Short-term outcomes for colectomy for cancer include morbidity, mortality, length of hospital stay, and intraoperative parameters such as conversion from laparoscopy. The most recent clinical trials that have examined operative techniques and the perioperative outcomes are the major multicenter, prospective, randomized trials comparing laparoscopic versus open colectomy for cancer, and they provide some of the best data for short-term outcomes. The COST trial reported an overall complication rate of 21 % for laparoscopy and 20 % for the open approach ($p=0.64$), with only 4 and 2 % ($p=0.11$) occurring intraoperatively, respectively [32]. The 30-day morbidity was similar between the groups, but the rate of specific complications was not reported. Overall mortality was 2 and 4 % ($p=0.40$). The conversion rate was 21 % and was associated with an increased length of stay and 30-day complication rate. The CLASICC trial reported an overall complication rate of 26 % in the laparoscopic group, 27 % in the open group, and 45 % in the converted group [35]. The mortality rate of laparoscopy was 2 and 4 % for open patients. They did include specific complications for the laparoscopic, open, and converted groups, which included wound complications of 5 %, 5 %, and 8 %; pneumonia rate of 7 %, 4 %, and 10 %; anastomotic leak rate of 3 %, 3 %, and 3 %; and deep venous thrombosis rate of 2 %, 0 %, and 0 %, respectively. The COLOR trial reported a similar morbidity and mortality profile [41]. The overall complication rate was 21 % for laparoscopy and 20 % for the open approach, with a 4 % and 3 % wound infection rate, 2 % and 2 % pulmonary complication rate, 1 % and 2 % cardiac complication rate, 2 % and 2 % rate of significant bleeding, 2 % and 2 % rate of urinary tract infection, 3 % and 2 % anastomotic leak rate, and 1 % and 2 % associated mortality, respectively. The complication profiles are very similar between the three clinical trials, so it would appear that this data sets a reasonable benchmark. It must be kept in mind that there were ASA and BMI exclusions for these studies, and those factors are associated with increased rates of morbidity and mortality. As mentioned in the beginning of the chapter, the ACS-NSQIP risk calculator can provide a reasonable assessment of operative and perioperative complication risk. Results regarding length of stay, return of bowel function, narcotic use, and quality of life were discussed previously.

Long-Term Outcomes

The 5-year survival and recurrence rates for colon cancer are dependent upon the stage of disease at the time of surgery. Based on data published from 2012 by the Surveillance, Epidemiology, and End Results Program (SEERS), the

5-year overall relative survival for stage I is 90 %, stage IIA is 87 %, stage IIB is 63 %, stage IIIA is 89 %, stage IIIB is 69 %, stage IIIC is 53 %, and stage IV is 13 % [62]. The survival has improved every 5 years since 1975, which reflects improvements in detection, surgical technique, and adjuvant therapy. The aspects of these statistics that need to be noted are that patients with stage IIB (T4, N0, M0) colon cancer behave similarly to patients with stage IIIB (T3–T4a, N1, M0; T2–T3, N2a, M0; or T1–T2, N2b, M0). Therefore, it is imperative for the surgeon to understand and recognize patients with stage IIB cancers, so they can be appropriately referred for adjuvant therapy in a timely fashion. Surgeons play a critical role in the referral of cancer patients to medical oncologist, so a comprehensive knowledge of the indications for adjuvant chemotherapy is essential. The other notable observation is that patients with stage IIIA (T1–T2, N1, M0 or T1, N2a, M0) do as well as those with stage IIA (T3, N0, M0). This highlights the importance of surgical technique and the importance of resecting all potentially metastatic lymph nodes. Additionally, the addition of adjuvant chemotherapy to node-positive colon cancer with FOLFOX-based therapies improved 5-year disease-free survival from 65 to 78 % [63, 64]. This improvement is significant, but it also demonstrates that surgical quality is the most important component of care because surgical clearance of potentially metastatic lymph nodes offers the greatest chance for cure.

Rectal Cancer: Preoperative Evaluation and Staging

Jorge Marcet

Key Concepts

- Accurate preoperative staging of patients with rectal cancer helps identify patients at risk for local or distant metastasis and guides treatment decisions.
- Endorectal ultrasound (ERUS) is effective for staging the depth of invasion (T stage), especially for early-stage rectal tumors (uT0, uT1) that may be considered for local excision.
- Magnetic resonance (MR) has the ability to delineate the extent of locally advanced tumors and estimate the involvement of the mesorectal fascia.
- ERUS and MR use surrogate markers to estimate nodal involvement—size and node morphology—and are not particularly accurate in predicting nodal metastatic spread unless there are multiple large nodes in the mesorectum.
- The potential for understaging and overstaging of patients should be realized and taken into account when making treatment decisions.
- High-resolution computed tomography (CT) can detect distant metastatic lesions greater than 1 cm in diameter.
- Positron emission tomography (PET) scan is the most accurate assessment of total body tumor burden, especially when combined with CT (PET-CT).
- PET-CT is indicated when there are equivocal findings on CT and finding distant metastatic disease would alter therapeutic decisions.

Introduction

Careful pretreatment evaluation of the patient with rectal cancer is paramount for the successful management of their disease. By identifying the location of the tumor and its stage at the time of presentation, the surgeon is best prepared to discuss treatment options and prognosis with the patient and his or her family. As such, all healthcare providers caring for patients with rectal cancer should have a thorough understanding of the evaluation and staging of this disease.

Preoperative staging is performed according to the TNM classification of malignant tumors, estimating the depth of invasion into the rectal wall (cT), the presence or absence of lymph node metastasis (cN), and the presence of distant metastasis (cM). Also of importance is the determination of invasion of the anal sphincter and pelvic floor musculature, adjacent pelvic organs, or pelvic sidewall, all with significant consequences of planning and treatment to the patient.

The prefix "c" is used to indicate clinical staging, which is the estimate of stage based on physical examination and radiographic studies. Unfortunately, there is often confusion regarding this distinction, with some authors describing treatment recommendations for "T3N0" tumors as determined by pretreatment staging, when instead they should describe the tumor as "cT3N0." The difference at first glance appears trivial but can have significant consequences if the clinician fails to understand that estimates of tumor stage are just that, estimates, and that treatment planning must take into account the potential inaccuracy of these estimates. For example, understaging of the cancer preoperatively may result in the omission of preoperative radiotherapy/chemoradiotherapy and lead to an increased risk of local recurrence. Conversely, overstaging may lead to overtreatment, increasing the overall morbidity and cost of treatment.

Pretreatment evaluation begins with physical examination and colonoscopic evaluation. Radiographic studies may include computed tomography (CT), endorectal ultrasound (ERUS), magnetic resonance imaging (MRI), and PET. These tests are complementary, each with their own advantages and disadvantages, and may be used in combination. Laboratory evaluation includes determination of the carcinoembryonic antigen (CEA) level.

Physical Examination

When evaluating a patient diagnosed with rectal cancer, the patient's history is recorded, and an inquiry is made as to the duration of symptoms, changes in weight, bowel habits, bowel control, and presence of pain. If restorative proctectomy

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_27

or local excision is to be contemplated, a detailed assessment of anal sphincter function and prior trauma (e.g., obstetrical history, prior anal operations) should be obtained. A general physical examination is performed with special attention for signs of muscle wasting, abdominal distension, hepatomegaly, and lymphadenopathy. A careful digital rectal examination is performed, noting the distance of the tumor from the anal verge and its proximity to the anal sphincter and pelvic floor. Tumors located in the anterior portion of the rectum have the risk of invasion into the genital structures, and special attention should be made to the potential for fixation to adjacent structures (i.e., prostate, vagina, sacrum, puborectalis). In a woman with an anterior rectal cancer, a pelvic examination should be done to ensure there is no invasion of the vaginal wall that may affect treatment. When the tumor is located in the posterior or lateral rectal wall, pelvic sidewall invasion should be considered. In addition, assessment of anal sphincter bulk and tone should be performed.

The texture of the tumor also gives a clue as to the stage. Benign adenomas are soft and the tumor may occasionally be difficult to detect on digital rectal examination. When a tumor invades the rectal wall, a desmoplastic reaction occurs and the resulting fibrosis will be felt as firm tissue. Evaluating the mobility of the tumor can also give information on how deep the tumor invades. A tumor tethered to the rectal wall, but that is otherwise mobile, is likely to invade into but not through the wall. Tumors that are fixed within the pelvis and are not mobile are locally advanced, deeply invading the full thickness of the rectal wall and possibly invading surrounding pelvic structures. Using these qualities of adherence of the tumor to the rectal wall and pelvis based on the digital rectal examination, Mason proposed a clinical staging system (CS-I to CS-IV) and recommended treatment options for patients with rectal cancer [1]. The digital rectal examination may occasionally also detect peritumoral lymphadenopathy, though this is often difficult. It should be noted that digital rectal examination has limitations in that only tumors of the distal rectal rectum can be adequately assessed. Furthermore, accuracy in staging depth of invasion is better for advanced tumors than for early tumors and improves with the surgeon's experience [2].

Clearance of the proximal large bowel, preferably by complete colonoscopy, should be performed in all patients with rectal cancer to exclude synchronous lesions and to confirm the histopathology of the tumor via biopsy. Other radiological testing may occasionally be used (i.e., CT colonography, air-contrast enema), though each has inherent limitations that providers should be aware of such as the need for an adequate preparation or failure to identify small lesions. Patients that are unable to be cleared prior to surgery due to an obstructing lesion should undergo proximal evaluation within 6 months after their operation. The endoscopic appearance of a tumor also gives a clue as to the relative degree of invasion, with benign tumors being soft to manipulation with the colonoscope or endoscopic forceps and malignant tumors being firm. Ulceration of the tumor implies invasion into the rectal wall, while deep ulceration may be a sign of transmural invasion.

Limiting pretreatment evaluation to digital rectal examination and colonoscopy prior to surgery for a rectal tumor is only appropriate for lesions that are considered benign. For patients with known or suspected rectal cancer, additional pretreatment locoregional imaging to stage depth of invasion and body scanning to detect distant metastasis should be performed prior to starting any treatment—whether with surgery, chemotherapy, or radiation.

Locoregional Imaging

Computed Tomography

Computed tomography (CT) is widely available and is one of the primary modalities used in preoperative staging of rectal cancer. CT accuracy is improved by administering oral, intravenous, and rectal contrast. CT can localize the tumor in the rectum but is not able to accurately delineate the layers of the rectal wall. For locally advanced tumors, CT may show extension beyond the rectal wall and invasion into surrounding structures. The addition of multidetector-row CT (MDCT) has improved accuracy for local staging of rectal cancer but still lacks the detail required. By including multiplanar (coronal, sagittal) images to standard axial images, this provides improved accuracy rates for higher T staging and N staging of rectal cancer than axial images alone [3].

Limitations to CT scanning for local staging of rectal cancer include the limited ability to define the mesorectal fascial layers and layers of the rectal wall. Although the mesorectal fat (MRF) surrounding a tumor can be clearly visualized on CT, perirectal fat stranding or induration secondary to rectal inflammation or peritumoral fibrosis cannot be definitively differentiated from tumor extension. In addition, the diagnosis of T4 tumors can be difficult due to lack of soft tissue resolution in the pelvis. Tumor involvement of an adjacent organ or the pelvic sidewall is also not accurate and is inferred by the loss of the fat plane between the tumor and the adjacent organ or structure.

Endorectal Ultrasound

On endorectal ultrasound (ERUS), the bowel wall is defined by five distinct sonographic layers of alternating hyper- and hypoechoic qualities [4]. Extending from the lumen outward, these layers correspond to (1) the interface between the ultrasound probe and the mucosa, (2) the interface between the mucosa and muscularis mucosa, (3) the submucosa, (4) the muscularis propria, and (5) the serosa or pericolic fat. The prefix "u" is used to describe ERUS T and N staging of rectal cancer (Figure 27-1, 27-2, 27-3, 27-4, and 27-5) [5].

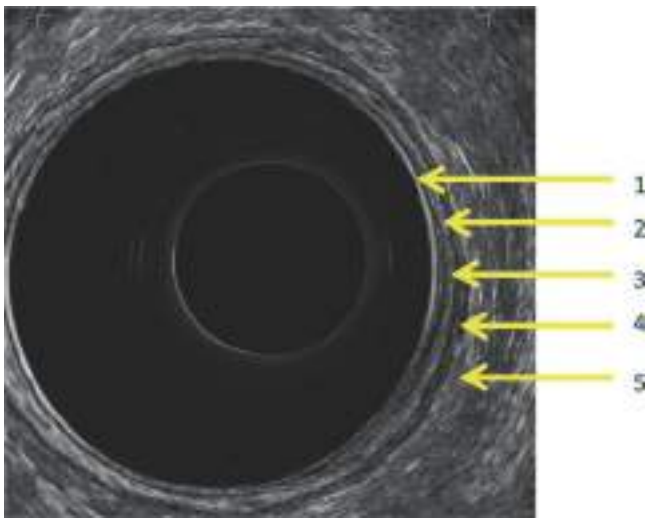

FIGURE 27-1. Endosonographic layers of the rectal wall. (1) Interphase of endoscopic balloon with mucosa. (2) Interphase of mucosa/submucosa. (3) Submucosa. (4) Muscularis propria. (5) Serosa and pericolic fat.

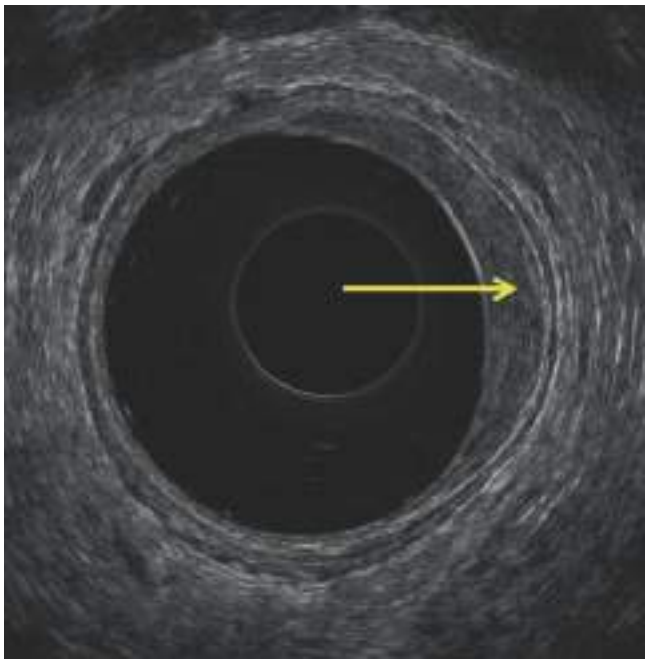

FIGURE 27-2. ERUS of uT0 tumor. Hypoechoic tumor (*arrow*) does not invade into the first hyperechoic layer. Notice that the submucosa (*white layer*) remains intact.

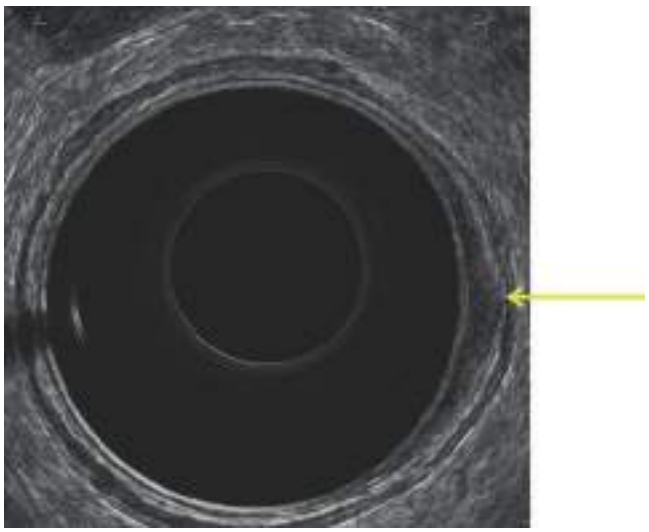

FIGURE 27-3. ERUS of uT1 tumor. Hypoechoic tumor invades into the middle hyperechoic layer (*arrow*) but does not invade the outer hypoechoic layer.

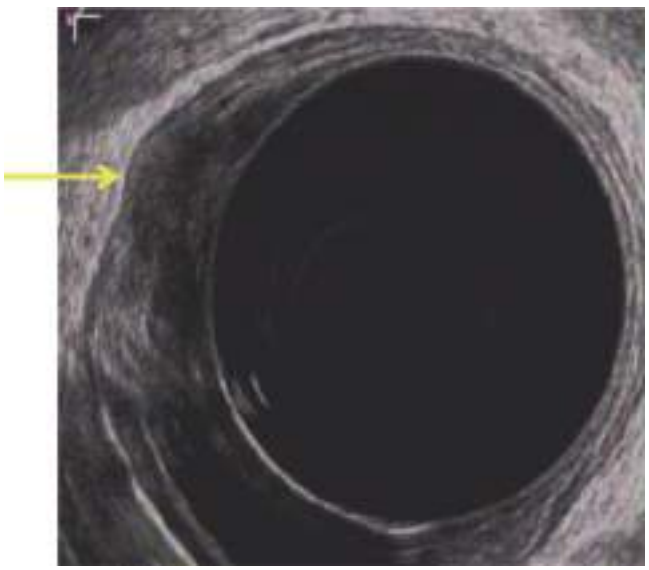

FIGURE 27-4. ERUS of uT2 tumor. Hypoechoic tumor invades through the middle hyperechoic layer and into the outer hypoechoic layer.

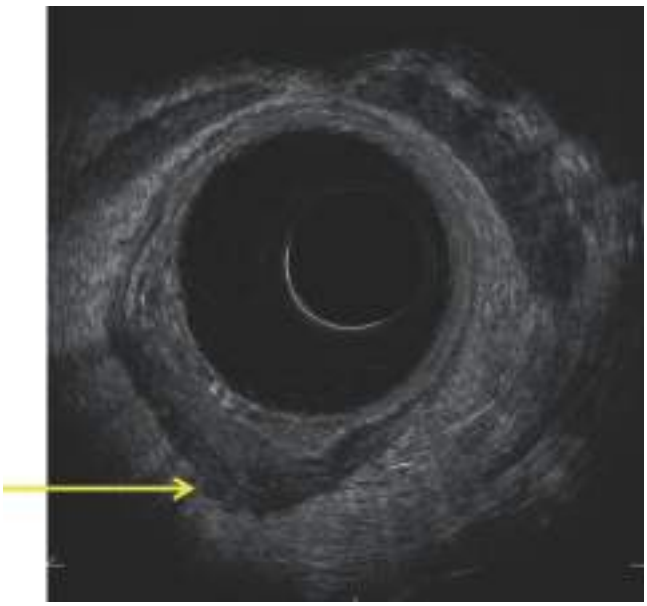

FIGURE 27-5. ERUS of uT3 tumor. Tumor extends through the second hypoechoic layer and into the outer hyperechoic layer (*arrow*).

ERUS has advantages in that it is simple to perform and inexpensive compared to CT or MR. The patient is given an enema to evacuate the rectum prior to the procedure. The procedure is often combined with a flexible or rigid proctosigmoidoscopy. Some patients require sedation to allay discomfort or anxiety. The ultrasound probe needs to pass proximal to the tumor in order to evaluate the entire extent of the tumor, thus making it difficult or impossible with obstructing lesions. 3-D ultrasonography records the image in real time and allows for subsequent manipulation of the image for axial, coronal, and sagittal evaluation. Malignant lymph nodes appear as hypoechoic and rounded peritumoral structures, whereas benign lymph nodes are less likely to be detected as they are isoechoic with the perirectal fat.

T Staging

There is variation in the reported accuracy of ERUS in accessing the T stage of rectal cancer, with an overall accuracy of about 84 % (ranging from 63 to 96 %), while the reported accuracy of CT and MRI is lower, 65–75 % and 75–85 %, respectively [6]. The accuracy of ERUS T staging in rectal cancer was analyzed in a meta-analysis of 42 studies ($N=5039$) where ERUS T stage was compared to pathological stage (Table 27-1) [7]. The authors reported that ERUS has a sensitivity of 81–96 % and a specificity of 91–98 %, showing a higher sensitivity for locally advanced rectal cancer or LARC (95 %), compared with early cancer (88 %). The authors concluded that ERUS should be the preferred test for preoperative tumor staging rectal cancer.

As with many interpretive studies, operator experience plays a significant role in staging accuracy. In a prospective, multicenter study conducted in 384 hospitals in Germany, investigators analyzed the diagnostic accuracy of preoperative ERUS (uT) with pathological (pT) findings in 7096 patients with rectal cancer who had not received neoadjuvant therapy [8]. The overall accuracy of uT to pT was found to be 65 %, with understaging occurring in 18 % and overstaging in 17 % of patients. The hospital volume of yearly ERUS procedures performed was found to affect the accuracy for staging, with uT-pT correlation of 63 % for hospitals undertaking ≤10 ERUS/year, 65 % for those performing 11–30 ERUS/year, and 73 % for hospitals where more than 30 ERUS/year were performed. The poorest correlation was found for T2 and T4 rectal cancers. The authors cautioned that ERUS is a useful tool for guiding the therapeutic strategy of rectal cancer only when performed by expert diagnosticians.

Several investigators have demonstrated a lower accuracy of ERUS in detecting T2 tumors compared to T1, T3, or T4 [9–11]. Reasons for this include difficulty in differentiating those tumors that have deep invasion into the muscularis propria from those with microscopic invasion into the perirectal fat and in differentiating peritumoral inflammation and edema from neoplastic infiltration. One group retrospectively subdivided patients with preoperative T2 tumors into uT2a, for tumors with focal invasion into the muscularis propria, and uT2b, for tumors with extensive invasion into the muscularis propria, and found improved weighted kappa accuracy (from 0.89 to 0.94) when the uT2b tumors were included in the enlarged uT3 group [12].

ERUS has been studied for the selection of patients with early-stage rectal cancer (T0, T1) who may benefit from transanal excision instead of traditional transabdominal rectal resection. In a study of 552 patients undergoing transanal excision of rectal tumors, investigators evaluated the accuracy of ERUS to clinical staging and found that ERUS had a sensitivity of 95 % vs. 78 % and a positive predictive value of 93 % vs. 85 % in detecting adenoma or T1 rectal carcinoma as compared to clinical staging, whereas specificity was similar in both (62 % vs. 58 %) [13]. A meta-analysis designed to evaluate the accuracy of ERUS in T0 staging of rectal cancers found 11 studies ($N=1791$) which met the inclusion criteria. The pooled sensitivity of ERUS in diagnosing T0 was 97.3 % (95 % CI: 93.7–99.1) and a pooled specificity of 96.3 % (95 % CI: 95.3–97.2) [9].

N Staging

Accuracy for detecting metastatic lymph nodes by endorectal ultrasound is less precise than for T staging, with a variable accuracy in reported studies of 63–85 % [6]. Differences in accuracy among studies may be due in part to differences in criteria used in defining nodal metastases. Hildebrandt et al. reported that hypoechoic, sharply demarcated nodes and those with heterogeneous pattern are more indicative of metastasis [14]. Katsura and associates found that nodes

Table 27-1. ERUS accuracy compared to histological stage.

Meta-analysis of 42 studies, $N = 5039$ patients		
T stage	Pooled sensitivity	Pooled specificity
T1	87.8 % (95 % CI 85.3–90.0 %)	98.3 % (95 % CI 97.8–98.7 %)
T2	80.5 % (95 % CI 77.9–82.9 %)	95.6 % (95 % CI 94.9–96.3 %)
T3	96.4 % (95 % CI 95.4–97.2 %)	90.6 % (95 % CI 89.5–91.7 %)
T4	95.4 % (95 % CI 92.4–97.5 %)	98 % (95% CI 97.8–98.7 %)

Adapted from Puli S, Bechtold M, Reddy J, Choudhary A, Antillon M, Brugge W. How good is endoscopic ultrasound in differentiating various T stages of rectal cancer? Meta-analysis and systematic review. Ann Surg Oncol 2009; 16:254–265 [7]

>5 mm, with well-defined boundaries and uneven and greatly hypoechoic patterns, were more likely to represent metastasis [15]. Akasu related the size of the short axis diameter of the largest lymph node to the rate of metastasis and found that for nodes <2 mm, the incidence of nodal metastases was 9.5 %, increasing to 47 % for nodes 3–5 mm in diameter and 87 % for nodes larger than 6 mm [16]. A meta-analysis of 35 studies evaluating the accuracy of EUS in diagnosing N stage in patients with rectal cancer showed a sensitivity of 73 % and specificity of 76 %. The data analyzed supported the hypothesis that ERUS is more accurate in excluding nodal involvement, rather than diagnosing it [17].

Staging accuracy for lymph node metastasis improves when the findings are associated with the T stage, with a higher risk of metastasis correlating with higher T stage. In a retrospective review of 134 patients with rectal cancer who underwent ERUS followed by radical surgery without neoadjuvant therapy, the accuracy of ERUS for N staging was 48 % for pT1 cancers, increasing to 84 % for pT3 cancers [18]. Notably, early rectal lesions are more likely to have lymph node micrometastases not detected by endorectal ultrasound. This may explain the somewhat high recurrence rates seen after local excision of early-uT-stage rectal cancer. On the other hand, CT has an accuracy of 55–65 % and MRI has an accuracy of 60–65 %. ERUS is more reliable than CT in being able to detect lymph nodes smaller than 1 cm and has comparable sensitivity and specificity to MRI [19].

Limitations to ERUS for staging rectal cancer include incomplete exams due to tumors that are bulky or stenotic. In women, these limitations may be overcome by vaginal insertion of the ultrasound probe [20]. Other causes of inadequate contact of the ultrasound probe with the tumor may be air or stool in the rectum or angulation of the tumor. Operator experience has also been shown to play a role in the accuracy of ERUS staging [21, 22].

Magnetic Resonance

High-resolution magnetic resonance (MR) with phased array pelvic coils is being increasingly used in the preoperative assessment of rectal cancer given its improved ability to evaluate the at-risk surgical circumferential resection margin. The pelvic coil is a wraparound surface coil placed around the pelvis. Patients are prepared with an enema on the morning of the examination. Thin-section (3 mm) T2-weighted fast spin-echo sequences are obtained in a plane orthogonal to the tumor [23]. Higher-resolution MRI allows improved definition of bowel and tumor infiltration [24]. MRI with endorectal coil is no longer recommended. Although endorectal MRI can show five layers of the rectal wall, the field of view is limited and the mesorectal fascia is not always visible. Additionally, the endorectal coil is more uncomfortable to the patient than the external coil and cannot be inserted in stenosing tumors [25]. Endorectal coil also has the potential to distort the tissues.

Three layers of the rectal wall are visible on a phased array external MRI. The innermost mucosa is thin and hypointense, the middle submucosa is hyperintense, and the outer muscularis propria is darkly hypointense. Below the peritoneal reflection, the rectum is surrounded by the MRF which is limited by the thin mesorectal fascia, which fuses with the rectoprostatic or rectovaginal fascia anteriorly and the presacral fascia posteriorly. The MRF surrounds the rectum completely only in the lower third and is best seen laterally as a thin hypointense line on T2W sequences. Inferiorly, the MRF thins out as it reaches the levator ani, which forms the roof of the ischiorectal fossa. MR is the best imaging modality to identify this avascular plane surrounding the mesorectum, which includes the mesorectum in its fascial envelope—the circumferential radial margin (CRM) (Figure 27-6).

In a meta-analysis of 21 studies designed to determine the accuracy of MR for T category (T1–2 vs. T3–4), lymph node metastases, and circumferential resection margin (CRM) involvement in primary rectal cancer that did not undergo preoperative chemoradiotherapy, MRI specificity was significantly higher for CRM involvement (94 %) than for T stage (75 %) or nodal metastases (71 %) [26]. Diagnostic odds ratio was significantly higher for CRM (56.1) than for nodal metastases (8.3) but did not differ significantly from T category (20.4) (Table 27-2). The authors concluded that MRI has good accuracy for both CRM and T category and should be considered for preoperative rectal cancer staging (Figure 27-7).

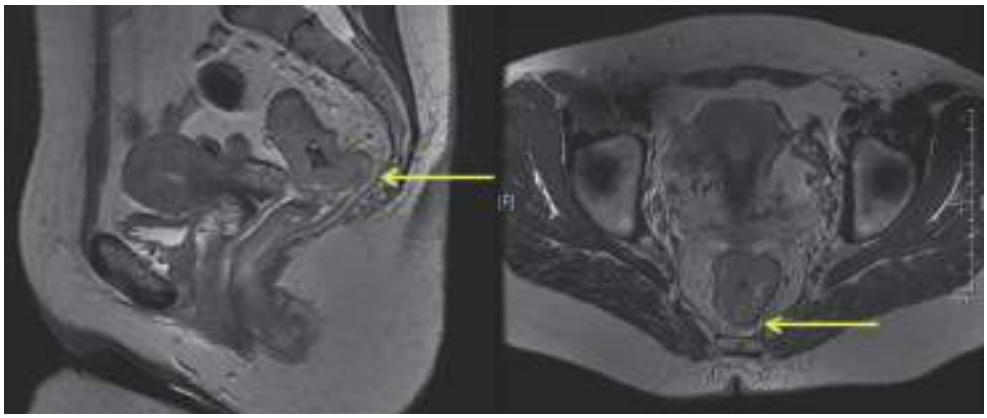

FIGURE 27-6. MR of cT3 tumor. Circumferential resection margin is preserved (*arrows*).

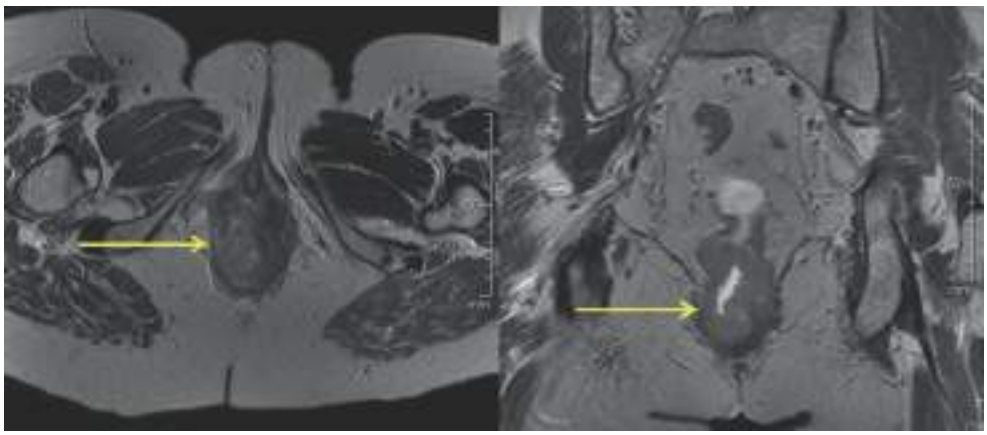

FIGURE 27-7. MR of cT4 tumor. Tumor invades the anal sphincter and levator ani (*arrows*).

TABLE 27-2. Meta-analysis of magnetic resonance accuracy in T stage, N stage, and circumferential resection margin (CRM)

	Specificity
T stage 19 studies ($N=1986$)	75 % (95 % CI 68–80)
N stage 12 studies ($N=1249$)	71 % (95 % CI 59–81)
CRM 10 studies ($N=986$)	94 % (95 % CI 88–97)

Adapted from Al-Sukhni E, Milot L, Fruitman M, Beyene J, Victor J, Schmocker S, Brown G, McLeod R, Kennedy E. Diagnostic accuracy of MRI for assessment of T category, lymph node metastases, and circumferential resection margin involvement in patients with rectal cancer: a systematic review and meta-analysis. Ann Surge Oncol 2012; 19:2212-2223 [26]

Park et al. [27] evaluated the accuracy of preoperative MRI in predicting pN stage by doing a node-for-node matched histopathology evaluation. The overall success rate of matching between the two techniques was 91 %. Preoperative MRI revealed a node-by-node sensitivity and positive predictive value of 58.0 and 61.7 %. Of the 341 nodes harvested, 120 were too small (<3 mm) to be depicted on magnetic resonance images, and 18 of these contained metastasis (15 %).

MR limitations include foreign bodies in patients that are MR incompatible. Foreign bodies that are compatible, such as surgical clips, may also obscure images. Movement-related artifacts may preclude accurate visualization of the rectal wall. MR is not portable to the operating room and is more expensive than ERUS [28].

