imposed on Boards are discussed at more length below. Though ABMS has been urged to accept the responsibility of collecting and storing this data to reduce the additional burden imposed on individual diplomates and member Boards, it has not moved to do so.

The general punitive approach to physician performance problems has often been identified as a barrier to physicians seeking help when it is needed [11]. Rules regarding how this sensitive matter is handled vary widely from state to state. Some states have well-developed confidential Physician Health Programs for problems including mental health, substance abuse, and professionalism issues, in which as long as the physician under treatment complies with all requirements of the program, the license is not reported as restricted [19]. Other states take a "legal" rather than a "treatment" approach [20]. In such jurisdictions, physicians may be forced to leave practice, at least temporarily, during treatment, and reinstatement can be an onerous and sometimes problematically public process. The ABMS MOC program does not contain any provision for how such licensure and professional standing instances might be managed within the program.

Part II contains a newly mandated requirement that within each 3-year cycle a specified number of CME credits must include a self-assessment (test) component, with a score 75 % or higher required to claim the CME credits. This represents a new hurdle for individual physicians as well as member Boards. Diplomates now have to seek out CME activities that

Table 70-2. The six core competencies defined by ACGME

1. Medical knowledge
2. Patient care
3. Professionalism
4. Interpersonal communication
5. Practice-based learning and improvement
6. System-based practice

ACGME accreditation council for graduate medical education

are both suitable for their specialty and self-identified needs that also include a self-assessment piece. Most of the self-assessment CME activities currently available are proprietary products, thereby adding an additional cost burden for diplomates, many of whom had often previously obtained CME credits at regional and national meetings at no additional cost.

The recognition that many issues with respect to professional standards can be related to one or several of the six competencies (Table 70-2) led ABMS first to encourage, then to require, that Part II activities have a clear definition of the competency or competencies each activity is meant to assess. At this time there is not a more specific requirement regarding whether or how each of the six competencies must be included in Part II activities.

Diplomates must report their Part II activities to their Board, noting the number with an associated self-assessment activity; the Boards are newly tasked to monitor and store this mass of data. Some larger Boards with more resources have undertaken to identify, or even produce, activities that the Board deems appropriate for their diplomates; other Boards have not done so for a number of reasons, including workforce and financial resource limitations. The member Boards have requested the ABMS develop or provide resources for a "clearinghouse" for Part II self-assessment activities that Boards might use to share or identify Part II activities suitable for their diplomates, with the hope of decreasing the burden for diplomates by identifying acceptable Part II activities. A joint project between ABMS and the American Association of Medical Colleges (AAMC) was recently announced that will develop the ABMS MOC Directory. MOC activities suitable for Parts II and IV may be submitted by members of the continuing professional development (CPD) and CME communities. ABMS will then work with member Boards to review and approve submitted activities that would be suitable for diplomates. Preliminary information suggests that member Boards will have the ability to approve activities, and ABMS will serve primarily as a facilitator. Potential cost to member Boards or diplomates for this service and/or the rights to a learning activity have not been defined to date.

With the specification of 90 credits every 3-year cycle for Part II, two-thirds or so of which must include self-assessment, member Boards have been tasked to police the efforts of their diplomates in a more exacting way. Still, member Boards currently retain the ability to determine what self-assessment activities are acceptable for Part II credit. Many boards have chosen to accept a wide variety of Category 1 American Medical Association (AMA) CME activities that include a self-assessment piece; although some boards have specified that the activity subject matter be closely related to the specialty or the diplomate's practice. ABCRS' self-assessment requirement may be satisfied with, among other activities, completion of the Colon and Rectal Self-Assessment Program (CARSEP) every 3 years. ABCRS also accepts completion of the Surgical Education and Self-Assessment Program (SESAP), a product of the American Board of Surgery (ABS) for Part II self-assessment requirement.

Data is mixed on whether participation in MOC can be shown to improve patient care or outcomes. Several studies have shown no difference in outcomes for patients cared for by internists with ABIM time-limited vs time-unlimited certificates across a panel of ten primary care performance measures [21], and no difference in ambulatory care-sensitive hospitalizations when comparing internists with ABIM time-unlimited and time-limited certificates [22], though there was a small reduction in the growth differences of costs for a cohort of Medicare beneficiaries [22]. Diplomates of American Board of Family Medicine (ABFM) who completed Performance in Practice modules related to hypertension showed improvement in most quality measures evaluated; however, though most had chosen lipid control as their quality improvement focus, no improvement was seen for that particular measure [23]. A similarly designed study evaluating ABFM diplomates' performance in diabetes care showed that while all physician and patient quality measures improved, no consistent association was seen between improvement and processes of care when comparing physicians with time-limited vs time-unlimited certificates [24]. The difficulty in defining what variable or set of variables might lead to improvement is again reflected in a study comparing a cohort of ABFM diplomates who participated in linked Part II and Part IV activities related to type 2 diabetes. Those who participated in the linked activities showed greater improvements in 11 of 24 process and outcomes measures when compared to diplomates who had not participated, though all groups demonstrated improvement [25].

Part III, the secure high stakes examination designed to assess broad knowledge of the specialty (previously the "recertification" exam), has remained largely unchanged. An examination is easily understood by the public as a measure of competence, and is acceptable in theory to most diplomates, as examinations are an essential part of the medical education process. As more diplomates progressed through their first 10-year cycle, however, nearly every Board received feedback from examinees that the secure MOC exam lacked relevance to their practices. Critics note that the examination tests material not relevant to everyday practice. As a result, the exams are perceived to have lower face and content validity. There is also little evidence that MOC examination scores can predict clinical competence in daily practice, as the requisite knowledge to pass a multiple-choice

examination may not correlate with real life clinical problems that require more nuanced solutions. Nevertheless, pass rates for MOC exams are high, as would be expected when testing a group of experts. Noting the high pass rates, some in ABMS adopted the stance that an examination that the majority of test-takers passed was a poor measure of continued content mastery, despite the fact that all examinees were by definition a highly educated and trained group of experts well versed in the majority of the content to be tested. Most member Boards did not share this view, expressing confidence in their MOC examinations' content and security. Interestingly, the first-time failure rate on the American Board of Internal Medicine's (ABIM) MOC exam has increased from 10 to 22 % over the past 5 years [26], with ABIM diplomates voicing a belief that the examination was being made intentionally harder to pass. While most candidates successfully passed the exam on retaking it, there was a great deal of consternation, increased costs, and more time away from active practice among diplomates who had not passed initially.

Evidence linking successful completion of the MOC exam with improved practice or patient outcomes is largely lacking. One study of ABIM diplomates showed that physicians who scored in the top quartile of the ABIM MOC exam were more likely to perform processes of care for diabetes and mammography screening than physicians who scored in the lowest quartile; however, no difference was seen for lipid testing in cardiovascular disease [27]. A study evaluating data from ABIM and ABS showed similar findings for surgeons and internists: those most likely to pass the MOC exam were younger, had higher scores on the initial certification exam, were in group (not solo) practice, and were US graduates. However, aside from performance on initial certification exam, the observed effects were small [28]. On the other hand, a study of ABFM diplomates showed that family physicians who maintained certification performed better on the MOC exam than recent graduates, with scores reaching their highest point 28–31 years after a diplomate's initial certification. Multiple comparison analyses confirmed the trend was significant; however, sub-analysis showed that while the trend remained significant for US medical graduates, it did not for international medical graduates. Family physicians who did not maintain certification performed significantly worse on the MOC exam than recent graduates [29]. In summary, although the individual and system variables that influence scoring on the MOC examination have been identified, there is limited evidence that higher scores on the examination are associated with higher quality patient care.

Part IV, Practice Performance Assessment and Improvement, has been the most difficult part of MOC to address in a way both meaningful to diplomates and also not overly burdensome. As with Part II activities, individual Boards were at first allowed considerable latitude in the activities each Board would accept for Part IV. For this reason, fulfillment of Part IV was initially attainable without undue burden for most ABCRS diplomates, since participation in NSQIP, SCIP, and a number of other regional and national databases and registries widely available in medical centers was considered acceptable (Table 70-3). An initial requirement for each diplomate to include patient satisfaction surveys in Part IV activities was placed on hold after ABMS received feedback from member Boards communicating concern over undue burden for diplomates in executing these as prescribed, as well as implications regarding data interpretation. However, advocates of a more stringent definition for Part IV activities have recently gained ground at ABMS, culminating in a new plan for Part IV activities that pursue reportable improvement of individual physician outcomes data. These activities would require diplomate participation in quality improvement activities endorsed by an ABMS-approved body, along with accurate documentation of substantial participation in aspects of project design as well as execution. This degree of specificity departs sharply from improvement activities already in wide use (such as Morbidity and Mortality Conference, and multidisciplinary disease management or service line conferences) with respect to acceptable activity structure, type and form of reported outcomes, and degree of individual participation in activity development and direction. There is considerable concern among member Boards that such requirements would pose a significant burden for a large fraction of diplomates. Quality outcomes are dependent on a number of discrete factors, many of which are outside the control of an individual physician. Few diplomates in active medical practice have had formal training in the methods of designing and executing a quality improvement and assessment project. Many well-designed quality improvement projects enfold a number of stakeholders that must interact to produce the desired outcome, and may require years for maturation of data. From the diplomates' point of view, the time and

effort that would be expended in design and participation in these studies represents an additional unfunded mandate, in addition to less time available for patient care activities that could impact compensation for many. ABMS has recently begun consideration of "group" or "team" MOC initiatives, chiefly as Part IV activities, in a nod to the recognition that many of the challenges posed to practitioners are systems or team based. Design of such activities has barely begun; consideration of how to execute and monitor these activities remains to be seen.

ABMS has set up a Multi-Specialty Portfolio Approval Program, dealing with quality projects that may be eligible for Part IV credit. The Portfolio Project began in 2009 as the "Primary Care Board QI Approval Pilot" with Mayo Clinic as the first "Pilot Portfolio Sponsor." The Portfolio Program subsequently became part of ABMS in 2014. The Portfolio Program does not produce quality improvement (QI) projects, but reviews proposals from outside sources, and grants approval (or not) for ABMS MOC Part IV credit for participating diplomates. Potential benefits for Portfolio Sponsors (i.e., medical schools, hospitals, medical groups, healthcare consortiums, and the like) include having diplomates in their organization receive MOC Part IV credit for current QI initiatives that originate in the home institution (after a favorable review by the Portfolio Project), and reduced time and effort for approval of QI projects applicable to diplomates in several specialties compared to applying to several Member Boards for project approval. The potential benefits for Member Boards would principally be a route for awarding ABMS MOC Part IV credit to diplomates for QI projects that receive a favorable review by the Portfolio Project, and potentially using the Portfolio Project as a more granular way to track the QI efforts of diplomates. The Portfolio Project has publicized that upwards of 6500 physicians, less than 2 % of American physicians currently meeting MOC requirements, have received MOC Part IV credit through projects vetted by the Portfolio Project. The cost for application and initial 2-year participation in the project has recently been raised to $7500. The Portfolio Program is only one pathway for physicians to obtain MOC Part IV credit; individual Boards offer a variety of other pathways for physicians to receive MOC Part IV credit.

Challenges Presented to Diplomates

Physicians remain committed to lifelong learning and improvement in practice. However, MOC has received at best a lukewarm response from individual diplomates; there are many reasons. ABMS and member Boards continue to receive criticism regarding the financial and time burden of MOC requirements, redundancy with other professional and regulatory requirements, and most especially lack of relevance to physicians' practices and an absence of proof that MOC produces improved patient outcomes. Approximately 375,000 board-certified physicians (about half the number that the 24 ABMS member boards certified initially) currently meet MOC requirements, according to ABMS [30]. However, as of 2012, 74 % of ABIM diplomates waited until the 9th year of their 10-year cycle before taking action to recertify [4]. Results of a survey of Oregon physicians showed that 91 % of respondents were board-certified; 95 % of those with time-limited certificates planned to recertify. However, they reported that their practice groups provided few to no resources for participation in the MOC process [31]. A study utilizing data from ABIM diplomates initially certified between 1990 and 1999 showed that physicians who participated in MOC tended to have higher initial certification scores, were younger, were US graduates, practiced as subspecialists and in the Midwest, worked in nonsolo practices, or were employed in counties with less than 20 % of persons in poverty [32]. A mail survey of 1693 pediatric diplomates with time-unlimited certificates had a response rate of 77 %, and found that while only one-quarter of generalists and 13 % of subspecialists agreed they would be willing to participate in general pediatrics MOC, fully half of the subspecialists would be willing to participate in subspecialty MOC, highlighting the importance of MOC relevance to one's practice. Three-fourths of both generalists and subspecialists did not agree that MOC was necessary for keeping up to date in clinical pediatrics [15]. The perception of MOC's lack of relevance to current practice is most often raised by subspecialty practitioners [15; personal communications.]

Physicians with fewer resources to devote to the MOC process (lack of practice support for MOC; solo practice; or practice in areas of poverty) appear to be those most at risk for non-participation, and therefore, for loss of board-certified status [32]. Physicians in solo practice, international graduates, and physicians with a higher percentage of poor patients all do worse on MOC exams [32]. A study of surgeons taking the MOC examination in 2008 showed that increased levels of peer interaction were associated with a higher score and a higher likelihood of passing the exam. Physicians in solo practice had fewer peer interactions, received lower scores, and were less likely to pass the exam. However, solo practitioners with high levels of peer interaction performed as well as those in group practice [33]. A study of ABIM diplomates showed that more frequent use of electronic resources was associated with modestly enhanced MOC exam performance. The authors also noted that physicians involved in residency education clinics and hospital inpatient practices had higher MOC exam scores than physicians working in private practice settings [34]; perhaps, this is related to more frequent peer interactions. A survey of American Board of Anesthesia (ABA) diplomates found that the majority perceived board certification to be of value in demonstrating competence. However, the elements of Part I, Professional Standing, and Part II, Lifelong Learning and Self-Assessment, were perceived as significantly more relevant to practice than Part III, the Cognitive Exam, or Part IV, Practice Performance Assessment and Improvement activi-

ties. ABA diplomates expressed concerns about the cost and complexity of MOC, a lack of evidence that MOC improves practice, and a belief that the Cognitive Exam covered topics not relevant to their current practice [30, 35]. Other frequent critiques of the MOC program as currently designed include a lack of assessment of appropriateness of care, and insufficient system-based evaluation [36].

Challenges for Member Boards

The MOC standards are intended to apply equally to all member Boards regardless of Board size, available resources, or specialty. This presents several difficulties, the most obvious being that of an unfunded mandate. Compliance with the standards requires significantly more work by each Board's support staff. Some of the subspecialty Boards have staffs as small as four full-time employees, and strategies to meet the need for the increased administrative workload are still being determined. Many Boards also recognized a need for website expansion to provide newly mandated diplomate services, as well as to house the growing body of data requiring storage as well. Website and server expansion is dependent on funds sufficient to support the desired capacity. The function and mission of Boards is the certification of specialty diplomates and related activities; fees for certification-related activities and the occasional bequest have historically been the financial foundation of most Boards, with Board resources therefore having a direct relationship to the size of the diplomate pool. However, Boards by definition have a finite and closed membership comprised of their diplomates; no drives can be held to gain new members. As a direct result of the increased administrative and website workload which are expected to be ongoing requirements, most of the ABMS member Boards felt there was no option other than to levy MOC fees to support this unfunded mandate. In the lay press, charges have been leveled at ABMS and its member boards that MOC exists largely as a revenue-raising tool. Costs for the 10-year MOC cycle range from $1250 (ABS) to $4280 (American Board of Plastic Surgery, or ABPS). Of ABIM's total revenue of $49 million in fiscal year ending June 2012, 62 % was derived from certification fees and 36 % from MOC fees [30].