Many referral centers with an expertise in rectal cancer treatment are now utilizing MR as the preferred locoregional staging evaluation, especially for locally advanced tumors.

ERUS is utilized for evaluation of early-stage lesions or used in combination with MR for select patients.

Whole Body Imaging

Computed Tomography

CT of the chest, abdomen, and pelvis is indicated in patients with rectal cancer to evaluate for distant metastasis, primarily of the liver and lung (Figure 27-8) [29]. The overall sensitivity of MDCT for liver metastases ranges from 77 to 94 % [30–32]. Most lesions measuring over 1 cm in size can be reliably differentiated from benign liver lesions (such as cysts or hemangiomas). However, for lesions under 1 cm in size, sensitivities drop to as low as 41.9 % [33]. The finding of small nonspecific hypodensities measuring <1 cm (also known as "too-small-to-characterize" hypodensities) is very common, perhaps present in as many as 17 % of all patients [34]. In the majority of cases, even in those patients with a known underlying malignancy, these small hypodensities in the liver are likely to be benign (~90 %) and can be followed over time.

Evaluation of lung metastases is also an important component of MDCT distant staging. In one study of 56 patients with rectal cancer, 18 % had evidence of at least one pulmonary metastasis on MDCT, with an increasing risk of pulmonary metastasis with rising tumor grade [35].

Positron Emission Tomography

PET is a whole body nuclear medicine imaging examination utilizing 2-(^{18}F) fluoro-2-deoxy-D-glucose (FDG) that exploits the increased rate of glycolysis in tumor cells to detect tumor. FDG is a glucose analog that is taken up by cellular glucose transport mechanisms and is phosphorylated by hexokinase. Most malignant cells have an increased metabolism of glucose and thus take up the FDG at a greater rate than surrounding tissues. FDG-6-phosphate then becomes metabolically "trapped" intracellularly, because of the relative lack of glucose-6-phosphatase activity in tumor cells. PET detects the increased FDG uptake. This uptake can be assessed both qualitatively (via visual examination of the degree of uptake of a tumor relative to other tissues) and quantitatively (via an SUV value). While PET was traditionally performed as a stand-alone examination, these studies are now typically performed in conjunction with CT to allow for more precise correlation of FDG activity with anatomy [30].

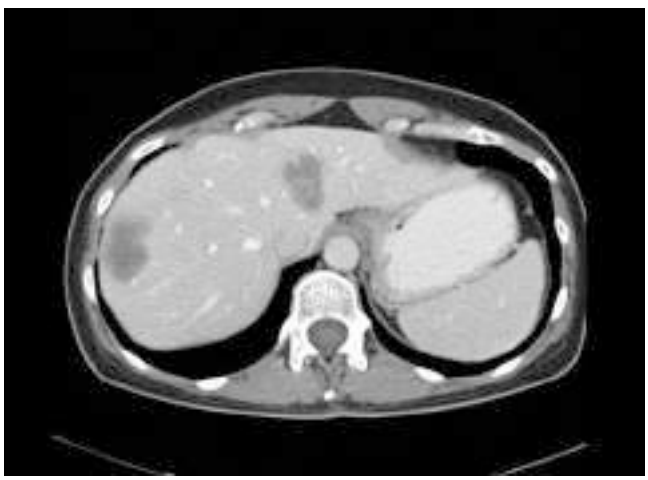

FIGURE 27-8. CT of the abdomen demonstrating two liver metastases.

Although PET has been demonstrated to be more accurate in the assessment of whole body tumor burden than a combination of conventional imaging [31], it does have limitations. There is a limit to the resolution of the scan, and lesions less than 1–2 cm may be missed. This makes accurate assessment of nodal metastases difficult. In addition, the activity of the primary tumor may interfere with detection of mesorectal lymph nodes due to the proximity of the primary rectal tumor. Lastly, mucinous adenocarcinomas may not be detected, given that the FDG uptake per unit volume of tissue is reduced as compared to non-mucinous tumor [31].

The role of PET in the management of patients with primary rectal adenocarcinoma is to investigate equivocal findings on CT, when the detection of metastatic disease would change treatment strategy. In addition, PET should also be performed prior to consideration of resection of distant metastatic disease or local pelvic recurrence, to exclude incurable occult disease that would make the operation palliative rather than curative. PET is extremely useful in the differentiation of pelvic scar from recurrent tumor in those patients who have undergone proctectomy for rectal adenocarcinoma.

In one study, PET-CT showed a diagnostic accuracy of 92 % (as opposed to 87 % for MDCT), changed the patient's stage in 13.5 % of cases, identified previously unknown disease in 19.2 % of cases, changed the patient's planned surgery in 11.5 % of cases, and changed the patient's therapy in 17.8 % of cases [32]. Another study found that PET-CT upstaged 50 % of patients, downstaged 21 % of patients, and changed the patient's treatment plan in 27 % of patients [36]. This study noted that PET-CT was particularly likely to identify "discordant" findings (i.e., findings not identified on MDCT) in patients with low rectal cancers due to the propensity of this group of lesions to metastasize to local lymph nodes in the pelvis (particularly nodes in the inguinal, femoral, or iliac chains), as PET-CT identified metastatic lymphadenopathy in 13.5 % of patients in this study which were not diagnosed on MDCT.

PET has been evaluated as a potential technique to determine histologic response to neoadjuvant chemoradiotherapy and better identify patients for local excision or nonoperative therapy, but like CT, MR and ERUS have not been found to be accurate in the assessment of residual tumor in the pelvis [37]. At present, PET is not recommended in the routine evaluation of patients presenting with primary rectal adenocarcinoma

[38] but is utilized to evaluate equivocal findings on CT when finding distant metastatic disease would alter management.

Rectal Cancer: Neoadjuvant Therapy

Andrea Cercek and Julio Garcia-Aguilar

Key Concepts

- Neoadjuvant radiotherapy is associated with an improvement in local pelvic control following proctectomy for rectal cancer as compared to surgery alone.
- Neoadjuvant chemoradiotherapy is associated with an improvement in local pelvic control and has lower toxicity as compared to postoperative chemoradiotherapy.
- Short-course neoadjuvant radiotherapy has been demonstrated to have similar outcomes in terms of overall survival, disease-free survival, and local pelvic control when compared to long-course neoadjuvant chemoradiotherapy and is associated with lower cost and shorter time to multidrug systemic cytotoxic chemotherapy.
- Current research is focused on limiting the morbidity of therapy, by omitting either proctectomy or radiotherapy in select patients.

Introduction

Neoadjuvant therapy is a critical component of the multidisciplinary treatment of patients with rectal cancer. The objective of neoadjuvant therapy, either radiotherapy, combined chemoradiotherapy, or chemotherapy alone, is to reduce the risk of local recurrence in patients with locally advanced rectal cancer (LARC) undergoing surgical resection. But neoadjuvant therapy provides other potential advantages to rectal cancer patients. It allows early assessment of tumor responsiveness to therapy, which is closely correlated with long-term oncologic outcomes [1–3]. In addition, neoadjuvant therapy could potentially enable the consideration of organ preservation by allowing for more effective local excision and nonoperative management (NOM) strategies. Finally, delivering systemic chemotherapy before surgery in patients at risk for distant metastasis has the potential to improve survival by addressing micrometastatic disease earlier and improving treatment compliance. Maximizing neoadjuvant treatment response can therefore have a profound effect on both oncologic and quality-of-life outcomes.

In this chapter, we will focus primarily on neoadjuvant therapy for LARC, widely accepted to be clinical stage II (cT3–4, cN0) or stage III (any cT, cN1–2) invasive adenocarcinomas of the rectum. We will review various treatment paradigms and the data supporting each.

Historical Context

The story of neoadjuvant radiotherapy and chemoradiotherapy for patients suffering from rectal cancer is long and convoluted, and although much has been published on the topic, there is no universally agreed-upon treatment strategy. It is important for the reader to understand how we arrived at our current state of affairs so that the data from published trials can be put in the proper context.

The concept of neoadjuvant therapy for rectal cancer was first introduced by Janeway and Quick in c. 1917, who noted significant tumor response when gold filtered radon emanation seeds were implanted directly into rectal cancers [4]. In the era when the surgical mortality and morbidity for a rectal cancer operation was prohibitive, contact radiation with emanation seeds containing radium salts or radon was explored as a curative treatment. Surgery was considered a salvage procedure for patients with tumors resistant to radiation [5]. As surgery became safer and the limitations of contact radiation as the only treatment modality became apparent, radiation lost its role as a primary treatment and

became an adjuvant to surgical resection. In fact, for many years, proctectomy alone became standard treatment for rectal cancer. It was eventually realized that the outcomes of surgery alone were often suboptimal, with 5-year local recurrence rates in published trials of 25–30 % [6–8]. It was demonstrated that adjuvant chemoradiotherapy improved oncologic outcomes, and in 1990 the National Institutes of Health advocated adjuvant external beam radiotherapy and chemotherapy for patients with stage II and stage III tumors [9]. In the United States, except for a few select referral centers, upfront proctectomy followed by selective postoperative chemoradiotherapy was the regimen utilized for most patients. However, postoperative radiotherapy is associated with relatively high toxicity and is poorly tolerated by many patients. Investigators in Europe and select US centers explored utilizing neoadjuvant radiotherapy and chemoradiotherapy, and eventually the benefits of administering radiotherapy in the preoperative period were demonstrated. In response to these data, many US clinicians simply moved the chemoradiotherapy package from the postoperative to the preoperative period. It is puzzling that, although much of the data demonstrating the benefits of neoadjuvant radiotherapy came from trials of short-course radiotherapy, and neoadjuvant short-course radiotherapy has been demonstrated to have similar oncologic outcomes as neoadjuvant long-course chemoradiotherapy in two prospective randomized trials [10, 11], the use of short-course radiotherapy has been limited in the United States.

At the same time that neoadjuvant radiotherapy was demonstrated to be more effective and less toxic than postoperative radiotherapy, there was a realization that oncologic outcomes following proctectomy for rectal cancer were highly technique dependent [12]. Wide variability in outcomes was seen, depending on who did the operation and how it was performed. So once again the wheel of opinion turned full circle, with some surgeons arguing that radiotherapy primarily compensated for“sloppy” surgery and that there was no need for the patient with non-fixed tumors to undergo radiotherapy if proctectomy was performed properly. Data from the Dutch Rectal Cancer trial and others, however, suggested that the oncologic benefits of neoadjuvant radiotherapy and good surgical technique were additive, not compensatory, with regard to pelvic control [13].

Clinicians are aware that therapies for rectal cancer are morbid and unfortunately the most effective treatment, proctectomy is associated witht he greatest chance of lasting morbidity. We continue to search for treatment regimens in which morbidity can be lessened while preserving the chance for cure, especially in patients with non-fixed tumors. Definitive chemoradiotherapy, or local excision +/− adjuvant chemoradiotherapy, would avoid proctectomy. Chemotherapy regimens are now more effective, and there is interest in upfront proctectomy in patients with mesorectal margins that are not threatened based on preoperative imaging followed by selective use of postoperative chemotherapy. In addition, there is interest in the use of neoadjuvant chemotherapy alone. Both of these strategies would avoid the toxicity of radiotherapy. Another approach that has been utilized extensively in Europe and in select US centers is to administer neoadjuvant short-course radiotherapy, followed by proctectomy and selective use of postoperative chemotherapy. The three aforementioned strategies allow the patient to receive effective systemic chemotherapy faster than the regimen commonly employed in the United States—long-course chemoradiotherapy (in which the patient receives only a radiosensitizing chemotherapeutic agent) followed by delayed proctectomy. This concept has intrinsic appeal, given that most patients with rectal cancer who ultimately fail treatment succumb to distant metastatic disease, not local pelvic recurrence, and that the benefit of neoadjuvant radiotherapy has primarily been to improve pelvic control without improvement in overall survival.

One of the difficulties in constructing guidelines for treatment of patients with rectal cancer is that treatment decisions must take into account multiple variables: tumor fixation, circumferential position in the rectum, relation to the pelvic floor musculature, pelvic morphology, clinical T and N stage, presence of symptoms, presence of metastases, continence status, planned operation, etc. It is virtually impossible to publish straightforward guidelines that account for all of these variables. At present, the clinician caring for the patient with rectal cancer must have a firm grasp of the rationale for, and the data supporting, any proposed treatment algorithm and be facile enough to tailor recommendations for therapy based on the characteristics of the patient and the tumor.

Postoperative Radiotherapy

Although currently out of favor, one of the advantages of the strategy of upfront proctectomy followed by selective chemoradiotherapy is that the exact stage of the tumor is known prior to initiation of radiotherapy, and radiation can be avoided in patients with early-stage tumors who may not derive benefit. A number of studies demonstrated that surgery followed by radiation, delivered in 180–200 cGy a day for a total dose of 45–50 Gy, was more effective than surgery alone in achieving local control in patients with stage II or III rectal cancer [14]. The Gastrointestinal Tumor Study Group (GITSG) trial was aimed to accrue 520 patients with rectal cancer located within 12 cm from the anal verge, extending to the perirectal fat or metastasizing to the regional lymph nodes, with no evidence of distant metastasis. After recovery from surgery, patients who had a complete resection were randomized to one of four arms: observation, postoperative radiation (40–48 Gy of total radiation in 1.8 or 2 Gy fractions), chemotherapy (bolus infusion 5-FU and semustine for 18 months), or radiation plus chemotherapy [6]. The study was terminated after 227 patients had been accrued because interim analysis showed statistical differences between

treatment arms. The combined modality therapy was superior to resection alone in preventing recurrence (33 % vs. 55 %; $p = 0.42$). Radiation and chemotherapy and chemotherapy were also associated with lower risk of recurrence compared to surgery alone, but the differences did not reach statistical significance [6]. A larger study from Denmark found that the probability of survival without local recurrence was higher when patients with Dukes' B or C rectal cancer received postoperative radiation, compared to surgery alone. The risk of distant metastasis was not influenced by radiation [15]. The Medical Research Council Rectal Cancer Group trial also demonstrated that postoperative radiotherapy reduced the risk of local recurrence with patients with mobile Dukes' stage B or C rectal cancer, without increasing the risk of serious late bowel complications. In this study, radiation did not affect the risk of distant metastasis or overall survival [16]. Finally, the NSABP-R02 protocol found that radiotherapy added to chemotherapy, either 5-FU/LV or 5-FU, semustine, and vincristine, reduced the risk of locoregional recurrence compared to chemotherapy alone in patients with Dukes' B or C rectal cancer [17].

Preoperative Radiotherapy

A number of prospective trials randomizing patients to preoperative radiation and surgery versus surgery alone provided mixed results [14–18]. These studies used variable total radiation doses, fractionation schemas, number of beams, portals, target volumes, radiation, and surgery. In general, only studies that use higher biologically equivalent radiation doses and a higher number of beams proved to reduce local recurrence in patients treated with preoperative radiation compared to surgery alone. The Swedish Rectal Cancer trial demonstrated that short-course preoperative radiation (25 Gy of radiation delivered in 5 equal doses in 5 consecutive days) improved not only local recurrence but also overall survival [7]. However, this study was later criticized because surgery was not standardized and the rate of local recurrence in the control arm was considered high for those years' standards. The Dutch Rectal Cancer trial (CKVO 95-04) was the first to prove that preoperative radiation also reduced the risk of local recurrence rate in patients having optimal surgery according to the principles of total mesorectal excision [13]. The study compared preoperative radiotherapy (5 Gy × 5) followed by quality-controlled TME with TME alone. In this study, the rate of local recurrence in the TME-only arm was substantially lower compared with patient treated with surgery alone in previous trials. Despite the improved surgical technique in both arms, the rate of local recurrence at 5 years was reduced from 10.9 % in the surgery-only group to 5.6 % in the radiotherapy plus surgery group ($p < 0.001$). While no benefit in overall survival was observed for the entire group, the 12-year updated results demonstrated that preoperative short-term radiotherapy significantly improved 10-year survival in patients with stage III disease and negative circumferential margins, and the benefit in terms of local control persisted [19].

Radiosensitizing Agents

Further improvements in local tumor control have been achieved by adding systemic chemotherapy to radiotherapy. Numerous chemotherapeutic agents including fluoropyrimidines (5FU) and capecitabine; irinotecan, oxaliplatin, and antiepidermal growth factor agents; and cetuximab and panitumumab have been tested in the neoadjuvant setting with radiotherapy. With the exception of fluoropyrimidines, however, none have been effectively validated in prospective trials.

Fluoropyrimidines

5-Fluorouracil (5-FU) is the primary agent for radiosensitization in rectal cancer. While its potential to create a state of radiosensitivity was recognized early on, numerous studies eventually led to the understanding that 5-FU's benefit was linked to the schedule of its administration. 5-FU must be present after radiation exposure to establish the radiosensitive state, and for this reason, bolus 5-FU quickly fell out of favor and continuous venous infusion (CVI) 5-FU 225 mg/m^2 daily became the standard [18, 20].

The GITSG proved the overall benefit of combining chemotherapy with postoperative radiation in patients with Dukes' B and C rectal cancer [6]. The North Central Cancer Treatment Group (NCCTG) study compared postoperative radiotherapy with 5-FU administered either as a bolus or as CVI. Patients in the NCCTG trial also received two months of systemic chemotherapy before and after the combined chemotherapy and radiation [21]. This study showed that CVI was associated with a significant decrease in the overall rate of local tumor relapse and distant metastasis, compared to bolus infusion of 5-FU during radiation [21]. Other trials from the Intergroup consortia have shown that CVI 5-FU was associated with lower hematologic toxicity compared to bolus 5-FU [22].

The European Organization for Research and Treatment of Cancer (EORTC) protocol 22921 was developed to assess the effect of adding chemotherapy (CT) to preoperative RT and the value of postoperative chemotherapy in LARC [23]. One thousand and eleven patients were randomized across four arms: (a) preoperative radiotherapy, (b) preoperative radiotherapy plus bolus 5-FU and leucovorin, (c) preoperative radiotherapy followed by postoperative CT, and (d) preoperative radiotherapy and bolus 5-FU and leucovorin followed by postoperative chemotherapy. Five-year local recurrence was significantly lower in all three arms receiving any form of chemotherapy (pre- or postoperative) compared to radiotherapy alone, though

there was no significant improvement in survival. Additional work by the Federation Francophone de la Cancerologie Digestive demonstrated that the addition of 5-FU to RT improves local control but not survival, consistent with the EORTC 22921 trial data [24]. More recently, in a randomized phase III trial, Hofheinz and colleagues were able to show non-inferiority of capecitabine, the oral prodrug of fluorouracil, when compared to 5-FU, providing us a convenient treatment alternative for reliable and motivated patients [25]. The equivalence of capecitabine and 5-FU has also been corroborated with the NSABP-R04 cohort [26].

Oxaliplatin

A number of large phase III trials have evaluated the potential role of oxaliplatin to increase radiosensitivity. The STAR-01 [27], the ACCORD 12/0405-PRODIGE2 [28], and the NSABP-R04 [26] trial each investigated the addition of oxaliplatin to a fluoropyrimidine as radiosensitizing agents. This combination, however, resulted in greater toxicity with no improvement in therapy. Conversely, the CAO/ARO/AIO-04 trial [28] found that the inclusion of oxaliplatin to a 5-FU-based CRT regimen led to a higher pCR rate, with no increase in toxicity [29]. While encouraging, their 5-FU dosing and schedule differed between the control arm and the arm with oxaliplatin, which could have affected the outcomes. At this point, oxaliplatin is not routinely included in the neoadjuvant regimens currently used for rectal cancer.

Irinotecan

This topoisomerase inhibitor has shown significant antitumor activity in metastatic colorectal cancer. While there have been small phase II trials to show that irinotecan may be effective and safe as an adjunct to traditional 5-FU and radiotherapy [30, 31], there has not yet been any trial to show its efficacy over 5-FU and radiotherapy alone.

EGFR Inhibitors

The success and efficacy of anti-EGFR agents like cetuximab and panitumumab in KRAS wild-type metastatic colorectal cancer have brought about a number of studies evaluating its use in the preoperative treatment of LARC. Response rates when EGFR inhibitors are used in the neoadjuvant setting with other agents and radiotherapy have been inconsistent, sometimes positive [32], but mostly equivocal or negative [33, 34]. Some studies have found worse response with their use, which suggests there may be mechanisms of response in tumors to these combined modality treatments that are not yet understood. EGFR inhibitors are not used in the setting of neoadjuvant chemoradiation.

Preoperative Versus Postoperative Radiation

Although there was once great debate on this subject, the preponderance of the evidence supports the use of neoadjuvant radiotherapy versus postoperative adjuvant radiotherapy. The rationale for this approach is logical: neoadjuvant radiotherapy requires less of a dose to achieve the same biologic effect, most likely due to the absence of postoperative scarring and tissue hypoxia in the pelvis. In addition the toxicity, both short term and long term, of neoadjuvant therapy is markedly reduced compared to postoperative radiotherapy, especially when the patient undergoes neorectal reconstruction. Lastly, the proportion of patients who can complete that therapy is markedly improved when radiotherapy is administered in the preoperative period. A small Scandinavian trial comparing preoperative short-course radiation (25.5 Gy in 1 week) for all rectal cancer patients with prolonged postoperative radiation (60 Gy in sever or 8 weeks) for patients with tumors that penetrated into the perirectal fat and/or involved the regional lymph nodes demonstrated that local recurrence was lower after preoperative radiation (13 % vs. 22 %), but survival was similar in both groups. Morbidity was also similar in both groups [35]. The RTOG 94-01 trial aimed to compare preoperative and postoperative CRT but closed after having accrued only 53 of the intended 770 patients. Similarly the National Surgical Adjuvant Breast and Bowel Project (NSABP R-03) also validated the role of neoadjuvant 5-FU-based chemoradiotherapy for LARC. While this study also failed to meet the accrual goal of 900 patients, the analysis of the 267 patients randomized before closure suggested that the preoperative CRT arm had better disease-free survival and probably better overall survival, but similar local recurrence compared to the postoperative arm [36].

The landmark German Rectal Cancer Study (CAO/ARO/AIO-94) compared pre- and postoperative chemoradiotherapy in 823 patients with LARC [37]. The local recurrence rate after 5 years was lower in the preoperative treatment group, 6 % vs. 13 % ($p = 0.006$), while overall survival and the frequency of distant metastases were not significantly different. Importantly, preoperative chemoradiotherapy was associated with a lower risk of grade 3 or 4 toxicities (27 %) compared to postoperative chemoradiation (40 %) [37]. Based on these studies, a commonly employed treatment paradigm for LARC is preoperative 5-FU-based chemoradiotherapy, followed by proctectomy and additional 5-FU-based adjuvant chemotherapy. Specifically, patients receive combined radiation (180 cGy/day/5 days a week for 5 weeks followed by a 540 cGy boost) and chemotherapy (either continuous infusion 5-FU or capecitabine), followed by proctectomy 6–8 weeks later, and postoperative systemic adjuvant chemotherapy, usually mFOLFOX6. In this treatment paradigm, now considered

standard practice in the United States (Figure 28-1), imaging has become increasingly important for preoperative tumor staging and patient selection.

Short- Versus Long-Course Preoperative Radiotherapy

The effectiveness of radiation depends on the balance between the cytotoxicity against cancer and the preservation of adjacent normal tissues. There is now evidence of a dose-response relationship with radiotherapy, with an improved cytotoxic effect with higher total doses of radiation. However, the total dose of radiation depends on the dose per fraction and the number of fractions, the dose-fractionation schedule. But the dose per fraction and the number of fractions used in clinical practice vary widely. To compare different dose fractionation schedules, radiation therapists have introduced the concept of biologically equivalent doses. The most common dose-fractionation schedules used in rectal cancer, 1.8–2 Gy per day, 5 days per week for 5 weeks (usually in combination with a fluoropyrimidine) and 5 Gy as day for 5 consecutive days, are considered biologically equivalent. The advantages and disadvantages of each one of these regimens have been the subject of a heated debate. Proponents of long-course chemoradiotherapy point to a greater tumor response, although this may be an artifact of the greater time delay prior to proctectomy typically utilized after long-course chemoradiotherapy (typically 6–8 weeks) as compared to after short-course radiotherapy (typically 1 week). Those in favor of short-course radiation argue that improved patient convenience, lower cost, reduced toxicity in the neoadjuvant treatment period, and faster time to effective systemic chemotherapy are important advantages. Two trials have compared these two approaches directly.

Bujko and colleagues prospectively compared the two regimens, randomizing 316 patients with clinical T3 or T4 disease to either neoadjuvant long-course chemoradiotherapy or neoadjuvant short-course radiotherapy, and found that long-course chemoradiotherapy was associated with a significantly decreased incidence of positive radial margins (4.4 % vs. 12.9 %, $p=0.017$) and a higher rate of pCR (0.7 % vs. 16.1 %), but this did not carry over into a significant difference in pelvic control, disease-free survival, or overall survival [10]. Moreover, they reported greater radiation toxicity in the long-course chemoradiotherapy group and poorer compliance to treatment schedule. Their conclusion was that short-course radiotherapy was a viable alternative to long-course chemoradiotherapy with neither holding a long-term oncologic advantage, but with short-course radiotherapy potentially benefiting from lower cost and lower morbidity associated with its use. More recently, theTrans Tasman Radiation Oncology Group 01.04 randomized 326

patients with ERUS- or MRI-staged T3, N0–2, M0 tumors to short-course radiotherapy and surgery followed by 6 months of adjuvant chemotherapy or chemoradiotherapy and surgery followed by 4 months of adjuvant chemotherapy [11]. Their study was powered to detect a 10 % difference in local recurrence at 3 years, with a 5 % level of significance. Similar to the work of Bujko et al., the Trans Tasman trial found no difference in pelvic control, disease-free survival, and overall survival between the groups. Patient imbalances between groups have been called to attention, with fewer patients with low rectal cancers in chemoradiotherapy than the short-course radiotherapy arms (which would bias the results in favor of the chemoradiotherapy group) and varying rates of APR. The quality of surgery and accuracy of MRI staging have also been criticized [38, 39]. Nevertheless, two prospective randomized trials have demonstrated no obvious oncologic differences between neoadjuvant long-course chemoradiotherapy and neoadjuvant short-course radiotherapy.

The short-course and long-course divide has remained somewhat static across national boundaries, with a Western preference for long-course chemoradiotherapy and a majority of European countries favoring short-course radiotherapy. It is puzzling that, except for a few expert centers, short-course radiotherapy has not been embraced by US physicians. One could argue that it is the best-studied neoadjuvant radiotherapy regimen, with demonstrated efficacy in prospective randomized trials of neoadjuvant radiotherapy versus surgery alone, and shortens the time to administration of full-dose adjuvant cytotoxic chemotherapy.

Because of a current trend exploring the incorporation of therapies traditionally reserved for the adjuvant period into the neoadjuvant regimen, combinations of either short-course radiotherapy or long-course chemoradiotherapy with systemic therapies are being explored and gaining greater traction. Therefore, it may never be clearly determined whether short-course or long-course RT is more effective as independent modalities.

Impact of Pelvic Radiotherapy on Quality of Life

Another advantage of preoperative radiotherapy is the potential ability to downstage tumors and to increase the potential for sphincter-sparing surgery, which can improve long-term quality of life for patients with low-lying rectal cancers [37]. The issue of sphincter salvage, however, is complicated. As one might imagine, the assessment of whether a restorative proctectomy could possibly be performed based on initial evaluation of a patient is somewhat subjective. In addition, given that radiotherapy does not kill tumor in a wave front, and that multiple studies have demonstrated residual tumor scattered throughout the bed of the initial volume of tissue involved with the tumor, many surgeons would argue that changing the operation based on the clinically observed effect of radiotherapy is potentially dangerous. However, by improving the chances of an R0 resection and decreasing the rates of local recurrence, which can be associated with significant morbidity, radiotherapy can improve long-term quality of life. Nevertheless, pelvic radiotherapy remains associated with significant short- and long-term side effects. Overall short-term toxicity has been reported in as many as 50 % of patients [40]. Long-term side effects of pelvic radiotherapy include fibrosis and autonomic nerve injury, which can lead to bowel and bladder dysfunction, sexual dysfunction, and infertility due to hormonal effects and uterine incompetence. Moreover, because the pelvis is an active site of bone marrow function, patients who undergo pelvic irradiation can suffer from diminished hematopoiesis.

Adjuvant Systemic Chemotherapy in Patients Treated with Chemoradiotherapy and Proctectomy

Although prevention of local recurrences is important for patients' quality of life, most patients with rectal cancer succumb to metastatic disease. Consequently, similar to patients with stage III colon cancer, patients with LARC patients treated with neoadjuvant chemoradiotherapy and proctectomy are considered for postoperative adjuvant chemotherapy independent of the histologic tumor stage in the proctectomy specimen [41]. Patients with clinical stage II and III rectal cancer treated with preoperative chemoradiotherapy and proctectomy usually receive 5-FU or capecitabine plus oxaliplatin-based adjuvant chemotherapy [41]. While the use of postoperative adjuvant chemotherapy in rectal cancer is not supported unequivocally by a prospective randomized trial, a recent meta-analysis of 21 randomized controlled trials concluded that postoperative 5-FU-based chemotherapy is effective in patients with LARC [42].

In spite of these recommendations, up to 27 % of eligible LARC patients never start adjuvant chemotherapy and less than 50 % [43] receive the full prescribed treatment without interruptions or delay [23, 29] due to postoperative complications, slow recovery, interference with closure of their temporary ileostomy [44], or simply treatment refusal [45]. A systematic review of ten studies including more than 15,000 patients evaluated the effect of timing on the efficacy of postoperative adjuvant chemotherapy and demonstrated that each 4-week delay in treatment correlated with a 14 % decrease in OS [46].

It is interesting to note that, despite the common practice of administering chemotherapy, a recent meta-analysis of adjuvant chemotherapy in LARC did not demonstrate a survival benefit. In total 1196 patients with stage II or III disease and R0 resection were evaluated; 598 were observed while 598

received adjuvant chemotherapy [47]. However, of the four studies included in the analysis, only one used oxaliplatin in combination with fluorouracil, the CHRONICLE trial which contributed only 75 patients to this analysis [48]. Moreover, completion of planned chemotherapy was low in all of the studies (43–76 %). This low adherence could certainly have affected the results [47].

Due to the low rate of completion of planned adjuvant therapy, splitting adjuvant chemotherapy and delivering a limited number of cycles pre-chemoradiotherapy, then delivering the remaining cycles postsurgery, has been proposed to increase tumor response in LARC patients. A number of randomized phase II trials have reported mixed results, without clear survival advantage for the split neoadjuvant or the postoperative regimen [48–52].

Another potential approach is to deliver all chemotherapy upfront. This neoadjuvant chemotherapy has several potential advantages compared to the standard adjuvant chemotherapy; it theoretically treats occult micrometastasis several months earlier and increases treatment compliance, potentially enhancing the efficacy of chemotherapy and ultimately improving survival [53, 54]. Other benefits of neoadjuvant chemotherapy include increased response of the primary tumor, early identification of nonresponders, and earlier removal of the loop ileostomy. A recent study at Memorial Sloan Kettering Cancer Center (MSKCC) investigated the safety and efficacy of FOLFOX before CRT, demonstrating excellent treatment compliance and no evidence of serious adverse effects requiring treatment delay. All patients undergoing proctectomy had an R0 resection, and nearly half had a tumor response greater than 90 % including 30 % who had either a pCR or a clinical complete response (cCR) [55]. Induction chemotherapy before chemoradiation and proctectomy is now considered as a valid alternative to the more widely accepted neoadjuvant chemoradiation, proctectomy, and postoperative systemic chemotherapy (Figure 28-1).

Chemotherapy can also be delivered as consolidation (after chemoradiotherapy completion and before surgery). The Timing of Rectal Cancer Response to Chemoradiation Trial, which completed accrual in 2012, showed that delivering 2, 4, or 6 cycles of FOLFOX after chemoradiotherapy in LARC patients increased the pCR rates up to 25 %, 30 %, and 38 %, respectively, compared to CRT alone (18 %), without any associated increase in adverse events or surgical complications [56]. Eighty percent of patients received consolidation chemotherapy without interruption. These studies suggest that delivering systemic chemotherapy in the neoadjuvant setting, both before or after chemoradiotherapy, is well tolerated and has potential advantages for the patient. Although solid data from large prospective studies are still lacking, in the most recent edition of the NCCN guidelines, neoadjuvant chemotherapy is contemplated as an option for the treatment of LARC patients. However, none of these studies have reported long-term oncologic outcomes.