In early February 2015, ABIM responded to a stream of continued strong criticism from its diplomates regarding the MOC program and suspended the Practice Assessment, Patient Voice and Patient Safety requirements (Part IV) for at least 2 years, changed the language used to publicly report a diplomate's MOC status on its website from "meeting MOC requirements" to "participating in MOC," and made plans to update the Internal Medicine MOC exam to better reflect what ABIM general internists are doing in practice with plans to do so in subspecialties as well. The ABIM also rolled MOC fees back to 2014 levels with a commitment to keep them at that level until at least 2017, and affirmed a plan to recognize most forms of Accreditation Council for Continuing Medical Education (ACCME)-approved CME for demonstration of self-assessment of medical knowledge. Many ABMS member Boards have also chosen this time to enact a moratorium on new MOC requirements, and are opening dialogues with diplomates to better assess their needs, with more user-friendly, meaningful, and value-added MOC programs as a goal.

Decreasing the Burden of MOC

Cook et al. proposed an integrative practice-based model for MOC, allowing Part II and IV topics to emerge from and remain embedded within the local clinical practice; directly improving patient care, ensuring that needed skills are developed and maintained, and providing context to stimulate knowledge retention [37]. The authors also postulated a smoother interaction for the parts of MOC: Part II learning would prepare diplomates for Part III, and might provide skills required for Part IV; Part IV could be used to define learning agendas for Part II; and feedback on Part III would also inform Part II learning agendas. ABMS recently incorporated this last suggestion into the MOC program with an expectation that diplomates receive feedback regarding performance on the MOC exam to help guide their individual learning and self-assessment activities in the next cycle.

It is clear that some form of individual evaluation will remain a part of the MOC process. The ABMS held a symposium for its member boards in June 2014 to discuss the future of Part III. Some boards have instituted novel approaches to Part III that seem to better serve the needs of their diplomates. In Plastic Surgery, for example, diplomates complete a core section for Part III and then choose their remaining test material from three of four defined subspecialty areas. As of 2014, the American Board of Anesthesiology began a pilot project to revamp Part III called the "MOCA minute". The program consisted of a continuous dynamic web-based assessment with focused content to assess knowledge and guide the diplomat to appropriate resources. Questions were sent out on a weekly basis and answered on line by the diplomate, who received immediate feedback in the form of the correct answer, a full critique, key points, and references. The pilot was very successful and was integrated into MOCA Part III as of January 2015. Progress will be monitored by the program; each individual will receive immediate reports on their own performance broken down by topic area to allow them to tailor their own MOC program accordingly.

There have been initiatives external to ABMS that may work to reduce the burden of MOC for individual diplomates and improve compliance. The AMA House of Delegates passed a resolution in June 2013 to determine if periodic secure recertification examination is needed, and to explore alternatives [38]. Evidence supporting alternatives to secure closed-book exams as proof of specialty knowledge content exists as far back as 1996, when Norcini et al. showed that an

open book web-based recertification exam was as reliable as a secure high stakes exam [39]. The ABIM recently conducted a structured review of the evidence for open versus closed-book exams, concluding that closed-book exams drive learning while open book exams decrease anxiety. Movement to an open book examination would improve face validity by reflecting real-time practice, provided there was access to multiple information sources such as Google Scholar, Uptodate, WebMD, ACP pier, Isabel/Watson, texts, journals, and crib sheets. This process is under review by the ABIM. A related option adopted by other Boards is for remote exam proctoring, in which a candidate logs in to a secure website and takes the examination on their own time and space.

Physicians who participated in both MOC and PQRS (Medicare's Physician Quality Reporting System) were eligible to receive a 1.5 % bonus in 2011 and a 1 % annual bonus between 2012 and 2014, in addition to regular Medicare fees. However, physicians who chose not to report these quality measures to the PQRS program by 2015 would have their Medicare fees reduced by 1.5 % in 2015 and by 2 % in 2016. Additionally, the Federation of State Medical Boards (FSMB) recommended in 2010 that physicians actively participating in MOC "could substantially meet" the more stringent requirements of Maintenance of Licensure. However, at this time only Massachusetts has announced a start date (2015) for such a reciprocity program.

ABCRS: Current Requirements; Initiatives Under Consideration

The ABCRS instituted its MOC program in 2011. The current requirements for the ABCRS MOC Program are listed in Table 70-4. When a diplomate initially certifies with ABCRS, or recertifies with successful completion of the Part III exam, s/he qualifies to have 50 self-assessment credits applied toward the Part II requirement in the 3-year MOC cycle immediately following. ABCRS is also considering awarding credit applicable to Part II self-assessment requirements for diplomates who author questions for the ABCRS examination process.

The ABCRS is keenly aware that a majority of its diplomates also maintain certification by the ABS, with the requirements that dual Board certification entails. ABCRS and ABS have agreed that Part II credits can be applied to both the ABCRS and the ABS MOC programs. In addition, each Board will accept completion of CARSEP or SESAP toward Part II credit. However, a diplomate must still successfully pass the MOC Part III exam for ABCRS and ABS separately to maintain certification by each Board.

The MOC Committee of the ABCRS is considering changes to the MOC program based in part on the practices of other Boards who have piloted innovative models for their MOC programs as well as feedback from ABCRS diplomates. There is a good deal of interest in a modular-type Part III examination, in which each diplomate completes a central module common to all examinees, but then may choose two to three modules from a range of three to five of specialty content. Another novel way to manage Part III would be to have each diplomate complete a set number of secure multiple-choice questions annually with more timely feedback rather than 200 every 10 years. The questions would be accessible on line for a set time period and feedback would include the answer, keypoints, a critique, references, and a link to provide feedback on the questions. The diplomat would also be asked to evaluate the confidence of their answer which could be used summatively by the candidate to identify gaps in their knowledge. This should allow for more intensive longitudinal assessment and targeted self-directed Part II learning activities, and could lead to Part IV involvement with direct applicability to one's practice. Ongoing involvement in learning, practice improvement, and quality activities requiring less dedicated time per episode, along with clear application to one's practice, may provide diplomates with more accessible and meaningful ways to manage their MOC needs.

Table 70-4. ABCRS MOC required components 2015

Part I. professional standing (every 3 years)
• Documentation of full-licensure in the state in which you practice
• Documentation of privileges for colon and rectal surgery at your hospital
• Letter of recommendation from the chief of staff at your hospital
Part II. Lifelong learning and self-assessment (every 3 years)
• Ninety hours of category 1 CME credits, 50 with a self-assessment activity (which can include CARSEP or SESAP)
Part III. Cognitive expertise (every 10 years)
• MOC cognitive exam
Part IV. Evaluation of performance in practice (every 3 years); suggested activities include:
• Communications and interpersonal skills activities
• Clinical practice data—Ongoing participation in a national, regional or local outcomes database or quality assessment program (see Table 70-3)

MOC maintenance of certification, *CME* continuing medical education, *CARSEP* colon and rectal self-assessment program, *SESAP* surgical education and self-assessment program

How Other Nations Manage MOC

In Canada and the United Kingdom, the processes that parallel our MOC program are mandatory for physicians to practice. Some interesting lessons may be learned from examination of these processes and their history. The Canadian process involved Fellows (the equivalent of Diplomates) early during the program's design, and continues to do so. All Fellows are automatically registered in the MOC program of the Royal College and are required to meet all of the requirements to maintain the designation Fellow of the Royal College of Physicians of Canada (FRCPC) or Fellow of the Royal College of Surgeons of Canada (FRCSC). All provincial licensing boards

require active participation in MOC to maintain licensure. Fellows must complete a minimum number of credits in each 5-year cycle, which are entered into an online database maintained by the College. Credits are self-reported in one of six areas and classified by the competency that is addressed. This must be supported by documentation, of which a portion must be sent in annually to the College. Each year a random sample of Fellows are audited for complete documentation. The recommendation of the Royal College Council to not include a secure exam as part of the process has been repeatedly supported by fellows, national specialty societies, and medical educators since the early 1970s [40]. At the present time Canadian Fellows involved in MOC through the Royal College can submit their MOC reports from the Royal College to the ABCRS for MOC credit. However, they are also required to take the ABCRS MOC examination to complete ABCRS recertification.

The process in the United Kingdom is not a system developed by doctors for doctors, but rather a "centralized system using employer (National Health Service) to employee (physician) relations to ensure accountability" [41]. The UK system is compulsory for all doctors who wish to practice in the UK, including doctors in training, in public or private practice, and those visiting the UK and practicing medicine. The system consists of the Good Medical Practice guidelines, which supply the core ethical guidance for UK medical practitioners, and Fitness to Practice, which incorporates general medical knowledge and skills along with elements of professionalism which "may include matters not directly related to professional practice." The main areas of scrutiny are professional standing and professionalism, in part due to several high-profile medical scandals in the past decade. There is no required specialty knowledge test that parallels the MOC examination.

Conclusions

At the present time, board certification and MOC is voluntary in the USA. Realistically, however, many hospitals require board certification for granting hospital privileges. In many fields of practice, a lack of certification leads to lower earning power [14]. In the future, participation in MOC may become a mandatory component for continued licensure and privileging. As a professional group we need to set the standards of our own educational assessment and evaluation. We must maintain the social contract with the public where there is a collective social trust with the expectation of self-management. The administration of MOC must remain under the control of physicians at the specialty Board level to avoid takeover by an external body who may develop a process that is more onerous, with a foreign agenda and little relevance to the practicing physician. The Boards themselves must evolve from simply developers and administrators of tests to organizations engaged in quality assessment and quality improvement.

Evidence considered to support the concept of MOC enfolds physician-specific factors, patient-specific factors, and systems issues [3]. At the present time diplomates are concerned regarding the cost and time involved in completing the process without solid evidence that it improves patient care. While physicians accept the concept of lifelong learning and personal development, the optimal approach has yet to be determined and awaits the results of ongoing research and innovation.

Some developments that may make the present process less onerous include structuring MOC so that it fulfills the requirements for all the different entities that assess physician performance; devising ways to have Parts II, III, and IV be more relevant to each diplomate's practice; addressing the real burden of both time required and financial costs for individual diplomates as well as member boards; and finding methods to assess the "systems issues" portions of practice that do not result in penalization of the diplomate for situations beyond his/her control. New considerations from ABMS for "team quality activities" may be a recognition that much of modern medical practice is related to factors separate from and not under the control of the individual physician; however, it is far from clear what place such activities would have, whether in the MOC setting or the local practice setting under the aegis of a hospital or healthcare system's quality improvement program. Context and relevance to practice of the individual diplomate also needs more attention within the MOC program. The specific care delivered by physicians working in different health care areas may vary greatly, dependent largely on systems issues [36]. However, the question of added burden for individual diplomates and boards has yet to be truly addressed.

71
Quality and Safety in Colon and Rectal Surgery

Elizabeth C. Wick and Jonathan Efron

Key Concepts

- Measurement of quality can be separated into structural, process, and outcome-based.
- Quality measures in colorectal surgery are both process and outcome-based.
- Transforming healthcare to a high reliability organization will provide the infrastructure for continuous quality improvement.
- Creating a culture of safety is essential for delivering high quality care.
- Patient and family engagement has emerged as a new and equally important domain of quality.

Background

In 2000, the Institute of Medicine (IOM) published the report *To Err Is Human*: *Building a Safer Health System*, a landmark document which raised awareness of the magnitude of the problem of medical mistakes, and remains the most frequently cited document in the medical literature in recent years [2]. The IOM report shocked both the healthcare community and the public by concluding that 44,000–98,000 deaths and over 1 million injuries occurred each year in American hospitals due to medical error. In fact, preventable medical errors represent one of the eight leading causes of death in hospitalized patients. As this report was disseminated, general awareness about medical errors increased, and physicians and other health providers began speaking openly about mistakes and the difficulties they face when dealing with them. The IOM report brought much-needed attention to the field of quality and safety. In addition, it standardized the language used to describe errors in medicine, defining important terms for future research and quality improvement. Following its publication, interest in the field increased exponentially and health services researchers began to collaborate with scientists from other disciplines such as engineering, psychology, and informatics to develop innovative solutions to longstanding lapses in quality and safety.

A follow-up report in 2001, *Crossing the Quality Chasm*: *A New Health System for the 21st Century*, provided a framework for how to re-work healthcare delivery in the USA [3]. The report called for federal and state policymakers, public and private purchasers of care, regulators, organization managers, governing boards, and consumers all to commit to reducing the burden of illness and to improve the health of the American population by focusing on making healthcare safe, effective, patient-centered, timely, efficient, and equitable (Figure 71-1). To meet these goals, the report outlined ten rules for redesign:

1. Care is based on continuous healing relationships.
2. Care is customized according to patient needs and values.
3. The patient is the source of control.
4. Knowledge must be shared and information flows freely.
5. Decision-making should be evidence-based.
6. Safety is a system property.
7. Transparency is necessary.
8. Needs need to be anticipated.
9. Waste should be continuously decreased.
10. Cooperation among clinicians is a priority.

The next milestone for the safety and quality movement was the *Patient Protection and Affordable Care Act* (i.e., "Affordable Care Act" or "Obama Care"), which was signed into law on March 23, 2010. While the primary goal was to increase the availability, quality, and affordability of insurance coverage, the Affordable Care Act was also designed to be a catalyst for the reinvention of the healthcare system with a particular emphasis on ensuring that the ten rules outlined in the IOM report were integrated into the delivery system. Specifically, the Affordable Care Act implemented policies and procedures that will over time shift the paradigm of care in the USA from being volume to value-driven. Policy makers further proposed that for healthcare, value equals the cost of care divided by a measure of quality

(value = cost/quality). One of the best examples of shifting the value equation is the enhanced recovery program following all types of surgery, including colorectal. Initially popularized in Europe, they have now gained significant traction in the USA—no doubt, in part because of the shifting healthcare climate. For example, recent implementation in colorectal surgery at an academic medical center resulted in a 2 day reduction in the length of stay, lower morbidity (50 % reduction in SSI), increase in patient satisfaction, and ~$2000 reduction in hospital costs (unpublished data, Elizabeth Wick).

A key tool for driving this transition to value instead of volume is the redesign of payment models, with a shift away from fee-for-service reimbursement in favor of global budgets, population health models, and accountable care organizations (ACO). While the cost-savings with the early experiments in these care delivery models have been mixed, there is no doubt that more regions of the country will see iterations of these models implemented [4]. Much of the early focus has been on primary care and avoiding preventable utilization of acute services like emergency rooms and hospitals, eliminating variations in care, and enhancing care coordination in cohorts of medical patients like those with diabetes mellitus, chronic kidney disease, congestive heart failure, or chronic obstructive pulmonary disease. In the years to come, ACOs will likely focus more on surgical care—highlighted by a survey of ACO leadership groups which listed eliminating unnecessary surgery as a prime area of interest (Table 71-1). In the interim, as we are in a state of flux, both Medicare and private payors have instituted value-based payment contracts with the goal of incentivizing hospitals and providers to focus on reducing preventable harms like falls, hospital acquired infections, and venous thromboembolisms [5]. For more on the evolution and changes in healthcare economics, see Dr. Orangio's extensive review in Chap. 66.

The Conceptual Model of Quality Measurement: Donabedian Model

Moving to this new paradigm of care is predicated on establishing standard measures of "quality." Presently, for surgery, there is little consensus on what the key reliable, attainable, generalizable, and meaningful measures will be. One of the most common conceptual models used to describe quality measurement is the Donabedian model. Avedis Donabedian was an early health services researcher whose seminal work was "Evaluating the Quality of Medical Care," presented in 1966 [6]. The Donabedian model of measuring quality identifies three main types of improvements: changes to structure, process, and outcome (Figure 71-2). *Structure* refers to the context in which care is delivered—this includes the facility and services, workforce, and payment structure. Structural measures ask, "Are the appropriate services, equipment, incentives, and people available?" *Process* is the application of these tools, equipment, and policies/procedures to patients (i.e., good practices and evidence-based medicine). Process measures ask, "Are the right tools, policies, and equipment being used for all patients?" *Outcome* is the result on patients. Outcome measures ask, "How often are patients harmed?" In this model, structure (how care is organized) plus process (what we do) influence patient outcomes (the results achieved) [7].

Structural Measures

Much of the early focus on quality in surgery revolved around structural measures, as they tend to be the most straightforward to assess. For example, researchers correlated outcomes in colorectal surgery to hospital factors (procedural volume and specialty service availability) as well as surgeon training (colorectal board certification) and availability of ancillary services (trained pathologists for rectal cancer) [8–10]. For colorectal cancer surgery, hospital and surgeon volume, as well as board specialization, are associated with a reduction in operative morbidity and 5-year mortality [11]. Additional relationships have been identified between high-volume providers and sphincter-preserving procedures in rectal cancer—i.e., surgeons who operate on rectal cancer patients regularly are less likely to do an abdominal-perineal resection for patients in whom a sphincter-preserving operation can be considered [12].

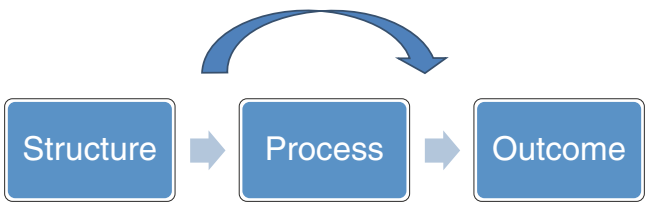

FIGURE 71-2. The Donabedian model of quality of care.

Although not as widely studied, similar relationships have been identified in complex inflammatory bowel disease surgery as well [13]. While relatively easy to quantify, the downside of volume as a measure is that it is a proxy measure and not easily "actionable" for quality improvement. There is no doubt that we all can identify some outstanding "low-volume" colorectal surgeons and as well as some "high-volume" colorectal surgeons who do not meet basic standards.

Accreditation programs are formalized processes for controlling structural measures. The most mature example of the accreditation process is in bariatric surgery. A joint venture of the American College of Surgeons (ACS) and the American Society for Metabolic and Bariatric Surgery, the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP) sets hospital standards for key physical, and human resources, as well as practice standards for bariatric surgery, and compliance is monitored with site visits. All centers are required to monitor and report their surgical outcomes to the MBSAQIP database [14–16]. CMS endorsed the program and mandated that all Medicare patients undergoing bariatric surgery must be treated in an accredited center. Although procedures done in centers of excellence were associated with superior quality by many measures, this was not reflected in a Medicare analysis and CMS endorsement of the program was discontinued in 2013 [17]. The American Society of Colorectal Rectal Surgeons and the Consortium for Optimizing the Treatment of Rectal Cancer (OSTRiCh) are a proponent of implementation of a standardized care pathways and a Centers of Excellence program for patients with rectal cancer, and has recently received an endorsement from the ACS [10, 18]. Founded in 2011, OSTRiCh currently has 144 institutions all aimed at a unified effort to improve safety and outcomes for patients with rectal cancer. The partnership is collaborating with the ACS Commission on Cancer and creating the "CoC Rectal Cancer Accreditation Program" based on their five core principles of evidence-based rectal cancer care:

- Total mesorectal excision (TME)
- Measurement of quality of surgery by specific techniques of pathology assessment
- Specialist imaging techniques identifying those patients at high risk of local recurrence
- The use of newer more effective neo-adjuvant and adjuvant therapies include radiotherapy and chemotherapy
- Multidisciplinary team (MDT) approach that identifies, co-ordinates, delivers, and monitors the ideal treatment on an individual patient-by-patient basis

Process Measures

Process measures focus on the details of care that likely lead to good clinical outcomes. Advantage of measuring quality through process measures is that most measures are evidence-based (frequently supported by high quality randomized

Table 71-2. Commission on cancer colorectal cancer measures

Colon			
ACT	Accountability	Standard 4.4 90 %	(NQF #0223) Adjuvant chemotherapy is considered or administered within 4 months (120 days) of diagnosis for patients under the age of 80 with AJCC Stage III (lymph node positive) colon cancer.

Rectum			
RECRCT	Quality improvement	Not applicable	Preoperative chemo and radiation are administered for clinical AJCC T3N0, T4N0, or Stage III; or Postoperative chemo and radiation are administered within 180 days of diagnosis for clinical AJCC T1-2N0 with pathologic AJCC T3N0, T4N0, or Stage III; or treatment is considered for patients under the age of 80 receiving resection for rectal cancer.

AJCC American Joint Commission for Cancer

controlled trials), relatively easy to monitor for compliance, and have imminently actionable results. The major downside is that for the most part excellent compliance with surgical process measures has failed to translate into improved outcomes. The best example of this in colorectal surgery is the Surgical Care Improvement Project (SCIP) [19, 20]. The measures, originally part of a pilot termed Surgical Infection Prevention (SIP), were intended to help hospitals adopt evidence-based practices for SSI prevention. SIP was transitioned to SCIP in 2006 and endorsed by multiple organizations, including the Joint Commission and CMS, with mandatory participation. Ultimately, measure compliance was publically reported via the hospital compare website and tied to value-based purchasing contracts. SCIP measures important for the practicing colorectal surgeon were those related to timing, selection, and discontinuation of antibiotics for surgical prophylaxis (i.e., surgical site infection [SSI]) prevention, maintenance of normothermia in the operating room (SSI prevention), use of venous thromboembolic event (VTE) chemoprophylaxis, and removal of the Foley catheter by postoperative day 2 (catheter-associated urinary tract infection [CAUTI] prevention). For the past decade, hospitals devoted significant resources to implementing the SCIP measures, and for many, success was associated with a "system fix" as opposed to "work arounds," which are unfortunately rampant in healthcare—frequently harnessing the electronic health record. On the positive side, there is no doubt that surgical care is in a better place today as compared to 2003, when less than 60 % of patients were receiving antibiotics pre-operatively and many patients were recovering on inpatient units with urinary catheters in place long after they were needed. However, despite these great strides in improving care processes, it was rare for hospitals to observe associated improvements in outcomes [21, 22]. The SCIP measures were officially retired in December 2014 with a commitment by CMS to move to more outcome-based measures over the next couple of years.

Another example of process measures relevant to the practicing colorectal surgeon are the colorectal cancer measures included in the Commission on Cancer site reports and endorsed by the National Quality Forum (NQF) (Table 71-2) [23]. The NQF is a non-profit organization with representation from over 400 different stakeholder organizations and has representation from consumers, payors, medical professionals, government agencies, drug companies among others. These measures, covering factors such as pathological examination of rectal cancer specimens and (neo)adjuvant chemoradiation, highlight the multidisciplinary approach to colorectal cancer. However, the ultimate impact on those institutions that do (or do not) follow these measures remains to be determined.

Outcomes

Ultimately, the quality movement aims to make meaningful improvements in **patient outcomes**. There is no doubt that outcome measures resonate the strongest with clinicians. The challenge is that collecting, validating, and risk-adjusting outcome measures are not trivial. The two major types of outcome measures available today are from administrative data and/or clinical registries [24]. Administrative data is derived from hospital billing information and relies on the accuracy of the clinical documentation and medical coders, and is heavily focused on the inpatient stay. Examples of sources of administrative outcome data include the University Health Consortium (UHC), Premier Advisor, and Medicare. Although some measures like readmissions and length of hospital stay may be reliably obtained from this type of data, more complex clinical outcomes like SSI, pneumonia, and CAUTI are not [24]. In contrast, surgical registry data, usually nurse abstracted, audited, and risk-adjusted, is outstanding for these complex clinical variables. In colorectal surgery, the American College of Surgeons' National Surgical Quality

Improvement Program (NSQIP) is considered the "best in class" registry. The leadership has prioritized data validity, and all data is collected by a trained abstractor and the data integrity is periodically audited. The program was originally developed in the Veterans Affairs Health System (National Veterans Administration Risk Study) in the 1990s as a means to benchmark 30-day outcomes for VA hospitals to the rest of the nation. Risk adjustment was a key focus of the program, as the Veterans Affairs Hospital population was notably different than other health systems with a preponderance of older, male patients with multiple co-morbidities [25]. The program, in addition to being successful for comparing hospitals, also turned out to be a catalyst for process improvement. In 2001, with support from the Agency for Healthcare Research and Quality (AHRQ), this was expanded to the private sector in collaboration with the ACS as ACS-NSQIP [26–28]. Colorectal surgery has been a key area of focus for the program with special colectomy and proctectomy disease specific variables developed within the program (see Appendix 1). Of note, in 2015, the program was awarded the Eisenberg Award for its contributions to patient safety and quality [29].

In colorectal surgery, SSIs have emerged as one of the first outcome measures embraced as a national metric. Beginning in 2013, hospitals were mandated to monitor SSIs after colon surgery using the National Healthcare Safety Network (NHSN) program of the Centers for Disease Control and Prevention, a public registry-type database that is available free of charge to hospitals. Given, the open access nature of the program, there is little quality control, and many elements are left for interpretation by individual sites. There are three types of SSI defined by NHSN: superficial, deep, and organ space; however, the public reporting metric only includes risk-adjusted *organ* space rates. NHSN uses the standardized infection ratio to risk-adjust hospital rates for patient co-morbidities. Yet, even with this limited scope, there is great variability in the "accuracy" of the NHSN SSI rates for colectomy. As evidence, when NHSN rates are compared to those abstracted via ACS-NSQIP at the hospital level, there is little correlation—further emphasizing the complexity of developing accurate surgical outcomes measures of quality [30].

A separate domain of outcome measurement is the patient experience. Today, the CMS requires the patient experience be measured using the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) survey. Hospitals send the survey to a sampling of patients discharged after an acute care stay. The goal is to assess hospital performance in domains that are meaningful to the consumer. Starting in 2012, hospital HCAHPS performance was included in value-based purchasing programs as legislated by the Affordable Care Act. To facilitate consumer assessment and data transparency, results are also compiled and published on the hospital compare website. As of 2015, hospitals are now rated based on survey performance using a star system [1–5].

While the Donabedian model provides a good framework for understanding elements of quality measurement, some contend that this oversimplifies the equation. An alternative is to consider composite measures which are a more global assessment of quality and include weighted structure, process, and outcome measures. An example of a composite measure is the Leapfrog Patient Safety Score for the US hospital. This measure is designed to be a standardized score for patients, providers, and healthcare purchasers to compare patient safety across hospitals, and includes 26 structural, process, and outcome measures. It is anticipated that more composite measures will be developed specific to disease management or procedures.

It is important to note that the structure, process, and outcome components of quality measurement all occur within the context of an organization's overall *culture*. The local culture impacts all aspects of the delivery of care because it affects how frontline personnel understand and deliver safe patient care. In fact, culture (i.e., the collective attitudes and beliefs of caregivers) is increasingly being recognized to be the fourth measurable component to the *structure–process–outcome* model. This recognition is based on growing evidence that local culture is linked to a variety of important clinical outcomes [7]. For any new patient safety initiative to be deemed successful, any change in structure or process must lead to a corresponding positive change in patient outcomes [31].

Safety

Patient safety is a discipline that applies safety science methodology toward creating a reliable healthcare delivery system that continuously strives to eliminate adverse events. Examples of events that stem from breaches in patient safety include wrong-site/wrong-procedure surgeries, retained foreign objects (sponges and instruments), mislabeled endoscopy or operating room specimens, unchecked blood transfusions, and overlooked allergies—all are potentially catastrophic events that can be prevented by implementing safer hospital systems. A key realization in patient safety is that adverse events occur because of a **breakdown in the system in which we operate** and are **not caused by a single person's actions**. A cornerstone of the patient safety movement is limiting blame—in the past, medical errors were thought to reflect incompetence and frequently clinicians tried to keep them undercover, essentially preventing organizations from learning from these events. There has been a dramatic change in this culture in the past decade, with all hospitals now being required to have non-punitive avenues for event reporting as well as forums for discussion and accountability for developing fixes to prevent recurrent events. Another important advance for the field was broad acceptance of "systems" thinking in healthcare—the idea that redesigning systems using a combination of clinician

input, human factors principles, systems engineering, and health information technology (among others) could result in mistakes being dramatically reduced. This approach to addressing defects and preventing adverse events can be applied at both the "micro" (e.g., developing surgical staplers that prevent accidental misfiring) and "macro" (e.g., hospital organizational structures where leaders are accountable for decisions) level.

Regrettably, healthcare is considered a high-risk system with a high error rate, but these two characteristics are not and do not have to be always correlated. In fact, other high-risk industries have managed to maintain an impeccably low error rate such as the nuclear power industry, commercial airlines, and amusement parks [32]. In the nuclear power industry, much of the credit for their safety record is due to the culture, with its insistence on individual ownership, responsibility, attention to detail, professionalism, moral integrity, and mutual respect. These characteristics have created the cultural context necessary for high quality communications under high-risk, high-stress conditions. Each reactor operator is aware of what is going on at all times and is responsible for understanding the implications and possible consequences of any action. Communication flows freely between operators and executives, and information about any mistakes that occur are dispersed rapidly through the entire system so that other workers can learn how to prevent similar mistakes in the future. Many of the principles and tools, including crew resource management and high reliability, used in these other industries are now being adapted for healthcare as tools to promote patient safety.

High Reliability Organizations

Focusing on the principle of high reliability has been proposed as a strategy to transition healthcare from a high-risk, high error rate to a high-risk, low error rate industry. Mark Chassin, the director of The Joint Commission, has been a key proponent of this approach. Writing in the April 2011 issue of *Health Affairs*, Dr. Chassin states, "What has eluded us thus far…is maintaining consistently high levels of safety and quality over time and across all healthcare services and settings. The pockets of excellence coexist…with enormously variable performance across the delivery system. Along with some progress, we are experiencing an epidemic of serious and preventable adverse events" [33]. However, high reliability organization theory suggests that proper oversight of people, processes, and technology can handle complex and hazardous activities and keep error rates acceptably low [34]. Studies of multiple high reliability organizations have demonstrated that the following principles are embraced [35]:

1. HROs are sensitive to operations (continually strive to improve the system).
2. HROs are reluctant to accept "simple" explanations for problems (do not finger point or accept simple reasons for adverse events).
3. HROs have a preoccupation with failure (always vigilant and looking for ways to prevent adverse events).
4. HROs defer to expertise (not committed to hierarchy and training, respect frontline wisdom).
5. HROs are resilient.