Setting the Right Limits

Chemoradiotherapy has clearly proved itself useful at improving local tumor control in patients with LARC. We find that the weight of evidence is also demonstrating that systemic chemotherapy—when applied in the neoadjuvant setting—is able to similarly control tumor progression, possibly acting on micrometastatic disease to improve distant control. But while the benefits of these intensive neoadjuvant regimens are alluring, they have also sparked a heated debate about whether all patients require such intensive treatment. The oncologic success in treating LARC has been achieved at the cost of significant morbidity and compromised quality of life [40]. The task before us is to develop treatment approaches that maximize oncological outcome while preserving quality of life by minimizing morbidity associated with this intense multimodality approach [57]. Do all patients with LARC really require chemoradiotherapy, chemotherapy, and proctectomy? The necessity of this intense multimodality approach is called into question.

The European Approach

In a number of European countries, the “right limits” have been framed around MRI-based measures of tumor aggressiveness. A risk stratification system that covers all rectal cancers and that incorporates the proximity of the primary rectal cancer to the mesorectal fascia, the depth of tumor invasion, the presence of metastatic lymph nodes, and the presence of venous invasion are used to classify LARC into “the good,” “the bad,” and “the ugly” [58, 59]. For the low-risk, “good” tumors, proctectomy alone is recommended; for intermediate-risk “bad” tumors, the recommendation is short-course radiotherapy followed by proctectomy; and for high-risk “ugly” tumors, chemoradiotherapy followed by proctectomy is recommended (Table 28-1). These MRI-based risk stratification schemas have been incorporated into clinical practice guidelines and clinical trial design (e.g., Expert-C and RAPIDO). However, the treatment approach guided by MRI risk categorization is based on prospective observational studies conducted in institutions with significant expertise in rectal cancer and has not been tested in prospective randomized trials.

Selected Adjuvant Systemic Chemotherapy

Many LARC patients experience variable degrees of response to chemoradiotherapy, and tumor response is now one of the most important prognosticators in LARC patients [2, 57]. The need for adjuvant chemotherapy in patients with a complete or near-complete response after chemoradiotherapy has been questioned [60–62]. Recent work from a multi-institutional, retrospective analysis of 3133 patients shows that the benefit of adjuvant therapy differs between LARC subgroups. For example, patients with ypT1-2 or ypT3-4 tumors benefitted

Table 28-1. European/Scandinavian model of stratification for patients with locally advanced rectal cancer based on magnetic resonance imaging and subsequent treatment decisions

Risk	Treatment
Low risk	
• T1–T3 (<5 mm) mid-/upper rectum • T1–T3 (superficial) lower rectum • N0 • Extramural vascular invasion: no mesorectal fascia clear • Risk of local recurrence <10%	Total mesorectal incision (TME)
Intermediate risk	
T3 (<5 mm)	• Preoperative short course radiation
T4 (posterior vaginal wall only), or N1/2, or Extramural vascular invasion: yes Mesorectal fascia clear (<1 mm) Risk of local recurrence: 10–20 %	• Total mesorectal excision • Adjuvant chemotherapy
High risk	
T4 (other than posterior vaginal wall)	• Preoperative chemoradiation
N01/2 Mesorectal fascia involved Risk of local recurrence >20 %	• Total mesorectal excision • Adjuvant chemotherapy

Modified from Smith JJ, Garcia-Aguilar J. Advances and challenges in treatment of locally advanced rectal cancer. J Clin Oncol 2005

the most from adjuvant therapy compared with ypT0N0 patients [63]. Some centers now use postoperative chemotherapy selectively based on tumor response to chemoradiotherapy. In the recently published ADORE phase II trial, which examined use of selective adjuvant chemotherapy, LARC patients with ypT3-4N0 or ypTanyN1-2 tumors after fluoropyrimidine-based chemoradiotherapy were randomized to adjuvant chemotherapy with either 4 cycles of 5-FU and LV or 8 cycles of FOLFOX. The administration of FOLFOX after surgery was associated with prolonged progression-free survival in stage III patients but not in stage II patients. Additionally, FOLFOX was associated with a prolonged overall survival for both stage II/III rectal cancer patients [64]. Identification of those patients who will most likely to derive benefit from adjuvant treatment will be better informed by carefully conducted correlative studies that more accurately delineate molecular, pathologic, and clinical markers of resistance.

Chemotherapy Only to Improve Local Tumor Control

The risk of local pelvic failure in LARC depends on tumor stage, but also on the distance of the tumor from the anal verge and the proximity of the tumor from the mesorectal fascia [13, 65]. Upper rectal tumors away from the mesorectal fascia have a low risk of local recurrence when treated with proctectomy. The added benefit of radiotherapy in these patients has been questioned [40, 66, 67]. A growing body of evidence suggests that radiotherapy could be safely avoided in patients with intermediate-risk rectal cancer (e.g., rectal cancers located between 5 and 12 cm from the anal verge that do not threaten the mesorectal fascia) on MRI [68, 69]. In a pilot phase II trial conducted at MSKCC, 32 patients with resectable, clinically staged II–III rectal cancer were treated with preoperative FOLFOX/anti-VEGF and selective chemoradiotherapy, based on tumor response. The 30 patients who completed preoperative chemotherapy had tumor regression and underwent proctectomy without preoperative chemoradiotherapy. Eight (27 %) had pathologic complete responses. No local recurrences were noted at 4 years, and an 84 % disease-free survival was achieved [70]. Given these data, a large multicenter phase II/III study is currently accruing patients. In the CALGB PROSPECT Study (Preoperative Radiation Or Selective Preoperative Evaluation of Chemotherapy and TME) [71], patients are randomized to either the standard arm (chemoradiotherapy, surgery, and adjuvant FOLFOX chemotherapy) or the selective arm with FOLFOX×6 cycles, evaluation of response followed by surgery or standard therapy with chemoradiotherapy if the reduction in the primary tumor is <20 % (Figure 28-2). Eligible patients must have biopsy-proven adenocarcinoma with the primary tumor located 5–12 cm from the anal verge. They must be candidates for sphincter-sparing surgery. The primary outcomes of the phase II component are R0 resection rate and time to local recurrence. The primary endpoints of the phase III components are time to local recurrence and disease-free survival. The selective chemoradiation arm will be favored if either the disease-free survival is superior compared to the standard arm or if it is non-inferior to the standard arm for both disease-free survival and local recurrence. In addition to this study, there is currently an ongoing study, the GEMCAD study, on induction chemotherapy with or without chemoradiation in intermediate-risk rectal cancer defined by MRI. This study was presented in abstract form in the 2010 annual ASCO meeting; the final data have not yet been presented [72]. In this study which is no longer accruing patients, patients with T3 or T1–2N1 tumors based on MRI were treated with bevacizumab and CapeOX (capecitabine and oxaliplatin) for three cycles followed by repeat MRI evaluation. Those patients with response went on to proctectomy, while nonresponders received standard chemoradiotherapy. A third study is a phase II randomized study of neoadjuvant FOLFOX/bevacizumab versus FOLFOXIRI/bevacizumab in patients with high-risk rectal cancer as defined by MRI. This study is not yet open to accrual but will also add insight into the response of the primary rectal tumor to chemotherapy alone [73]. These studies will provide important insight into the potential for a more individualized treatment approach through selective use of radiation in LARC.

Selective Nonoperative Management

Proctectomy is the cornerstone of the treatment algorithm for LARC patients. However, up to 33 % of LARC patients treated with neoadjuvant chemoradiotherapy exhibit

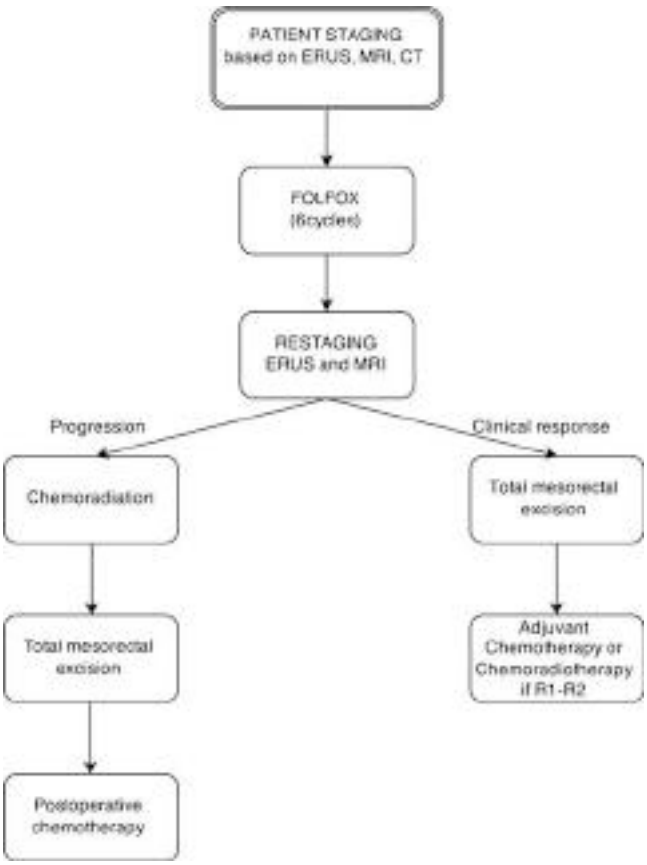

FIGURE 28-2. PROSPECT (Chemotherapy Alone or Chemotherapy Plus Radiation Therapy in Treating Patients with Locally Advanced Cancer Undergoing Surgery) trial schema. A phase II/III randomized study designed to evaluate the impact of selective use of radiotherapy compared with nonselective use of chemoradiation for patients with locally advanced rectal cancer. (*FOLFOX* infusional fluorouracil, leucovorin, and oxaliplatin, *LAR* low anterior resection, *FUCMT* fluorouracil or capecitabine plus radiotherapy, *TME* total mesorectal excision.) a pathologic complete response (pCR) at the time of surgical resection [74, 75]. Patients with a pCR have improved oncologic outcomes with local recurrence rates of less than 1 % and a 5-year survival rate of over 90 % [3, 76], leading us to question the added benefit of proctectomy for these patients. The potential gains of avoiding proctectomy—reduced morbidity, improvement in quality of life, and potential reduction of health care expenses—could be significant. The current challenge lies in accurately identifying which patients have achieved a pCR and could safely avoid proctectomy [77]. Although cCR does not always correlate with pCR, and current imaging modalities cannot distinguish with certainty tumor remnants from tissue fibrosis [78, 79], a number of institutions have reported their experience with the selective use of an organ-preserving or NOM approach in patients with a complete clinical response after chemoradiotherapy (Table 28-2) [80–84]. The largest experience with the NOM approach to rectal cancer comes from Habr-Gama's group in Sao Paulo, Brazil [80–82]. Patients with persistent tumor underwent proctectomy; those with a complete clinical response were enrolled in a strict follow-up protocol. Patients with evidence of tumor relapse were directed to surgery, while patients with a sustained complete clinical response after 1 year continued surveillance every 3 months for an additional year and every 6 months thereafter. Twenty-seven percent of rectal cancer patients treated according to this protocol had a sustained complete clinical response and were spared from proctectomy. Of the patients who survived 1 year following treatment and did not show any evidence of tumor progression, local recurrence during follow-up developed in 10 %, but all had proctectomy with curative intent. The oncologic results in this NOM group were equivalent to those of patients who had a pathologic complete response after proctectomy. However, the authors did not evaluate patients on an intention-to-treat basis. By excluding those patients who failed treatment during the first year, results were heavily biased in favor of the NOM group. A group from Maastricht University in the Netherlands reported their NOM experience in 21 patients with complete clinical response as determined by clinical exam, MRI, and endoscopic biopsy among 192 patients treated with chemoradiotherapy between 2004 and 2010 [83]. After a mean follow-up of 25 ± 19 months, 1 patient developed LR, but was able to undergo curative salvage surgery. The other 20 patients are alive without disease. Outcomes in patients with complete clinical response treated according to the NOM protocol were similar to outcomes of patients with a pathologic complete response after proctectomy. At MSKCC, rectal cancer patients with a complete clinical response have been managed under an NOM strategy since 2006. Of the 32 patients starting treatment before 2010 who were followed for a median of 23 months, 6 patients developed relapse, and all underwent salvage surgery with curative intent; additionally, 3 of these patients also developed distant metastases [84]. The combined experience of these series suggests that NOM may be an alternative approach to proctectomy in highly select patients with distal rectal cancer who achieve a complete clinical response to neoadjuvant therapy (Table 28-2). However, the safety and efficacy of the NOM approach outside of centers specializing in the treatment of rectal cancer is controversial. It is now clear that even with strict complete clinical response definitions, some patients will later develop local recurrence, emphasizing the importance of close surveillance, because the success of this approach relies on the early diagnosis of recurrences and timely salvage therapy. In addition, the risk of distant metastases in patients with an apparent complete clinical response that develop local tumor regrowth and subsequent outcomes is unknown. Therefore, at the present time, the NOM of rectal cancer should be considered experimental.

The design of large, prospective randomized trials investigating the efficacy of the NOM approach is challenging,

given the relatively small proportion of patients with a complete clinical response to standard neoadjuvant chemoradiotherapy and the disparity of the treatment arms—observation versus proctectomy. However, a number of prospective observational studies [85–87] and phase II trials, including our own (Figure 28-3), are underway to test the feasibility of incorporating an NOM approach to the multimodality treatment of rectal cancer in a multi-institutional setting [88, 89].

Summary

Decades of clinical research have resulted in a variety of multimodality treatment paradigms for rectal cancer patients providing unprecedented local tumor control and patient survival. Although this represents a significant achievement in oncologic outcome, multimodality therapy can be associated with significant morbidity and long-term sequelae that can impair quality of life permanently. Identification of patients at

different risk levels for tumor recurrence and survival based on baseline tumor characteristics and response or resistance to therapy should enable us to tailor treatments accordingly and in certain cases omit radiation or surgery to decrease morbidity without compromising outcomes.

Local Excision of Rectal Neoplasia

Mark H. Whiteford

Key Concepts

- When anatomically appropriate, local excision is the preferred over proctectomy for benign rectal polyps due to high success rates and lower morbidity.
- If local excision is to be utilized as definitive surgical therapy for rectal cancer, the depth of dissection should be full thickness of the rectal wall.
- Histologic predictors of lymph node metastasis in early rectal cancers include tumor depth, lymphatic and vascular invasion, poor differentiation, and tumor budding.
- Five-year disease-free survival after local excision of rectal cancer is lower than after proctectomy, although it is unclear whether overall survival is different.
- Survival and local recurrence rates for T2 rectal cancers treated with neoadjuvant chemoradiation and local excision appear to be similar to those of T1 cancers treated with local excision alone.
- Transanal endoscopic surgery may be associated with improved outcomes as compared to conventional transanal excision, although the quality of comparative studies is suboptimal.

Transanal Surgery, a Historical Perspective

The initial report of transanal excision (TAE) of a rectal tumor is attributed to Dr. Jacques Lisfranc in the early 1800s whereby a protruding and painful rectal tumor was excised via a prolapsing and incising technique [1]. There was no mention of anesthesia, no defect closure was attempted, and hemostasis was eventually maintained with serial intrarectal packing. Sir Alan Parks popularized the era of modern TAE in the 1960s [2]. This more familiar technique employed anesthesia, a self-retaining rectal retractor, epinephrine injection, a submucosal resection plane, use of stay sutures, and primary closure of the defect [2]. The appeal and benefits of TAE are obvious: direct endoluminal approach to the target pathology via the natural orifice; avoidance of a stoma; and avoidance of the morbidity associated with abdominal or transacral operations.

The goal of local excision is to completely remove the target pathology en bloc with negative margins. When applied to benign rectal polyps, this should be curative. When applied to rectal cancer, this has the potential to be curative if the tumor has not spread beyond the rectal wall. Due to technical limitations of the anus, rectum, and surgical instrumentation, conventional TAE has been limited to lesions within 8 cm from the anal verge, at or below the first rectal valve, ≤3 cm in size, and occupying ≤40% of the rectal circumference. Lesions that exceed these parameters are technically more challenging to remove.

In the early 1980s, Prof. Gerhard Buess, inspired by the poor visibility and limited reach of conventional TAE, ushered in the era of transanal endoscopic surgery (TES) when he invented a new technique and series of instruments for removal of rectal tumors [3]. His technique and instruments were termed transanal endoscopic microsurgery (TEM, Richard Wolf, GmbH, Knittlingen, Germany). TEM involves a 4×12 (or 20) cm cylindrical metal reusable operating rectoscope mounted to the operating table. The rectoscope has a sealed faceplate with multiple access ports that permit simultaneous pneumodistention of the rectum along with passage of a stereoscopic camera and modified laparoscopic instruments into the rectum. Stable pneumorectum is maintained with a dedicated TEM suction-CO_2 insufflation pump. TEM instruments could now remove larger lesions as well as lesions up to the rectosigmoid junction (~17 cm from the anal verge).

TEM proved to produce a specimen with less fragmentation and more negative margins and lead to a lower local recurrence than conventional TAE. Larger lesions and lesions up to the upper rectum could now be removed without the need for radical surgery. A similar reusable rigid proctoscopic transanal endoscopic operations (TEO®) system is also commercially

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_29

available (Karl Storz, GmbH, Tuttlingen, Germany). The acceptance of TEM and TEO, however, was very slow due to the high capital cost of the equipment, requirement for specialized training, and complexity and technically challenging nature of the instrumentation and procedure. An additional obstacle was the lack of a category 1 CPT code for the procedure in the United States that made reimbursement problematic.

In 2010, Atallah first described the use of a commercially available single port laparoscopic platform placed transanally in conjunction with standard laparoscopic instruments and insufflators to perform transanal surgery [4]. This technique has been coined transanal minimally invasive surgery (TAMIS) and appears to show similar benefits as TEM [5]. This technique offers the promise of instrument simplicity and low upfront cost. Due to the similarities of the techniques and clinical results, TEM, TEO, and TAMIS are collectively termed TES.

Techniques

Technique for Conventional TAE

Patients undergo routine surgical history and physical examination with including evaluation of comorbidities, bowel function, and continence [6]. Examination should include digital rectal examination with proctoscopy to determine and document the longitudinal and circumferential location, extent of the lesion, and its proximity to the sphincter. Repeat or deeper biopsy can also be performed if colonoscopic biopsy was nondiagnostic. When concern for malignancy exists, then additional imaging studies such as endoscopic ultrasound, MRI, or CT scan may be considered.

The patient receives a full mechanical bowel prep and perioperative antibiotics. General anesthesia is the most common mode of anesthesia, but spinal anesthesia an acceptable option. Patient positioning is chosen such that the target pathology is placed dependently: lithotomy position for posterior lesions, prone jack knife for anterior and lateral lesions. Exposure is obtained via the surgeons preferred method of self-retaining anal retractor, lighted anoscope, operating proctoscope, Lone Star® retractor (Cooper Surgical, Inc, Trumbull, CT). A headlight provides ideal illumination in the tight confined operating field. Electrocautery is then utilized to demarcate a 5–10 mm margin around the lesion. Stay sutures may be placed laterally for retraction and improved visibility. Dissection progresses distally, laterally, then proximally with sharp or electrocautery dissection. Depth of dissection is in the submucosal plane for benign appearing lesions or to avoid sphincter injury, and full thickness dissection for biopsy-proven malignant lesions or lesions with gross features of malignancy. Additional stay sutures may be placed as one progresses proximally in order to maintain control of the proximal edge. Most authors advocate for primary transverse closure as longitudinal closure is thought to predispose to stricture. At times, there may be too much tension to close the defect. These can then either be partially closed or left open to heal by secondary intention if the defect is extraperitoneal (Figure 29-1).

FIGURE 29-1. Open wound following local excision.

Technique for TEM and TEO [7]

Bowel preparation, anesthetic choice, and positioning are the same as TAE. Gentle digital dilation is performed to accommodate the 4 cm diameter proctoscope, which is then inserted and attached to the table mount. Both 12 and 20 cm lengths are available. The faceplate attached and tubing connected to the suction insufflator unit. Pneumorectum is established and the proctoscope adjusted to view the target lesion through the stereoscopic microscope or the laparoscopic video monitor. Three 5–9 mm instrument ports are available for use of the modified angled TEM laparoscopic instruments. Needle tip electrocautery is utilized to demarcate a 5–10 mm margin around the lesion. Submucosal or full thickness dissection is then initiated. This is most easily started in the distal right corner of the lesion with progression towards the proximal left corner. Partial en bloc resection of the mesorectum has also been described for deeper malignant lesions [8]. Continuous suction functions to clear the cautery smoke during the procedure. The integrated suction-insufflation unit prevents loss of pneumorectum from the suctioning. Following specimen removal, the defect is closed transversely using a running absorbable suture. A metal clip is locked at each end of the suture in lieu of intracorporeal knot tying. With the increased proximal reach of TEM, intraperitoneal entry occasionally occurs, and in experience hands, can safely be closed via the TEM instrumentation [9, 10]. TEM does suffer from technical limitations of the rigid proctoscope causing significant instrument conflict and has a longer learning curve for both technique and instrument troubleshooting than compared to other transanal techniques (Figures 29-2, 29-3, and 29-4).

Technique for TAMIS

TAMIS is a modification of TEM whereby the reusable rigid 4 cm diameter operating proctoscope is replaced by a flexible, disposable single port laparoscopic platform. Standard laparoscopic insufflators, camera, instruments, and vessel sealing devices are also utilized. Patient selection and preparation is similar to TAE and TEM. The shorter length and flexible platform of the TAMIS technique more easily permits operating on the non-dependent (downward) wall of the rectum, as is required with TAE and TEM. For this reason the majority of cases can be done in the lithotomy position. Dissection is performed in a similar fashion as with TEM. Laparoscopic suctioning must be done judiciously as not to lose pneumorectum and exposure. A more liberal use of laparoscopic vessel sealing devices provides improved hemostasis over that of monopolar cautery, thereby reducing the need for suctioning. Defect closure techniques vary among authors and include use of different laparoscopic suturing devices or barbed sutures [5]. Intraperitoneal entry during TAMIS is more likely to require laparoscopic assistance for defect closure due to loss of rectum and visualization of the defect via the transanal device [11]. Since the TAMIS devices rely on radial fixation to the top of the sphincter complex, low-lying rectal polyps become partially obscured by the transanal device and require a hybrid TAMIS and TAE resection technique. This involves dissection of the proximal portion of the lesion utilizing the TAMIS technique, and then removal of the TAMIS device followed by the conventional TAE technique to complete the distal dissection and defect closure.

All forms of TAE techniques have limitations such as the potential for incomplete resection or the requirement for conversion to an alternate technique, such as staged transanal procedures or need for an abdominal approach to complete the resection or defect closure. These events are more likely when the tumor is too bulky to permit adequate working space, the proximal extent of tumor cannot be visualized around a fold or sigmoid bend, uncontrolled bleeding is encountered, or there is an inadequate bowel preparation. Fortunately these situations are uncommon and or can be avoided with proper preoperative patient selection and preparation.

Transcoccygeal (Kraske) and transsphincteric (York-Mason) approaches to locally excise rectal neoplasia have largely been supplanted by these purely transanal techniques. If interested, the reader is directed to the previous addition of ASCRS textbook for an excellent overview of these topics [12].

TAE of Benign Rectal Polyps

The ideal indication for TAE is for the complete removal of benign lesions in the rectum. Radical surgery, in the form of proctectomy, which includes a complete regional lymphadenectomy, provides no clinical benefit over TAE in the setting of benign disease, yet subjects the patient to considerable perioperative morbidity and significant long-term risk of urinary, sexual, and defecatory dysfunction. Local excision has

the advantage of acting as a "total biopsy" to assess for completeness of resection and presence of otherwise occult cancer.

Most rectal polyps are detected on screening colonoscopy in asymptomatic patients. Occasionally rectal polyps produce symptoms such as rectal bleeding, blood or mucus on the stool, change in stool caliber, or tissue prolapse symptoms. While most small polyps are readily removed using colonoscopic polypectomy, larger polyps that would generally require piecemeal snare polypectomy are better served with TAE which provides a higher chance of complete polyp removal and a resultant lower chance of polyp recurrence.

Larger rectal polyps, particularly villous adenomas, have a higher incidence of harboring an occult cancer despite benign appearance and biopsies. For this reason preoperative assessment with endoscopic ultrasound is always reasonable to further assess tumor and nodal staging. Interpretation of endoscopic ultrasound performed soon after a full-thickness excision may be more challenging due to scar tissue, cautery artifact, and difficulty in differentiating between reactive and potentially malignant lymphadenopathy. These factors may result in overstaging of patients.

Benign polyps can be removed using either a partial thickness (submucosal plane) or full-thickness technique (deep to muscularis propria). Partial thickness dissection is facilitated through the use of submucosal injection of saline with or without epinephrine to help raise the polyp and mucosa off the muscularis propria. A non-lifting sign is worrisome for invasive cancer and is an indication for consideration of conversion to full-thickness excision for complete histologic assessment. A true submucosal dissection does not require defect closure provided there is no concern for full-thickness intraperitoneal entry. Alternatively, the mucosa is usually fairly mobile, and most defects can be closed primarily.

It should be noted that the submucosal plane is much more likely to be scarred or obliterated if the patient has undergone prior piecemeal hot snare polypectomy or multiple attempts at endoscopic excision. Full-thickness excision may be required in this situation if the layers of the rectal wall are fused by scar [7].

Results

Local excision with TAE, TEM, and TAMIS is typically performed in the outpatient setting. The goal of TAE is complete en bloc removal of the target pathology with minimal morbidity and mortality. Numerous case series and several comparison trials demonstrate a low perioperative complication rate (10–17%) and a less than 1% mortality rate following TAE and TEM [13–15]. There are some non-randomized studies that suggest that the quality of TEM excision, however, is better than TAE with the incidence of specimen fragmentation (1–6% vs. 24–35%), positive margins (10–12% vs. 29–50%), and local recurrence (5–6% vs. 27–29%) favoring TEM [14, 15]. Long-term recurrence data following TAMIS is not yet available.

Unfortunately, the quality of the studies of outcomes following local excision is distressingly suboptimal. Heterogeneous study populations (mixing benign and malignant pathology of various T stage), lack of appropriate time-to-event analysis, retrospective study design, and selection bias plague much of the published literature on the topic. It should also be remembered that, as of this writing, there have been no prospective, randomized comparisons of local excision techniques. Thus, although a few non-randomized retrospective analyses favor transanal endoscopic microsurgery vs. traditional local excision [16], it is unclear whether any surgical technique is truly superior to any other, especially for lesions in the distal rectum.

Some newer advanced colonoscopic techniques, endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD), are being utilized for excision of benign colorectal polyps. EMR is usually a piecemeal resection whereas ESD attempts a single en bloc resection. These techniques are primarily utilized in Asia with limited North American and European experience. In early comparisons between TES and EMR, EMR shows a slightly lower complication rate (3.8% vs. 13%) but a higher local recurrence rate (11.2% vs. 5.4%) [17]. In comparisons between TES and ESD, TES shows higher percentage of en bloc excision (99% vs. 88%) and negative margins (89% vs. 74%) while maintaining similar rate of complications (8.0% vs. 8.0%) [18].

While there are no guidelines that mandate a recommended follow-up strategy following TES for benign rectal polyps, many institutions performed endoscopy every 6–12 months for 2–3 years. Routine endoscopic ultrasound and imaging are not recommended for benign disease.

TES for Rectal Cancer

Curative surgery for rectal cancer aims to maximize the oncologic clearance of the primary tumor as well as the mesorectal lymph nodes. Proctectomy is the accepted gold standard surgical procedure for rectal cancer with 5-year local recurrence rates in the 5–10% range. The procedure, however, comes with significant risk of perioperative complications, long-term defecatory, urinary, and sexual dysfunction, and frequent need for temporary or permanent ostomies [19–21].

Local excision has long been an appealing option for rectal cancer because of its low risk of morbidity and mortality, relative paucity of long-term functional sequelae and the potential for curative treatment of disease limited to the bowel wall. The ideal candidate for local excision is a patient who has no lymph node metastasis and has a primary tumor can be excised with negative margins. In such a situation local excision should be curative. The great controversy, however, is that our ability to predict lymph node metastases are disappointingly poor and local recurrence following TAE remains much higher than with radical surgery.

Local excision can be utilized as a tool to gain additional information regarding tumor biology and risk of lymph node metastasis. This may help guide clinical judgment in deciding whether or not a patient can be spared radical surgery. It is wise to clarify this concept with the patient preoperatively. The local excision will be utilized as a "total biopsy" to help guide treatment recommendations and that if this total biopsy reveals high risk histologic features then a recommendation for subsequent radical surgery will be made. However, if no high-risk features are identified and the priorities and values of a patient are such that they accept a potentially higher risk of local recurrence than with proctectomy, local excision may be considered acceptable treatment. Local excision remains most appealing in patients who are unfit or unwilling to undergo radical surgery.

Lymph node status dramatically effects patient prognosis as well as our treatment decisions and recommendations. Current efforts to predict lymph node status consist of identifying high-risk histopathologic features from biopsy specimens. This is complemented with selected imaging modalities. When considering patients for local excision, it is imperative to choose those with the lowest risk of harboring locoregional metastatic disease.

Predicting Risk of Lymph Node Metastasis

Prediction of lymph node metastasis for rectal cancer is an imprecise science. No single histologic feature can solely predict risk of lymph node metastasis nor is there any currently available genetic or molecular marker that is predictive. Through a combination of histopathologic characteristics and imaging modalities the surgeon and the patient try to roughly generate a risk-benefit calculation to guide clinical strategies related to local excision vs. radical surgery. Colonoscopic biopsies alone sample but a small portion of the tumor, whereas an excisional full-thickness biopsy allows the fullest examination of the tumor histology, death of invasion, and margin status. Unfavorable histologic features are not only independently predictive of lymph node metastasis, but multiple unfavorable features also have an additive risk [22].

Depth of Invasion

Depth of tumor invasion into the wall of the bowel has traditionally been one of the best predictors of lymph node metastasis and is assessable variable in nearly all complete excisions. T1 tumors, which are limited to the submucosa, are associated with a 10–15% incidence of occult lymph node metastases detected at the time of radical surgery. T2 tumors, which invade into but not through the muscularis propria, are associated with a 20–26% risk of lymph node metastasis [22–25]. Kikuchi further identified the importance of depth of submucosal invasion on lymph node metastases and local recurrence amongst T1 cancers. They analyzed a large series of patients subdivided by the cancer depth of invasion into the upper, middle, and lower thirds of the submucosa (SM1, SM2, SM3) and demonstrated an incremental increase in risk of lymph node metastasis or local recurrences with deeper depth of invasion. Tumors invading to the SM3 level were shown to have a similar risk of lymph node metastasis and local recurrence as T2 cancers [26].

Lymphovascular Invasion

Lymphovascular invasion is found in 12–32% of T1 rectal cancers [22, 27] and is a strong predictor of lymph node metastasis with an odds ratio between 3.0 and 11.5 reported on multivariate analysis [22, 24, 28]. Bach reviewed 487 rectal cancer subjects tracked prospectively in a national proctectomy database. The incidence of local recurrence based on depth of invasion, lymphatic invasion, and tumor diameter is shown in Table 29-1 [28].

Table 29-1. Local recurrence rates (percentage) at 36 months following TEM excision of rectal cancer

	Lymphatic invasion	Maximum tumor diameter (cm)					
Depth of invasion		≤1	1.1–2	2.1–3	3.1–4	4.1–5	≥5.1
pT1 sm1	No	3.0	3.6	4.4	5.4	6.6	8.1
	Yes	5.2	6.4	7.7	9.4	11.4	13.7
pT1 sm2–3	No	10.5	12.7	15.3	18.5	22.1	26.4
	Yes	17.8	21.4	25.5	30.3	35.7	41.8
pT2	No	9.8	11.9	14.3	17.3	20.7	24.7
	Yes	16.7	20.0	23.9	28.5	33.7	39.5
pT3	No	19.7	23.6	28.0	33.2	39.0	45.4
	Yes	32.2	37.9	44.1	51.0	58.3	65.7

Poor Differentiation

Poorly differentiated histology also predicts for lymph node metastases in rectal cancer [22–24, 29]; however, this trait is seen infrequently, present in only 2–4% of early rectal cancers [22, 28, 30]. Odds ratio for probably of poorly differentiated tumors having lymph node metastasis is 4.8–6.1 [31, 32].