Developing these characteristics is an important step toward achieving a low error rate in any organization. Recognizing that the transition in healthcare will be slow and labor intensive, the Joint Commission has outlined a framework with 14 components to facilitate the transformation [33]. The components fall into three domains: leadership, safety culture, and robust process improvement. Many hospitals and health systems are mandating HRO training for all employees. Connecticut has even gone so far as to legislate this approach for all hospitals in the state with HRO training now mandatory.

Creating a Culture of Safety

Culture is to an organization what personality is to an individual—a hidden, yet unifying theme that provides meaning, direction, and mobilization [34]. One way to think about it is that one person's opinion is an attitude, while everyone's opinion is a reflection of the culture. Organizations with effective safety cultures share a constant commitment to safety as a top-level priority that permeates the entire organization. These organizations frequently share the following characteristics [36]:

1. An acknowledgment of the high-risk, error-prone nature of an organization's activities.
2. A non-punitive environment where individuals are able to report errors or close calls without fear of punishment or retaliation.
3. An expectation of collaboration across ranks to seek solutions to vulnerabilities.
4. A willingness on the part of the organization to direct resources to address safety concerns.

Traditional surgical culture stands almost in direct opposition to the values upheld by organizations with effective safety cultures for several reasons. Surgeons have been hesitant to discuss errors; rather mistakes have been equated to incompetence. Surgeons also tend to minimize the effects of stress on their ability to make decisions [37]. The surgical culture, especially in the operating room (OR), is extremely hierarchical with the surgeon at the leader. Ultimately, while there needs to be clear role clarity, hierarchy can prevent nurses and other OR staff from pointing out potential errors or mistakes made by the team, resulting in potentially preventable adverse events. Moreover, this culture is not limited to the OR. Medicine strongly values professional autonomy, which frequently promotes individualism over cooperation, but often to the detriment of patient care [38]. Finally, patient safety, although often viewed as important, is seldom promoted as an organizational priority or an organizational value.

Finally, organizations often do not feel the need to devote resources to overhauling their patient safety systems as long as they perceive their existing processes to be adequate.

Measuring Safety Culture

Efforts to foster cultural change within an organization with regard to patient safety have been limited in the past by the inability to measure the impact of any given intervention. However, studies have shown that employee attitudes about culture are associated with error-reduction behaviors ranging from the aviation industry to medicine with central line-associated blood stream infections. The Safety Attitudes Questionnaire (SAQ) and the HSOPS (Hospital Survey on Patient Safety Culture) are validated survey instruments that can be used to measure culture in a healthcare setting [39]. The Joint Commission encourages all hospitals to measure safety culture every 18 months to 2 years. The surveys consist of a series of questions measuring six domains: teamwork climate, safety climate, job satisfaction, perception of management, stress recognition, and working conditions.

As an example, in the SAQ survey, the safety climate scale portion of the questionnaire consists of the following seven items:

1. I am encouraged by my colleagues to report any patient safety concerns I may have.
2. The culture in this clinical area makes it easy to learn from the mistakes of others.
3. Medical errors are handled appropriately in this clinical area.
4. I know the proper channels to direct questions regarding patient safety in this clinical area.
5. I receive appropriate feedback about my performance.
6. I would feel safe being treated here as a patient.
7. In this clinical area, it is difficult to discuss mistakes.

Although perceptions of teamwork climate can differ as a function of one's role in the OR, perceptions of safety climate are relatively consistent across OR providers in a given hospital. Using a survey, hospitals can compare culture between different types of healthcare workers within a department as well as culture between departments throughout the institution. Scores can be compared to those of other participating institutions to compare safety climates. This allows hospitals to collaborate with one another to implement programs to improve safety culture. In addition, scores can be used to evaluate the effectiveness of safety interventions by comparing the survey safety climate scores post-implementation to baseline scores.

Strong teamwork is at the core of any effective organization and is a key element to ensuring patient safety in the OR. Teamwork is dependent on the underlying culture and patterns of communication. The ability for all team members to "speak up" about patient safety concerns is one of the most important elements of creating a culture of patient safety.

Teamwork and Communication

According to the Joint Commission, communication breakdown is one of the top three root causes of sentinel events such as wrong-site surgery. Poor communication contributed to over 60 % of sentinel events reported to the Joint Commission on Accreditation of Healthcare Organizations in 2011 [40]. Good communication is an essential component of teamwork and is especially important in the OR, one of the most complex work environments in healthcare.

Within the realm of patient care, there are enormous amounts of information being exchanged between healthcare providers on a daily basis. Much of this information, if prioritized correctly, has the potential to prevent unintended medical errors and serious harm to patients. The importance of good communication in preventing medical error is undeniable; however, it is surprisingly difficult to achieve. The traditional surgical hierarchy can prevent OR personnel from sharing important patient data and expressing safety concerns. One perioperative field study showed a 30 % rate of communication failure in the OR, with 36 % of these breakdowns having a substantial impact on patient safety [41].

In addition to overcoming the cultural barrier to better teamwork and communication, Christian and associates' prospective study of patient safety in the OR demonstrated that the standard workflow of the OR itself presents many opportunities for the loss or degradation of critical information [42]. Handoffs of patient care from the OR to other locations or providers are particularly prone to information loss, which has been demonstrated in other clinical settings. Handoffs and auxiliary tasks, such as the surgical count, frequently take place during critical portions of the case and place competing demands on provider attention from primary patient-centered activities. Communication between the surgeon and pathologist also is vulnerable, as the communication often occurs through secondary messengers such as nurses or technicians. This information loss can lead to delays, overuse of staff and resources, uncertainty in clinical decision-making and planning, and oversights in patient preparation.

Measuring Teamwork

Research in commercial aviation has demonstrated a strong correlation between better teamwork and improved safety performance. Cockpit crew members' reluctance to question a captain's judgment has been identified as a root cause of aviation accidents. Good attitudes about teamwork are associated with error-reduction behaviors in aviation, and have also translated to medicine with improved patient outcomes in ICUs and decreased nurse turnover in the OR. It is also associated with higher job satisfaction ratings and less sick time taken from work.

Safety culture surveys can be used to measure teamwork and provide benchmarks for departments or hospitals seeking to measure and improve their teamwork climate [43].

The teamwork scores are responsive to interventions that aim to improve teamwork among operating teams, such as the implementation of crew resource management or team training, executive walk rounds, and preoperative briefing team discussions. The communication and collaboration sections of the surveys reflect OR caregiver views on teamwork and can be used to distinguish meaningful interventions from impractical and ineffective programs.

In a survey of operating room personnel across 60 hospitals, the SAQ identified substantial differences in the perception of teamwork in the OR depending on one's role. Physicians frequently rated the teamwork of others as good, while nurses at the same institutions perceived teamwork as poor. These discrepancies can be attributed to differences in the communication skills that are valued by surgeons and nurses. For example, nurses describe good collaboration as having their input respected, while physicians describe good collaboration as having nurses who can anticipate their needs and follow instructions. Efforts to improve the communication that takes place between physicians and nurses can directly improve the perception of teamwork and collaboration by the OR team. Empowering well-respected surgeons to promote principles of teamwork and communication can go a long way toward transforming attitude and behavioral changes in fellow physicians, as well as other members of the surgical team. Surgeons are increasingly encouraging the respectful and timely voicing of concerns of OR personnel, and that will likely pay dividends.

Tools for Improving Safety Culture, Teamwork, and Communication

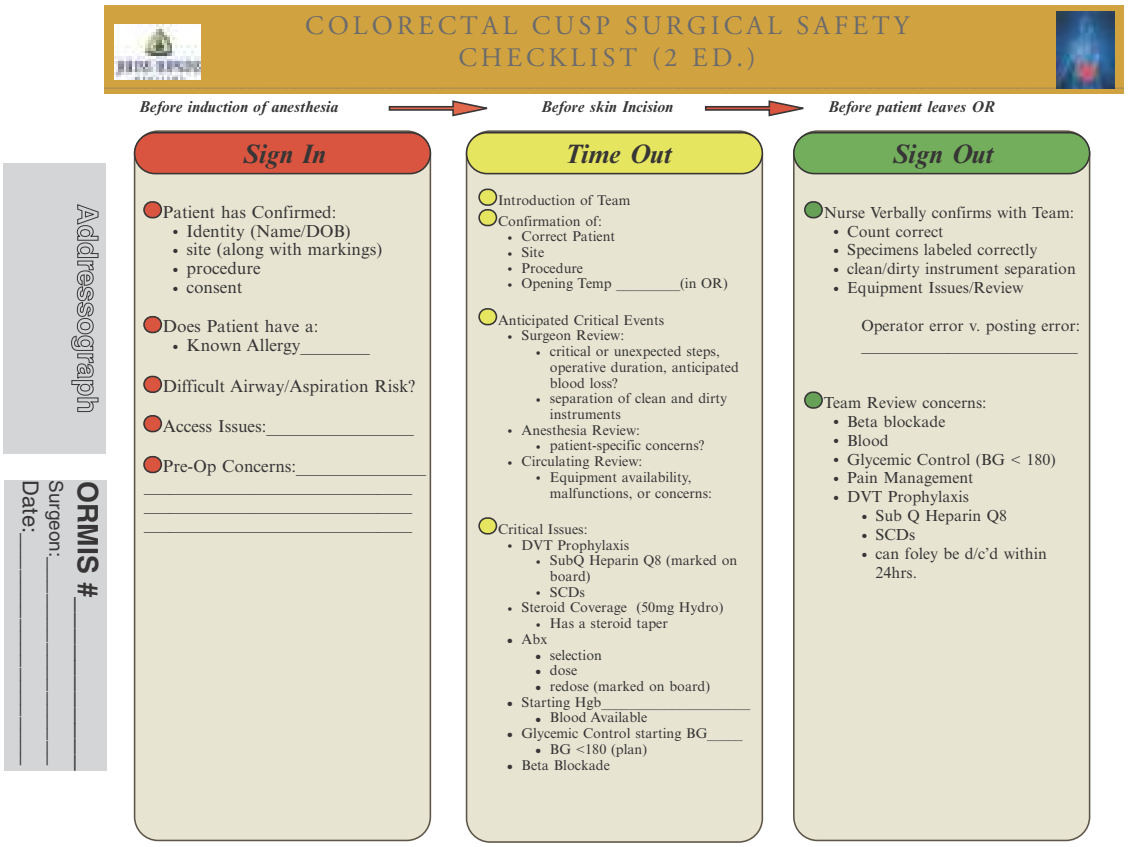
A hallmark of high reliability organizations is the frequent use of tools such as prompts, checks, standard operating protocols, and communication interventions such as team briefings and debriefings. These tools identify and mitigate hazards and allow an organization to complete tasks more efficiently. They also foster a culture of open communication and speaking up if a team member senses a safety concern. Safety checks and standardized team discussions serve as prompts to help "engineer out" human error, providing quality assurance and improving information flow. They also can prevent errors related to omissions, which are more likely to occur when there is information overload, multiple steps in a process, repetitions in steps, planned departures from routine processes, and when there are other interruptions and distractions present while the process is being executed. These same interventions have been shown to improve patient safety in ORs and ICUs [44, 45].

Preoperative briefings and checklists, when used appropriately, can help to facilitate transfer of information between team members. A briefing, or checklist, is any pre-procedure discussion of requirements, needs, and special issues of the procedure. Briefings are best when locally adapted to the specific needs of the specialty. They have been associated with an improved safety culture, including increased awareness of wrong-site/wrong-procedure errors, early reporting of equipment problems, reduced operational costs, and fewer unexpected delays. In one study, 30.9 % of OR personnel reported a delay before the institution of OR briefings, and only 23.3 % reported delays after briefings were instituted [46, 47]. OR briefings are increasingly being used to ensure evidence-based measures, such as the appropriate administration of preoperative antibiotics and deep vein thrombosis (DVT) prophylaxis, are used. Briefings also allow personnel to discuss potential problems *before* they become a "near miss" or cause actual harm.

The World Health Organization (WHO) has developed a comprehensive perioperative checklist as a primary intervention of the "Safe Surgery Saves Lives" program—an effort to reduce surgical deaths across the globe [48]. The WHO checklist includes prompts to ensure that infection prevention measures are followed, potential airway complications are precluded (e.g., anesthesia has necessary equipment and assistance for a patient with a difficult airway), and the groundwork for effective surgical teamwork is established (e.g., proper introductions of all OR personnel). Aspects of the Joint Commission's pre-procedure "Universal Protocol" (or "time-out") also are included in the checklist (e.g., checks to ensure operation performed on correct patient and correct site). The initial WHO checklist study was associated with significant reduction in mortality worldwide, but follow-up studies evaluating the efficacy of the checklist in governmental programs have failed to reproduce the same impact on morbidity and mortality. It is now understood that the efficacy of checklists is largely dependent on the safety culture in which they are implemented [47]. Simply mandating use is unlikely to change the quality of care delivered, but a system of comprehensive interventions to improve safety culture and implement checklists ***will*** likely result in meaningful improvement. Similar to briefings, it is important to adapt checklists to the local environment (Figure 71-3).

Tools such as checklists, sign outs, briefings, and debriefings improve communication between healthcare providers and create a safer patient environment. Although their use in healthcare is still highly variable, several specialties that have incorporated them, such as intensive care and anesthesia, have made impressive strides in patient safety. Currently, communication breakdowns, information loss, hand off, multiple competing tasks, and high workload are considered "annoying but accepted features" of the perioperative environment [17]. As physician attitudes toward errors, stress, and teamwork in medicine become more favorable toward the common goals of reducing error and improving teamwork and communication, medicine will likely achieve many of the milestones in safety that high reliability industries such as aviation have already accomplished.

As a major example, the comprehensive unit-based safety program (CUSP) was initially designed for the intensive care



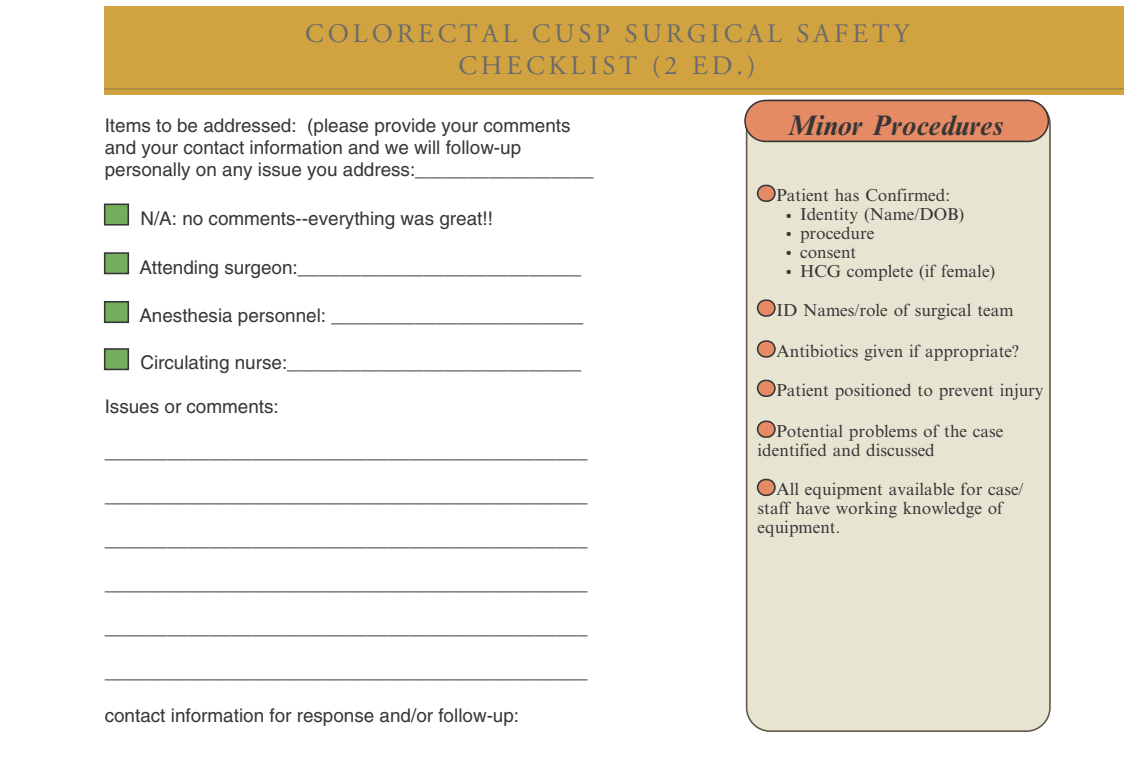


FIGURE 71-3. Local adaptation of briefing checklist to colorectal surgery. *With Permission from Hicks CW Improving Safety and Quality of Care With Enhanced Teamwork Through Operating Room Briefings JAMA Surg. 2014;149(8):863–868. doi:*10.1001/jamasurg.2014.172. *© American Medical Association 2014.*

unit, but has been translated to different clinical areas [49]. CUSP is an effective tool for improving both safety culture and clinical outcomes. Every clinical area that implements CUSP assembles a multidisciplinary team and follows five iterative steps: training on the science of safety, identify patient safety hazards, partner with senior executive, learn from defects, and implement tools to improve teamwork and communication. All teams include providers from relevant disciplines such as nurses, physicians, hospital infection control practitioners, technicians, advanced practice providers, resident physicians, and clerks. This approach has been successfully used to reduce colorectal SSIs from 27 to 18 % in a university based setting [50]. It has also been adapted to other perioperative settings across the country through a national implementation project in collaboration with the ACS [51].

"Never Events" in Surgery

Never events are errors in medical care that are clearly identifiable, preventable, and serious in their consequences for patients, and that indicate a real problem in the safety and credibility of a healthcare facility [52]. The term was popularized by Dr. Ken Kizer after the IOM report.

Criteria for inclusion as a "never event" are listed below. The event must be:

- Unambiguous (i.e., the event must be clearly identifiable and measurable, and thus feasible to include in a reporting system);
- Usually preventable, with the recognition that some events are not always avoidable, given the complexity of healthcare;
- Serious, resulting in death or loss of a body part, disability, or more than transient loss of a body function;

And any one of the following:

- Adverse and/or,
- Indicative of a problem in a healthcare facility's safety systems and/or,
- Important for public credibility or public accountability.

These events are not a reasonable medical risk of undergoing surgery that the patient must accept, but medical errors that ***should never happen***. The occurrence of any of these events signals that an organization's patient safety culture or processes have defects that need to be evaluated and corrected (Table 71-3).

Table 71-3. "Never Events"

1.	**Surgical or invasive procedure events**
1A.	**Surgery or other invasive procedure performed on the wrong site (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
1B.	**Surgery or other invasive procedure performed on the wrong patient (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
1C.	**Wrong surgical or other invasive procedure performed on a patient (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
1D.	**Unintended retention of a foreign object in a patient after surgery or other invasive procedure (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
1E.	**Intraoperative or immediately postoperative/postprocedure death in an ASA Class 1 patient (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices
2.	**Product or device events**
2A.	**Patient death or serious injury associated with the use of contaminated drugs, devices, or biologics provided by the healthcare setting (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
2B.	**Patient death or serious injury associated with the use or function of a device in patient care, in which the device is used or functions other than as intended (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
2C.	**Patient death or serious injury associated with intravascular air embolism that occurs while being cared for in a healthcare setting (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, long-term care/skilled nursing facilities
3.	**Patient protection events**
3A.	**Discharge or release of a patient/resident of any age, who is unable to make decisions, to other than an authorized person (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
3B.	**Patient death or serious injury associated with patient elopement (disappearance) (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
3C.	**Patient suicide, attempted suicide, or self-harm that results in serious injury, while being cared for in a healthcare setting (updated)** Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

(continued)

TABLE 71-3. (continued)

4. Care management events

4A. Patient death or serious injury associated with a medication error (e.g., errors involving the wrong drug, wrong dose, wrong patient, wrong time, wrong rate, wrong preparation, or wrong route of administration) (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

4B. Patient death or serious injury associated with unsafe administration of blood products (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

4C. Maternal death or serious injury associated with labor or delivery in a low-risk pregnancy while being cared for in a healthcare setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers

4D. Death or serious injury of a neonate associated with labor or delivery in a low-risk pregnancy (new)
Applicable in: hospitals, outpatient/office-based surgery centers

4E. Patient death or serious injury associated with a fall while being cared for in a healthcare setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

4F. Any Stage 3, Stage 4, and unstageable pressure ulcers acquired after admission/presentation to a healthcare setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, long-term care/skilled nursing facilities

4G. Artificial insemination with the wrong donor sperm or wrong egg (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices

4H. Patient death or serious injury resulting from the irretrievable loss of an irreplaceable biological specimen (new)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

4I. Patient death or serious injury resulting from failure to follow-up or communicate laboratory, pathology, or radiology test results (new)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

5. Environmental events

5A. Patient or staff death or serious injury associated with an electric shock in the course of a patient care process in a healthcare setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

5B. Any incident in which systems designated for oxygen or other gas to be delivered to a patient contain no gas, the wrong gas, or are contaminated by toxic substances (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

5C. Patient or staff death or serious injury associated with a burn incurred from any source in the course of a patient care process in a healthcare setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

5D. Patient death or serious injury associated with the use of physical restraints or bedrails while being cared for in a healthcare setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

6. Radiologic events

6A. Death or serious injury of a patient or staff associated with the introduction of a metallic object into the MRI area (new)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices

7. Potential criminal events

7A. Any instance of care ordered by or provided by someone impersonating a physician, nurse, pharmacist, or other licensed healthcare provider (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

7B. Abduction of a patient/resident of any age (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

7C. Sexual abuse/assault on a patient or staff member within or on the grounds of a healthcare setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

7D. Death or serious injury of a patient or staff member resulting from a physical assault (i.e., battery) that occurs within or on the grounds of a healthcare setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

Although there is widespread agreement that surgical never events are preventable and despite several national and local programs being launched to decrease them, never events are still a significant problem. A study from Mehtsun et al. showed that from 10/1990 to 10/2010, there were 9744 paid malpractice claims for never events in the USA alone. Of these, mortality was reported in 6.6 %, permanent injury in 33 %, and temporary injury in 59 %. The cost of the never events totaled 1.3 billion dollars. Also, of physicians who were named in a surgical never event claim, 12.4 % were named in another future never events claim [53].

An unintended retained surgical item refers to any surgical item found to be inside a patient after he or she has left the OR, thus requiring a second operation to remove the item [39]. Estimates of retained foreign bodies in surgical procedures range from one case per 8000–18,000 operations, corresponding to one case or more each year for a typical large hospital or approximately 1500 cases per year in the USA [54]. This estimate is based on an analysis of malpractice claims, but is likely to *underestimate* the true incidence. Retained surgical items in colorectal surgery are usually laparotomy pads, needles, or instruments. The risk of having a retained surgical item increases during emergency surgery, when there are unplanned changes in procedure (due to new diagnoses encountered in the OR), long procedures with multiple surgeons, nurses, and scrub technicians, and in patients with higher body-mass index [54]. Retained foreign objects are most commonly identified on postoperative imaging, either incidentally or as part of an evaluation for pain or obstructive symptoms. In virtually all cases where there is a delay in identifying the retrained foreign object, review of the original operating room record will reveal a correct surgical count—a "falsely correct count." This occurs in 21–100 % of cases with retained foreign object [55]. Given this, it is recommended that an X-ray is obtained at the completion of an operation if there is any concern for a foreign body based on confusion regarding the counts by even a single member of the OR team, or in the presence of a risk factor. There is also growing interest in using sponges with radiofrequency identified laparotomy pads to eliminate human error from the equation. While these systems virtually eliminate retained laparotomy pads, other items can still be retained. Interestingly, retained foreign objects do still occur even when the final count is "incorrect"—though this usually occurs when there is poor communication among the operating room team. Institutional policies for standard operating protocols in the case of an incorrect count (such as requiring a mandatory radiograph while the patient is still in the OR) can avoid conflict among caregivers and mitigate the likelihood of a retained surgical item occurring as a result of a known incorrect count. Additionally, fostering a culture of safety in the operating room where everyone feels comfortable speaking up in the case of an adverse event will also go a long way to preventing this unfortunate scenario.

Patient and Families as Partners

Historically, risk management professionals and legal counsels have recommended against open lines of communication between providers and patients about patient safety events and medical errors; however, one of the hallmarks of the patient safety movement is a new commitment to disclosure of the risks associated with procedures, occurrence of patient safety events, and the recognition of the patient as an essential partner in the delivery of safe, cost-effective care. In the chronic disease literature like diabetes, hypertension, and congestive heart failure management, it is clear that patients who are active participants in their care achieve better outcomes. It is less clear what this looks like in the acute care setting. A study by Waterman et al. revealed that most hospitalized patients very much want to participate in their care (91 %) to prevent medical errors, but it was highly variable as to the tasks they would embrace—with 85 % being agreeable to asking about medication indications versus only 46 % willing to question providers about hand hygiene. Many believe that shared decision-making is the pinnacle of patient-centered care. At present, though, what encompasses shared decision-making in surgery is evolving. It is generally defined as the patient and physician sharing responsibility in the clinical decision-making process (two way dialogue), and incorporating the patients' values and beliefs in that process. Technology and decision support aids are emerging as an important tool in implementing this approach in surgery. While medicine has yet to fully incorporate and achieve buy-in for this concept, it represents another component of allowing all members of the healthcare team, patient, and providers to actively participate in achieving the best outcomes possible.

Conclusions

The fields of quality and safety have seen exponential growth in the past 15 years. Much of the terminology is now commonplace. Ultimately, to realize meaningful improvement in surgical care, we need valid, meaningful, and transparent measures available for all hospitals. Policy makers must support development of a culture where hospital leaders can declare a goal of zero preventable harm and work to establish an enabling infrastructure, and a system of accountability [56]. As colorectal surgeons, we must be dedicated to acquiring the competencies and serving as leaders in improvement efforts.

Practice Management

Eric M. Haas

Key Concepts

- Lack of awareness about practice management could lead to poor career decisions, financial distress, and surgeon burnout.
- If joining a hospital model, a surgeon may have benefits of a work RVU-based compensation, as well as the support and resources of the institution. However, the surgeon may need to align their personal goals to the goals of the institution and accept lack of autonomy for purchasing and decision-making.
- In the private practice model, the physician is essentially self-employed, their goals and practice mission are basically aligned, and decisions are made real-time to meet the immediate needs of the practice. However, the financial state of the practice figures into decision-making and can limit the physician's ability to realize their goals.
- Revenue in the private practice model is based on professional fee collections and ancillary investments, while the hospital model generates revenue through professional fees, facility fees, downstream revenue, market share, and outcome incentive programs.
- Effective marketing and networking are necessary to develop and maintain relationships with patients and referring physicians.

Introduction

While solid medical knowledge and sound surgical skills are paramount for colorectal surgeons, practice management is an essential—and often overlooked—consideration for a successful career. Practice management is a broad term that covers all daily operations of a surgical practice, including the practice model, office operations, financial planning, patient interaction, personnel, technology, medical records, marketing and business development, coding, billing, reimbursement, practice set up, and compensation. Most commonly, the principles of practice management are not considered at the start of one's career, and many of the key concepts are not addressed in residency or fellowship. The subject of the "business of medicine" is often thought of as distasteful, and therefore not discussed among young surgeons. As a result, new surgeons may not be aware of many considerations and the implications of their decisions when accepting a job and joining a specific practice model.

Patients are consumers, and consumers demand high quality care at a low cost to be satisfied. To meet these needs, physicians and practice administrators must think outside of the box when designing their practice model. They need to look to a model that is reliable, efficient, and effective at producing a high quality outcome and a happy customer. That ideal business may be a fast-food chain restaurant. Fast-food restaurants are a demanding, high-volume, customer-focused industry. Proper management in these chains has a system of consistent, reproducible products and customer satisfaction in place before the restaurant opens, and management continues to oversee the daily operations to ensure the systems meet pre-determined goals at every level. Regardless of the time of day, geographic location, or franchise specifics, they are a model of efficiency, reproducibility, standardization, and excellent customer service to meet expectations. A customer can walk into a McDonald's in Houston, Texas at 6 am or a McDonald's in Cleveland, Ohio at 6 pm, place the same order, and receive the same product at the same price with the same overall experience. This cannot occur without a system of process control, standards, check and balances, and quality improvement. The same concepts apply to medical practice management.

In reality, the paradigm that discussing the business of medicine is uncouth should be replaced with the model that unawareness of practice management could lead to poor career decisions, financial distress, and surgeon burnout. Awareness of the many business-related aspects of practice management can help meet the current challenges with

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_72

patient satisfaction, physician satisfaction, and financial solvency. In today's practice environment, the business of medicine may dictate one's ultimate aspirations, achievements, and job satisfaction. Burnout is a critical issue, impacting an estimated 25 % of surgeons [1]. Studies have demonstrated burnout is directly associated with a diminished quality of life, quality of practice, and quality of care provided, by increasing the likelihood of medical errors [1–3]. Without addressing the root causes, more serious complications can result, including depression, suicidal ideation, and alcohol abuse [1–3]. Practicing in an unfit environment is a main factor leading to burnout, as physicians cannot achieve their optimal work-life balance needed for personal and professional career satisfaction [4]. Colorectal surgery has been reported as the surgical specialty with the highest job satisfaction in young surgeons within their first 10 years after board certification [5]. Thus, understanding practice management and guiding colorectal surgeons to the best fitting practice model to continue reports of high job satisfaction and high performance is a challenge for the American Society of Colon and Rectal Surgeons.