Tumor Budding

Tumor budding, defined as small nests of five or more, usually poorly differentiated, cancer cells along the invasive front, is a histologic trait not routinely mentioned on biopsy reports in the North America, but has been extensively reported in the Asian gastroenterology literature [27, 30, 32] as a strong predictor of lymph node metastasis in colon and rectal cancer. Tumor budding is present in 16–25% [27, 33] of T1 cancers and multivariate analysis has demonstrated an odds ratio of 5.1–5.8 in predicting lymph node metastasis [31, 32].

Location of the cancer within the rectum may also be a risk factor for lymph node metastasis. Nascimbeni reported 8 and 11% risk of lymph node metastasis for high and mid rectal cancers, and 34% for low rectal tumors [29]. Mucinous histology and gender have not consistently been associated with increased risk of lymph node metastasis [29]. Molecular markers are not yet able to reliably predict nodal status (Figure 29-5) [31].

Imaging for Early Rectal Cancer Staging

Imaging is a standard recommendation for the staging of rectal cancer [34]. Despite innumerable technological advances in medicine, however, imaging remains an unreliable and inadequate measure of lymph node metastasis for rectal cancer. At present, endoscopic rectal ultrasound (EUS) is the imaging modality of choice to distinguish between T1 and T2 rectal cancers. CT scan and MRI do not have adequate resolution to differentiate between layers of the bowel wall in T1 and T2 rectal cancers, but are better than EUS at determining deeper T3 and T4 tumors.

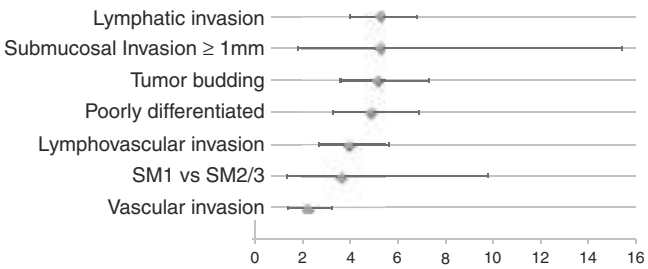

FIGURE 29-5. Relative risk (95% confidence intervals) of lymph node metastases in pT1 rectal cancers. (SM1 = invasion into superficial third of submucosa. SM2/3 = invasion into middle and deep third of submucosa). *With permission from Bosch SL, Teerenstra S, de Wilt JH, Cunningham C, Nagtegaal ID. Predicting lymph node metastasis in pT1 colorectal cancer: a systematic review of risk factors providing rationale for therapy decisions. Endoscopy. 2013 Oct; 45(10):827–34* [30].

Imaging features that are suspicious for malignant lymph nodes include presence of a round shape, internal heterogeneity, irregular border, and to a lesser extent, size. Lymph node size alone is not a reliable indicator of node positivity, but nodes greater than 8 mm are considered highly suspicious on EUS, CT, and MRI. MRI and EUS are the more reliable modalities for assessing lymph node metastasis in early rectal cancer [35, 37]. CT and MRI are more accurate than EUS in the setting of locally advanced and metastatic disease. There is some promise for improved lymph node accuracy through the use of gadofosveset-enhanced MRI [38].

Oncologic Results Following Local Excision of Rectal Cancer

As noted above, the methodology of many reported series of local excision for rectal neoplasia is suspect. In addition to the problems noted above, trials of local excision for rectal cancer suffer from additional issues. One is inclusion of patients who have cancer in a polyp that is completely or mostly removed by endoscopic polypectomy, and local excision is performed for unclear margins. Many of these patients will have no residual tumor in the local excision specimen and have an extremely low risk of local pelvic failure, biasing the results of the series in favor of local excision. Another is retrospective subgroup analysis, in which patients are only included in the analysis after review of the histology. This allows for exclusion of patients who have positive margins of resection, greater than T1 stage, or other unfavorable histologic features. This obviously biases the analysis in favor of local excision, but fails to replicate the true clinical situation in which margins and T stage cannot be known with certainty preoperatively. Nonrandomized comparative trials of local excision vs. proctectomy suffer from lack of information regarding mesorectal nodal status in the local excision group, which would most likely favor proctectomy. Although this bias can be mitigated by inclusion of patients in each group based on T stage alone, it cannot be completely eliminated as there may be hidden selection bias. It is thus difficult to make firm conclusions regarding the optimal place for local excision in our armamentarium of therapies for patients suffering from rectal cancer.

Local Excision for T1 Cancer

Local excision of T1 rectal cancer is a widely available and technically feasible procedure with low risk of short-term morbidity and mortality. Approximately 15% of all rectal cancers present at stage 1 with no metastatic lymph nodes and tumor confined to the bowel wall. In theory, these patients will gain no clinical benefit from the lymphadenec-

tomy associated with a low anterior or abdominoperineal resection. Therefore there is great controversy over whether the decrease in short-term morbidity is worth the long-term oncologic compromise. As discussed in the previous section, the unmet challenge is the inability to predict with high reliability, which patients have no cancer in their regional lymphatics. The reported rate of local recurrence following TAE varies considerably in the literature, but is universally higher than for proctectomy. For these reasons, proctectomy remains the oncologic gold standard for rectal cancer surgery.

The CALGB 8984 study reported a phase 2 trial in patients with adenocarcinoma of the low rectum less than 10 cm proximal to the dentate line and less than 4 cm in diameter who underwent local excision. Fifty-nine patients with T1 rectal cancers were followed for median a 48 months. Local recurrence occurred in three patients, two local only, one local and distant recurrence. Six-year disease-free survival was 83% [38]. However, approximately one-third of the patients initially enrolled were excluded from analysis, most for positive margins of resection. Several subsequent single institution case series within the United States demonstrated local recurrence rates from 7 to 18%, cancer-specific survival rates ranging from 89 to 92%, and overall survival 72–75% [39–42]. You reported the largest cohort study comparing TAE ($n=601$) and proctectomy ($n=493$) for excision of T1 rectal cancers tracked in the National Cancer Database with a median follow-up of 3.7 years [43]. Local recurrence rates were higher for TAE compared to proctectomy (12.5% vs. 6.9%, $p=0.003$) with concomitant lower 5 year disease-specific survival (93.2% vs. 97.2%, $p=0.004$) but similar 5 year overall survival (77.4% vs. 81.7%, $p=0.09$).

A meta-analysis by Kidane reviewed 1 randomized controlled trial and 12 observational studies comparing local to radical resection in adults with T1N0M0 rectal adenocarcinoma [44]. This showed a significantly lower 5-year overall survival with local excision as compared to radical resection (relative risk (RR) 1.46, 95% CI 1.19–1.77). This difference was not present in the TEM excision subgroup. Five year local recurrence was significantly higher for local excision (RR 2.36, 95% CI 1.64–3.39) including both the TAE and TEM subgroups. With regards to postoperative complications, local excision is associated with significantly lower perioperative mortality (RR, 0.31:95% CI, 0.14–0.71), postoperative complications (RR 0.16:95% CI, 0.08–0.30), and lower need for permanent ostomy (RR 0.17:95% CI, 0.09–0.30) when compared to radical surgery. Meta-regression analysis showed that when local resection and radical resection were compared only in distal rectal cancer, then there was no significant difference in between overall survival (RR 1.13, 95% CI 0.93–1.37). This supports the observation that distal rectal cancers have a higher risk of local recurrence than mid and upper rectal cancers [29]. The authors of this meta-analysis concluded that based on low to moderate quality evidence, TEM is the preferred surgery for T1N0M0 rectal cancer because of its low risk of complications, mortality, and permanent stoma compared to radical resection without sacrificing 5 year overall survival. However, as noted above, it is impossible to know whether a patient is truly "T1N0" prior to embarking on local excision.

There exists a concern that performing local excision for cancer may oncologically contaminate the embryonic surgery planes and make subsequent restorative radical proctectomy prohibitively difficult or result in a high incidence of local recurrence. This concern did not appear to be founded in a study of 63 local excision patients identified as having high-risk histology who soon thereafter underwent radical proctectomy. Fifty-three (84%) had restorative procedures. Local recurrence occurred in 1 patient whom had a T3 tumor found following TEM. No local recurrences were seen in the T1 or T2 patients [45]. No data exists to determine if immediate proctectomy results in a higher rate of permanent colostomy.

Local Excision for T2NX Cancer

The deeper T2 rectal cancers invade into the muscularis propria permitting them greater access to the lymphatics. As a consequence, the incidence of lymph node metastasis and local recurrence is double that of T1 cancers. Even more so than for T1 cancers, proctectomy is the oncologic procedure of choice. That said, as with T1 cancers, organ sparing options have been explored but in conjunction with the supplemental use of radiation therapy. The CALGB 8984 trial included 51 patients with T2 rectal cancer whom underwent post-op chemoradiation (5400 cGy with 5-fluorouracil). Local recurrence occurred in seven patients. Six year overall survival and failure-free survival was 85 and 71%, similar to historical data for radical surgery from the National Cancer Database [38].

Neoadjuvant chemoradiation prior to radical resection of locally advanced rectal cancer has been shown to downsize and downstage rectal cancers. Read et al. reviewed 649 consecutive rectal cancer patients and found a robust pathological response of the primary tumor to chemoradiation (ypT0-1) in 87 (23%) patients. Lymph node metastasis were identified in only 3% (3 of 87) of these patients indicating that response to neoadjuvant therapy may help predict low risk of lymph node metastasis in rectal cancer [46]. Rullier reviewed data from nine studies of preoperative radiotherapy followed by local excision in cT2-T3N0 rectal cancer. Local and distant recurrence occurred in 28/365 and 24/302, respectively. Complete responders had an 87% disease-free recurrence compared with that of 64% for partial or incomplete responders [47]. These data suggest that a robust primary tumor response to neoadjuvant chemoradiation can be utilized as a surrogate marker for a patient to have low risk lymph node metastasis and, hence, a candidate for organ

sparing local excision. This selection factor was included in the GRECCAR 2 multicenter, phase 3, randomized controlled trial for uT2-3 N0 low rectal cancers. Patients underwent neoadjuvant chemoradiation and the clinical response was reassessed. Good responders ($n=120$) were randomized to local excision or radical proctectomy surgery. Poor responders were not randomized and went directly to radical proctectomy as they were considered high risk for nodal metastasis. Study endpoints include operative mortality, recurrence, major morbidity, and severe side effects after randomization. This trial has completed accrual and its follow-up and data collection phase [48].

The ACOSOG Z6041 trial was a phase 2 trial of 84 patients treated by neoadjuvant 5400 cGy radiation with capecitabine and oxaliplatin followed by local excision of uT2N0 rectal cancers in the low rectum (≤8 cm from the anal verge). Complete pathologic response was seen in 44% of patients and down staging to ypT0-1 was seen in 64% of patients. Thirty-nine percent of patients experienced grade 3 toxicity, high enough for the capecitabine and radiation doses to be reduced mid trial [49]. After an average 4.2-year follow-up in 72 patients who underwent local excision for ypT0-2 cancers, local recurrence developed in 2 patients, distant metastasis in 5 patients. Disease-free and overall survival was 87 and 96% at 3 years and 97% of patients had rectal preservation [50]. While this study and other studies are encouraging, inadequate evidence exists to demonstrate the equivalence of neoadjuvant chemoradiation followed by local excision for uT2N0 rectal cancers. A single center, randomized control trial compared radical surgery to TEM following neoadjuvant chemoradiation in 70 patients with clinical T2N0 low rectal cancer [51]. Forty-nine percent of patients in each arm were down staged to ypT0-1. After a median follow-up of 84 months, the local recurrence rate was 6% in the TEM group, and 3% in the radical surgery group. Five-year survival was 94% in both groups. At present, this combination therapy should be reserved for patients unfit or unwilling to undergo the accepted standard therapy of proctectomy.

Surveillance and Salvage Following Local Excision of Rectal Cancer

Surveillance following local excision is recommended to assess for early identification of local recurrence. No formal guidelines are in place but a summary of several retrospective series suggests a follow-up strategy of proctoscopy or flexible sigmoidoscopy with high resolution rectal MRI or endorectal ultrasound every 3–6 months for 3 years, then q 6–12 months through year 5, colonoscopy at years 1, 4, and 9, and CT of abdomen and chest annually.

Median time to recurrence ranges from 13 to 47 months with most occurring between 12 and 24 months. The addition of radiation therapy often delays identification of local recurrence an additional 1–2 years [28, 52–55]. Despite close follow-up, recurrences have a relatively poor prognosis. Patients with local only recurrences who were candidates for resection had an R0 resection in 79–96% of cases resulting in a 53–58% disease-free survival [53, 54, 56]. These poor results of salvage therapy should provide a sobering reminder that the best chance of curing a patient suffering from rectal cancer is with initial treatment. Trying to "mop up" after local pelvic or distant failure has occurred is often futile. In addition, it should be remembered that patients undergoing local excision are typically those with the smallest, early stage lesions, those most easily cured by proctectomy.

Complications of TAE

Complications following local excision of rectal polyps and cancers occur in 5–25% with mortality rates in the 0.3–0.6% range [16, 57, 58]. Major intraoperative bleeding is a rare event. Bleeding is usually addressed with monopolar cautery, sutures, injection of epinephrine solution, or laparoscopic vessel sealing devices. Intraperitoneal entry during TEM was initially discouraged due to the concern for intraabdominal injury or leakage at the closure site. Gavagan reported their small case series that demonstrated the safety of intraperitoneal entry and closure during TEM [9], results that have been confirmed by other groups [10, 59]. The current TAMIS platforms do not have the rigid TEM operating proctoscope which stents open the operative field during the loss of pneumorectum into the peritoneal cavity during intraperitoneal entry. In this instance, closure of the full thickness defect is more likely to require combined transanal and laparoscopic assistance or conversion to open [11].

The most common complication with local excision is postoperative urinary retention. This occurs in up to 11% of patients and is thought to be due to a combination of direct pressure on the urethra, anal stretch, local edema, and pain. This is almost always self-limiting and can be treated by intermittent straight catheterization or short-term indwelling catheter placement. Postoperative bleeding is rare and tends to occur several days post-op corresponding to a suture line dehiscence, sloughing of a scab, or reinstitution of anticoagulant medication. Minor episodes are often self-limiting but frank hemorrhage warrants evaluation with volume assessment and resuscitation followed by endoscopic evaluation and treatment. Suture line dehiscence is more common in lower rectal excisions and in irradiated fields. The patient may report feeling well for a few days post-op followed by a constellation of dark blood and mucous with bowel movements, throbbing rectal pain, fevers, and night sweats. In the absence of sepsis, treatment is usually non-operative and based on symptom control. Symptoms should slowly resolve over 2–3 months.

The concern over potential sphincter damage during TES has been raised. While mild fecal incontinence has been reported immediately post-op, return to preoperative baseline function and quality of life typically occurs within 6 weeks of surgery [60, 61].

Conclusion

Local excision of benign rectal polyps and highly selected early rectal cancers is technically feasible and is associated with a markedly reduced morbidity and mortality when compared to radical surgery. Local excision techniques include conventional TAE and TES. Local excision of early rectal cancers does not remove or adequately sample the regional mesorectal lymph nodes. Preoperative prediction of lymph node positivity is an imprecise science. Increased risk factors for lymph node metastasis and local recurrence include depth of invasion, lymphatic or vascular invasion, poor differentiation, tumor budding, and abnormal lymph nodes identified on imaging. Because of imprecise staging and possibly greater chance of positive resection margins, local excision results in a higher incidence of local recurrence when compared to radical surgery. Patients who are unfit or unwilling to undergo radical surgery may choose an oncologically less sound local excision option in order to avoid the increased short- and long-term complications related to radical surgery. The decision to perform local excision must be individualized, the patient's values and personal preferences regarding cure vs. quality of life.

30
Rectal Cancer: Watch and Wait

George J. Chang

Key Concepts

- Pathologic complete treatment response following neoadjuvant chemoradiation therapy and surgery for rectal cancer is associated with favorable prognosis.
- Pathologic complete treatment response is observed in approximately 15–20% of rectal cancer patients following chemoradiation therapy.
- Clinical and radiographic assessment of neoadjuvant therapy treatment response is suboptimal, and remains a primary challenge for safe implementation of watch and wait strategies.
- Approximately one in three patients exhibiting clinical complete response will develop tumor regrowth.
- At present, watch and wait should be offered to patients only in the context of a clinical trial.
- Local excision following neoadjuvant chemoradiation therapy is associated with significant risk for pain and poor wound healing.

Introduction

Over the past few decades, the management of rectal cancer has become increasingly complex. What was once a disease with high mortality and limited treatment options that typically necessitated a permanent colostomy has become a model for multidisciplinary evaluation and treatment and surgical advancement. For over a century, surgical resection has remained the cornerstone of curative treatment of rectal cancer. The principles of treatment include complete *en bloc* resection of the tumor-bearing rectum and mesorectum with clear margins along with clearance of pelvic lymphadenopathy and, when possible, restoration of intestinal continuity [1]. However, because of the historically high risk of local failure after surgery alone, clinicians have utilized neoadjuvant radiotherapy or chemoradiation therapy (nCRT) which has improved the rate of local tumor control [2]. Now the oncologic outcomes following treatment of rectal cancer in the modern era can equal outcomes following treatment of colon cancer [3]. Despite these advances, the multimodal treatment for rectal cancer is associated with a significant impact on long-term functional and quality of life outcomes including risks for bowel, bladder, and sexual dysfunction, pain, and potential need for permanent colostomy. Therefore there is great interest in strategies to decrease the toxicity of treatment, including strategies that employ the selective use of radiation, chemotherapy, or even surgery.

The modern concept of selective use of surgery following chemoradiation therapy for patients with rectal cancer are based on the fact that pathologic complete response (pCR) is observed in approximately 10–20% of patients following long course chemoradiation therapy. In 2004, Habr-Gama and her group first reported outcomes for selective surgery with a nonoperative (a.k.a. "watch and wait" or "wait and see") strategy in select patients who achieved a clinical complete response (cCR) following chemoradiation therapy [4]. In the decade since that initial report, a number of other investigators have attempted to bring further light to understanding the potential for a selective surgical approach. They have also highlighted a need for considering a number of important factors including assessing and improving the effectiveness of neoadjuvant therapy, predicting pCR prior to pathologic evaluation, determining the true risk for locoregional failure following a watch-and-wait approach, and understanding the potential for salvage surgical treatment and subsequent long-term survival outcome following treatment failure. While definitive surgical resection remains the standard of care for all patients with non-metastatic rectal cancer, a growing number of studies are providing supportive evidence for a watch and wait, organ-preserving approach in highly selected patients with rectal cancer.

Neoadjuvant Chemoradiation Therapy

For patients with locally advanced rectal cancers, traditionally considered as clinical stage II and III, neoadjuvant therapy has been administered to improve local control. Building upon the demonstrated oncologic benefit of total mesorectal excision (TME) surgery by Heald, the Dutch Colorectal Cancer Group randomized patients to preoperative radiotherapy (5×5 Gy) followed by immediate TME surgery to TME surgery alone [5, 6]. This demonstrated that preoperative radiotherapy, when compared to TME surgery alone, was associated with a significant reduction in local recurrence although no improvement in overall survival could be demonstrated [7]. Meanwhile, the EORTC 22921 and FCCD 9203 studies demonstrated that addition of concurrent chemotherapy administered over a 5–6 week duration followed by delayed surgery demonstrated improvement in local recurrence free survival when compared to preoperative radiotherapy alone [8, 9]. However, the landmark study of the German Rectal Cancer Study Group definitively established the superiority of preoperative (neoadjuvant) vs. postoperative chemoradiation therapy, followed by surgery 6–8 weeks later, with improved local control and sphincter preservation [2].

Preoperative chemoradiotherapy is typically administered in "long course" fashion, with radiotherapy and a radiosensitizing chemotherapeutic agent administered over a 5–6 week period with a 6–10 week treatment break prior to proctectomy. This extended period of time allows for tumor regression, if the tumor is sensitive to the therapy [10]. This may facilitate more optimal surgery, including sphincter preservation, by reducing the tumor bulk and permitting surgery to be safely conducted in previously uninvolved but inaccessible adjacent tissue planes [11]. It also provides potential clearance of microscopic tumor spread, safely permitting a closer distal margin at resection with subsequent restoration of intestinal continuity [12, 13]. The surgeon should be cautious, however, not to leave tissue in situ that was previously involved with tumor, as radiotherapy does not induce tumor kill in a "wave front," and residual nests of tumor cells can be found spread throughout the initial volume of tissue involved by the tumor. Lastly, studies demonstrating improved sphincter preservation must be taken with a grain of salt, as estimation of whether a surgeon will be able to perform restorative proctectomy or not based on initial clinical examination is subjective.

As one would expect, similar responses to pelvic short-course preoperative therapy were previously not observed, as proctectomy was typically performed within a week or 2 of short-course radiotherapy, prior to the development of radiation induced inflammation, and too short a time to allow for significant tumor regression [14]. More recent trials in which proctectomy was delayed 4–8 weeks after short course radiotherapy reveal that tumor regression and relatively high rates of complete pathologic response do occur [15]. In addition, oncologic outcomes following short course radiotherapy and long course chemoradiotherapy for patients with locally advanced rectal cancer have been demonstrated to be similar in prospective randomized trials [14, 16]. Thus, it is likely that significant tumorcidal effect can be achieved with either regimen, but the added time delay prior to proctectomy with long course chemoradiotherapy results in more tumor involution seen on histologic evaluation of the proctectomy specimen. Furthermore, the potential systemic effects of the concurrent chemotherapy are not well understood.

Response to treatment has been an important observation, and following completion of CRT up to 50% of patients will experience a cCR as defined by replacement of the tumor bed by scar or normal appearing mucosa on clinical and endoscopic examination [17]. Pathologic complete response (specimen without evidence of residual tumor cells) or pathologic near-complete response (specimen with only single or small groups of tumor cells) can be observed in 10–40% of patients following neoadjuvant chemoradiation therapy (nCRT) [18, 19]. Complete clinical response, however, is not necessarily predictive of pathologic response. It is now widely recognized that tumor regression in response to neoadjuvant treatment is an important prognostic indicator of long-term outcome. It can be associated with tumor volume reduction, down-staging and nodal sterilization and a number of pathologic grading systems now exist to describe the extent of response (Table 30-1). It is a pathologic biomarker of the effectiveness of local and systemic tumor control and major response with complete or near complete resolution is

Table 30-1. Tumor Regression Grading Systems

TRG	Mandard [22]	Dworak [23]	Rödel [10]	Ryan [24]	CAP [25]
0		No regression	No regression		No residual tumor cells
1	No residual cancer cells	Dominant tumor mass with obvious fibrosis and/or vasculopathy	Fibrosis <25% of tumor mass	No residual cancer cells or single cells	Single or small groups of cancer cells
2	Rare residual cancer cells	Dominantly fibrotic changes with few tumor cells or groups	Fibrosis 25–50% of tumor mass	Residual cancer outgrown by fibrosis	Residual cancer outgrown by fibrosis
3	Fibrosis greater than residual cancer	Very few (difficult to find microscopically) tumor cells in fibrotic tissue with or without mucous substance	Fibrosis >50% of tumor mass	Significant cancer outgrown by cancer or no fibrosis with extensive residual cancer	Minimal evidence of fibrosis
4	Residual cancer greater than fibrosis	Complete regression	Complete regression		
5	No regression				

highly associated with a favorable prognosis [20]. In a large study of 725 patients treated with neoadjuvant chemoradiation and total mesorectal excision for locally advanced rectal cancer at The University of Texas, MD, Anderson Cancer Center, local recurrences were virtually absent and systemic recurrences occurred in fewer than 10% of patients exhibiting complete response or major downstaging to ypT0-2 N0 disease [21]. In fact in the modern era of TME surgery, distant, rather than local, disease recurrence has emerged as the primary concern.

Surgery for Rectal Cancer

The principles for surgical curative treatment for rectal cancer have been established since the beginning of the twentieth century with Ernest Miles' description of abdominoperineal excision (APE) with end colostomy for carcinomas of the rectum and pelvic colon [26]. Since then, a number of surgical and multidisciplinary advances as outlined above have improved treatment outcomes, reduced operative mortality, and offered the potential for sphincter preservation. However, for patients with distal rectal cancer, the excellent oncologic outcomes of nCRT and surgery can be associated with the need for permanent colostomy or with significant risk for bowel dysfunction including fecal incontinence and soiling following coloanal reconstruction.

Quality of life among rectal cancer patients undergoing surgical resection with or without a permanent colostomy was compared in a systematic review of 5127 patients from 35 non-randomized studies. Fourteen of the studies reported that APE was not associated with poorer quality of life measures than low anterior resection among patients with rectal cancer. The remaining studies found some difference, although it was not always in favor of non-stoma patients. These results may in part reflect underlying bowel dysfunction among patients undergoing TME surgery with sphincter preservation, so-called low anterior resection syndrome (LARS) [27]. In a long-term follow-up study at 14 years of patients randomized to preoperative radiotherapy followed by proctectomy with TME to proctectomy with TME alone in the Dutch trial, 56% of the patients randomized to preoperative radiotherapy followed by proctectomy and 35% of the patients randomized to proctectomy alone reported major LARS [28].

Finally the prevalence of male and female sexual dysfunction is high after surgery for rectal cancer and up to one-half of the patients undergoing surgery with rectal cancer will report a deterioration in sexual function, and a third of patients will report the development of urinary dysfunction [29, 30]. While some of these effects may be attributed to pelvic autonomic injury from radiation therapy, the majority of the effect is caused by nerve injury at surgery. This is a particular concern among distal rectal cancer patients undergoing APE. While the case can be made that these effects are exacerbated when surgery is performed by less experienced surgeons, these issues remain significant problems that impact quality of life following even among patients undergoing sphincter preserving rectal cancer surgery. Thus there is a need for approaches to treating rectal cancer that can also safely preserve functional and quality of life outcomes.

The Watch and Wait Approach

Based on these concerns, the appeal of a watch and wait, organ preserving, nonoperative approach is obvious. If radical surgery to resect rectal cancer could be avoided, then patients would not be subject to the associated surgical morbidity and potential long-term effects on quality of life. However before such a strategy can be more broadly applied, it is important to ensure that oncologic outcomes are not being compromised, particular for this group of patients who are expected to have excellent outcomes, with an extremely low risk for either local or distant disease recurrence, with proctectomy. What is also unknown is if response to chemoradiotherapy is just a biologic response indicator of favorable tumor biology, or if similarly good outcomes can be achieved by increasing the rate of pCR. In light of the fact that nCRT has been associated with improvement in pelvic control, but not overall survival suggests that the former may be true. However, the body of evidence regarding the prognostic value of even an intermediate response indicates that tumor behavior is a continuum from favorable to poor. Moreover, it is now recognized that the interval from the completion of chemoradiation therapy to clinical or pathologic assessment can impact the rate of complete response as ongoing regression can be observed well beyond the traditional 6–8 week interval to assessment.

Following Habr-Gama's original report, other investigators initially reported a wide range of success with an initially nonoperative approach, including a locoregional treatment failure rate of up to 50–60%, much higher than the 3% failure rate initially reported by Habr-Gama [31, 32]. While not fully explained, the reasons for this discrepancy may have included differences in initial tumor burden, selection of patients for a watch and wait approach following neoadjuvant therapy, method and timing of assessment, or the neoadjuvant treatment regimen. In addition the method of selection of patients for nonoperative therapy in Habr-Gama's initial report may have played a major role [4]. Specifically, patients were not included in the study (observation) group until they had been followed for 12 months following chemoradiotherapy. Put another way, patients initially selected for nonoperative therapy who failed in the first 12 months were excluded from analysis. This has the potential to bias the results heavily in favor of the observation group.

Recent data, including from an updated report by Habr-Gama, indicates that the true risk for locoregional treatment failure is approximately 30% [17, 33]. This suggests that a

Table 30-2. Comparison of selected modern studies

Series	Number of patients observed	Number of patients operated	Median follow-up (months)	cCR	Local regrowth	Outcome
Mass 2011 [36]	21	20	15 (observed)	100%	1 patient	2-year OS 100%
			35 (operated)			2-year DFS 89%
Dalton 2012 [31]	12	37	25.5 (mean)	24%	50%	Disease free at follow-up
Habr-Gama 2014 [17]	93	90	60	49%	31%	5-year OS 91%
						5-year LRFS 69%
						5-year DFS 68%
Smith 2015 [34]	73	72			26%	4-year OS 91% (obs) vs. 95% (surg)
						4-year DSS 91% (obs) vs. 96% (surg)
Smith 2015 [37]	18	30	68.4 (mean)		1 patient	Alive with pelvic disease at 54 months

number of patients initially thought to have a pCR based on clinical assessment of complete response actually had undetected viable tumor, highlighting one of the major challenges and pitfalls of the watch and wait approach. One potential solution to the challenge of clinically identifying patients with a pCR is to ensure a close follow-up strategy. This will only be effective, however, if salvage treatment is proven to be effective. We recommend that patients be monitored with digital rectal and endoluminal examination every 3 months along with carcinoembryonic antigen level determination and biopsy of any suspicious lesions. The majority of tumor regrowth will be detected within the first 12 months, in which case patients may be eligible for curative resection with the possibility for coloanal reconstruction for tumors without anal canal involvement precluding partial sphincter resection with anastomosis. There is concern that a longer delay to surgery will result in making the salvage resection more difficult. Although it has been reported that salvage surgical resection after nonoperative management is feasible, longer delays in identification of regrowth has been associated with more than a 50% decrease in the ability to perform sphincter preserving salvage surgery [17, 33]. Tumor regrowth occurring deep to the mucosa may be difficult to identify before more extensive sphincter involvement and the addition of radiation-induced posttreatment fibrosis along the pelvic floor or anal sphincter complex may also preclude subsequent sphincter-preserving resection.

Thus when tumor regrowth occurs, subsequent sphincter preservation cannot be assured. In fact this is quite understandable and reasonable if patients are indeed selected for a watch and wait approach based on distally located tumors. Finally, what remains to be settled is if leaving the rectum containing residual viable tumor in patients with cCR but not pCR increases the risk for distant failure. Recent data regarding 73 patients from Memorial Sloan Kettering suggest that there is the potential for increased risk of distant metastasis among patients undergoing watch and wait when compared to those with pCR, but the sample size was relatively small and the difference did not achieve statistical significance ($p = 0.09$) [34].

Despite these concerns the evidence in support of a watch and wait approach is growing. A limited number of prospective series have reported on nCRT followed by observation (Table 30-2). A review of the wait and see approach published in 2012 identified 30 publications from 9 series including 650 patients. While demonstrating proof of principle, significant heterogeneity of the studies in staging, inclusion criteria, study design, and follow-up rigor limit our ability to draw firm conclusions [35].

Clinical Assessment of Treatment Response

The clinical assessment of treatment response is difficult and is perhaps the greatest challenge and limiting factor for safe implementation of the watch and wait approach. A number of different strategies have been considered including clinical assessment, full-thickness local excision, metabolic imaging, and high-resolution pelvic MRI imaging.

The concordance between clinical and pathologic evaluation has traditionally been poor both in terms of sensitivity (~25%) for detecting pCR, and specificity (~60–90%) for excluding residual disease [38, 39]. Moreover, there has not existed a standard method for the clinical evaluation of complete response. Investigators have advocated for a combination of digital rectal examination and endoluminal visualization to identify residual mass, ulceration, nodularity, or stenosis, all of which may suggest persistent tumor [40]. Findings in support of a complete response include regular and smooth mucosa, and changes such as whitening or presence of telangiectasias. However, in a recent study, the false-positive rate for pCR based on preoperative clinical assessment was 27% [41]. Improvement in the clinical detection of pCR may be possible with a higher pretest probability of complete response, as demonstrated by the ACoSOG Z6041 trial of nCRT with concurrent capecitabine and oxaliplatin followed by local excision for cT2N0 rectal cancers that observed a sensitivity of 85% for detection of pCR based on

digital rectal examination and proctoscopy. However even in the setting of a prospective trial with a primary endpoint of pCR, the false positive rate was 33% [42]. These data suggest that while the detection of pCR can be improved, the risk for false-positivity remains a significant concern.

Given the challenges for clinical assessment of residual disease within the bowel wall, a number of investigators have considered local excision of the tumor bed as both a diagnostic test to assess pathologic treatment response and a therapeutic maneuver to excise any residual tumor cells residing within the bowel wall. Endoscopic biopsy alone has the obvious limitation of being able to provide only a superficial sampling of the tumor bed that can miss residual disease that may be present more deeply within the bowel wall or away from the site of biopsy. Among 39 patients exhibiting clinical response to nCRT but not meeting clinical criteria for pCR, endoluminal biopsies were associated with a negative predictive value of only 11% [43].

Full thickness excision of the entire tumor bed may be performed through a variety of approaches including transanal excision, transanal endoscopic microsurgery (TEM), or transanal minimally invasive surgery (TAMIS). However, while complete pathologic assessment of the bowel wall can be performed, it still cannot provide information regarding the status of the unresected lymph nodes, which may contain viable tumor in up to 9.1% of patients who achieve ypT0 status and 17.1% of patients with ypT1 disease [18, 44, 45]. However, the presence of ypN+ status may be influenced by pretreatment patient selection and ypT0 status among patients with earlier stage initial disease may be associated with a relatively low risk for ypN+ disease [46]. Another major limitation of full-thickness excision following nCRT is that it is associated with significant treatment associated toxicity including poor healing and pain. In fact the risk for wound dehiscence has been reported to be 26–70% following nCRT [47, 48]. Consistent with these single institutional findings, the multicentered ACoSOG Z6041 study reported a 54% overall rate of perioperative complications following local excision [42]. Moreover, local excision following nCRT is still associated with a significant risk for anorectal and sexual dysfunction. In a study of 44 patients, 51% and 46% reported incontinence of flatus and loose stool, respectively, and 59% reported clustering and 49% reported urgency. In addition, 19% of men and 20% of women reported negative impacts on sexual quality of life [49]. Finally, the watch and wait strategy may perhaps have the greatest appeal for patients whose tumors involve the anal sphincter for whom sphincter preservation would be impossible. Full-thickness excision in this circumstance would necessitate at least partial resection of the internal sphincter. Thus the role for full-thickness excision in a watch and wait approach remains limited.

Two primary approaches to radiologic imaging for the assessment of treatment response have been investigated. Despite its utility in signaling response to systemic therapy for a variety of malignant diseases, metabolic imaging with ^{18}fluorodeoxyglucose positron emission computed tomography (PET) has not been shown to be reliable for the identification of complete responders (AUC 0.57–0.73) [50]. Although comparing the change in baseline with 12-week posttreatment standardized ^{18}FDG uptake values may provide some improvement in test performance [51].

Table 30-3. MRI tumor regression grade (mrTRG) [54]

mrTRG	Description
1	Tumor bed with low signal intensity signaling fibrosis with no residual intermediate tumor signal
2	Tumor bed with predominance of fibrosis with minimal residual intermediate tumor signal
3	Substantial intermediate intensity tumor signal present, but does not predominate over low intensity fibrosis
4	Minimal fibrosis
5	No change from baseline

Perhaps one of the most useful imaging tests is high-resolution MRI. Areas of treatment response and fibrosis are characterized by low signal intensity on T2 weighted imaging. The presence of uniform low signal intensity with the absence of areas of intermediate signal intensity within it is suggestive of a pCR. Based on these findings and a comparison to pretreatment MRI, a tumor regression grade has been proposed by the Mercury Study investigators (Table 30-3) [52]. The so-called mrTRG of 1–3 correlated with better survival outcomes when compared to mrTRG 4–5, comparable to the difference in survival observed when comparing ypT0-3a vs. ypT3b or greater [52]. There is currently great interest in the potential for the addition of diffusion weighting or functional dynamic contrast enhanced MRI to improve the detection of response, and other technologies may still be on the horizon [53]. In the meantime, MRI may play an important role in identifying patients with significant treatment response and more favorable prognosis who may be eligible for a watch and wait approach. Such a strategy was employed by a group from Maastricht University in the Netherlands to identify 21 patients for a wait and see approach that were compared to 20 matched control patients exhibiting pCR treated with surgery. They utilized strict selection criteria requiring evidence of cCR, including by posttreatment high-resolution magnetic resonance imaging (MRI) and then MRI-based follow-up every 3 months for the 1st year and biannually thereafter. With their approach, 75% of the pCR patients who had undergone resection were classified by MRI incomplete responders. After a median follow-up of 15 months (vs. 35 months in the surgery group), only 1 patient experienced a local recurrence in the study arm [36]. The TRIGGER trial lead by investigators at the Royal Marsden and the Pelican Cancer Foundation in the United Kingdom will randomize patients to deferral of surgery with watch and wait for good (mrTRG 1–2) and systemic therapy for poor (mrTRG 3–5) responders based on MRI with an opportunity for the poor responders to be converted to complete response vs. immediate surgery in the control arm.

Increasing the Rate of Complete Response

Based on the presumption that patients with pCR are eligible for an organ-preserving watch and wait approach, a number of investigators have tried to improve the rate of PCR with neoadjuvant therapy. These can broadly be categorized as (1) radiotherapy dose intensification including contact radiation; (2) utilization of more active chemotherapeutic regimens; (3) increase in the time interval from chemoradiotherapy to surgery; and (4) a combination of these approaches.

Perhaps the most common strategy for radiotherapy dose escalation is local boost therapy to the tumor volume. This approach has the advantage of increasing the delivered dose to the tumor volume without increasing toxicity to uninvolved surrounded bowel and can be achieved through IMRT or contact therapy [55]. In a randomized trial of external beam radiotherapy to 39 Gy in three fractions with endocavitary boost to 85 Gy compared to external beam radiotherapy alone, there was significant increase in complete or near-complete sterilization (57% vs. 34%, respectively) [56]. Unfortunately, while boost therapy to the primary tumor bed can increase the rate of response within the bowel wall, the lymph nodes may remain unaddressed; however these strategies appear to be well tolerated and remain the subject of further investigation.

A number of studies have attempted to increase the treatment response by incorporating more highly active concurrent chemotherapy regimens. Indeed, it has been reported that systemic chemotherapy alone may be associated with pCR in up to 25% of patients with relatively early rectal cancers [57]. Unfortunately, after several randomized studies of concurrent fluoropyrimidine-based oxaliplatin containing regimens, an increase in pCR has been observed only in the German CAO/ARO/AIO-04 randomized trial at the cost of increased toxicity as demonstrated in NASBP R-04 and STAR-01 [58–61].

The time interval between nCRT and surgery is another important factor associated with pCR. The Lyon R90-01 trial randomized patients to an interval of 6–8 weeks vs. <2 weeks and found a higher rate of complete response (26% vs. 10.3% $p = 0.005$) following the longer interval [62]. However, subsequent long-term follow-up after a median 6.3 months demonstrates no difference in local recurrence or survival [63]. Thus while it is well recognized that a longer treatment interval is associated with a higher rate of pCR, it has not been demonstrated that patients exhibiting pCR after a longer treatment interval have the same good prognosis of those who were more rapidly sterilized. Thus tumor cell death is initiated immediately (during neoadjuvant therapy), but the pCR rate can be manipulated by changing the duration of delay prior to proctectomy. Therefore, one cannot assume that one neoadjuvant therapy regimen is superior to another based on pCR rate if proctectomy occurs at different intervals following neoadjuvant therapy.

Additional strategies for improving treatment response while providing systemically active therapy include induction and consolidation chemotherapy. Induction chemotherapy has the potential to improve survival outcomes by improving tumor regression and the ability to deliver systemic chemotherapy with a lower rate of associated toxicity. The EXPERT and EXPERT-C phase II studies of pretreatment capecitabine with oxaliplatin and with cetuximab in patients with high-risk rectal cancers showed that a high rate of R0 resection could be achieved although there was not a remarkable increase in the rate of pCR [64]. The addition of the EGFR inhibitor resulted in greater rates of radiographic response, although not in the rate of pCR [65].

Capitalizing on the potential for improved tumor regression with increased time interval to surgery, the Timing of Rectal Cancer Response to Chemoradiation trial, delivering up to six cycles of mFOLFOX6 after standard CRT was associated with an increase in pCR to 38% vs. 18% with standard nCRT alone [66]. The rate of surgical complications was not increased and no increased risk for progression was observed. Others have reported have provided supportive evidence for consolidation chemotherapy, but its potential role in improving durability of treatment response for patients undergoing a watch and wait strategy is unknown [67]. And the Rectal cAncer and Preoperative Induction therapy followed by Dedicated Operation (RAPIDO) trial is currently randomizing patients to short-course (5×5 Gy) pelvic radiation followed by six cycles of capecitabine and oxaliplatin and TME vs. standard nCRT and TME with the goal of improving disease-free and overall survival without compromising local control [68]. There is also an ongoing randomized study of induction vs. consolidative chemotherapy for patients with rectal cancer undergoing nCRT that is intended to improve disease-free survival when compared to standard CRT (NCT02008656). While these studies are not designed to investigate a strategy of watch and wait, it may shed new light on the role of consolidative chemotherapy in patients with high-risk rectal cancer.

Finding the Way Forward

The management of rectal cancer has become increasingly complex. While currently most patients with clinical stage II or III disease are treated with neoadjuvant chemoradiotherapy or short course radiotherapy followed by proctectomy, there is increasing recognition of the potential to avoid radiation therapy associated toxicity, as excellent results can be achieved with high-quality resection in appropriately selected patients without high-risk features on initial evaluation [69]. We also continue to learn about the role of neoadjuvant chemotherapy alone for treatment of intermediate-risk mid-rectal cancers [57]. Patients with intermediate-risk dis-

tal rectal cancers in whom a permanent colostomy will be required may be the optimal candidates in whom to study a watch and wait approach. These patients with small tumors close to or involving the sphincters are most likely to both require permanent colostomy at surgery and to achieve a complete response to chemoradiation therapy.

However a number of unresolved questions remain. The long-term oncologic efficacy of the watch and wait approach still requires validation, especially given the high cure potential associated with definitive surgery in this patient population. While it appears that surgical salvage for tumor regrowth is feasible, it is unknown if the delay can lead to lost window of opportunity for patients with distal cancers who were otherwise candidates for coloanal reconstruction. The potential that the risk for distant recurrence may be increased with a nonoperative approach must also be examined. Finally, there exists no reliable method for identifying patients with pCR who may then be eligible for a watch and wait approach and local tumor excision still carries significant morbidity risk without providing complete information regarding the status of the regional lymph nodes. Currently, the most objective method for identifying potential candidates for a watch and wait approach seems to be comparison of pre- and posttreatment high-resolution MRI imaging to assess response. Using MRI response to clinical response criteria with a strict protocol for follow-up may be the most reliable way of implementing a watch and wait strategy but it is far from a perfect test. Systemic chemotherapy, either as induction or consolidation, is another approach to increasing the likely of achieving pCR and identifying the low-risk in whom selective surgery can be considered and may play a role in reducing the risk for distant recurrence [66]. Finally, while there is great interest in molecular analysis that should be incorporated into all future trials, as of yet there are no molecular signatures that can predict the likelihood of achieving a pCR.

Until recently, most surgeons would have been reluctant to consider a nonoperative approach for rectal cancer, but the increasing emergence of data may have turned the tide on opinion [70]. As of yet there is no evidence from randomized controlled trials to support nonoperative strategies for patients with rectal cancer. Questions regarding patient selection, optimal method for inducing pCR, methods for assessing treatment response, and adequacy of follow-up remain unanswered.

Given the infrequent primary outcome of recurrence in this patient population, a randomized non-inferiority study is likely not feasible. But there is a critical need for evidence, perhaps through well-conducted prospective cohort studies, so that the watch and wait strategy can be safely incorporated into the overall management strategy for patients with rectal cancer. For now, radical surgery should remain standard treatment for rectal cancer, and watch and wait should only be performed in the context of clinical trials.

Proctectomy

Emmanouil P. Pappou and Martin R. Weiser

Key Concepts

- A proper proctectomy with sharp dissection along the visceral and parietal layers of the endopelvic fascia facilitates margin-negative resection, reduces local recurrence, and limits nerve injury associated with sexual dysfunction.
- Precise understanding of pelvic anatomy including fascial planes, autonomic nerves, and pelvic floor musculature is critical in performing a proper proctectomy.
- The quality of mesorectal excision and the distance of the circumferential radial margin are associated with local pelvic control.
- Proctectomy can be performed using open, laparoscopic, and robot-assisted techniques.

Background and History

At the beginning of the twentieth century, the majority of patients diagnosed with rectal cancer in Europe and the United States underwent perineal proctectomy—the preferred operation of the day. While this operation was an improvement over previous surgeries, it was highly morbid, with poor oncologic results. In 1908, William Ernest Miles of St. Mark's Hospital in London recognized that nearly all of his patients suffering from rectal cancer died of recurrent disease within 3 years after perineal proctectomy. On autopsy, he noted that most recurrences were identified in the part of the mesorectum that had been left in place and/or within lymph nodes situated near the left common iliac artery. Miles termed these areas the "zone of upward spread." He concluded that perineal proctectomy was inadequate because it failed to address the ultimate cause of local recurrence: incomplete excision of the mesorectum, including its lymphovascular supply.

Based on his observations, Miles devised a different procedure, which he described as abdominal perineal excision (APE) or, as it came to be called, abdominoperineal resection (APR). APR soon became the surgical procedure of choice for treatment of carcinoma of the rectum [1]. As Miles described it, APR actually comprised two procedures performed during the same operation: an abdominal operation and a perineal operation. The abdominal part of the APR includes dissection of the rectum and mesorectum and creation of a colostomy; the perineal part includes detachment of the rectum, anus, and levator muscles from the genital/urinary organs and the ischiorectal fat. Describing the perineal approach in 1910, Miles stressed that the levator muscles should be "divided as far outwards as their origin from the white line so as to include the lateral zone of spread" [2]. Compared with perineal proctectomy, long-term outcomes following this new operation improved considerably.

Miles' emphasis on the necessity of removing the mesorectum in its entirety would become the guiding principle of what is now known as total mesorectal excision (TME). Today, TME remains the gold standard in rectal cancer surgery. TME entails sharp—rather than blunt—dissection of the visceral and parietal layers of the endopelvic fascia, resulting in intact removal of the rectum and mesorectum [3]. In Miles' time, however, most surgeons continued to perform traditional blunt dissection, limiting the benefits of APR and resulting in a 25% rate of positive resection margins, with high rates of recurrence and mortality.

The absolute necessity of sharp dissection in every rectal cancer operation—i.e., meticulous removal of the entire mesorectum along the areolar plane outside of the rectal fascia propria—was reemphasized in 1982 by Bill Heald. Heald defined TME as an "optimal dissection plane around the cancer which must clear all forms of extension and circumscribe predictably uninvolved tissue," in other words, sharp mesorectal excision along definable tissue planes. He described this as the "holy plane" of rectal cancer surgery [4]. The aims of TME are to excise the rectum and surrounding mesorectum, including its blood vessels and pararectal lymph nodes, within an intact visceral fascial "envelope"; to complete en

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_31

bloc resection of the lymph nodes along the superior rectal and inferior mesenteric arteries; and to achieve clear resection margins.

Advocates of "total mesorectal excision" have focused attention on two critical components of oncologic proctectomy: the lateral (radial) margin and the distal margin of mesorectal excision. Sharp dissection in the avascular plane surrounding the mesorectum, so as to remove the mesorectum in its fascial envelope and achieve a wide circumferential radial margin (CRM), has been demonstrated to be essential in avoiding local recurrence of tumor in the pelvis [5–7]. Although this concept is not novel [8, 9], it has served to refocus attention on surgical technique during proctectomy, which is warranted, given the widely divergent local recurrence rates reported in the literature [10]. In 1985, Quirke and colleagues showed that pelvic relapse was the result of residual tumor at the CRM, and they were among the first to describe a systematic assessment of the CRM [7]. Since the original publication of this paper, numerous studies (including prospective trials) have confirmed that CRM involvement is a strong predictor of local recurrence, as well as distant metastasis and poor survival [11].

The second component of TME, as advocated initially by Heald et al., is the removal of the entire mesorectum distal to the tumor. However, the necessity of removing mesorectum more than 4–5 cm distal to a proximal rectal tumor is not supported by pathologic studies of lymph node involvement in the mesorectum [9, 10, 12–16]. Furthermore, it may have contributed to a high anastomotic leak rate (17%) in early series [17] and has not been shown to be of benefit in a large clinical review [18]. At present, many advocates of "total mesorectal excision" limit mesorectal resection to 4–5 cm distal to proximal rectal tumors [6, 19–21], although some authors still refer to this technique as "total" mesorectal excision [19–22], which has caused confusion. Other groups have termed the concept of tailoring the mesorectal excision to the position of the tumor "tumor-specific mesorectal excision" [6], which may be more accurate.

In summary, for all patients with rectal cancer, it is critical that the primary tumor is removed in its entirety. In addition, mesenteric tissue at greatest risk for nodal metastases should also be resected. For patients with mid and distal rectal cancers, appropriate proctectomy technique will involve removing the entire mesorectum. For patients with proximal rectal cancers, it is important to remove the mesorectum for a distance of approximately 4–5 cm distal to the tumor, although resecting the mesorectum distal to that point does not appear to confer benefit.

Anatomy of the Mesorectum/Rectal Fascia

Chapter 1 has an in-depth look at the anatomy of the colon, rectum, and anus; however, surgical anatomy as it relates to proctectomy will be covered here. The proctectomy technique is based on an understanding of the anatomy of the rectum and the mesorectal fascia. The rectum is located at the end of the large intestine, where the taeniae coalesce to form a complete lineal muscular layer. This is surrounded by a recognizable annular envelope: the rectal fascia (or mesorectum, as it is better known to surgeons). The mesorectum contains the lymphovascular supply of the rectum and upper anal canal. It encloses the branches of the superior rectal artery and the perirectal lymph nodes, which drain in a caudal direction toward the inferior mesenteric artery. Around the rectum is an avascular plane, surgically recognizable as a cobweb of areolar tissue.

The mesorectum is asymmetrically distributed. The bulk of it sits posterior to the rectum, identified by two protruding bulges (the "mesorectal cheeks"); anteriorly and laterally, the perirectal tissue is thinner. Similarly, the mesorectal fascia is most developed on the posterior aspect. Anteriorly, the mesorectum is thinner and bordered by the recto-genital septum known as Denonvilliers' fascia. In men, Denonvilliers' fascia separates the rectum and mesorectum from the prostate and seminal vesicles. In women, the thinner rectovaginal fascia separates the rectum from the vagina. Ligaments below and lateral to the peritoneal reflection connect to the parietal fascia on the pelvic sidewall.

An extensive autonomic nervous system of sympathetic and parasympathetic fibers supplies the rectum and genitourinary tract, controlling continence and sexual function. The sympathetic autonomous system is responsible for urinary continence and ejaculation, whereas the parasympathetic system controls micturition, as well as genital erection and lubrication. Precise knowledge of the anatomy of this pelvic autonomic network is essential in rectal surgery, as injury to these nerves during proctectomy can lead to sexual dysfunction and incontinence. The sympathetic autonomic plexus arises from lumbar sympathetic nerves originating in the T12–L2 spinal junction, which pass anterior to the aorta and form a network in close proximity to the origin of the inferior mesenteric artery. This is known as the superior hypogastric plexus. The superior hypogastric plexus enters the pelvic cavity anterior to the sacral promontory and splits into fairly well-defined left and right hypogastric nerves (Figure 31-1). Damage to this sympathetic plexus during ligation of the inferior mesenteric artery, or damage to the hypogastric nerve trunks during mesorectal mobilization, can lead to urinary incontinence and retrograde ejaculation. The hypogastric nerves course posterolateral to the mesorectum and ultimately join parasympathetic nerves—also known as the pelvic plexus, pelvic splanchnic nerves, or nervi erigentes—to form the inferior hypogastric plexus. The parasympathetic nerves that join the sympathetic system originate from the S2–S4 sacral spinal nerve roots, lying posterolaterally along the mesorectal fascia. Preservation of the pelvic splanchnic nerves and the inferior hypogastric plexus, and careful separation of these from the rectum, is one of the most challenging aspects of proctectomy. The inferior hypogastric plexus forms an extensive network of interlocking fibers of the sympathetic

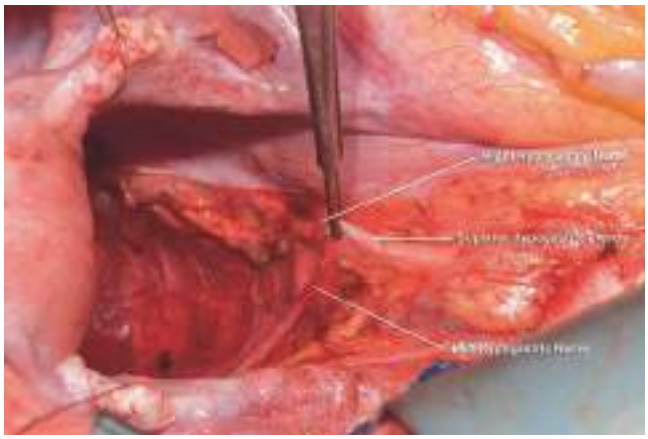

FIGURE 31-1. The superior hypogastric plexus splits into the *right* and *left* hypogastric nerves as it enters the pelvic cavity. Parasympathetic pelvic splanchnic nerves, also known as nervi erigentes, arise from sacral spinal nerves S2–S4 and pierce the presacral fascia on the *left* and *right side* to join the hypogastric nerves, forming the inferior hypogastric plexus (not shown). *With permission from Lee-Kong et al.: Autonomic nerve preservation during rectal cancer resection. J Gastrointest Surg 2010;14:416–422. © Springer* [104].

left and right hypogastric nerves, and parasympathetic pelvic splanchnic nerves are situated on the pelvic sidewall. Various nerves leave the inferior hypogastric plexus to enter the rectal wall, while the remaining neurovascular bundles extend anterolaterally to the seminal vesicles, distal ureters, vasa deferentia, urinary bladder, prostate and cavernous bodies in men, and in the similar anatomic area in women, for whom the lower portion of the inferior hypogastric plexus runs along the lower lateral wall of the vagina.

Laterally, the mesorectum is sometimes not completely covered by a layer of fascia and is penetrated by the middle rectal vessels (coming from the internal iliac vessels, present in about 10–20% of patients) and autonomic nerves from the inferior hypogastric plexus. The mesorectum is tethered inferolaterally to the inferior hypogastric plexus, necessitating a more challenging dissection that is best achieved with precise monopolar diathermy and subtle traction and countertraction, in order to draw the autonomic nerve fibers controlling urinary continence and sexual function carefully away from the surface of the mesorectum.

Posterior to the mesorectum is the presacral fascia, which follows the concavity of the sacrum. The presacral fascia is a thickened parietal fascia that covers the presacral veins and fat, extending laterally to join Denonvilliers' fascia anteriorly. Inferiorly, between the levels of the third and fourth sacral vertebra, the mesorectum and the presacral fascia fuse. The thick connective tissue bridging these two separate fascias is also known as the rectosacral fascia or Waldeyer's fascia. Waldeyer's fascia is an important surgical landmark during posterior rectal mobilization, because of its close relationship to the sympathetic hypogastric nerves and the inferior hypogastric plexus. Inaccurate dissection at this level can lead anteriorly to breach of the mesorectum and posteriorly to tearing of the fascia, resulting in considerable bleeding from the presacral veins. At the most distal part of the rectum, the mesorectum thins out as a recognizable structure so that it is virtually absent over the final 1 cm of the rectum. Distal rectal cancers are thus at greater risk of invading surrounding structures than proximal rectal cancers, particularly the pelvic floor/external anal sphincter, vagina, or prostate, because of the relative paucity of mesorectum at this level.

Surgical Principles of Proctectomy for Rectal Cancer

The basic principles of proctectomy are as follows [23]:

1. Sharp dissection circumferentially around the mesorectum in an avascular areolar plane between the visceral and parietal layers of the endopelvic fascia (Figure 31-2a)
2. Identification and preservation of the autonomic nerve plexus that controls bladder and sexual function (Figure 31-2b)
3. Achievement of a circumferential margin that is macroscopically and microscopically clear of tumor
4. Preservation of the anal sphincter complex and pelvic floor, with restoration of gastrointestinal continuity when appropriate

Pathological Assessment

In addition to assessment of proximal, distal, and CRMs, pathologists can grade the quality of the mesorectal specimen. This has been demonstrated to have prognostic significance. Quirke et al. described a grading system which classifies rectal cancer specimens according to whether the surgeon has dissected outside the mesorectal fascia, in the correct plane (the mesorectal excision plane), or has violated the mesorectum, leaving mesorectal tissue behind in the pelvis by following a plane within the mesorectum (intramesorectal plane) or directly on the muscularis propria (muscularis propria plane) [24]. This mesorectal grading system has been evaluated in subsequent studies and has been found to be an independent predictor of local pelvic control [25, 26]. One study reported a significant association between plane of surgery and survival—even in patients with an uninvolved CRM [27]. However, these studies also showed that the surgical plane was related to CRM positivity rates, with the lowest rates of positive CRM in surgery that achieved sharp dissection along the mesorectal plane.

Pathological analysis of the excised proctectomy specimen provides important prognostic information on the stage and biology of the tumor. It is also a means of assessing the

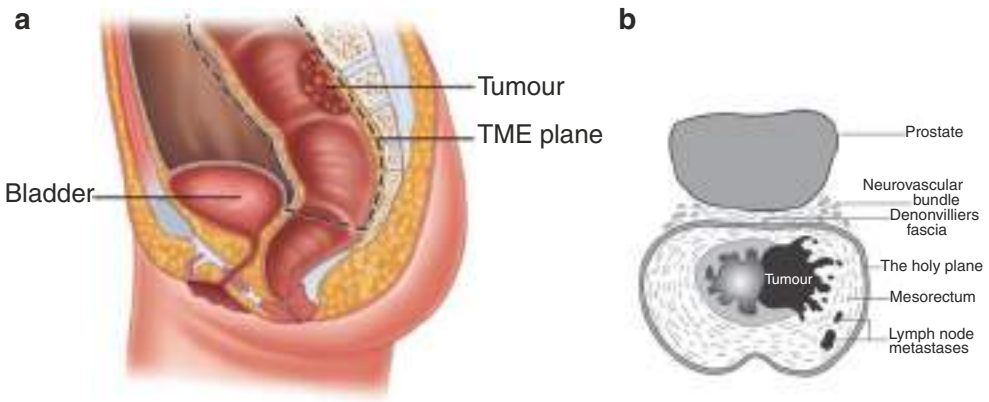

FIGURE 31-2. Total mesorectal excision. (**a**) Dissection follows the *dotted line*. Tumor deposits are often present within the lymphovascular tissue surrounding the rectum (mesorectum). Incomplete resection leaves residual deposits which are most likely the origin of local treatment failure. *With permission from Janjua AZ, Moran B, Heald RJ. Open surgical management of rectal cancer. Patel HRH, Mould T, Joseph JV, Delaney CP. (Eds). Pelvic Cancer Surgery: Modern Breakthroughs and Future Advances. quality of surgery, because margin status and quality of mesorectal excision can be used as surrogates for oncologic outcome assessment. The College of American Pathologists (CAP) has implemented standardized assessment of rectal cancer specimens [28]. The surgeon or pathologist should ink the non-peritonealized radial margin of the fresh resection specimen to help guide this analysis. A standardized synoptic report should include a subjective assessment of mesorectal grade and quantitative measurement of CRM in millimeters. A margin is considered positive if the primary tumor or involved lymph node extends to within 1 mm of the resection margin.

Preoperative Preparation

All patients undergoing rectal cancer surgery require preoperative preparation aimed at optimizing the technical success of the procedure and avoiding perioperative complications. Oral mechanical bowel preparation with polyethylene glycol, to reduce the bacterial load and risk of intraoperative fecal spillage, has been considered an axiom in colon and rectal surgery. However, a number of prospective trials have failed to demonstrate any benefit from mechanical bowel cleansing in preventing surgical site infections (SSIs) [29, 30]. These results were confirmed by a Cochrane systematic review of 5805 patients, in which the authors concluded that there is no statistically significant benefit from mechanical bowel preparation or the use of rectal enemas [31]. Another recent systematic review by the Agency for Healthcare Research and Quality reached similar conclusions [32]. Oral mechanical bowel preparation appeared to be protective, compared to no preparation, for peritonitis or intra-abdominal abscess, but the evidence was weak. The study could not draw any conclusion on potential harms, such as dehydration and electrolyte imbalances, related to use of oral mechanical bowel preparation.

Despite the lack of solid data regarding the impact of bowel preparation on wound infection, there are other valid reasons for preoperative cathartic bowel preparation prior to proctectomy. It is preferable to have the rectosigmoid cleared of stool, in order to accurately assess the position of the tumor intraoperatively. In addition, division of the colon and rectum is more easily accomplished if the lumen is free of stool. Lastly, if the patient is to undergo a temporary diverting proximal stoma, it is preferable to have the intervening colon free of stool, in case of anastomotic leak. Although it is theoretically possible to have patients clear stool from the rectosigmoid with preoperative enemas, in practice this is often difficult to accomplish due to the rectal tumor itself and physical disabilities associated with the advanced age of many patients. In addition, enemas do not clear the proximal colon of stool, mitigating the benefit of proximal fecal diversion if anastomosis is performed.

High-quality evidence indicates that preoperative antibiotics covering aerobic and anaerobic bacteria, delivered orally, intravenously, or both, reduce the risk of postoperative surgical wound infection by as much as 66% in elective colorectal surgery [33]. Oral neomycin- and erythromycin-based antibiotics are typically administered the day before surgery, in combination with oral mechanical bowel preparation. For patients without penicillin allergy, a second-generation cephalosporin (cefotetan or cefoxitin) is administered intravenously within 60 min of the surgical incision, with re-dosing

during the procedure as required, according to the half-life of the drug and the duration of surgery. For penicillin-allergic patients, metronidazole or clindamycin combined with either ciprofloxacin or gentamicin is acceptable, as are aztreonam and fluoroquinolones [34]. Ertapenem, a long-acting carbapenem active against gram-negative anaerobe, is an accepted alternative to second-generation cephalosporins for prophylaxis. Other measures that prevent SSI include tight glucose control in diabetic patients, smoking cessation, clipping rather than shaving the skin of the abdominal wall, and maintaining normothermia and adequate oxygenation during anesthesia [35]. Patients undergoing rectal cancer surgery are also at risk of deep venous thrombosis and pulmonary embolism and should have thromboembolic prophylaxis with unfractionated heparin or low molecular weight heparin during the perioperative and postoperative period [36].

As the incidence of rectal cancer increases with age, many patients also have cardiovascular or respiratory conditions requiring medical clearance before surgery. While technical advances have made rectal cancer operations safer, optimal outcomes require special effort to ensure that the patient's overall health is acceptable at the time of surgery. Many patients with other comorbid conditions such as diabetes, hypertension, and coronary artery disease require medical evaluation before undergoing surgery. Comorbidities can impact decision-making and affect short- and long-term outcomes. Patient's clinical and performance status should be optimized to reduce the risk of perioperative complications. Fertility options should be discussed with all individuals of childbearing potential. In the setting of Lynch syndrome, discussion regarding oophorectomy and hysterectomy is appropriate. Patients who may require a stoma should be seen before surgery by an enterostomal therapist. Adequate marking of the stoma site improves outcomes. Preoperative teaching shortens the time required by patients to gain proficiency in managing their stoma and reduces length of hospital stay [37].

The enhanced recovery after surgery (ERAS) protocols were introduced in open colorectal surgery in the 1990s, with the aim of speeding patient recovery, improving patient outcomes and satisfaction, shortening hospitalization, and reducing healthcare costs [38]. ERAS protocols span the entire perioperative period and attempt to minimize surgical stress and postoperative ileus through patient education, preoperative hydration and carbohydrate loading, goal-directed intraoperative fluid management, narcotic sparing for intraoperative and postoperative pain control, and early mobilization and oral feeding in the postoperative period. A number of prospective trials and reviews have indicated that the implementation of ERAS protocols reduces length of hospital stay, compared to conventional recovery in patients undergoing open or minimally invasive surgery for CRC [39, 40].