While surgeons can control outcomes in the operating room, understanding practice management is essential to actually practicing medicine and running a successful operation in line with one's expectations and goals. This chapter cannot replace the detailed books and course offerings essential when setting up a practice; however, it's a good introduction to the fundamental key concepts of practice management. This chapter also uniquely focuses on the physician and physician satisfaction. The concentration is on finding the best environment for the surgeon to start and maintain a successful practice, with the assumption that a surgeon must be content, comfortable in their environment, and working in line with their own expectations in order to provide quality surgical care and produce excellent patient outcomes and satisfaction. In this chapter, we aim to describe the key principles of practice management for colorectal surgeons. Unlike other chapters in this text, "Practice Management" is not written based on the history, evidence, and published literature on the topic. The chapter is written based on personal experiences, anecdotal learning, best practices, and pearls from colleagues in private practice, hospital, and academic settings on opening, developing, and practicing in an ideal colorectal surgery practice model.

Practice Models

For the purposes of this chapter, there are two main practice models in which a colorectal surgeon can practice: institution-based and private practice. The institution-based model encompasses hospital, university, and academic institutions. Under this broad umbrella are the environments of hospital employee and university employee. Integrated Health Care Models, such as Kaiser Permanente, which offer not-for-profit health plans and insurance, a tax-exempt shelter for the for-profit medical groups, and physician-owned for-profit partnerships, are also considered in the institution-based category [6]. Private practice models include solo and group practices, including single specialty and multispecialty group practices. Each model has unique merits and limitations and regardless of which model you work in, there are common considerations. To simplify, we will refer to the models as "hospital" and "private practice" throughout this text.

Practice Philosophies in Hospital and Private Practice Models

There are several philosophic differences between the hospital and private practice models that are important to understand and consider before deciding which pathway to follow. Entering into an agreement without fully understanding and addressing the philosophical and practical components of the work environment is what often leads to physician discontent, underperformance, and burnout. When choosing a practice model, multiple factors must be taken into consideration including the overall mission and goals of the workplace, the practice environment, compensation and benefits packages, future opportunities and job advancement, performance and production expectations, and levels of autonomy. With the various models and considerations in mind, one can choose the best fitting model for their individual needs, professional expectations, and career success. A summary of the distinctions between the hospital and private practice models is seen in Table 72-1.

The Hospital Model

The primary mission of the hospital or institution-based model centers around serving the needs of the community to improve overall patient care and offering value over competitors in the marketplace. These lofty goals are not necessarily aligned with the individual needs and goals of the employed surgeon. The hospital administrators' goals are for the hospital system to be profitable, serve the community, achieve local, regional, and national recognition, and advance research and teaching. In theory, this will lead to increased patient market share, physician resources, institutional name recognition, and professional growth for both the institution and the physician. Many of the components for success in the hospital model may not result in the individual surgeon's personal job satisfaction. Once part of the larger hospital model, the surgeon may need to conform their personal goals and agenda to the goals of the division, department, and institution. When joining a hospital model, the physician is an employee and, as such, loses the ability to make independent decisions regarding staffing, purchasing, recruiting, growth and expansion, and office administration and processes. Even when afforded certain levels of decision-making, there are generally layers of bureaucracy in place,

Table 72-1. Distinctions between the hospital and private practice models

Overall gestalt	Carry out the global goals of the hospital's strategic mission	Concentrate on patient care and the needs of the doctors
Role of the hospital	Employed	Self-employed; voluntary medical staff member to facilitate patient care
Practice philosophy	Physicians exist to help meet the mission of the hospital and assure the hospital is profitable	Hospital exists to help me care for my patients
Management	CEO, CFO, Board of Directors, Vice Presidents, and many clinical/administrative department, division, and group heads	Managing partner, practice administrator, office manager
Decision-making process	Formal processes of committees, administration, and the Board of Directors; decisions take a longer time to make and are met with resistance, and often require negotiation for action	Made by individual or group of physicians; decisions often be made to address immediate needs
Time frame of action	Weeks to months for action; layers of bureaucracy to navigate through and consideration of the hospital's strategic plan and budget cycles	Real-time implementation to address current needs
Communication	Bureaucratic, numerous meetings, and politics	Autonomist, consensus decision-making
Resources	More resources available, but acquisition more difficult	Limited resources based on financial state of the practice
Culture	Group, formal organization	Individual, informal organization
Staffing	Run by the institution's Human Resources department. Formal processes for hiring and firing, which may interfere with physician's staffing preferences	Physician has direct control over staffing decisions
Compensation	Salary, Relative Value Unit (RVU) based	Collections based
Outcome metrics	Data acquisition and reporting supported by the hospital system and data widely available; source of revenue for the hospital	Data acquisition not feasible: expensive and labor intensive

which delay adaptation of changes. In the typical employed environment, the surgeon is accountable to a direct boss, and multiple levels of supervisors—many of which are not physicians—and may not always see patient care and professional needs through the eyes of the surgeon.

Physician advancement in the hospital model is generally based on a combination of performance evaluations and financial productivity. Institutions may also provide incentives for high patient satisfaction, clinical outcomes, academic achievements, and participation in graduate medical education. Financial productivity is assessed on meeting the budgetary calculations of the employed surgeon's proforma, their individual total "cost" with salary, benefits, and overhead. The proforma is composed of the surgeon's calculated cost center, which factors in overhead, salary, and benefits. The concept of a cost center is important to understand and is germane to most institution's budget calculations. A surgeon's cost center is the total costs based on calculated direct and indirect costs attributed or assigned to each individual employed physician. The components of one's cost center may vary from hospital to hospital, but is imperative to understand what overhead is assigned into one's budget. Achievement of cost neutrality based on one's individualized budget will be assessed at a quarterly and yearly basis and, if not achieved, may result in salary reductions and other negative consequences. Clinical outcome metrics are typically measured using federal programs, such as the National Surgical Quality Improvement Program (NSQIP) and the Centers for Medicare and Medicaid Physician Quality Reporting System and Readmission Reduction Program [7–10]. Some institutions offer bonuses or incentives for the surgeon to achieve at or above expected outcomes benchmarks. Additionally, patient satisfaction is often measured using the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) survey of patients' perspectives of hospital care [11, 12]. HCAHPS are important for hospitals to realize national incentives.

There are numerous benefits specific to joining a hospital model. First, in the current unstable healthcare environment, being employed by a hospital or institution lends stability and security. Contracts range from 3 to 5 years, and many surgeons find the appeal of "guaranteed" income outweighs the potential for higher income in private practice. The hospital model provides layers of support, experience, and expertise, allowing for multidisciplinary care of complex surgical patients that would be difficult to achieve in the private practice model. With that support comes layers of administrative help to mitigate the non-medical responsibilities of the physician, and experts in the legal, compliance, and coding fields to attenuate exposure to scrutiny and liability. There is also the prestige of association with an established, recognized hospital system. In addition, there are greater opportunities for mentoring, research, and career development in the hospital model than a private practice due to the sheer size, funding, and infrastructure of the institution. The hospital model has greater market share and holds significantly more leverage over payers, resulting in much higher contracted fee schedules for reimbursement than private practice. This can further translate into a stable environment in regards to salary expectations. There are additional benefits, such as the built-in referral base from the large number of referring doctors employed by the hospital. Lastly, hospital models usually offer robust benefit packages and a resource-based relative value scale compensation model that will be addressed in the next section.

The Private Practice Model

In private practice, the mission of the practice and physician are basically aligned at every level. However, the financial state of the practice can limit the physician's ability to realize many of their goals and aspirations. The primary goal of a private practice model is to provide a working environment that fosters best practices in patient care and satisfaction among patients, staff, and physicians—all while proving to be a viable and profitable arrangement. The private practice administrator's goals are to provide a sound workflow, a profitable system for the doctors, and high rates of job satisfaction. This will ultimately lead to high patient satisfaction, which will bring in more patients and lead to continued growth to successfully compete in the community and service area. The philosophy of a private practice is to meet the immediate needs of the doctors and the patients with the surgeon as autonomous. Surgeons in private practice are self-employed and serve as a voluntary medical staff member at the hospital to facilitate patient care. Decisions are made in the best interest of the practice, and made real-time to meet the immediate needs of the practice. The practice may make expenditures without a formal review or budget approval regarding the financial consequences. In contrast, institutions will usually need to justify the cost, benefit, budget, and cost centers at multiple levels before making any decisions or purchases, leading to frustrating delays. The private practice physician usually needs to seek a consensus from their associates or partners, but there is little bureaucracy governing needs, rationing requests, or granting permissions.

In private practice, physician advancement is typically based on the individual's productivity measured in patient collections and the time they have been a part of the practice. Although national recognition and academic pursuits into graduate medical education and scientific research may be an important part of a private practice, these components are secondary to the financial success of the practice. The support systems that are offered by the hospital model cannot be duplicated in the setting of private practice. Private practice models lack the infrastructure, economic resources, and incentives to perform intensive data collection and reporting efforts for formal benchmarking programs. Private practices generally do not measure clinical outcomes, patient satisfaction, or productivity against national standards. Clinical outcomes are followed anecdotally and measured through conference participation, such as multidisciplinary tumor boards and morbidity and mortality to gauge individual outcomes. Patient satisfaction is measured from individual relationships with patients, colleagues, referral sources, and Internet-based patient reviews rather than federal HCAHPS programs. Productivity metrics and financial viability of the practice is also generally addressed with the practice accounting firm in a less formal process compared to the hospital setting. Monthly accounting-based metrics are personalized to the practice needs and rarely involve a formal budgetary process.

There are specific benefits to the private practice model. There is the freedom of being your own boss, making your own decisions, and implementing changes to meet the immediate needs of the patients and the practice. The physician can maintain personal goals, preferences, and identity without the need to negotiate with third part administrators. There is also no restriction on the ability to invest in ancillary health care services, such as outpatient surgery or endoscopy centers, which have become a significant source of additional income for many practicing surgeons. In contrast, hospital model doctors rarely have the ability to participate in physician-owned businesses or maintain entrepreneurial interests in future developments. Lastly, one can maintain the intellectual property and patents on any research or devices in the private practice model. These rights are usually owned by the hospital when employed.

The Basics of Payment, Compensation, Profits, and Billing

To first understand compensation, it is important to understand the financial platforms from the perspective of the private practice and hospital models. In private practice, the financial relationship with the hired surgeon is based primarily on collections from professional fees generated by the surgeon. Professional fees are relatively universal and based primarily on Medicare and federal allowable rates, as well as negotiated rates from third party commercial payors. In the private practice model, salary and compensation plans are closely linked to the profitability of the surgeon, which is reflected in the amount of collections they bring into the practice, less the overhead attributed to that surgeon. Maximizing workflow, efficiency, and productivity financially rewards the surgeon. Although professional fee collections are the main source of practice income, many private practice surgeons seek outside healthcare-driven investments as secondary income sources. These secondary sources of revenue are generally physician-owned or physician-partnered surgery, endoscopy, or ancillary service organizations. There are many financial, legal, and ethical considerations that factor into a decision to partner with an investment entity. Although there are many successful and profitable agreements, there is a certain level of risk and exposure with any agreement, and professional accounting and legal investigation of the investment is paramount regardless of how tempting the investment may appear. In general, outside investment opportunities are not offered until the practice surgeon has established a sound patient base and reputation.

While the private practice model bases revenue streams on professional fee collections and, to a lesser extent, ancillary investments, the hospital model has several major avenues to generate revenue including professional fees, facility fees, downstream revenue, market share, and outcome incentive

programs that are not available in the private practice setting. Professional fee reimbursement is usually a percentage higher than private practice since the hospital or institution usually has market share, which allows them to negotiate a higher allowable fee schedule. Facility fee reimbursement is the allowable amount of fee that a hospital collects for having the procedure or encounter performed at their institution. Facility fees are multiples of the professional fees, making a tremendous profit for the hospital facility with each procedure and visit. In addition, downstream revenue adds further to the profitability. Downstream revenue is the revenue generated through the patient's utilization of hospital services during their encounter, including radiology, pathology, radiation oncology, medical oncology, cardiac catheter labs, and other services. The professional fees generated from consulting doctors are also a source of downstream revenue if those doctors are hospital-employed physicians. Hospitals also generate profit by gaining market share of a service area. Once a hospital accrues a critical mass of physicians, it has a sizable market share and can represent physicians collectively to negotiate with third party commercial carriers for reimbursements above Medicare rates and even above private practice negotiated rates. Finally, the fifth source of revenue stream is realized through federal incentives and reimbursement programs by accumulating and reporting data points of outcomes and satisfaction metrics. The greater the volume of patient encounters, the greater the ability to receive incentives based on the volume of data points. Employed physicians should understand the multiple ways hospitals gain profitability through their employment relationship to gain negotiating leverage.

The downside of employing a surgeon from the hospital perspective is the high associated costs and inefficiencies of management and administration of a doctor's practice. Hospitals are notorious for abundant and excessive layers of administration and human resources with resulting higher indirect costs that far exceed those of a private practice model. The overhead of the employed surgeon usually outweighs the revenue generated from the professional fee collections. Although there are many variations by institution, for each employed colorectal surgeon, the hospital may assume an estimated loss of up to $200,000 per year. The goal of the hospital administrator is to achieve cost neutrality, where the overhead of the surgeon is equal to the revenue generated from professional fees alone. In this scenario, the hospital achieves pure profit from the other revenue streams generated from every patient encounter that the surgeon brings to the hospital through facility fees, downstream revenue, market share, and incentives programs. The pros and cons of the two main models are seen in Table 72-2.

There are other models that exist where the hospital system functions as an academic center, with well established direct and tertiary referrals independent of the surgeon employee. In this setting the surgeon is usually offered a salary and incentives that may be independent of financial productivity.

Compensation

There are several different compensation models used in practice. Depending on the practice model, various models may be offered. In this section, we will address the most common types for each practice model, with emphasis on the relative value scale system, which plays a role in all models.

Relative Value Scale System

Hospital models usually follow a Resource-based relative value scale (RVU). The RVU system was developed by the Centers for Medicare and Medicaid Services in 1992, based on the Medicare Physician Fee Schedule, to assign numeric value to encounters and procedures based on the difficulty of the service provided, the risk involved, and the overall care requirements of the patient [13]. In the USA, Medicare uses RVUs and nearly all health maintenance organizations (HMOs) to determine how much money providers should be paid for physician services, including office visits and surgical procedures [14]. Every procedure and Current Procedural Terminology (CPT) procedure code has an RVU assigned to it for reimbursement rates. Each RVU has three components associated with calculation for payment: physician work (54 %), practice expense (41 %), and malpractice overhead (5 %). The work component reflects the physician's relative time and intensity associated with furnishing a service and is known as work RVU (wRVU). The practice expense component reflects the costs of maintaining a practice, including costs for office space, supplies and equipment, and staff. The malpractice overhead piece represents the costs of malpractice insurance. Each of the three RVU components is adjusted by geographic region (GPCI) to create a compensation level for that service.