Operative Approaches

Optimal resection of rectal cancer according to the oncologic principles of TME can be achieved by open or minimally invasive (laparoscopic or robotic) surgical techniques. Herein, we describe methods for both open and minimally invasive approaches. General concepts such as nerve preservation are detailed in the "open" section but apply to minimally invasive approaches as well.

Open Low Anterior Resection

The patient is placed in a modified lithotomy or supine split-leg position. A variety of incisions can be utilized; however, it is important to keep the incision line away from the area of potential stoma and stoma appliance, so as to not interfere with management of the stoma postoperatively. The abdominal cavity is explored thoroughly, especially the liver and the peritoneum, to identify signs of distant metastatic disease. If unresectable distant metastatic disease is encountered, then the surgeon should carefully consider whether low pelvic anastomosis is warranted. Patients with unresectable distant metastatic spread often undergo prolonged treatment with chemotherapy, and the presence of a temporary diverting ileostomy may increase the severity of chemotherapy-induced enteritis. In addition, the added risk of colorectal or coloanal anastomotic leak may not be warranted because, if leak occurs, systemic chemotherapy may be delayed. In addition, chemotherapy must be stopped temporarily to close the ileostomy; if complications ensue from this second procedure, systemic chemotherapy may again be delayed. Lastly, the functional derangements associated with low pelvic anastomosis will only be exacerbated if the patient receives cytotoxic chemotherapy, which may produce enteritis. In sum, it may be preferable to simply perform a Hartmann's resection for mid and distal rectal adenocarcinoma that does not invade the pelvic floor or anal sphincter, in patients with unresectable distant metastatic disease. For patients with proximal rectal cancer who may not require temporary fecal diversion and are at low risk for anastomotic complications, it is reasonable to perform anterior resection with primary anastomosis, even in the setting of unresectable distant metastatic disease (if this was the original plan).

Our preferences regarding the technical aspects of restorative proctectomy are described as follows: The small bowel is carefully packed and retracted to the right, providing access to the pelvis. The sigmoid and left colon is mobilized by dissection laterally to medially along the white line of Toldt. The sigmoid colon is retracted medially. In this loose connective tissue plane, first the gonadal vessels and then, more medially, the left ureter are encountered. Dissection is continued in this plane, and the left colon is dissected away

from Gerota's fascia. At the base of the sigmoid mesocolon, the retrorectal avascular plane is entered. While the sigmoid colon is elevated from the left lateral side, gonadal vessels, the left ureter, and the left hypogastric nerve are preserved in the embryologic avascular plane, and the mesorectal dissection plane is reached. The sigmoid is retracted in the right lateral direction. Then, from the right side, the sigmoid mesocolon is entered through a window over the surgeon's hand at the pelvic brim. Through this window, the inferior mesenteric artery is liberated, and separate ligations of the artery and vein are performed. The superior rectal artery (just distal to the left colic artery) or inferior mesenteric artery, at its origin 1–2 cm from the aorta, is ligated and divided to preserve the sympathetic plexus. High ligation of the IMA is useful when bulky adenopathy is present at the base of the vessel or when a coloanal anastomosis is necessary and maximal length of the left colon is required. When the inferior mesenteric artery is ligated, care must be taken to preserve the marginal artery, which provides the blood supply from the middle colic vessels to the left colon and anastomosis.

The inferior mesenteric vein is ligated at the paraduodenal (ligament of Treitz) location just inferior to the pancreas and again adjacent to the ligation site of the inferior mesenteric artery. Dividing the vein at the ligament of Treitz is critical in order to accommodate full mobilization of the splenic flexure, which is then allowed to rotate into the pelvis for maximal length. Splenic flexure mobilization is performed by continuing the lateral dissection of the descending colon superiorly, retracting and dissecting the descending colon off Gerota's fascia. Colonic attachments to the pancreas are then taken down, and care is taken to avoid aggressive retraction on the colon, which can tear the splenic capsule. Omental attachments are then taken down from the distal transverse colon to complete the mobilization.

The sigmoid mesentery is divided to the bowel wall, which is stapled and divided. The left colon is packed superiorly, facilitating visualization of the pelvis. The stapled sigmoid is retracted anteriorly, which opens the perimesorectal planes. A sharp dissection is carried out under direct vision, circumferentially around the mesorectum. The presence of the superior hypogastric plexus posteriorly must be kept in mind throughout the dissection (Figure 31-3a). Starting the dissection in the posterior and then the lateral plane, in a stepwise manner, facilitates identification of the correct mesorectal plane (Figure 31-3b). If bleeding is encountered in one area, it is reasonable to proceed to the opposite circumference, so that pressure is applied while progress continues. The key to this phase is the recognition of the areolar tissue on the back of the mesorectum, through which the dissection should proceed when the areolar tissue is on stretch. Once there is sufficient space, a St. Mark's Pelvic Retractor is introduced behind the specimen. Traction and countertraction are critical to the pelvic dissection and are optimized by use of the retractor. The lateral dissection is carried out by extending the posterior plane of dissection anteriorly and around the sidewalls of the pelvis. At this point in the dissection, the inferior hypogastric plexuses curve around the surface of the mesorectum and are vulnerable to inadvertent injury. While retracting the divided rectosigmoid forward, the tangentially running hypogastric and pelvic parasympathetic nerves are carefully identified and dissected away from the mesorectal surface on each side (Figure 31-4a). This area of adherence between the nerves and the mesorectum is one of the most challenging and critical in proctectomy. As the lateral dissection moves deeper into the pelvis, one or two middle rectal arteries may be encountered. Middle rectal arteries are present in less than 20% of patients and, if encountered, can be easily divided with cautery. Dissection anteriorly progresses along Denonvilliers' fascia down to the pelvic floor (Figure 31-4b). Forward retraction with the help of the St. Mark's Retractor facilitates the development of the space anteriorly. Anterior tumors require resection of Denonvilliers' fascia, which puts the parasympathetic nerves at risk, as they extend anteriorly toward the prostate. For posterior tumors, dissection can pro-

FIGURE 31-3. (**a**) The distal sigmoid/proximal rectum is elevated anteriorly, exposing the aortic bifurcation and sacral promontory, with identification of the left ureter, left iliac vein, and superior hypogastric plexus. The hypogastric nerves may appear as an obvious discrete band of tissue or as multiple smaller bands. (**b**) Careful dissection of the sigmoid mesentery distally results in an avascular, areolar plane separating the mesorectal fascia propria from the presacral fascia. *With permission from Lee-Kong et al.: Autonomic nerve preservation during rectal cancer resection. ceed below Denonvilliers' fascia. Adequacy of the dissection distal to the lower edge of the tumor is examined by palpation and/or endoscopy to ensure a proper distal margin. When mesorectal mobilization down to the pelvic floor is considered complete on both anterior and posterior sides, the rectum is elevated above the pelvic floor and cross-clamped. At this point, washout of the anorectal stump can be performed with saline solution or water. Following this, the rectum is transected with a linear stapler (TA-45), and the specimen is removed. The anastomosis between the colon conduit and the rectal stump is constructed with a circular EEA™ Stapler (Figure 31-5a). The serosa and mucosa are visually evaluated for adequate vascular supply. Intraoperative anastomotic air testing of the colorectal anastomosis is performed by filling the pelvis with saline solution and insufflating the rectum with air through a sigmoidoscope. A handsewn coloanal anastomosis is shown in Figure 31-5b and is discussed separately below.

Laparoscopic Low Anterior Resection

The patient is placed in a modified lithotomy position. A 5-trocar technique is generally utilized, with an umbilical camera port, two left-sided and two right-sided working (Figure 31-6). This allows the surgeon and second assistant to stand on the patient's right, with the first assistant standing on the left. The dissection is performed in a medial-to-lateral fashion, first dissecting the vessels, followed by takedown of the splenic flexure, and then the lateral colonic attachments before entering the pelvis for rectal resection. With the patient in head-down and right-sided tilt, enabling the surgeon to move the small bowel mesentery out of the pelvis and away from the colonic mesentery, dissection begins at the sacral promontory. The superior rectal vessels are lifted ventrally, and a plane is developed beneath the sigmoid mesentery. Dissection is carried out just beneath the vessels, in order to sweep the sympathetic nerves toward the retroperitoneum. Dissection proceeds medial to lateral beneath the mesentery and along Toldt's fascia, preserving the ureter and gonadal vessels. The root of the IMA is exposed by creating an additional window on the superior border of the IMA. The IMA is ligated, taking care not to injure the aortic nerve plexus, either just below the left colic branch or at the origin of the vessel. The IMV is subsequently divided along with the sigmoid mesentery. The left mesocolon is further mobilized along with the splenic flexure. The IMV is divided adjacent to the pancreas to allow full mobilization and rotation of the left colon, so as to reach the pelvis for a tension-free anastomosis. Again, in a medial-to-lateral fashion, dissection continues along the ventral plane of the pancreas, with entry into the lesser sac. Often, the lateral attachments of the splenic flexure can be divided in a medial approach, exposing the spleen. The transverse colon is then retracted caudally, and the omentum is dissected off the transverse colon, meeting the prior dissection place. Lastly, the remaining lateral and splenic attachments are divided by retracting the colon medially.

For pelvic dissection, it may be necessary to position the patient in a more head-down position, often with less rotation to the right. The rectum is retracted anteriorly and the retrorectal space is identified. Sharp dissection is carried out posteriorly along the areolar plane that defines the junction of the visceral and parietal layers of the endopelvic fascia. Care must be taken to sweep the hypogastric nerves laterally, and dissection proceeds posteriorly along the mesorectum. Once posterior mobilization is completed, dissection continues in the same perimesorectal plane on the lateral sides of the pelvis. The rectum is mobilized circumferentially, applying standard open TME surgical principles. Dissection can be performed with cautery, ultrasonic dissector, or vessel-sealing devices. After TME dissection is completed, the level of rectal transection is confirmed with digital rectal and endoscopic examinations. The rectum is irrigated and then stapled and divided with endoscopic staplers. The specimen is extracted via a wound protector at the umbilical camera port or the future diverting ileostomy site. The proximal sigmoid/left colon is divided, and the anvil is secured for laparoscopic circular anastomosis. An air leak test confirms the integrity of the anastomosis, and a diverting ileostomy is fashioned selectively.

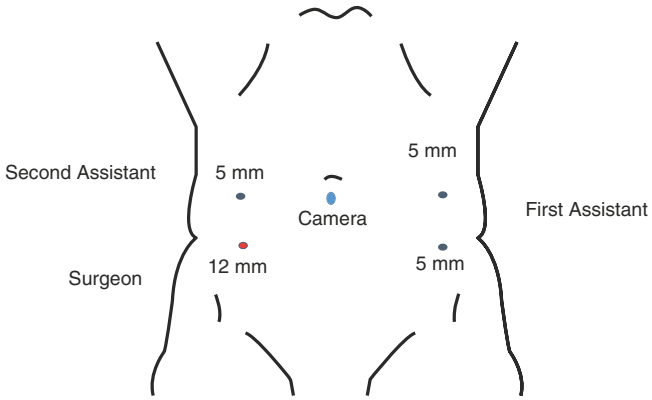

FIGURE 31-6. Preferred port placement for laparoscopic LAR with TME.

In patients with a narrow pelvis or elevated body mass index, pelvic dissection can be challenging. In such cases, a lower midline or Pfannenstiel incision may be utilized to allow open pelvic dissection, rectal division, and restoration of intestinal continuity. A combination of laparoscopic and open surgery in this manner is often referred to as a "hybrid" approach.

Robotic Low Anterior Resection

Robotics has emerged as a useful technology in pelvic dissection and may have advantages for the surgeon with respect to manual dexterity, versus standard laparoscopy. The straight laparoscopic instruments make dissection within the confines of the narrow, bony pelvis difficult and subject the surgeon to ergonomic stress. The robotic platform allows for stable retraction; enhanced three-dimensional (3D), high-definition visualization; and articulating instruments. There is some indication that use of the robot has been associated with a reduced rate of conversion to laparotomy during proctectomy as compared to standard laparoscopic surgery (although many of the studies on this topic are plagued by selection bias) [41].

A single-docking technique using the da Vinci® Si™ robot is first described. This entails single docking of the robot for the entire procedure, from colon mobilization to pelvic dissection. The patient is placed in a modified lithotomy position. Pneumoperitoneum is established with a Hasson technique through a supraumbilical incision. The abdominal cavity is examined using the robotic camera. Four additional robotic ports are inserted, along with an assistant port, as shown in Figure 31-7a. The greater omentum and the small bowel are retracted out of the pelvis. The patient is placed in Trendelenburg position, with right-side down. The robotic cart is brought to the left lower quadrant. The robotic arms are first docked, with robot arm 1 in the right lower quadrant using monopolar curved scissors or vessel sealer, robot arm 2 in the right upper abdomen using a fenestrated bipolar forceps, and robot arm 3 in the left mid-abdomen using a ProGrasp™ or Cadiere forceps for retraction. Arm 3 begins on the left side of the robot, on the same side as arm 1. Dissection proceeds in a medial-to-lateral fashion, as in standard laparoscopic dissection. Following division of the IMA and IMV, splenic flexure mobilization, and division of the left colic mesentery, robot arm 3 is repositioned (Figure 31-7b). The robot does not need to be moved, and patient position can be maintained. On occasion, a slightly more accentuated head-down and minimal tilt is utilized for the pelvic dissection, in order to keep the small bowel out of the pelvis. This configuration ensures that all instruments can reach the pelvic floor without conflict. Proctectomy proceeds, as described above for standard laparoscopy, but with a few exceptions. Care is taken to maintain dissection along the mesorectal plane laterally and avoid dissection into the pelvic sidewall. This is facilitated by early anterior dissection, which is easily visualized with the camera setup, as described, and use of articulating instruments. We often use a tie around the rectum

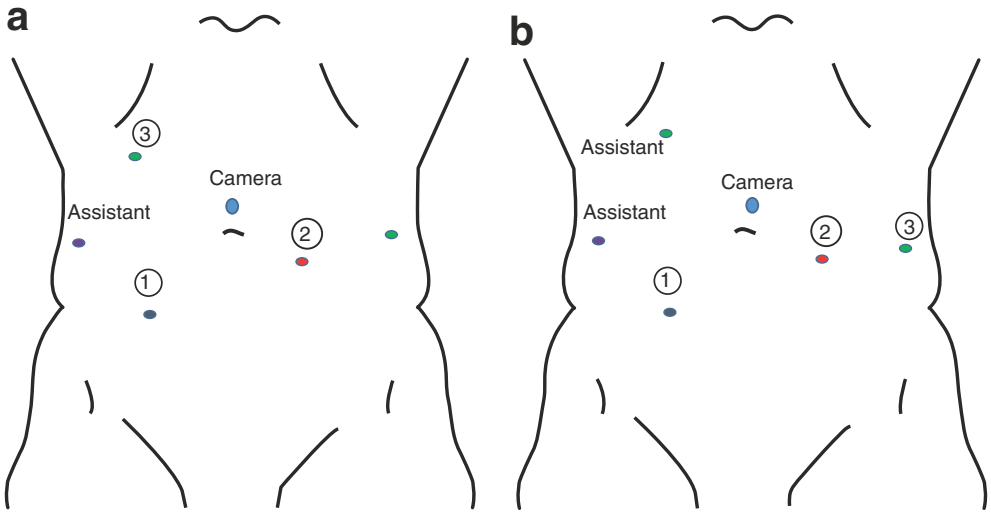

FIGURE 31-7. Trocar placement for robotic LAR using the da Vinci® Si™ robot with the two separate phases of the operation: (**a**) pedicle ligation, splenic flexure mobilization; (**b**) pelvic dissection.

(such as thin vaginal packing) to facilitate rectal retraction. During pelvic dissection, the bedside assistant utilizes the lateral assistant port and the right upper quadrant robotic port (which was used for pedicle ligation and flexure takedown). Intraoperative endoscopy, with picture-in-picture technology, allows the operating surgeon to visualize the rectal tumor at the robotic console and optimize the distal resection margin. We use cautery and the Vessel Sealer, along with the robotic stapler (EndoWrist® Stapler 45), to achieve low pelvic stapling. Superior visualization and retraction, along with articulating instruments, greatly facilitates deep pelvic dissection along the prostate and in the intersphincteric groove for coloanal anastomosis. When the distal rectum has been divided, the robot is undocked, and the rectum is extracted via a wound protector at the umbilical port or future stoma site. The descending colon is divided, the anvil secured, and the laparoscopic anastomosis performed.

A similar setup is utilized with the da Vinci® Xi™ robot. This system has more flexibility, as the camera is 8 mm and can be used in any port. This is referred to as "port hopping" and is useful if dissection becomes difficult and a new vantage point is needed. The da Vinci® Xi™ robot instruments are longer, eliminating problems related to reaching the splenic flexure and the deep pelvis. Port setup is shown in Figure 31-8a, b.

Abdominoperineal Resection

APR is necessary for very low rectal tumors that invade the external sphincter or the levator muscles. The relative indications for APR include external sphincter involvement at any time in the patient's workup. Relative indications include patients with poor preoperative baseline bowel function who are not candidates for a Hartmann resection. Furthermore, care should be taken when planning surgery in patients with bulky low tumors that show minimal response or progression on neoadjuvant chemoradiation. This portends aggressive tumor biology with extension along lymphovascular and perineural spaces, making complete margin-negative resection more challenging. Wide resection, including APR, should be considered in such cases.

During APR, left colon/splenic flexure mobilization is not required. Dissection is generally taken down to the pelvic floor, and then the perineal phase is begun. Perineal dissection can be performed in lithotomy or prone position. Some assert that the prone dissection is more comfortable for the surgeon and facilitates anterior dissection but requires abdominal closure and stoma maturation prior to repositioning the patient facedown. When beginning the perineal phase, additional Betadine® preparation is utilized, and the anus is sutured to reduce contamination. A wide elliptical incision is created to encompass the sphincter complex, and dissection proceeds into the ischiorectal space. Care is taken to dissect just superior to the coccyx, where the pelvic floor is divided and the perineal dissection meets the anterior dissection. The lateral pelvic floor musculature is divided widely, and the anterior dissection is then performed, carefully avoiding injury to the vagina or membranous portion of the urethra. Following specimen removal and pelvic irrigation, the perineum is closed in multiple layers to eliminate the dead space. Pelvic drains are used liberally to reduce fluid buildup in the contaminated pelvis.

Extralevator or "Cylindrical" APR

In recent years, several authors have shown that oncologic outcomes after APR have not improved to the same degree as those seen after low anterior resection (LAR). In fact, compared with patients undergoing LAR during the same time period, patients undergoing APR have higher rates of local recurrence and poorer survival [42, 43]. The difference in oncologic outcomes may be explained to a substantial degree by the increased risk of tumor-involved margins (CRM) and inadvertent bowel perforations associated with APR, as both of these factors are significantly related to local control and survival. It is important to keep in mind that the distal rectum is devoid of surrounding mesorectum; therefore, tumor extension beyond the muscularis propria can invade surrounding tissues, resulting in positive CRM with standard resection. Higher rates of CRM were highlighted in a 2005 study from the UK and subsequently verified in a joint study of specimens from the Dutch trial [42, 44]. In the latter study, Nagtegaal and colleagues assessed 846 LAR and 373 APR specimens. They found that the plane of resection was within the sphincteric muscle, the submucosa, or lumen in more than one-third of the APR cases, resulting in a positive CRM rate of 30.4% in APR versus 10.7% in LAR and a perforation rate of 13.7% versus 2.5%, respectively. Others have reported improved outcomes with wide anatomic resection [45, 46].

An approach to reduce CRM involvement and specimen perforation, proposed by the Karolinska Institute in Stockholm and termed extralevator or "cylindrical" APR, involves wide resection of the levator muscles en bloc with the sphincter muscles, anal canal, and mesorectum. The abdominal component of the procedure terminates higher in the pelvis, and the levator ani muscle is divided along its attachments to the sidewall to avoid a "waist" in the specimen (Figure 31-9). The perineal phase widely resects the ischiorectal space and completes the dissection. In a report comparing cylindrical to conventional APR specimens, Holm and colleagues demonstrated a marked reduction in CRM involvement and perforation with cylindrical APR [47]; however, flap closure is usually required, and perineal wound complications, as well as chronic pain, were significantly increased in the extralevator group [48, 49]. Many advocate "selective extralevator dissection" in areas of

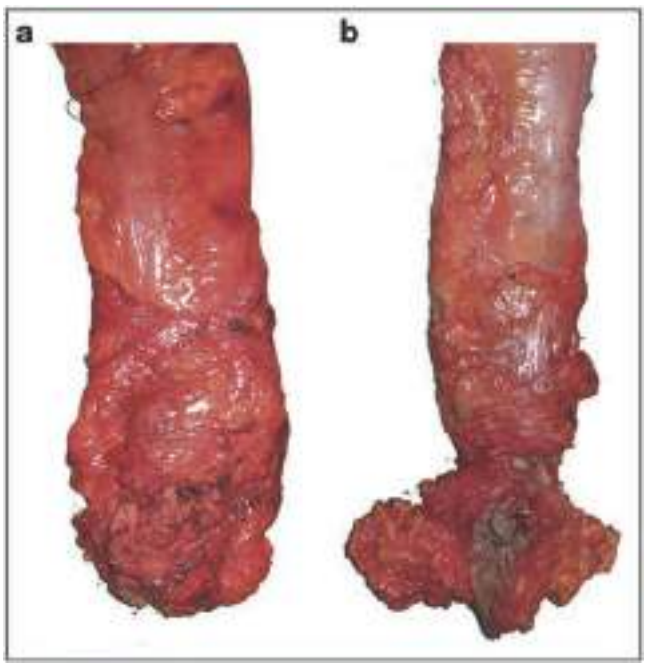

FIGURE 31-9. Abdominoperineal resection specimens. Dissections from above and below meet above the anal canal. (**a**) APR specimen with a waist. Courtesy of Eric K Johnson, MD. (**b**) Specimen with a cylindrical resection and no waist (intact mesorectum). Courtesy of Conor Delaney, MD.

tumor, stressing the need for accurate preoperative imaging and examination [50]. Prone positioning for the perineal phase is not mandatory, and minimally invasive approaches are feasible [51–53]. Appropriate patient selection, methods of closing the pelvic floor to reduce wound complications and perineal hernias, and an optimal approach (open versus laparoscopic or robotic) are pertinent issues warranting further investigation in extralevator APR.

Special Considerations

Rectal Washout

It has been suggested that implantation of exfoliated malignant cells is a possible mechanism of luminal tumor recurrence in colorectal anastomoses. Intraoperative rectal washout with saline solution or water theoretically decreases the amount and viability of these cells. A study from Sweden reported a reduction in local recurrence from 10.2% with no washout to 6% with washout. However, there is no conclusive evidence regarding the effect of rectal washout on local recurrence after rectal cancer surgery. Although it may be merely a surrogate marker for attention to detail, we routinely use intraoperative rectal washout. It is a simple procedure, with minimal morbidity and with potential benefits [54].

Distal Margin

The distal resection margin is an important consideration in rectal cancer surgery. Although lymphatic drainage of the rectum generally occurs in a cephalad direction toward the major lymph node stations, pathological studies have shown distal mesorectal spread as far as 2–3 cm below the lower palpable edge of the tumor. Thus, for upper rectal cancers, mesorectal resection should include mesorectum at least 4–5 cm distal to the lower edge of the tumor, and the mesorectum is divided perpendicular to the longitudinal access of the rectum for a tumor-specific mesorectal excision. It is critical not to "cone in" and leave mesorectum behind when performing this maneuver. For mid to low rectal cancers, dissection 4–5 cm below the tumor generally ends at the pelvic floor. Thus, as long as the entire mesorectum can be removed and negative margins of resection obtained for the primary tumor, it is reasonable to consider restorative proctectomy with coloanal anastomosis for patients with distal cancers [55–58]. The exact distance that constitutes an adequate distal mural margin in this situation is the subject of debate, but an attempt to achieve 1 cm seems reasonable.

Coloanal Anastomosis

In carefully selected cases in the setting of an ultra-low rectal cancer, continued dissection along the intersphincteric plane (which is an extension of the muscularis propria of the rectum) may facilitate sphincter preservation. A handsewn anastomosis is commonly performed, with good oncologic outcomes, especially in patients with a significant response to preoperative chemoradiotherapy [53, 58]. Patient selection and counseling are critical, as patients with coloanal anastomosis have worse bowel function and potentially poorer quality of life than those with a standard stapled colorectal anastomosis [59].

Options for Reconstruction of the Gastrointestinal Tract

Following rectal resection, patients often describe frequent bowel movements, incomplete evacuation, clustering, urgency, and, at times, incontinence. In order to mitigate these symptoms, which are collectively known as LAR syndrome, various techniques have been attempted to recreate the reservoir function of the resected rectum. These are known as colonic neorectal reservoirs and include the colonic J-pouch and the end-to-side (or "Baker-type") anastomosis.

A colonic J-pouch is constructed in similar fashion to an ileal J-pouch; however, the colonic J-pouch is much smaller, about 6–8 cm in length. Randomized trials, a meta-analysis, and Cochrane review have all concluded that a colonic J-pouch results in improvement of symptoms (decreased frequency, urgency, and nocturnal bowel movements) and a better quality of life for at least 1 year after surgery, compared to an end-to-end anastomosis [60–62]. Coloplasty, longitudinal colotomy closed transversely, was proposed for patients with a narrow pelvis for whom J-pouch was not technically feasible; however, this has not been shown to be an improvement over straight anastomosis. The additional suture line has a risk of leak that can be difficult to treat, and generally coloplasty has fallen out of favor. It is difficult to interpret the results of some trials, given the variation in surgical technique: specifically, the use of either sigmoid colon or descending colon for construction of the neorectum. The use of the sigmoid colon for construction of the neorectum in patients with significant muscular hypertrophy or diverticular disease may negatively impact postoperative function.

An end-to-side or Baker anastomosis, first described in 1950, has recently been revisited as another option for improving postoperative bowel function. This side-to-end anastomosis appears to confer many of the functional advantages of the colonic J-pouch. Compared to a straight anastomosis, it is associated with significantly fewer anastomotic leaks, and overall it is safe, easier, and faster to create than the colonic J-pouch. A 2008 Cochrane review of four randomized trials comparing colonic J-pouch to the side-to-end anastomosis, as well as a more recent meta-analysis of six randomized trials, found similar functional outcomes between the two groups [63]. In many instances, there is insufficient bowel length, or the pelvis is too narrow to permit creation of a reservoir. Ensuring sufficient length of the bowel to adequately sacralize in the pelvis is crucial to

healing and function. Some experts prefer to avoid the multiple staple lines associated with reservoirs and the risk of anastomotic leaks, which are difficult to remedy.

Fecal Diversion

Anastomotic leakage following proctectomy occurs in up to one-quarter of patients. Creation of a defunctioning stoma following restorative proctectomy may decrease the sequelae of anastomotic leak and pelvic sepsis. However, the value of a protective stoma has been a subject of controversy for many years. A randomized controlled trial in 2009 reported a reduction in leak rate from 28% without to 10% with a stoma [64]. A 2009 meta-analysis comparing defunctioning stoma to no stoma after rectal resection concluded that the defunctioning stoma resulted in lower rates of leak and reoperation [65]. This meta-analysis included data from four randomized controlled trials and 21 non-randomized studies, involving 11,429 patients in total. A recent meta-analysis of 13 studies published between 2004 and 2014, pooling data on 8002 patients, reported similar conclusions [66]. However, diversion does require a second operation, may result in dehydration, entails an increased risk of bowel obstruction, and is not popular with patients. Therefore, most centers divert selectively, based on anastomotic height, patient-related factors such as diabetes and previous pelvic radiation, and the results of intraoperative leak test.

Extended Resection

Up to 10% of patients with rectal cancer present with tumor invading adjacent structures, necessitating en bloc resection of the affected organ(s) [67]. En bloc resection of adjacent pelvic organs has been associated with good oncologic outcomes when pathologically negative microscopic (R0) margins can be achieved [68, 69].

Involvement of the uterus and vagina in women is best treated with en bloc resection of the rectum with the uterus and the posterior vaginal wall, in order to achieve R0 resection. Closure can be done easily after partial vaginectomy by flap reconstruction or primary closure, preserving sexual function.

Involvement of the seminal vesicles on one or both sides in men can be managed by dissection anterior to the vesicles, removing them en bloc with the rectum. The neurovascular bundles arising from the inferior hypogastric plexus, which control urinary and sexual function, are at risk during this dissection—as are the distal ureters, which should be identified and preserved. Involvement of the prostate by rectal cancer usually requires urologic consultation and is usually treated either with a partial prostatectomy or a pelvic exenteration, depending on the extent of tumor invasion. It should be noted that en bloc resection of the seminal vesicles only, with preservation of the bladder and prostate, is a challenging operation, often much more difficult than pelvic exenteration.

Involvement of the distal ureters by a locally advanced rectal tumor is rare. However, if encountered, it is best managed with en bloc resection of the ureter, with primary ureteric anastomosis over a stent or a psoas hitch, depending on the length of the ureteric defect. Rectal cancers that adhere to the urinary bladder require partial or total cystectomy, especially when the trigone is involved.

Lateral pelvic sidewall lymph node involvement has been reported in up to 20% of T3/T4 rectal cancer cases [70]. In general, pelvic sidewall lymph node involvement is associated with low-lying tumors and worse prognosis [71]. In Japanese studies, selective use of lateral pelvic lymphadenectomy has reportedly led to good outcomes. A meta-analysis of 20 studies demonstrated no improvement in survival or local recurrence when an extended lymphadenectomy was performed compared to standard proctectomy [72]. However, in selected cases where lymphatic spread is suspected clinically or radiographically, an extended lymphadenectomy is warranted in order to obtain an R0 resection.

Intraoperative Radiation Therapy

Intraoperative radiation therapy (IORT) has been used in patients with locally advanced primary rectal cancer and an involved or threatened CRM following surgical resection. The goal of IORT is to sterilize any microscopic foci of tumor, thus decreasing the risk of local recurrence. During IORT, the radiosensitive bladder and bowel can be excluded from the radiation field, allowing a higher dose to be delivered to the tumor bed. In the United States, IORT is most commonly administered by two different techniques: intraoperative electron-beam radiation therapy (IOERT) or high-dose-rate (HDR) brachytherapy. IOERT is delivered by means of a linear accelerator over the course of a few minutes; it can be used in any operating room because electrons do not penetrate the tissue as deeply as conventional radiation. The radiation is delivered through a cone, usually toward the tumor bed. HDR treatment, however, can be administered only in adequately shielded rooms. It is delivered through parallel catheters in a flexible plastic flap, which can be cut to fit the region at risk and packed onto the curving pelvic surface. HDR brachytherapy may take up to an hour.

IORT has been used in locally advanced rectal cancer for more than 30 years, yet there is no convincing evidence that it decreases local recurrence or improves survival. The only multicenter randomized trial to date included 142 patients with locally advanced rectal cancer, who had received preoperative chemoradiation and were randomly assigned to either surgical resection alone or surgery plus IORT [73]. After a 5-year follow-up, the trial did not demonstrate any significant improvement in local recurrence or disease-free survival. Observational studies have reported conflicting results with respect to the efficacy of IORT. A recent systematic review of 15 individual studies, including the previously mentioned randomized trial, with 1929 patients in the IORT

group and 2343 in the non-IORT group, concluded that IORT resulted in no definite improvement in overall survival or rate of recurrence for patients with R0 resections or for the total group (including R0, R1, and R2 resections) [74]. In the setting of locally advanced primary rectal cancers, we recommend having IORT available for patients if a close or threatened CRM is highly suspected, based on preoperative imaging. IORT is more commonly utilized in resection of recurrent rectal cancer if tissue planes have been previously disrupted, and discontinued foci of tumor may be present.

Flap Closure Following APR

Special attention to perineal closure is required after APR. The bony confines of the pelvis prevent tissue collapse, leading to significant dead space. Pelvic infection requiring opening of the perineum, prolonged wound healing, and chronic perineal sinuses are not uncommon. Multilayered closure to reduce dead space and liberal use of drains are common. However, in some cases rotating a well-vascularized omentum [75] or a mucocutaneous flap [76] into the pelvis should be considered, in order to reduce dead space and facilitate perineal healing after APR, especially in patients who have received pelvic radiation. A properly designed omental pedicle graft can be easily devised by dividing the gastrocolic omental attachments, detaching the left omentum from the spleen, and ligating the left gastroepiploic pedicle and the short gastric vessels. Care is taken to avoid injury to the right gastroepiploic, which allows the bulk of well-vascularized left omentum to rotate into and fill the pelvis. Rotation of the right omentum, based on the left gastroepiploic, is also feasible. In cases of exenteration, sacrectomy, extensive perineal skin loss, or requirement of vaginal reconstruction, a myocutaneous (vertical rectus abdominus myocutaneous, gracilis, or gluteal) flap is utilized.