Table 72-2. Pros and cons of the hospital versus private practice model

Model	Hospital	Private practice
Pros	– Stable environment	– Maintain freedom, autonomy, and personal goals and aspirations
	– Prestige of institution	– Better total compensation
	– Mentoring and research opportunities	– Opportunities to supplement income with outside investments
	– Favorable benefits, RVU compensation	– Maintain intellectual property over research and devices
	– Federal incentives for participation in data collection and outcomes metrics	
Cons	– Cannot invest in ancillary care centers	– No formal benchmarks for outcomes or satisfaction
	– Own the individual's intellectual property, research, and patents	

RVU-Based Compensation

While the RVU system was initially developed as a payment method for the Medicare fee schedule, the role of RVUs has expanded and been adapted for physician compensation and productivity. Many institutions use the work component of the RVU system as the basis of their compensation package. In this model, a base salary is calculated based on an expected amount of production measured as wRVU. Annual compensation reports and benchmarked trends are available annually from the Medical Group Management Association (MGMA) and the American Group Medical Association (AGMA) [15, 16]. Recent surveys estimate the 50th percentile salary for colorectal surgeons in the first 5 years of practice between $262,000 and $360,000, [17, 18], and the median wRVUs at approximately 6500 [19]. Based on these estimates, hospitals will generally set the wRVU expectations or threshold at 50 % MGMA, then use the MGMA salary data to offer a salary commiserate with the 50 % level for colorectal surgeons. RVUs are weighted to reflect patient complexity and standardized nationally, so they can also serve as a valid metric for clinician productivity [13]. The hospital will reassess these benchmarks at the end of each year, and may adjust the wRVU threshold, which will affect the base salary. Some contracts allow a 2- or 3-year ramp up period in which to achieve the threshold wRVU without incurring reductions in salary.

When negotiated appropriately, the wRVU-based compensation model serves the employed physician well, and can be a major advantage of joining a hospital practice. Benefits of the wRVU-based system are that physicians can concentrate more on patient care and less on uninsured rates or insurance type. Since the hospital model usually assigned the coding and billing to a separate center out of the immediate control of the employed surgeon, there is comfort in that actual collections does not directly effect the surgeon's compensation. It is important for new physicians to realize they will likely not attain their wRVU threshold in their first year after entering practice. A common mistake in the wRVU-based model is to set one's wRVU threshold low for fear of not meeting goals. The disadvantage here is that income will also be reduced, as the wRVUs are linked to a specific salary. We recommend setting the wRVU level at least at the 50th percentile, and having a contract stipulating no penalties for not meeting threshold during the initial 2 years.

Production-Based Compensation

The second model is "production-based compensation." In this model, compensation is closely linked to surgeon's actual collections rather than wRVU. A surgeon joining the practice will usually be offered a starting salary based on established MGMA values for the first year or two and then is offered partnership or a compensation plan where the salary is proportionate to collections less overhead. There are rarely any wRVU calculations figured into this model, as it is the actual collections that translate into profitability. Table 72-3 demonstrates Medicare allowables for common colorectal procedures. Bonus plans are based on excess cash flow once collections attributed to the surgeon are offset by the surgeon's salary and attributed expenses. In this model, the surgeon needs to be very involved in billing and collections because unlike the hospital model, where wRVU-based compensation is received regardless of billing, in the production-based compensation model actual collections received by the practice are the most important factor.

TABLE 72-3. Example of wRVU payment formula for common colorectal procedures

Common colorectal procedures	wRVU value per unit	Medicare allowable
CPT 99203—New patient visit, moderate severity	1.42	$110.09
CPT 46221—Rubber band ligation	2.36	$278.46
CPT 45378—Screening colonoscopy	3.69	$223.34
CPT 46260—Surgical hemorrhoidectomy	6.73	$493.84
CPT 44204—Laparoscopic-segmental colectomy	26.42	$1604.27
CPT 44145—Open low anterior resection	28.58	$1728.83

The conversion factor is 35.7547 for Houston, TX

Non-Production Based Compensation

Non-production based compensation is typically a salary-based plan seen in the university academic setting. The incentive plan is based on various determinants—patient care production in the form of wRVU, education, research, and academic endeavors. Academic centers set the average compensation on MGMA or AGMA benchmarks, then adjust the overall salary based on the percentage of time attributed to each of the parameters. For instance, a surgeon scientist may have 30 % of their salary dedicated to research and education requiring a lower wRVU threshold by 30 %. Other centers offer a baseline salary that is set according to the level of scholarship, and offer bonus incentives based on academic achievements.

Bonus Structure

Bonus payments may also differ between hospital and private practice models. Hospital-based bonuses are usually wRVU-based. Once one reaches the threshold wRVU established in their contract, a bonus is calculated by multiplying each wRVU above the threshold level by a conversion factor. For example, with an individual's threshold of 6500 wRVU, each wRVU above that level will be multiplied by a conversion factor ranging from 20 to 75 dollars per wRVU, resulting in the bonus. The conversion factor differs significantly among institutions. Some institutions build in a security gap—an arbitrary, set number of wRVUs above your threshold where no bonus is paid out until exceeded. For instance, in the individual with a threshold of 6500 wRVU, if a gap of 500 wRVU is set, they will not realize their bonus until 7000 wRVU has been achieved. From the hospital's vantage point,

this gap helps guard against losses from wRVUs that may not be reimbursed, such as indigent care.

The second form of hospital-based bonuses is a collection-based model. In a collection-based structure, the surgeon recoups a percentage of collections minus expenses once the threshold wRVU number is attained. This model places risk on the surgeon, who has little control over collections in the hospital setting and should be avoided when possible.

Private practice bonus models usually begin 1 or 2 years after employment and correspond with the surgeon's ability to bring in revenue above expenses. Some practices have a formal partnership offer after 1–3 years. The downside is that most of these partnerships come with a "buy-in" provision. The concept of partnership varies significantly among practices and the surgeon candidate should fully understand the partnership arrangements before signing the initial employment contract.

In summary, for a hospital-based model, the most favorable contract is production based using a wRVU model with threshold that is at the 50th percentile of national benchmarks for base salary. We recommend a wRVU-based bonus structure because it guarantees a bonus after reaching threshold regardless of the uncertainty of reimbursement, allowing the colorectal surgeon to maintain a level of control. In the private practice model, beginning salary should be at MGMA levels and once the surgeon is able to attain collections above expenses, they should be eligible for bonus structure.

Budgets, Billing, and Collections

In a hospital model, a budget is created by the hospital, including expected income and expenses, with quarterly reviews. As a hospital employee, you have limited control over multiple parts of the budget, especially indirect costs, and you will be held accountable for staying in the black. In the hospital model, the surgeon also surrenders control over billing and collections. There are dedicated departments to code and bill. This can be advantageous in that these responsibilities can be cumbersome and at times overwhelming as long as collections do not directly affect your pay scale as it does in private practice. It is still highly recommended to be knowledge of billing and coding fundamentals and to be able to review what the hospital is processing. Even if not directly linked to your salary, under-coding and under-billing for your work will reflect poorly on your budget in one way or another.

In private practice, there is no budget per se. There is a dynamic balance sheet that tracks the current state of the practice's finances without holding any individual accountable for the financial state. Billing is the engine of the ship for private practice models. Whether to have an in-house billing department or outsource billing is a very important decision to consider. Establishing an in-house billing department should be the final step of independent practice management. Initially, outsourcing billing is recommended as it gives the surgeon proper time to dedicate to developing a practice, establishing patient flow, and all having all aspects of the business process in place before taking on the responsibilities of billing, coding, and compliance. Outsourcing also provides a valuable learning resource in the billing company to help the physician understand the billing, coding, and revenue cycles. The ultimate goal is to transition the billing tasks in-house, as no third party billing company has the personal stake in collections for your practice that you do. Ensure you understand the basics and have your practice system running smoothly before making this change to ensure efficient and effective billing practices.

When moving the billing system in-house, ensure a billing manager is appointed to oversee the financial side of the practice. A financial "Checks and Balance" system should also be in place. We recommend three levels where numbers and revenue cycles are evaluated to minimize risk of exposure and theft from the practice. Options to assess the numbers are a professional accountant, the billing manager, the surgeon, and the practice manager. We caution against having any one person evaluate the numbers alone. Finally, the role of the front office should be stressed in billing. The front office staff is responsible for verifying insurance coverage and creating a "superbill" for each office visit, so education on billing and collections should include this part of the practice.

Billing and Coding

Billing and coding are an essential part of today's medical practice, and a basic comprehension of these principles is essential fund of knowledge for a colorectal surgeon in any practice model. There are many facets to billing and coding for time and procedures, and the systems are continually undergoing modifications, so the colorectal surgeon needs to understand the basics and stay on top of new developments.

While coding may be auto-generated through electronic Practice Management Systems, the surgeon should be as familiar with the coding points, levels, and compliance as they are with staging of colon cancer. If encounters are over- or under-coded, you could expose yourself, your practice, and your institution to scrutiny. Regardless of the model in which you practice, it is recommended that you code for patient encounters and procedures yourself. In the hospital model, compliance officers and coding personnel will review the operative reports and patient encounters to generate the codes to submit to payors. It is important that the employed surgeon assumes an active role in this process and reviews the codes, as well as provides feedback to the coding officers. This is the ideal collaborative model, as the surgeon enlightens the coders of the technical aspects of the encounters and procedures, while the certified coding personnel understands tips and tricks to optimize reimbursement. While this will initially be time consuming, it's an important part of practice management to do this regularly. Furthermore,

the process will become streamlined quickly, as the coding team becomes familiar with your practice and common procedures, and the surgeon learns the key elements to include in the documentation process. In the private practice model, the billing departments may outsource to a third party billing company; in this scenario, the coding process is similar to that of the hospital. In private practice models where billing is performed in-house, it is important to consider having a certified coder as part of the billing department to perform self-audits and review coding practices. There are educational resources on billing and coding for the surgeon, including the American College of Surgeons CPT Coding Workshops [20]. Often more than one course is needed to learn the full breadth of technical billing details. At a minimum, the physician should aim to learn from these courses (1) how to bill for office visits and be compliant with regulations, and (2) how to bill for surgery.

There are two main types of billing and coding for reimbursement that applies to surgeons—one reflects patient encounters in the office or hospital setting, called Evaluation and Management, and the other represents surgical procedures, called CPT codes. Evaluation and Management (E/M) codes are the billing codes used to document the patient–doctor encounter such as a history and physical exam. They were introduced in the 1992 update of Physicians' CPT, with published documentation guidelines updated in 1997 by the Centers for Medicare and Medicaid Services. Full documentation for the 1992 and 1997 guidelines is available online in the Evaluation and Management Services Guide provided by the Centers for Medicare and Medicaid Services [21]. The E/M codes have very specific reporting, documentation, and compliance guidelines. The codes for each encounter are detailed on a "superbill," an itemized record of services generated by the office for an outpatient visit and the main data source for creation of healthcare claim. It is strongly recommended to become very familiar with the guidelines to ensure proper coding and compliance.

For surgical procedures, CPT procedure codes are used. CPT was developed by the American Medical Association, and new editions are updated annually. Each procedure is assigned a CPT code with descriptors. CPT codes for surgery of the digestive system include 40490–49999. Regardless of whether an E/M or CPT code is used, all codes require a diagnosis code. For diagnosis, International Statistical Classification of Diseases and Related Health Problems, ninth edition (ICD-9) codes are currently used, but will be evolving to ICD-10 codes. ICD-9 codes are similar to E/M and CPT codes, except that they identify the diagnosis on the claim, not the procedure performed. These codes link the diagnosis to the patient encounter, and it is imperative to document the appropriate codes to avoid denials from the insurance plans. Common ICD-9 codes for colorectal surgery are seen in Table 72-4. The importance of proper coding cannot be emphasized enough. If the CPT or E/M codes and the ICD-9 diagnosis codes are not properly chosen, the claims may be deemed medically unnecessary and not covered by payors.

TABLE 72-4. Common ICD-9 diagnosis codes for colorectal surgery

(078.11) Condyloma acuminatum
(211.3) Benign neoplasms/polyps of the colon
(211.4) Benign polyps of the rectum or anal canal
(153) Malignant neoplasm of colon
(154) Malignant neoplasm of rectum and anus
(455.2) Internal hemorrhoids with other complication
(455.4) External thrombosed hemorrhoids
(455.9) Residual hemorrhoidal skin tags
(555) Regional enteritis
(555.0) Crohn's, small intestine
(555.1) Crohn's, large intestine
(556.9) Ulcerative colitis, unspecified
(562.1) Diverticulosis of colon
(562.11) Diverticulitis of colon, NOS
(564.01) Slow transit constipation
(564.02) Outlet dysfunction constipation
(564.1) Irritable bowel syndrome
(565) Anal fissure and fistula
(565.0) Anal fissure nontraumatic
(566.0) Abscess perianal
(569.1) Rectal prolapse
(569.3) Bleeding rectal
(787.6) Incontinence of feces
(787.99) Change in bowel habits

The approval or denial of services will be relayed to patients in an Explanation of Benefits (EOB). An EOB is how the insurance company processes a claim. After an encounter or surgical procure, an EOB statement will be generated and sent by the health insurance company to the covered patient and provider explaining the treatments and services covered by the payor. It is good practice for physicians to review EOBs frequently to better understand how the system actually works and appreciate the patient's point of view when undergoing a medical encounter. The EOB will show the surgeon's codes and allowable reimbursements, as well as the adjusted rates and any reasons for denials of the claim. By reviewing EOBs often, the surgeon will gain a better appreciation of the work entailed with insurance processes and enrich their understanding of how to code and bill appropriately and effectively.

In summary, it is essential for the physician to be familiar with E/M, CPT, and ICD-9 coding, as well as billing documentation, such as the superbill and the EOB to ensure proper practice management. We also recommend the physician participates in billing and coding to stay actively involved in reimbursement and proper compliance for their procedures and services.

Setting Up Your Office

Starting a practice and setting up your office in any model requires many considerations in order to be successful. When you sign a contract and join a practice or hospital, patients and referrals are not usually lined up at your door. There is a fine art to recruiting and retaining patients, fostering relationships with referral sources, colleagues, and staff. This

section discusses the basics of contracts, how to attract patients and referral sources, as well as joining and leaving a practice.

Attracting Patients

Healthcare is a business, and patients are the customers; without them, the practice will fail. The classic three A's of medicine continue to be true and pertinent—a physician must be available, affable, and able. In reality, attracting and retaining patients goes far beyond the classic A's, and is an essential part of practice management. There are four main methods to attract patients: physician referrals, insurance referrals, word of mouth, and marketing. The paramount referral source is from fellow physicians, however, there are many obstacles in this path. Most established physicians have already developed strong bonds and referral relationships with other surgeons that will be difficult to tap into. Younger, less established doctors may be more open to developing relationships with new surgeons; however, they usually do not have large patient base. In addition, there are now outside pressures on many referring physicians to direct referrals to certain locations and surgeons depending on the economic environment they practice in. For instance, referring physicians may participate in a hospital or outpatient partnerships and will tend to refer patients to other participant surgeons in that entity. Hospital employees may also be directed to refer to other fellow employees. Despite this reality, physician referrals are by far the most valuable referral source. Primary care physicians and gastroenterologists are the major focuses for a colorectal surgeon. A busy gastroenterologist will refer out an estimated 2–4 patients per month in need of a colorectal resection. Try to identify these gastroenterologists in your community and align yourself with them. Most will refer to a set list of surgeons. The established gastroenterologist will usually initiate basic anorectal and straightforward referrals to a new surgeon in the community to develop a comfort level with their patient care before referring patients for colon resections. If one positions themselves as the eager recipient of all referrals, you will quickly establish a very positive reputation with referral sources.