Functional Outcomes

High rates of postoperative sexual and urinary dysfunction were a well-known phenomenon in the early years of rectal cancer surgery, ranging from 20 to 40% [77]. For example, registry data from Norway demonstrate that less than 50% of sexually active male were able to achieve erection 2 years after rectal resection. The rate fell to less than 20% in the cohort undergoing pelvic radiation and surgery [78].

Along with the advent of sharp dissection and precise technique emphasized in TME came the goal of identifying and preserving the autonomic pelvic nerves. As an integral part of the procedure, autonomic nerve preservation resulted in improved functional outcomes.

In an early study of 42 men undergoing sphincter-preserving operations for treatment of rectal cancer, Enker and colleagues reported high rates of potency (87%) and normal ejaculation (88%) after nerve-preserving proctectomy [79]. In a comprehensive study assessing sexual and urinary function in both women and men, through retrospective questionnaires, Havenga and colleagues reported the results of 136 patients undergoing nerve-sparing proctectomy [80]. They found that the ability to engage in intercourse was maintained by 86% of patients younger than 60 years and by 67% of patients 60 years and older. Eighty-seven percent of men maintained the ability to achieve orgasm. Type of surgery (APR compared to LAR) and age greater than 60 years were significantly associated with male sexual dysfunction. Women had similarly good results: 85% were able to experience arousal with vaginal lubrication, and 91% could achieve orgasm. The majority of patients had few or no complaints related to urinary function. Serious urinary dysfunction, such as neurogenic bladder, was not encountered.

The importance of autonomic nerve identification and preservation during proctectomy is also highlighted in a study by Shirouzou and colleagues, who assessed outcomes in 403 patients undergoing proctectomy, with or without autonomic nerve preservation, over a 20-year period [81]. In male patients who had proctectomy with nerve preservation, urinary function was preserved in greater than 80%, erection was preserved in 79%, and ejaculation in 65%; when proctectomy was performed without nerve preservation, urinary disorders were found in more than 90% and sexual dysfunction in virtually all patients, even those younger than age 60.

However, in patients with extensive pelvic disease, autonomic nerve preservation may not be feasible or oncologically sound. Involvement of the autonomic nerves by tumor, or lymphadenopathy in the pelvic sidewall, generally requires a resection that will affect nerve function permanently.

Despite suffering micturition and defecation problems, quality of life has consistently been shown to be better following an LAR compared an APR. This has been confirmed by comparative studies and in a meta-analysis of several studies [82–84]. Body image is consistently higher in patients undergoing an LAR versus APR, which may contribute to the inferior sexual function associated with APR.

In patients who undergo LAR, poor bowel function has been associated with the level of the anastomosis and the administration of pelvic radiotherapy. Low anastomoses (<3 cm) and coloanal anastomoses are associated with more incontinence of gas and solid stools compared to higher anastomoses [85]. Neoadjuvant radiation therapy causes fibrosis, leading to reduced compliance of the rectum and damage to the myenteric (Auerbach's) plexus, and has been associated with higher rates of urgency, frequency, and fecal incontinence [86]. Some of the most telling data emanates from the prospective Dutch rectal cancer study, in which patients were randomized to proctectomy or neoadjuvant short-course radiotherapy plus proctectomy. Daytime incontinence was noted in 38% of patients in the surgery alone

group and 62% of patients in the surgery plus radiotherapy group. Of even more concern is the finding that bowel dysfunction increased over time (studied at 2 years and 5 years after proctectomy) in the radiation cohort [87].

Oncologic Outcomes

Attention to detail during proctectomy, especially with regard to appropriate mesorectal excision, has been associated with improved local control and survival rates. Local pelvic failure rates following proctectomy at centers of excellence are now in the single digits [19, 21, 22, 88–91]. This is a substantial improvement compared to the local pelvic failure rates following proctectomy in the past, which were 3–5 times higher.

The importance of proper proctectomy technique is also reflected in a study from the Karolinska Institute reporting that in more than half of local recurrences in Sweden, evidence of residual mesorectal fat was identified on cross-sectional imaging, suggesting that incomplete mesorectal excision was the principal cause of local recurrence [92]. The same study claimed that extra-mesorectal lateral lymph node involvement accounted for only 6% of all locoregional recurrences.

The impact of training in proper proctectomy technique has been well documented. Surgical TME educational programs in Sweden, Norway, and the Netherlands have been shown to markedly reduce local recurrence, improve survival, and reduce the rate of permanent stomas [93–96]. In an observational national cohort study of 3319 patients in Norway, implementation of TME resulted in a decrease in local recurrence from 12 to 6% [96]. Survival rates were 73% after TME and 60% after conventional surgery—an overall improvement of 10–14%. In the Netherlands, the widespread adoption of TME led to a reduction in local recurrence of 16–9% [93]. In Sweden, implementation of specialized proctectomy training, utilization of neoadjuvant short-course radiotherapy, and referral of patients with rectal cancer to specialists has led to a fall in local recurrence rates: from 15% in the control group of the Stockholm I trial, and 14% in the Stockholm II trial, to 6% [97]. Cancer-related deaths fell from 15% to 16–9%. During the same period, the proportion of APR procedures performed in Sweden decreased by more than 50%. Along with participation in workshops and the increase in surgeons' expertise, case volume directly influenced patient outcomes; when surgeons with high operative volume were compared to those with low volume, local recurrence was additionally reduced (from 10 to 4%), and there were fewer deaths from rectal cancer (18% vs. 11%) [94].

Another factor associated with oncologic outcome is the training and experience of the operating surgeon. Studies have shown that subspecialty training, surgeon experience, volume of cases, and treatment in high-volume tertiary care centers influence and enhance patient outcomes with respect to postoperative morbidity and mortality, local recurrence, and long-term survival [98–100].

Multidisciplinary Rectal Cancer Care

There is increasing evidence that multidisciplinary team management is associated with improved clinical decision-making, superior outcomes, and better patient experience in several types of cancer, including rectal cancer [101]. Cancer centers of excellence have been successfully established in several European countries over the past decade to address variability and disparity in the quality of rectal cancer care. Similar efforts in standardizing care to improve outcome have begun in the United States. The OSTRiCh (Optimizing the Surgical Treatment of Rectal Cancer) Consortium, founded in 2011, comprises a group of healthcare institutions across the United States, dedicated to improving delivery of rectal cancer care by relying on evidence-based and standardized care [102].

Variability in care was recently demonstrated in a study analyzing data from the National Cancer Data Base, which examined adherence to neoadjuvant chemoradiotherapy in 30,994 patients with clinical stage II and III rectal cancers [103]. The use of neoadjuvant radiation therapy and chemotherapy varied significantly by type of cancer center, with the highest rates of adherence observed in high-volume centers compared with low-volume centers (78% vs. 69%; adjusted odds ratio = 1.46; $P<0.001$). This variation was mirrored by hospital geographic location, with little improvement observed over the last 5 years. These results further support the implementation of standardized care pathways for patients with rectal cancer.

Conclusion

The impact of optimal proctectomy technique in reducing the incidence of recurrence and improving long-term survival in rectal cancer is well established. The associated improvement in disease-free, recurrence-free, and overall survival, and increased improvement in bowel, bladder, and sexual function postoperatively, make proctectomy—with appropriate mesorectal excision and autonomic nerve preservation—the standard of care and a required part of colorectal surgical training. Complete surgical resection of the tumor and draining lymph nodes using sharp dissection are the basic principles of TME. Attention to preservation of the autonomic nerves can reduce the morbidity of this operation, improve functional outcomes, and provide a more acceptable quality of life. The use of multidisciplinary disease management teams, and implementation of centralization for the treatment of rectal cancer, has a strong potential to provide efficient delivery of evidence-based care.

Rectal Cancer Decision-Making

W. Donald Buie and Anthony R. MacLean

Key Concepts

- Sound decision-making requires a full assessment of the primary lesion, the presence of metastatic disease, the patient's surgical risk, and goals of care.
- A submucosal excision may be used as a radical biopsy to assess a polyp for adverse features without compromising future radical excision.
- Following endoscopic excision of a malignant polyp, the pathology should be rereviewed and strict criteria adhered to regarding the need for radical surgery.
- While cT2 (clinical stage T2) lesions can be treated with radical excision alone, neoadjuvant treatment can be selectively given to patients with cT3 lesions, based on preoperative staging by MRI and multidisciplinary discussion.
- Pretreatment staging can be inaccurate, especially with regard to mesorectal nodal status. Treatment planning should include a discussion of what will be recommended if stage changes based on histologic analysis. This is especially true if patients are assumed to be node negative, undergo up-front proctectomy, and are found to be node positive or if patients undergo local excision and are found to have higher T stage than anticipated.
- Most operative decisions should be made prior to entering the operating room. The patient and the surgeon must be prepared for all eventualities. In some situations the ultimate surgical decision may depend on intraoperative findings.
- Patients with potentially curable Stage IV disease require multidisciplinary discussion with early involvement of hepatobiliary surgeons and medical oncologists to determine the optimal sequence of treatment.

By three methods we may learn wisdom: First, by reflection, which is noblest; Second, by imitation, which is easiest; and third by experience, which is the bitterest.
Confucius

Introduction

While a comprehensive knowledge base and consummate operative skill are required for optimal management of rectal cancer, sound decision-making is essential. Poor decisions whether preoperative, intraoperative, or postoperative may have a profound and irreversible affect on both short- and long-term patient outcomes. Thus, it is important to understand not only what you can do but what you should do.

The aim of this chapter is to examine common clinical situations encountered by the colorectal surgeon who treats rectal cancer and analyze the decision points. This includes identification of the variables that affect treatment decisions, the potential treatment options including the advantages and disadvantages of each, and finally the logic behind specific treatment decisions. The chapter is organized to include early rectal cancer, endoscopically removed cancers, locally advanced lesions, synchronous metastatic lesions, and special situations. While no chapter can cover all clinical situations, it is hoped that the principles outlined below can also be used as a guide in more unusual circumstances.

Assessment

Each situation like each patient is unique. Knowledge and a comprehensive understanding are paramount to making good surgical decisions. When first encountering a patient with a rectal neoplasm, our first step is to gather information. We assess the lesion in terms of size, location (distance from anal verge, distance from the superior aspect of the anorectal muscular ring, and circumferential position—anterior/posterior/lateral), morphology, fixation (fixed, tethered, mobile), and general appearance. Additional information is needed with respect to the presence of metastatic disease [1, 2]. Finally we assess the patient for surgical risk including anesthetic risk, procedural risk, and patient risk [3, 4]. As the surgeon you are responsible for ensuring that each patient is

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_32

fully evaluated and optimized for the required treatment; the right procedure at the right time as safely as possible [5].

An important part of assessment includes goals of care. Oncologic surgery is a balance of cure versus morbidity, mortality, and quality of life. Patients with significant comorbidity or those who are elderly may place greater emphasis on quality rather than quantity of life and make decisions accordingly. You must facilitate this discussion and provide information to help each patient make a decision (s)he is comfortable with. The risk-benefit profile of each potential treatment should be outlined and discussed thoroughly.

The final part of assessment is a firm understanding of your own strengths, skills, and limitations. Utilizing senior colleagues for a second opinion or as an intraoperative assist is a sign of good judgment. The management of rectal cancer is multidisciplinary, and you must cultivate strong relationships with your colleagues in the associated disciplines of diagnostic radiology, radiation oncology, medical oncology, pathology, and hepatobiliary surgery to provide optimal patient care. Ideally rectal cancer patients should be discussed at regular multidisciplinary conferences which have been shown to enhance care and outcomes. In a study by Snelgrove et al., multidisciplinary conference resulted in a change in management plan in 29 % of patients, due in a large proportion to reinterpretation of the MRI [6].

Early Rectal Cancer

Local Excision

For rectal lesions that appear early (benign or cT1 cancers), we would typically arrange for local staging, most commonly with endorectal ultrasound to examine the depth of invasion as well as a pelvic MRI, for staging regional nodes, and to document the baseline appearance of the pelvis going forward [7–10]. If the lesion has a malignant appearance or is a proven cancer on biopsy, we also arrange systemic staging with a CT scan of the chest, abdomen, and pelvis.

As long as there are no features on biopsy or imaging that are high risk for nodal disease, we would offer local excision as a "radical biopsy." We typically use the transanal endoscopic microsurgery (TEM) technique for most lesions, although TAMIS is a good alternative [11–13]. For distal lesions below 7 cm from the anal verge, conventional transanal excision can be considered, though there are data suggesting a higher rate of specimen fragmentation and subsequent local recurrence [14].

We believe it is critical to have a thorough discussion with the patient prior to performing a local excision. While the prevailing opinion described in most textbooks advocates for full-thickness excision in all cases, we tend to be more selective in our approach.

For lesions that appear benign on biopsy and imaging or at worst T1, we try to gauge the patient's thoughts on what their wishes would be in response to the biopsy results. If the patient decides that he or she would want a radical excision for anything other than the most early, most favorable cancer, we feel that a partial thickness excision is a very reasonable option, as it provides definitive histology and allows assessment of high-risk features, including differentiation, lymphovascular invasion, tumor budding, and depth of invasion in microns (Table 32-1). For lesions invading to <1000 μm with no adverse pathologic features, particularly with no evidence of high-grade budding, local excision alone is felt to be an acceptable treatment, with close follow-up [16–18]. Additional reasons to consider a partial thickness excision also include less perioperative risk and no significant change in the perirectal fat that can affect the difficulty of (and complications from) subsequent radical excision in cases with unfavorable histologic features. Importantly, if the lesion is proven to be benign, then excision in the submucosal plane should be curative and will avoid the added morbidity of full-thickness excision.

Table 32-1. Risk of nodal involvement

	# Tumors	Nodal involvement (%)	Odds ratio	*P*-value
Tumor grade				
Favorable	176	5.7		
Unfavorable	75	29.2	2.9	0.023
Vascular invasion				
Absent	176	5.7		
Present	75	30.7	2.7	0.039
Cribriform pattern				
Absent	192	7.3		
Present	59	32.2	3.9	0.002
Tumor budding				
Negative	213	8		
Positive	38	42.1	3.7	0.008

On the other hand, if the patient is more strongly in favor of avoiding radical surgery and would tolerate a slightly higher risk of local recurrence, we feel that a full-thickness excision is warranted for lesions that are proven on biopsy to be adenocarcinoma preoperatively or have gross features of malignancy, which again allows for histologic evaluation but also provides a wider deep margin for more significant lesions.

Once the histologic information is available (for which we also typically request a second opinion from an experienced GI pathologist), we have a thorough discussion with the patient about the results and define their risk of lymph node disease. For patients with T1 adenocarcinoma with high-risk features and/or depth of invasion greater than 1000 μm (or Kikuchi level SM2) [15, 18, 19], we recommend radical excision. However, in situations where the patient understands the risks and prefers to avoid radical excision, close follow-up is an acceptable alternative. For patients who are frail or have significant comorbidity that would preclude a radical excision, we consider extending our indications for local excision to more significant lesions.

Our follow-up depends somewhat on the characteristics of the lesion excised and the patient's age and comorbidity but, in general, would include sigmoidoscopic examination at 3–4 month intervals for the first 2 years when the risk of recurrence appears to be highest, then at 6-month intervals for an additional 2 years with colonoscopic evaluation as indicated for surveillance at year 1 and year 4. Additionally, we survey the pelvis with pelvic MRI scans at 6-month intervals for the first 2 years to look for nodal recurrence. Lastly, we typically arrange yearly CT scans of the chest, abdomen, and pelvis for the first 3 years to look for metastatic disease.

Endoscopically Excised Malignant Polyps

Occasionally we will be referred a patient who has had endoscopic excision of a malignant rectal polyp. In these situations, we obtain a pathologic review and then try to determine the risk of intraluminal recurrence as well as the risk of nodal disease and systemic recurrence. We examine the polypectomy site with sigmoidoscopy and, if not already done, mark it with a tattoo especially if completely excised. The patient is staged as in the early rectal cancer section above. However, it is important to remember that imaging can be affected by the thermal injury to the bowel wall from a large polypectomy. Occasionally lymphadenopathy related to local inflammation will be seen, that can be confused for nodal metastases. The risk of intraluminal recurrence is dependent on the margin of excision—while many textbooks advocate a 2 mm minimal margin, current evidence suggests that in the absence of other high-risk histologic features, a 1 mm margin is adequate [15, 20]. In terms of the risk of nodal disease, important factors include differentiation, lymphovascular invasion, tumor budding, and depth of invasion (see Table 32-1). When all histologic features are favorable and the margin is greater than 1 mm, close follow-up is recommended. When all histologic features are favorable, but the margin is <1 mm, we discuss re-excision transanally versus radical excision. When high-risk features for nodal metastases are present, we typically recommend radical excision assuming the patient is a suitable candidate. In high-risk patients where radical excision is not an option, we extend our indications for observation.

Operable and Locally Advanced Lesions

For lesions that are not amenable to local excision, our approach is to again assess the lesion as described above but also perform local staging with pelvic MRI and systemic staging with a CT of the chest abdomen and pelvis. We do not routinely advocate the use of PET scan in the preoperative staging of rectal cancer, except to help resolve an indeterminate lesion identified on CT or MRI.

For lesions that are T2 on imaging, we typically advocate a radical excision. We do not currently feel that there is sufficient evidence to recommend local excision in association with neoadjuvant [21] or adjuvant chemoradiation [22], though there is ongoing interest in this approach and further evidence could possibly change that opinion in the future.

The current standard of care for all clinical stage 2 and stage 3 rectal cancers is to receive neoadjuvant therapy followed by radical surgery when diagnosed on preoperative imaging and to receive postoperative chemoradiotherapy when final pathology unexpectedly demonstrates stage 2 or 3 disease [23]. However, it has become clear that some of these patients derive very little benefit from chemoradiotherapy and do suffer potential long-term complications from the administration of postoperative radiotherapy, including fibrosis/stricture of the anorectum and other issues with bowel, bladder, and sexual function [24–26]. It is also clear that receiving postoperative radiotherapy is less effective than neoadjuvant radiotherapy. Thus identifying those who are likely to derive the most benefit is important [27].

Current staging modalities are very accurate at determining T stage and distance to the expected mesorectal margin but are much less accurate in determining N-stage. TRUS, CT, and MR all suffer from a lack of sensitivity and specificity when queried to predict mesorectal nodal status [7, 28–31]. All the techniques suffer from the inherent limitation that they do not detect tumor but rather the size and morphology of the node. Tumor deposits in lymph nodes do not reliably produce lymphadenopathy greater than 1 cm; in fact more than 50 % of all positive nodes will be less than 5 mm in size. In addition, the inflammatory reaction from previous biopsies, or from the tumor itself, can result in nodal enlargement without tumor involvement, resulting in false positives. Metabolic imaging with 18-fluorodeoxyglucose positron emission tomography (FDG-PET) may not be effective in

detecting mesorectal nodal status because emission from the primary tumor may obscure adjacent nodal signal or because of the small size of some of the nodal metastases.

Given the limitations of preoperative staging, locally advanced lesions require a considerable amount of careful thought when deciding on the most appropriate course of treatment. One can decide that all patients with stage 2 or 3 disease require chemoradiotherapy and mandate that all patients with clinical stage 2 and 3 tumors receive neoadjuvant therapy and that all unsuspected stage 2 and 3 tumors receive postoperative chemoradiotherapy. An alternative strategy is to be more selective, trying to select those patients who are more likely to derive benefit from chemoradiotherapy, while avoiding the negative consequences of radiation in more favorable patients. We generally use the Mercury study group criteria [32, 33] to help decide which patients should be referred for neoadjuvant therapy. cT3a tumors with less than 5 mm of intrusion into the perirectal fat and predicted negative resection margins generally behave more as T2 lesions and thus can be spared the negative consequences of radiation therapy (Figure 32-1) [34]. For cT3 lesions with a close but predicted negative (>2 mm) margin based on staging MRI, neoadjuvant therapy is warranted. In this situation, both short-course radiation and long-course chemoradiation can be considered. For cT3 lesions with a predicted positive margin and for cT4 lesions, long-course neoadjuvant chemoradiation is required for tumor downstaging.

However, preoperative staging alone should not drive all treatment decisions with regard to neoadjuvant therapy. Pelvic morphology and tumor position may have a significant effect on decision-making. For example, a proctectomy in an obese man with a narrow pelvis and an anteriorly based tumor of the mid or distal rectum can be very challenging. Such a patient should be considered for neoadjuvant therapy and should be discussed in a multidisciplinary setting, ideally with radiologic review. Alternatively, proctectomy in a thin woman with a wide pelvis and a posteriorly based tumor should be relatively straightforward with little chance of positive margin if the tumor does not extend beyond the mesorectal fascia on preoperative imaging.

The inability to predict nodal status before embarking on a treatment course is of particular concern for the subset of patients staged as cN0 who undergo proctectomy as a first step in treatment and are upstaged to pN1+(2) following histologic review of the operative specimen. Prior to simply recommending postoperative radiotherapy because of N+status, it should be remembered that postoperative radiotherapy is not as effective as preoperative radiotherapy, must be administered at a higher dose with concurrent chemotherapy to achieve similar oncologic benefit, and has the downside of higher toxicity [35].

One strategy to avoid the issue of radiating patients postoperatively who are found unexpectedly to have node positive disease at proctectomy is to radiate all patients preoperatively regardless of pretreatment imaging results. Short-course radiotherapy is probably the best regimen for patients with non-fixed tumors if this strategy is adopted, as the oncologic results are equivalent to long-course chemoradiotherapy. In addition, short-course radiotherapy can be administered more quickly (shortening the time to full-dose cytotoxic chemotherapy in appropriate patients), is less costly, and is associated with less toxicity in the neoadjuvant period. The main downside of this approach is the large number of patients who would be treated and exposed to the

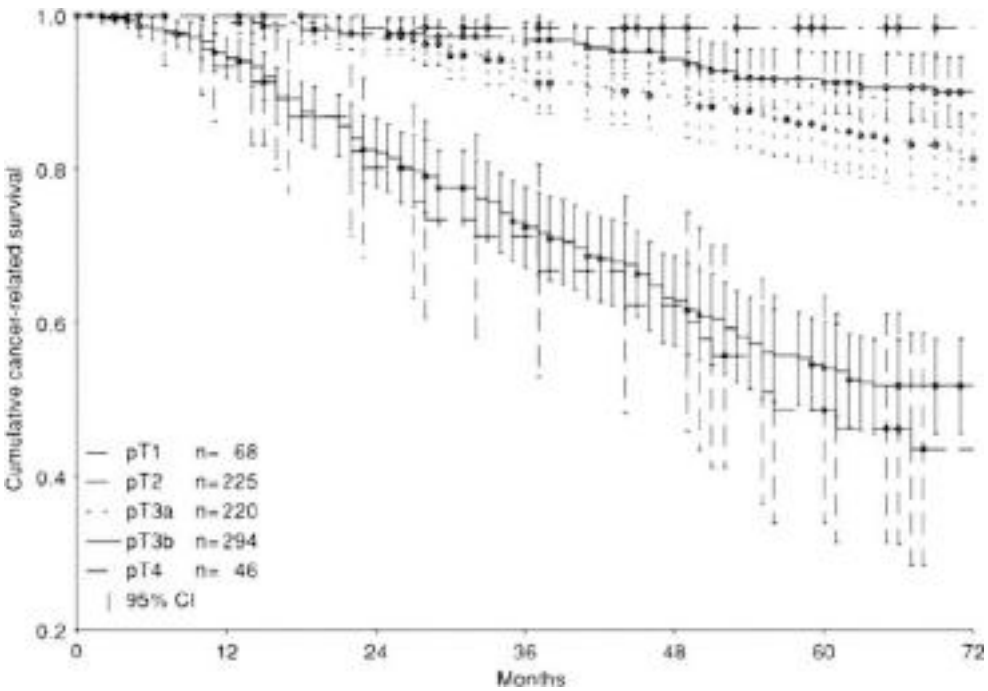

FIGURE 32-1. Cancer-related survival in relation to extended pT classification based on depth of invasion: pT1 submucosa, pT2 muscularis propria, pT3a<5 mm extramural disease, pT3b>5 mm extramural disease, and pT4 other organs. *With permission from Merkel S, Mansmann U, Siassi M, Papadopoulos T, et al. The prognostic inhomogeneity in pT3 rectal carcinomas. Int J Colorectal Dis 2001:16:298–304 © Springer 2001* [34].

long-term consequences of radiotherapy without deriving any significant benefit.

Another approach is to agree at the initial multidisciplinary conference that patients recommended for up-front proctectomy will not be considered for postoperative radiotherapy unless margins of resection are positive, and will be treated with chemotherapy alone if they are found to be node positive and resection margin negative. This strategy will also shorten the time to full-dose cytotoxic chemotherapy and avoid the toxicity of postoperative radiotherapy, which can be substantial. The argument that this is not "standard of care" is based on recommendations from decades past, when trials were conducted without surgery or pathology quality control, radial margins were not assessed, and chemotherapeutic agents were less effective. This is our current treatment approach for patients who are upstaged on pathologic review following proctectomy.

Lastly, there is continued interest in a "watch and wait" approach following neoadjuvant therapy with complete clinical response [36–38]. The issue remains that complete clinical response does not always equate with complete pathologic response. Except in situations of compromise due to patient frailty or comorbidity, we feel that this approach should be relegated to participation in a clinical trial [39]. This opinion may change as additional information becomes available.

As one may see from the above discussion, decision-making for patients with rectal cancer is complex and nuanced. Unfortunately, this complexity cannot be easily transformed into simple treatment guidelines.

Surgical Considerations

Intraoperative Decisions

Most operative decisions should be made prior to entering the operating room. There is no substitute for advance preparation having thought through the potential problems and solutions away from the OR when planning and reflection can occur without distraction and emotion. In difficult situations we will seek the advice of a colleague and plan to have a second surgeon available intraoperatively should the decision have far-reaching consequences or should the unexpected arise.

Despite the surgeon's best intentions, there are occasions where the final decision can only be made at the time of surgery. The surgeon must be flexible and have very precisely articulated goals of care; know why you are there and what you are trying to accomplish. In exceptional cases, this may include backing out if the situation requires more than what has been planned for. It is better to return on another day when the patient and surgeon are emotionally and physically prepared for the operation that is required.

Midrectal Cancers

As mesorectal spread can extend up to 3–4 cm distal to the gross tumor margin, a 5 cm mesorectal margin is required to ensure complete removal of at-risk nodal tissue [40, 41]. We advocate a tumor-specific mesorectal excision for tumors in the upper third of the rectum, preserving rectal length and function without compromising cure. When the tumor is located in the distal third of the rectum, 5 cm or less from the end of the mesorectum, we advocate a total mesorectal excision (TME) to remove all nodal tissue [40–43].

For tumors in the middle third especially in obese patients, it may be very difficult to perform a tumor-specific mesorectal excision and save 2–3 cm of viable rectum above the pelvic floor. We feel it is often technically easier and safer for the patient to extend the resection for an additional 2 or 3 cm to complete a TME. The decision is based primarily on the technical feasibility of dissecting through the distal mesorectum at that level while preserving the viability of the rectal stump.

Low Rectal Cancers

Surgical decision-making in low rectal cancer is complex balancing cure with function. In most situations, the decision to proceed with a sphincter-preserving procedure rather than an abdominoperineal resection is made preoperatively based on history, physical examination, imaging studies, response to chemoradiation, and the ability to obtain clear surgical margins. In addition patient factors including age, comorbidities, body habitus, continence, and patient wishes must be considered [44]. Good quality MRI with careful interpretation is important to identify any absolute indications for APR including involvement of the levators or external sphincter [45].

On rare occasions due to body habitus, tumor size, or pelvic shape, it may be difficult to predict preoperatively whether a tumor can be successfully resected with sphincter-preserving techniques. In this situation the patient must be fully informed and all options discussed in detail including the reasoning behind the decision, the expected outcomes, and potential complications. We consent the patient for "a low anterior resection-possible abdominoperineal resection" and emphasize that we are operating for local control and will proceed with sphincter preservation provided that cure is not compromised. The patient should be counseled and marked for both a colostomy and a loop ileostomy.

Preoperatively, all approaches that enhance distal dissection should be considered including a stapled coloanal anastomosis and a hand-sewn coloanal anastomosis with or without intersphincteric resection. Although a stapled anastomosis results in better function and less morbidity, an intersphincteric dissection provides additional distal margin length [46–48]. We restrict this technique to very low tumors

that are contained within the rectal wall, that do not invade the pelvic floor or anal sphincters, in patients who can tolerate and accept the functional compromise [44]. The functional results depend on preoperative sphincter function, the effect of neoadjuvant radiation, and the variable amount of residual internal sphincter left below the dentate line [49–52]. We feel it is critical that the surgeon carefully reviews and correlates the preoperative imaging and the findings on physical examination prior to considering an intersphincteric dissection, as it is essential that the tumor is well clear of the intersphincteric plane, to prevent a positive margin and consequently a high risk of local recurrence.

Generally speaking we will accept a 1 cm distal margin although a margin less than 1 cm may be acceptable following chemoradiation [53, 54]. Every effort should be made prior to rectal division to ascertain if the margin will be adequate. Once the rectum is divided and the specimen has been removed, it should be examined off table and if possible in concert with the pathologist. If the distal mural margin is inadequate, we would proceed directly with a completion proctectomy after repositioning in prone jack-knife position.

In the obese male with a bulky tumor and relatively small pelvis, distal mesorectal dissection under direct vision and thus sphincter preservation may be impossible using standard open or laparoscopic techniques such that an APR may be required to obtain clear margins. We discuss this situation with the patient preoperatively to ensure they are aware of the surgical limitations and the potential consequences. Transanal TME (taTME) with either TEM or TAMIS is a promising new technique to augment a technically difficult distal dissection. The distal margin and lower mesorectum are dissected transanally under direct vision and when combined with a laparoscopic or open TME extends the distal limits of dissection in these patients. While the initial case series are promising, this technique is not ready for universal adoption as the oncologic results are not mature, indications and contraindications remain to be refined, and the learning curve has yet to be established [55–57].

A clear circumferential margin is also critical to local control. Every effort should be made preoperatively in conjunction with your radiologist to identify potentially difficult areas of dissection where the margin may be compromised with steps taken to extend resection to an uninvolved plane as necessary. If, the decision to proceed with an APR is made intraoperatively, it should be made as soon as possible to maximize the circumferential tumor margin with a cylindrical dissection. The mesorectal plane leads the surgeon through the levator hiatus onto the bare area of the rectum with potential compromise to the circumferential margin in an ultralow tumor [58, 59]. All options need to be considered prior to entering this area of dissection. Intraoperatively, as we proceed distally, we frequently don an extra glove and bimanually palpate the tumor changing gloves prior to reentry into the operative field. If we feel that sphincter preservation will compromise the circumferential margin, we stop and proceed with a proctectomy in prone jack-knife position. We will often make this decision with a second surgeon present to ensure optimal care.

Low Hartmann's vs. APR

Patients with poor preoperative anal sphincter function who would normally have a low anterior resection with a coloanal anastomosis may also be treated with a low Hartmann resection. While this obviates the need for a perineal wound with its attendant risks of nonhealing and chronically draining sinus tract, a low Hartmann's is occasionally complicated by blowout of the stump and chronic pelvic sepsis [60]. We use this option primarily in the elderly in situations without preoperative radiation.

Special Situations

Obstructing Rectal Cancer

Obstructing rectal cancers present a challenging situation and require careful thought and planning to ensure that the patient's oncologic outcome is optimized. In the case of widely metastatic disease that is clearly not resectable, endoluminal stenting is a reasonable consideration provided that the bottom of the stent will lie clearly above the anorectal ring, to avoid causing pain and tenesmus [61, 62]. The tumor should be quite tight to ensure that the stent is held in place.

Alternatively, in patients with partial obstructive symptoms and without evidence of proximal colonic dilatation, administration of chemoradiotherapy will usually relieve the obstructive symptoms if instituted without delay.

In the case of curable disease, several scenarios can present themselves.