Another avenue to develop relationships with referring physicians is to find physicians who may not have an established, "go-to" colorectal surgeon. Gynecologists and urologists are potential sources of many referrals, which may be open to establish a relationship with you. These specialties are highly concentrated on preventive care and screening, which could be a rich referral source for colonoscopy. Another approach is to seek doctors outside of your immediate medical service area who do not have a colorectal surgeon in their community. These outside physicians need a tertiary-level referral, have typically never met the referring physician, and will instantly develop a special personal relationship with you for giving them the respect of traveling out for a face-to-face visit.

Networking is another essential way to meet and retain referring doctors when starting in practice. There are two main ways to network: office visits or working the doctor's lounge. An office visit can be frustrating, as the surgeon may need to wait, reschedule their own activities to take time out during the day, and meet opposition from the targeted physician's staff for disrupting the office flow. Despite these obstacles, it is very important to try to meet the doctors in their office. If you make an office visit, be sure to make an impression and try to make a personal connection to have that impression last. Be especially cognizant in your interactions with the office staff, as the front office personnel may be in control of your cards and referrals. Ask specifically if there is a referral coordinator or referral nurse. It would be valuable to explain your line of service and make a connection with them. If you just leave cards or leave the office with the feeling that the physician will not send you patients, the premonition is likely correct. Additionally, realize that the doctor's staff may just as important as the doctor to obtain future patients. The other valuable way to network is in the doctor's lounge of the hospital. New partners in our practice are encouraged to put on the "Freshman 15" by making the doctor's lounge their home outside of the operating room, being present for every meal there at every hospital they work at. Networking and meeting the other doctors in the hospital can bring a plethora of referrals. There are other methods of networking to be aware of: insurance plans are a minor referral source, as you will be listed as a provider for all plans you accept, but a source nonetheless. Word of mouth is a more powerful source of referrals. However, a physician typically needs to be established in practice and have earned a solid reputation from clinical outcomes and patient experiences before word of mouth occurs.

Finally, marketing has great potential to bring in patients. The effort you put into marketing will be directly related to your outcomes. Consider hiring a consultant familiar with the region of your practice to assist with networking and business development in the community. It is essential to provide a presence on the internet and have a landing page linking your practice site to the hospitals website, where potential patients can understand who you are, what you do, and what might set you apart from other surgeons. The importance of Internet presence cannot be over emphasized. Harness the power of social media on sites like Facebook, Twitter, LinkedIn, Google+, Doximity, Sermo, and doc2doc, which allow direct connections and education to an unlimited number of potential patients and referral sources. After seeing satisfied patients, professionally direct them to online ratings to share their experience and expand your name as a quality colorectal surgeon in the community. Encourage satisfied patients to write reviews, on physician and other popular review sites such as Vitals, Healthgrades, RateMDs, and Ucompare. Review sites have become a key source to pick-

ing a doctor, and are used by as many as 25 % of patients to help choose physicians. A negative review is inevitable, and best countered by having a plethora of positive reviews. Finally, market yourself directly by giving grand rounds in the hospitals, sponsoring community events, and working with local chapter of relevant colorectal agencies, such as the Colon Cancer Alliance and the Crohn's & Colitis Foundation of America.

Playing Nicely with Others

It is essential to learn how to practice effectively without estranging referrals, as alienating other physicians can hurt your reputation and bottom line. A prime example is colonoscopy by the colorectal surgeon. Since gastroenterologists' per capita can be the largest referral source, a new colorectal surgeon entering a practice area should be cautious when performing colonoscopies. With this regimen, you could alienate yourself from the established gastroenterologists, who may feel you are attempting to cut into their practice. Consider the consequences of promoting yourself as performing routine, screening colonoscopies. If you choose to perform a substantial volume of screening colonoscopies, a prudent option may be to perform the procedures in a center where you are not directly competing with established gastroenterology colleagues. Also, be very cautious of performing future surveillance colonoscopy on a patient who was referred to you for a colon resection by a gastroenterologist. Often the colorectal surgeon is placed in a precarious position as the patient will entrust the surgeon for future care and insist they not return to the original referring gastroenterologist. In this situation, it is very important to remain loyal to your referring doctor, and not assume the future colonoscopies, or you could lose future referrals. Another word of advice is to avoid performing upper endoscopy procedures. While you are trained and may be proficient in these procedures, performing upper endoscopy as a colorectal surgeon is likely to be seen as a threat to your referring doctors. For patients that require both upper and lower scopes, consider referring them to a gastroenterology colleague. This will strengthen your relationship with your possible referral source, show respect for their line of work, expertise, and established practice patterns, and the single referral will come back to you in spades. It may also be beneficial to refer patients who will require medical management to gastroenterology initially, such as Crohn's disease patients, to scope, diagnose, initiate treatment, and medically optimize. These situations are an opportunity to spare your patients from repetitive procedures and build your relationship with your referring doctor.

Another important consideration is your relationship with the general surgeons. Colorectal surgeons are fully trained and competent to perform most general surgery procedures following fellowship. It may be tempting to market yourself as a "full service" colorectal surgeon, who is happy to perform common general surgery procedures, such as a laparoscopic cholecystectomies and inguinal hernia repairs. One may even choose to be in the general surgery call rotation, as a means to keep busy, earn extra income, and establish relationships with consultants and referring doctors. However, there are major consequences of including general surgery duties in your practice, and this decision should be carefully considered. First, marketing yourself as a general and colorectal surgeon may alienate the established general surgeons. While your goal may be to increase your overall case volumes, network, and establish referrals, you may instead cost yourself referrals, damage your reputation, and jeopardize acceptance by established peers in your new practice environment. A better strategy is to align yourself with the general surgeons. Show your colleagues you are not a threat, can work side-by-side with them, and even assist them with undesirable cases, like the inevitable perianal abscess consult in the middle of the night. With this strategy, before long, the general surgeons will refer you the complex anorectal and colorectal procedures as well. A second concern before incorporating general surgery into your practice is that once you develop the reputation as performing general surgery, it will be difficult to transition to a colorectal-based practice. Your general surgery referral sources that helped you get busy initially will not take well to the fact when you inevitably want to remove yourself from the general surgery arena. In addition, as you move away from general surgery cases to concentrate on colorectal cases, it will be very difficult for you to pick and choose which referrals you will accept without offending your referring physicians. If you cherry pick your patients in this manner, you run the risk that your referral base could run dry for both general and colorectal cases.

Staff and Colleagues

In private practice, hiring and terminating staff and associates to ensure all patient needs are being met falls under the role of practice management. Adding new staff to your practice is one of the most costly aspects of practice management and can entail extensive research, interviewing, and training to ensure that staff member is appropriate for the practice and their position. When interviewing staff members, take note of how often the candidate has moved from prior jobs, their reasons for leaving, and their attitude towards prior employers. A staff member with a history of a job changes every few months is likely to continue that trend. Almost as important as interviewing the candidate is communicating with the candidate's most recent employer and references provided for a more in-depth view of the applicant and their work habits. Be weary of the candidate who does not permit you to contact their supervisor, under the pretense that their employer does not know they are looking for a job and might fire them for going out to interview. It is essential to com-

municate with a candidate's current or prior employer so you can make an informed decision about hiring them.

Successful practice management requires effective communication from the staff with patients. The first impression a patient obtains of you is often through your staff and often the patients misidentify your staff's words as coming directly from you. When your staff talks to a patient, the patient often feels the information relayed is directly from the physician, which is most often not the case. While it may seem superficial, appearances matter and reflect the professionalism of the surgeon. Assure the potential staff member's appearance will be perceived as friendly, approachable, and appropriate. Take the time to train staff on effective patient communication techniques, as all medical office personnel come into contact with patients in some capacity. Also, take the time to appropriately educate the staff on aspects of colorectal surgery and your specific practice preferences. Good patient communication at the office level will improve customer satisfaction, reflect positively on the professionalism of the doctor, and often lead to positive feedback back to your referring doctors. Conversely, poor or inappropriate communication will often portray the surgeon as incompetent, uncaring, and unprofessional, even though the surgeon may have no idea that such conversations are occurring. You might be surprised to hear your staff turn down potential patient because they do not understand all of the services you provide or give (un)solicited medical advise that goes well beyond their duties and responsibilities. As a new surgeon, take the time to educate your staff, listen to how they communicate with your patients, and give continuous feedback until you are confident that your practice is being represented appropriately.

Contracts

When joining any practice, an employment contract is part of process. Having a contract attorney review the terms and conditions before entering into any arrangement is a strong recommendation. While considering a contract, there are two main questions to answer: (1) What am I getting into, and (2) What are the options if things do not go as planned. The items to deliberate to answer the first question include compensation, bonus structure, benefits, causes for termination, coverage duties and call responsibilities, cure period to address and "cure" issues before termination, tail coverage and insurance, practice restrictions (confidentiality, proprietorship), and the contract term (automatic renewal versus set time frame). At the start of a surgeon's career, it is common to have a 2–3 year contract, and then different terms offered thereafter. If a short-term contract is presented, you should try to negotiate the terms of the second contract at the time of the original contract, as your negotiating power is significantly diminished after signing the original contract.

How to exit a practice is an important but often overlooked part of a contract. Regardless of how promising the opportunity appears you should always understand all option and consequences of early termination. Often these terms are not discussed, reviewed, or understood until the physician is ready to make a change. It is better to negotiate the possibility of leaving at the start of an exciting position than when trying to exit, as the physician may be desperate and lack negotiating power.

Finally, before entering into any contractual employment agreement, it is essential to seek professional legal representation. There are specialized lawyers for the healthcare industry who can explain the nuances of the language, terms, conditions, and penalties detailed in the contract to assure you fully understand what you are entering into before signing. All too often, young surgeons choose to bypass legal consultation, either for the cost, time involved or belief that it is just not necessary. This is an unnecessary risk that can be very detrimental, especially at the start of ones career. Avoid the risk and assure you obtain legal representation before committing to an employment agreement. The essential components of an employment contract and terms of termination are seen in Table 72-5. These variables are broken down into two overall themes—terms of employment and terms of termination of employment. These variables are not meant to incorporate every aspect of a contract, but to direct you to the key features that need to be addressed.

Considerations When Moving Between Practice Models

An increasing number of physicians are selling their practices to hospitals and becoming hospital employees. Key trends driving the increase are cuts in reimbursement, a rise in the uninsured population, reform challenges, practice expenses, and work-life balance [22]. Hospitals welcome the trend, as physician employees enhance their competitive position in local and regional markets, generate revenue and patient volumes to maintain the financial strength of the hospital, advance improvements in clinical and translational research, achieve synergies among academic and clinical program development activities, and leverage new models for healthcare delivery and health services management [21]. There are many factors to consider when transitioning from private practice to a hospital system. First, there is the change in practice model philosophies. The private practice surgeon will give up various degrees of autonomy. They will now have a boss and levels of non-physician employees to report to. The goals and success of the hospital are often not aligned and independent of the physician's goals and happiness. Further, they may feel that the goals of their superiors interfere with their practice. This will require understanding, compromise, and preparation. The compensation model

Table 72-5. Essential components of an employment contract

	Hospital model	Private practice model	Notes
a. Terms of Employment:			
Reporting structure	X		Responsible party or parties that you directly report to and the chain of command
Partnership tract		X	The criteria to become a practice partner; usually defined by time invested in the practice
Salary and compensation	X	X	Collections based versus RVU based
Bonus structure			Various models exist and can be individualized based on your practice environment
Benefits	X	X	Health and dental insurance, paid time off, retirement, medical malpractice, life, and disability insurance
Continuing medical education (CME)	X	X	Allowance for continuing medical education, including conferences, travel, and housing accommodations
Intellectual property	X	X	Rights to research, patents, inventions, and other creations developed during terms of employment
Clinical duties and responsibilities	X	X	Service area of admitting hospitals and practice locations, call coverage
Academic responsibilities	X		Expectations of productivity, presentations, teaching, mentorship, and publications
Secondary income from healthcare related interests	X		Ownership interests in surgical centers, hospitals, pathology labs, radiology centers, and other healthcare entities
Consulting income	X		Consulting, honoraria, educational courses and lectures, and expert witness legal fees
b. Terms of termination:			
Causes for termination	X	X	Defined causes for termination including loss of license, misconduct, fraud, failure to perform duties defined in the contract
Tail coverage	X	X	Malpractice coverage extending after employment to cover any claims made while employed in prior coverage
Cure period	X	X	A specified period of time to adequately and appropriately correct a material breach in duties before termination
Accounts receivable		X	The outstanding payments due to the doctor from patents and insurance companies for charges submitted
Non-compete (restrictive covenant)	X	X	The physician agrees not to practice in competition with their current employer for a defined time and geographic scope
Non-solicitation of staff	X	X	Agreement not to solicit employees to leave for the benefit of a competitor if employment is terminated
Confidentiality agreement	X	X	Agreement forbidding disclosure of any confidential or proprietary information to a third party in competition with the practice or hospital

usually shifts from a collection-based to RVU-based revenue stream. At the end of the fiscal year, if one does not meet the budget, compensation and bonus structure could be adjusted accordingly. Staffing and administrative support are controlled by the institution. Once your staff is brought to the hospital, you lose the ability to make significant changes, so choose wisely. The hospital model will almost always have an electronic medical records (EMR) system in place. The physician will need to transition to the new system, which will decrease efficiency and productivity, increase work hours, and consume tremendous amounts of staff and resources during the transition phases. Negotiating a scribe to assist with documentation while the physician becomes proficient with the new EMR might be beneficial to all parties. To transition the physical goods from private practice to the hospital system, a Bill of Sales or Purchase Agreement is required to negotiate the hard assets of the practice, including furniture, exam tables, computers, manometric equipment, and scopes. The hospital evaluates the equipment, taking depreciation (approximately 20 % per year) into account. The physician generally overvalues hard assets, so they should be prepared for the purchase agreement to be significantly less than expected. The physician should also be aware that ancillary income sources could be restricted. Ownership stakes in outpatient surgical centers and outside medical ventures that supplement private practice compensation are commonly restricted or banned as a hospital employee.

Conclusions

Practice management is a vital component of a successful surgical practice. While there is little emphasis on the principles of practice management during surgical training, knowledge of these tenets is essential for every colorectal surgeon to make informed decisions about their career. Abasic understanding of practice management will help a surgeon decide the best practice model to meet their personal and professional goals, reimbursement and billing patterns in each model, how to be professionally successful in their chosen model, and, if needed, how to leave for other pursuits.

Correction to: The ASCRS Textbook of Colon and Rectal Surgery

Scott R. Steele, Tracy L. Hull, Thomas E. Read, Theodore J. Saclarides, Anthony J. Senagore, and Charles B. Whitlow

Correction to:
S. R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, https://doi.org/10.1007/978-3-319-25970-3

This book was inadvertently published with the incorrect copyright holder name. This has now been amended in the book and the correct one is ASCRS (American Society of Colon and Rectal Surgeons). An erratum for this book can be found at https://doi.org/10.1007/978-3-319-25970-3_73.

The updated online version of this book can be found at https://doi.org/10.1007/978-3-319-25970-3