In cases requiring fecal diversion where an abdominoperineal resection will ultimately be required, we recommend using a loop colostomy for fecal diversion. At the time of the APR, the distal limb of the stoma can be divided, leaving the colostomy in situ if it is functioning well, or it can be revised to an end colostomy if needed. These patients are not good candidates for endoluminal stenting, because the stent will lie in contact with the anal canal and become symptomatic.

In cases requiring fecal diversion where an eventual reconstructive surgery is anticipated, decision-making can be more complex. In the "near-obstructing" but not clinically obstructed situation, and in situations where significant patient symptoms are a relative indication for fecal diversion, we select the type of stoma based primarily on the degree of stenosis. If the lesion can be passed by a colonoscope or gastroscope and the proximal bowel can be visualized, we would in general select a diverting loop ileostomy, which can be left in situ following the low anterior resection if needed. If the lesion cannot be passed with a colonoscope

or gastroscope, then we would generally construct a diverting loop colostomy. This prevents the possibility of a "closed loop" developing between the tumor and a competent ileocecal valve should the lesion swell and obstruct during neoadjuvant therapy. It also allows us to perform a colonoscopy preoperatively through the stoma to clear the rest of the colon. If fecal diversion is required following the reconstructive procedure, a loop ileostomy can still be brought through the previous left-sided loop colostomy site. A transverse loop colostomy is another option in these situations but is a more difficult stoma to manage for the patient and in general we avoid using them.

In cases presenting with a complete obstruction requiring emergency treatment, endoluminal stenting can be considered to relieve the obstruction and allow for semi-elective treatment of the cancer. The benefits of this approach include a rapid recovery from the procedure, that allows for prompt initiation of neoadjuvant chemoradiation if required, or to proceed on to radical surgery in the less common situation where neoadjuvant therapy is not indicated. The potential downsides of stenting include the risk of perforation and stent migration. The other main treatment option in the case of complete obstruction is a diverting loop colostomy. This strategy also provides relief of the obstruction and will reliably allow the patient to get through their neoadjuvant therapy, in addition to allowing for a preoperative colonoscopy prior to radical excision. The downsides include the fact that these cases do not always lend themselves to a laparoscopic approach (e.g., if there is loss of domain because of the distended colon) and therefore might require a longer period of recovery prior to initiation of neoadjuvant therapy. The open approach can also cause adhesions and make the future radical excision slightly more difficult. Our approach for these situations in general is to consider endoluminal stenting followed by semi-urgent radical excision (tumor-specific mesorectal excision) for the proximal rectal cancers and to use a diverting colostomy for most mid and distal rectal cancers, followed by neoadjuvant therapy, and radical excision.

Perforated Rectal Cancer

We tend to think of perforated rectal cancer in two ways: intraperitoneal perforations and extraperitoneal perforations.

For free intraperitoneal perforations, urgent surgery is generally required. The operation ideally should include an oncologic resection of the primary tumor. The decision on whether to perform a primary anastomosis (with or without and proximal diverting stoma) or a Hartmann procedure depends on several factors, including the overall health of the patient, their perioperative stability, the duration and extent of fecal contamination, and the anticipated intraoperative technical difficulties. Rarely should one simply divert these patients, as they risk having ongoing intraperitoneal tumor dissemination.

For contained intraperitoneal perforations, for example, those presenting with an abscess, we typically arrange percutaneous drainage, ensure that the patient is stable and fully staged, and then typically proceed with radical excision with or without an anastomosis.

For contained extraperitoneal perforations, we typically advocate proximal fecal diversion, drainage of sepsis, neoadjuvant chemoradiation, followed by radical excision, to include all tissues felt to have been contaminated by the perforation. This can require an exenterative procedure and/or an extrafascial dissection.

In the situation where a rectal cancer presents with perianal sepsis and fistulas, we generally ensure that the sepsis is well controlled, strongly consider fecal diversion with a laparoscopic loop sigmoid colostomy, and then arrange for neoadjuvant chemoradiotherapy. This is then followed by an APR with wide pelvic and perineal excision. These patients typically have large perineal wounds, and many benefit from a rectus abdominis myocutaneous flap for perineal reconstruction.

Synchronous Hepatic Metastases

Advancements in liver surgery and systemic chemotherapy have made it possible to consider alternative approaches to traditional primary tumor resection (PTR) in stage IV rectal cancer with synchronous hepatic metastases. These include synchronous resection (SR) and primary liver resection (PLR) [63]. No all-encompassing protocol exists for resectable stage IV rectal cancer as each alternative targets a different subpopulation [64]. SR and PLR should be used selectively and require multidisciplinary discussion with group ownership of the patients and the decisions.

Assuming that the patient is a surgical candidate, there are three overriding questions that need to be answered: is the primary resectable, is the metastatic liver disease resectable, and is there extrahepatic metastatic disease?

Prior to considering liver resection, the primary tumor must be staged and determined to be resectable, either primarily or following neoadjuvant therapy. We involve the hepatobiliary (HPB) surgeon very early to determine if the liver lesions are either resectable, potentially resectable with downstaging, or unresectable. It has been shown that resectability is best judged by an HPB surgeon [65].

Provided both the primary and hepatic metastases are resectable, then the decision is made to perform the rectal and liver resections either sequentially or in low-risk situations synchronously. We would typically consider PTR followed by liver resection for most patients [66]. Synchronous resection is offered to very selected patients to take advantage of a shorter overall recovery time accepting the increased risk of morbidity [67–69]. Generally speaking the magnitude of the two surgeries, the experience of the operating teams, the level of perioperative support and patient comorbidities/operative risk determines whether or not synchronous resections can

Table 32-2. Ideal criteria for liver-first protocol

1. Local regional control does not require downstaging with neoadjuvant therapy
2. Liver metastases are very clearly resectable for cure with adequate residual liver
3. Good overall operative risk patient with normal physiologic status and no known risk factors for perioperative infectious complications and major morbidity
4. Surgery can be performed in a high-volume liver unit with low-operative mortality and acceptable morbidity
5. Delays due to unexpected postoperative complications will not jeopardize local control or cure

and should be performed [70, 71]. For example, a high anterior resection can be combined with a nonanatomic resection in a low-risk patient with expected good results. On the other hand, an extended right hepatectomy and an extended low anterior resection should be done sequentially. The volume of resected liver is an important risk factor for postoperative complications. In a recent retrospective study, patients with postoperative complications averaged 350 g of resected liver tissue vs. patients in the non-complication group who averaged only 150 g [72].

When the rectal lesion is clearly resectable and the liver lesion is borderline or requires an extended resection, a PLR may be the best option [73]. In this situation the liver disease is the major determinant of survival. Because PLR is associated with a considerable increase in morbidity without the application of stringent selection criteria, it should be limited to very specific situations (Table 32-2) as a significant complication following liver resection may delay treatment of the primary [74–76]. Although it is tempting to push these limits, it is important to remember that it is the patient who takes on all the risk.

Patients with liver metastases and locally advanced primaries requiring neoadjuvant therapy are much more complicated. Most liver-first protocols exclude locally advanced rectal cancer patients due to the radiotherapy requirements of neoadjuvant therapy. In addition, the chemotherapy in long-course neoadjuvant therapy is relatively low dose; consequently liver metastases run the risk of growing and becoming unresectable. The presence of a borderline liver lesion further complicates the decision. In this situation, we typically use full-dose chemotherapy to downstage both lesions [77]. If there is a favorable response to several cycles of chemotherapy, then the patient may be treated with neoadjuvant chemoradiotherapy followed by either SR, PTR or PLR as determined by multidisciplinary discussion weighing the risks and benefits of each treatment course [77].

A promising new technique for this situation is the use of short-course radiotherapy to control margins followed by full-dose chemotherapy to allow time for tumor downstaging and systemic treatment for liver metastases. Prospective trials are currently underway to assess the efficacy of this pathway [78].

The presence of extrahepatic disease is generally a contraindication to hepatic resection for cure in stage IV disease. However, in select situations, in a good risk highly motivated patient, we will consider a lung resection following curative resection of the primary and all liver lesions. Surgery should be done sequentially at a reasonable time interval after recovery from the previous resections to ensure that the disease remains localized and the patient is fully optimized.

Conclusion

Nowhere in colorectal surgery are therapeutic decisions more complex or more important to long-term patient outcomes than in the treatment of rectal cancer.

As a young surgeon, decisions are made primarily by imitating our mentors. With experience we find that not all situations fit cleanly into algorithms, and we are forced to make decisions without a complete data set or in situations where there may not be a single correct answer only a best answer given the available information and the specific circumstances.

The treatment of rectal cancer is ever changing as new information is brought forward into practice. The surgeon must keep abreast of new developments, with a fundamental knowledge of all potential treatment options including the risks, benefits and alternatives. In addition to application of this knowledge set, each patient requires a full assessment of the primary lesion, the presence of metastatic disease, the patients' operative risk, and goals of care.

While skills and knowledge are important for optimal patient care, it is often a surgical decision that ultimately determines patient outcomes. Much like surgical skills, decision-making requires practice with continuous analysis and reflection for improvement to ensure the right care, at the right time as safely as possible for each patient.

Colorectal Cancer: Postoperative Adjuvant Therapy

Stephen M. Sentovich and Marwan Fakih

Key Concepts

- Patients with stage III colon cancer should be considered for adjuvant chemotherapy.
- Oxaliplatin-based adjuvant chemotherapy regimens improve survival of stage III colon cancer patients by an absolute 20–25 % at 5 years versus no chemotherapy.
- Adjuvant chemotherapy has not been demonstrated to have significant impact on survival for stage II colon cancer patients, but it can be considered for patients whose tumors have high-risk features.
- In colon cancer patients, radiotherapy should be considered when tumors penetrate other fixed structures (T4) and can be guided by placing surgical clips at the time of operation.
- Patients with clinical stage II and III rectal cancers who undergo neoadjuvant chemoradiotherapy should be considered for postoperative adjuvant chemotherapy, regardless of the final pathologic staging, although the efficacy of adjuvant chemotherapy in this setting has not been firmly established.

While surgery remains the primary treatment for patients with colon and rectal cancer, adjuvant treatment with chemotherapy and radiotherapy plays an increasingly important role. For patients with stage III colon cancer, adjuvant chemotherapy has been recommended since 1990 [1]. More recently the National Quality Forum has endorsed metrics related to the administration of chemotherapy in stage III colon cancer patients in order to ensure that patients with stage III colon cancer not only are considered for chemotherapy but are given chemotherapy in a timely fashion [2]. For patients with stage I colon cancer, surgery alone is highly successful, and thus no adjuvant therapy is currently recommended. On the other hand, patients with stage II colon cancer may benefit from adjuvant treatment, although this is controversial and remains the focus of clinical trials. Finally, stage IV colon cancer patients are usually primarily treated with chemotherapy—this is the subject of a later chapter (see Chap. 36).

For patients with rectal cancer, adjuvant treatment has been recommended for both stage II and stage III disease. This treatment involves both chemotherapy and radiotherapy and usually begins preoperatively (see Chap. 28). After surgery, clinical stage II and stage III rectal cancer patients are recommend to undergo adjuvant postoperative chemotherapy regardless of the final surgical pathology. As with stage I colon cancer, surgery alone is highly successful for patients with stage I rectal cancer. This chapter will present the current recommendations regarding the use of postoperative adjuvant therapy for stage II and stage III colon and rectal cancer.

Colon Cancer

Stage III Colon Cancer

Adjuvant chemotherapy is recommended for all stage III colon cancer patients because it decreases recurrence and increases survival when compared to surgery alone [3, 4]. After surgery alone for stage III colon cancer, overall 5-year survival is 40–60 % [5]. Current chemotherapeutic regimens improve overall survival to 70–80 % [6]. Thus, 5-year overall survival of stage III colon cancer patients improves by an absolute 20–25 % with adjuvant chemotherapy. Table 33-1 summarizes the results of key clinical trials establishing the efficacy of adjuvant chemotherapy for nonmetastatic colon cancer [4, 6–11]. If all patients with stage III colon cancer receive adjuvant chemotherapy, roughly 1/3 to 1/2 of disease recurrences would be prevented.

Given the significant survival benefit of adjuvant chemotherapy, colon and rectal surgeons need to ensure that their stage III colon cancer patients are evaluated for chemotherapy after surgery. The National Quality Forum has endorsed two metrics regarding the treatment of stage III colon cancer patients [2]. The first metric estimates how many stage III patients are referred or treated with chemotherapy whereas the second metric looks at the timeliness of the administration

Table 33-1. Key clinical trials establishing the efficacy of adjuvant chemotherapy for colon cancer

Trial	Tumor stage	Comparison	Results	Conclusion
INT 0035 1990	Stage III	Surgery alone vs. 5-FU/levamisole	3 Years survival 5-FU/levamisole 71 % Surgery alone 55 %	Postop adjuvant chemo improves survival for stage III colon cancer
IMPACT 1995	Stage III	Surgery alone vs. 5-FU/leucovorin	3 Years survival 5-FU/leucovorin 71 % Surgery alone 62 %	Postop adjuvant chemo improves survival for stage III colon cancer
QUASAR 2000	Stage III	5-FU/levamisole vs. 5-FU/folinic acid vs. 5-FU/placebo	Decreased survival and increased recurrence with levamisole compared with placebo	Postop adjuvant chemo with levamisole inferior to placebo
IMPACT 1999	Stage II	Surgery alone vs. 5-FU/leucovorin	5 Years survival = no difference 5-FU/leucovorin 82 % Surgery alone 80 %	Postop adjuvant chemo does not improve survival for stage II colon cancer
NSABP (CO-1, CO-2, CO-3, and CO-4) 1999	Stage II	Surgery alone vs. 5-FU +	5-Year survival improved with adjuvant treatment 30 % Mortality reduction with adjuvant treatment	Postop adjuvant chemo improves survival for stage II colon cancer
MOSAIC 2009	Stage II and III	FOLFOX vs. 5-FU/leucovorin	6-Year survival in stage III only FOLFOX 73 % 5-FU/Leucovorin 68 %	FOLFOX superior to 5-FU/LV for stage III colon cancer
XELOXA 2011	Stage III	XELOX vs. 5-FU/leucovorin	3 Year disease-free survival: XELOX 71 % 5-FU/Leucovorin 67 %	Capecitabine plus oxaliplatin superior to 5-FU/leucovorin

of chemotherapy. Specifically, the first metric (measure 0385) determines the percentage of patients ≥18 years old who are either referred for adjuvant chemotherapy, prescribed adjuvant chemotherapy, or have previously received adjuvant chemotherapy in the last 12 months. The other metric (measure 0223) determines the percentage of patients under the age of 80 for whom adjuvant chemotherapy is considered or administered within 4 months of the *diagnosis*. Thus, it is important for colon and rectal surgeons to promptly refer all stage III colon cancer patients for adjuvant chemotherapy.

For patients with stage III colon cancer, the National Comprehensive Cancer Network (NCCN) guidelines recommend adjuvant treatment with FOLFOX or CapeOx for 6 months [12]. FOLFOX has been found to be superior to 5-FU/leucovorin [6, 13], and CapeOx is superior to bolus 5-FU/leucovorin [14, 15]. While used frequently in patients with metastatic disease, biologic therapy with antibodies directed at VEGF-A (bevacizumab) and EGFR antibody (panitumumab, cetuximab) is not recommended for adjuvant therapy of stage III disease [16–19]. The current FOLFOX regimen, mFOLFOX6, and the CapeOx regimen are outlined in Table 33-2. These agents act in different ways on colon cancer cells. 5-Fluorouracil is a pyrimidine analog that incorporates into DNA to stop DNA synthesis. Capecitabine is an oral 5-FU prolog and thus works in the same way as 5-FU. Folinic acid (leucovorin) is a vitamin B derivative that increases the cytotoxicity of 5-FU. Oxaliplatin inhibits DNA synthesis by forming inter- and intra-strand cross-links in DNA preventing replication and transcription. Using FOLFOX, the survival benefit of adding oxaliplatin to 5-FU does come at a price, the added side effect of peripheral sensory neuropathy (PSN). While 40–50 % of patients given oxaliplatin will develop PSN, only 10–20 % of patients will have grade 3 PSN which is defined as severe symptoms limiting activities of daily living [20]. Fortunately only 1 % of patients will have grade 3 PSN at 12 months after treatment [6]. Since the benefit of the addition of oxaliplatin to 5-FU/leucovorin is unproven in patients over the age of 70, capecitabine alone or 5-FU/leucovorin should be considered in elderly patients with stage III colon cancer [12]. Capecitabine-based regimens can be particularly complicated by palmar-plantar erythrodyskinesia (hand-foot syndrome), but this side effect can be limited by symptomatic treatment and resolves after treatment is concluded [21].

Stage II Colon Cancer

The 5-year overall survival of patients with stage II colon cancer is 65–85 % with surgery alone [22]. Unlike stage III disease, the role of adjuvant chemotherapy in stage II disease remains controversial, with some studies showing a benefit [10] and others showing no benefit [23]. If there is a benefit to adjuvant chemotherapy in stage II colon cancer patients, the benefit does not improve survival by more than 5 % unlike the 25–30 % improvement for stage III patients receiving adjuvant chemotherapy [12].

Following surgery for stage II colon cancer, the current NCCN guidelines (February 2015) recommend observation (surgery alone), enrollment in a clinical trial or adjuvant chemotherapy [12]. To sort out these options, a detailed discussion with the patient is recommended to highlight the potential benefits and risks of chemotherapy. Any high-risk features should be identified and discussed (Table 33-3). Patients with or without high-risk features should consider observation,

Table 33-2. Current recommended adjuvant chemotherapy regimens for stage III colon cancer

Regimen	Agents and dosage	Frequency
mFOLFOX6	Oxaliplatin 85 mg/m^2 IV over 2 h, day 1	Every 2 weeks
	Leucovorin 400 mg/m^2 IV over 2 h, day 1	
	5-FU 400 mg/m^2 IV bolus on day 1, then 1200 mg/m^2/day × 2 days IV continuous infusion	
CapeOx	Oxaliplatin 130 mg/m^2 IV over 2 h, day 1	Every 3 weeks
	Capecitabine 850–1000 mg/m^2 PO twice daily for 14 days	

Table 33-3. High-risk factors for recurrence

- Poorly differentiated histology (exclusive of those that are MSI-H)
- Lymphatic/vascular invasion
- Perineural invasion
- Close, indeterminate, or positive margins
- Bowel obstruction
- Localized perforation
- Less than 12 lymph nodes examined

clinical trial or chemotherapy with capecitabine or 5-FU/leucovorin. Only those patients with high-risk features should be considered candidates for FOLFOX or CapeOx. It is important to remember that the addition of oxaliplatin has not been shown to improve survival in stage II colon cancer patients [6]. Finally, decision-making regarding the use of adjuvant chemotherapy for stage II disease may be aided by performing genetic testing of the tumor after surgical resection.

Genetic testing of stage II tumors has been shown to be independently predictive of prognosis. High microsatellite instability (MSI-H) or defective mismatch repair (dMMR) status has been shown to be associated with a lower recurrence rate (11 % vs. 26 %) after surgical resection alone [24]. In addition, MSI-H tumors do not benefit from 5-FU adjuvant therapy [24]. Thus, MSI/MMR testing is recommended in all patients with stage II disease in order to avoid giving adjuvant chemotherapy in patients who will derive no benefit from it. In addition to MSI/MMR testing, multigene colon cancer assays such as Oncotype Dx, ColoPrint, and ColDx are now available that can also predict prognosis and risk of recurrence. All three of these multigene assays predict recurrence independent from other factors such as TNM stage, MMR status, tumor grade, and nodes [25–31]. While these assays provide additional information regarding prognosis and recurrence risk, they are not predictive of the potential benefit of chemotherapy, and consequently are, to date, of limited clinical value.

Radiotherapy for Colon Cancer

Radiotherapy plays a limited role in patients with colon cancer. A few retrospective, single institution studies have shown that adjuvant radiotherapy improves local control for colon cancer patients at high risk of recurrence after surgery [32–34]. Unfortunately, the single randomized prospective trial comparing chemotherapy alone with combined chemotherapy and radiotherapy lacks sufficient power to draw valid conclusions [35]. Current NCCN guidelines recommend that radiotherapy for colon cancer be considered in patients with T4 tumors with penetration to a fixed structure [12]. The radiation field should include the tumor bed as defined by preoperative imaging and the placement of surgical clips at the time of operation. A dose of 45–50 Gy in 25–28 fractions is recommended and should be delivered with concomitant 5-FU chemotherapy [12]. Thus, the colorectal surgeon should always be ready to place clips in and around the tumor bed during operations involving the resection of a fixed T4 colon tumor in order to help direct postoperative radiotherapy. Neoadjuvant chemoradiotherapy can be considered for select patients with bulky tumors invading other structures.

Rectal Cancer

Treatment of patients suffering from rectal cancer is far more complex than treatment of patients with colon cancer, due to the multitude of therapeutic options and timing of those therapies. In addition, pretreatment staging is not always accurate, and this imprecision must be taken into account when planning treatment. Initial staging, neoadjuvant therapy, and surgical treatment are covered in other chapters, and thus we will focus on postoperative therapy.

Decisions regarding postoperative adjuvant treatment for rectal cancer are based primarily on tumor location, clinical stage, histologic stage, and history of neoadjuvant therapy. Proximal rectal/rectosigmoid tumors are located at least 12 cm proximal to the anal verge and are above the peritoneal reflection. Although somewhat controversial, non-advanced proximal rectal/rectosigmoid tumors are treated in the same fashion as tumors elsewhere in the colon, with surgical resection followed by postoperative chemotherapy for stage III and select stage II tumors. Tumors of the middle/lower rectum are located from 0 to 12 cm from the anal verge as measured by rigid proctoscopy [36]. They typically have a worse prognosis, stage for stage, when compared to more proximal tumors and thus treatment recommendations are slightly different.

Patients Who Did not Undergo Neoadjuvant Therapy

Like stage I colon cancer, 5-year survival after surgery alone for stage I rectal cancer exceeds 90 % [37]. Thus, no adjuvant treatment is recommended for patients undergoing proctectomy alone who are found to have T1-2N0M0 disease, assuming that margins of resection are negative for tumor. For those found to have stage II or III disease after proctectomy, decision-making

is more complex. Postoperative chemotherapy is indicated for patients with stage III disease, but the benefit for stage II disease is less certain. Postoperative radiotherapy should be considered for patients with stage II and III disease, but this recommendation is primarily based on data from the past, when there was little emphasis on surgical quality or assessment of circumferential radial margins. Postoperative radiotherapy is also associated with substantial long-term toxicity, most notable in patients undergoing restorative proctectomy. The recommendation for routine postoperative radiotherapy for patients with T3N0 disease with negative circumferential margins has thus been questioned, including in the most recent iteration of the ASCRS Practice Parameters for the Management of Rectal Cancer [38]. Even for patients with N+ disease, it is unclear whether the small benefit of postoperative radiotherapy in terms of local control is worth the risk of toxicity, which can be substantial.

If patients are to be treated with postoperative chemoradiotherapy, it is usually administered using a sandwich technique. This involves giving chemotherapy (FOLFOX or CapeOx) followed by chemoradiotherapy (Capecitabine + radiation or infusional 5FU + radiation) followed by more chemotherapy (FOLFOX or CapeOx). The radiotherapy dose is usually 45–50 Gy in 25–28 fractions using 3 or 4 fields. External iliac nodes should be included for T4 tumors involving anterior structures, and inclusion of the inguinal nodes should be considered for tumors invading the distal anal canal. In stage II and III rectal cancer patients, postoperative chemotherapy should be administered as soon as the patient has recovered from surgery as each 4 week delay in chemotherapy results in a 14 % decrease in overall survival [39].

Patients Who Underwent Neoadjuvant Radiotherapy/Chemoradiotherapy

After neoadjuvant radiotherapy/chemoradiotherapy, decisions regarding postoperative chemotherapy are more complex. Although a recent Cochrane review concluded that postoperative adjuvant chemotherapy after resection of rectal cancer was associated with improved survival regardless of stage [40], the data come from trials as old as 1975. Thus, it is difficult to draw any firm conclusions from this meta-analysis, given that some data are derived from trials in which patients were not given neoadjuvant therapy, nor was there surgical quality control or measurement of circumferential margins. Overall, there is a paucity of data on which to rely when making decisions regarding postoperative chemotherapy for patients with rectal cancer because neoadjuvant therapy regimens, surgical quality control, and pathologic processing have evolved so rapidly in the past 30 years. This evolution is ongoing, with different neoadjuvant regimens currently under investigation.

Traditionally, patients with ypT3 or ypN+ disease have been recommended to undergo postoperative chemotherapy [36]. However, a recent meta-analysis of published data found that adjuvant fluorouracil-based chemotherapy did not improve overall survival, disease-free survival, or distant recurrences, calling these recommendations into question [41]. If chemotherapy is utilized, it is also controversial as to which regimen to utilize. Two randomized clinical trials have reported a disease-free survival advantage to FOLFOX vs. fluoropyrimidine monotherapy in patients previously treated with neoadjuvant chemoradiotherapy followed by rectal surgery [42–44]. A summary of several key clinical trials regarding chemoradiotherapy for rectal cancer is shown in Table 33-4 [40, 42–44, 48–52].

Clinicians should be aware that current NCCN guidelines for clinical stage II and III rectal cancer recommend either (1) preoperative chemoradiotherapy, surgery then postoperative chemotherapy or (2) preoperative chemotherapy followed by preoperative chemoradiotherapy then surgery (see Table 33-5) [36, 45, 46]. The total duration of perioperative therapy (preoperative chemoradiotherapy and chemotherapy) should not exceed 6 months [36]. However, as noted above, these recommendations are based on incomplete and sometimes conflicting data.

Patients Undergoing Local Excision

Due to the oncologically inferior results of local excision as compared to proctectomy, even in highly select patients, many authors have recommended treatment with adjuvant chemoradiotherapy, either in the preoperative or postoperative period. The advantage of utilizing chemoradiotherapy in the postoperative period is that T stage can be known with certainty, and one can ensure healing of the wound prior to institution of radiotherapy. The advantage of utilizing neoadjuvant chemoradiotherapy is that ypT stage correlates more closely with ypN stage than T stage correlates with N stage [53] and there may be downsizing of the tumor prior to excision. The major downside of neoadjuvant therapy combined with local excision is that wound healing may be impaired, and patients may suffer substantial morbidity as a result.

For patients treated with neoadjuvant chemoradiotherapy followed by local excision, standard radiotherapy of 50.4 Gy over 28 fractions is typically given with either 5-FU or capecitabine chemotherapy. For clinical stage T2 tumors these standard neoadjuvant regimens result in complete pathologic response rates as high as 40–60 % [54, 55]. While overall 5-year survival data are insufficient, the current data suggests that there is a 90 % 5-year survival after a complete pathologic response but only a 75 % 5-year survival if there is residual disease (ypT1 or ypT2) [55]. Thus, in select stage I patients and patients with significant comorbidities that preclude an abdominal procedure, a non-standard approach using neoadjuvant treatment with or without subsequent transanal excision may be considered (see Chap. 28).

Table 33-4. Key clinical trials establishing the efficacy of chemoradiotherapy for rectal cancer

Trial	Tumor stage	Comparison	Results	Conclusion
Swedish rectal cancer trial 1993	Stage II and III	Surgery alone vs. preop short course XRT	Local recurrence: 27 % vs. 12 %	Preop XRT decreases local recurrence, improves survival (?)
			5 Years survival: 48 % vs. 58 %	
Dutch TME rectal cancer trial 2001	Stage II and III	TME alone vs. preop XRT + TME	Local recurrence: 11.4 % vs. 5.6 %	Preop XRT improves local recurrence even with TME
			Survival: no difference	Preop XRT no effect on survival
German CAO/ARO/AIO-94 2003/2004	Stage II and III	Preop chemo XRT vs. postop chemo XRT	Local recurrence: 13 % vs. 6 %	Decreased toxicity and local recurrence with preop chemo XRT
			Toxicity: 40 % vs. 27 %	Pre vs. post: no effect on survival
			Survival: no difference	
EORTC 22921 2006	Stage II and III	XRT vs. chemo XRT	Survival benefit for ypT0-2 responders	Chemo in addition to XRT can improve survival in the subgroup of responders
Cochran review: postop chemo 2012	Stage II and III	No postop chemo vs. postop chemo after neoadjuvant	Recurrence reduced 25 %	Postop chemo reduces recurrence and death rate after neoadjuvant
			Deaths reduced 17 %	
ADORE 2014	Stage II and III	FOLFOX vs. 5-FU/leucovorin after neoadjuvant	3 Year disease-free survival: 72 % vs. 62 %	Postop FOLFOX superior to 5-FU after neoadjuvant
German CAO/ARO/AIO-04 2012/2014	Stage II and III	Neoadjuvant and adjuvant FOLFOX vs. 5-FU/leucovorin	Complete pathologic response: 17 % vs. 13 %	Preop and postop addition of oxaliplatin improves survival and pathologic response
			3 Years survival: 76 % vs. 71 %	

XRT Radiation therapy, *TME* Total mesorectal excision, *preop* Preoperative, *postop* Postoperative, *chemoxrt* Combined chemoradiation therapy

Table 33-5. Neoadjuvant and adjuvant treatment of stage II and III rectal cancer

Option I	Capecitabine + Radiotherapy OR Infusional 5-FU + Radiotherapy	→	Surgery	→	FOLFOX OR Capecitabine + Oxalplatin	
Option II	FOLFOX OR Capecitabine + Oxaliplatin	→	Capecitabine + Radiotherapy OR Infusional 5-FU + Radiotherapy	→	Surgery	

Future of Adjuvant Treatment of Colorectal Cancer

While significant progress has been made in defining optimal cytotoxic regimens in the adjuvant treatment of colorectal cancer, several questions remain regarding the optimal duration of chemotherapy treatment, the role of radiotherapy in rectal cancer, the possibility of nonsurgical interventions for rectal cancer, and the emerging role of immunotherapy.

Clinical Trials in Stage II–III Colon Cancer

Prior studies have shown no benefit from extending adjuvant therapy beyond 6 months in patients with stage III colon cancer [56]. However, a shorter duration of chemotherapy has not been adequately investigated. CALGB 80702 is currently investigating 6 cycles (3 months) vs. 12 cycles (6 months) of FOLFOX chemotherapy in patients with resected

stage III colon cancer (NCT01150045). This will be one of 6 ongoing clinical trials evaluating 3 vs. 6 months of adjuvant oxaliplatin-based chemotherapy. A meta-analysis of these studies (IDEA) will test the non-inferiority of 3 months to a 6 months strategy. In addition to the investigation of the duration of adjuvant treatment in colon cancer, efforts are ongoing to define the role of COX inhibition on disease recurrence. Analysis of the Nurses' Health Study (NHS) and Health Professional Follow-up Study (HPFS) has shown a decreased recurrence rate in patients with a diagnosis of colon cancer with regular aspirin intake [57]. The benefit appeared to be limited to patient with COX-2 overexpressing tumors [58]. These analyses were limited by their retrospective nature and require further support from prospectively conducted trials. CALGB 80702 randomizes all enrolled subjects to celecoxib vs. placebo in order to investigate the role of COX-2 inhibition in the adjuvant treatment of colon cancer. Similarly, the ASCOLT clinical trial (NCT00565708) is randomizing patients with stage II or III disease to 3 years of aspirin vs. placebo to address the role of aspirin in preventing colorectal cancer recurrence. Finally, several studies are investigating immunotherapy as an adjuvant form of treatment in colon cancer. An ongoing phase III clinical trial is evaluating the role of cytokine-induced killer cell immunotherapy for stage III colon cancer following surgery and completion of adjuvant therapy (NCT02280278).

Clinical Trials in Stage II–III Rectal Cancer (Table 33-5)

Recent phase II and retrospective trials have investigated the role of FOLFOX as a neoadjuvant treatment for rectal cancer. These series have been associated with a remarkable complete pathological response rates and were associated with a low risk of local recurrence, questioning the role of adjuvant or neoadjuvant therapy in the era of effective combination therapy [59]. To test this question, the Alliance PROSPECT clinical trial (NCT01515787) is currently randomizing patients to neoadjuvant FOLFOX chemotherapy with selective use of chemoradiotherapy (in poor responders) vs. the standard approach of neoadjuvant chemoradiotherapy. Other studies are sequencing intense chemotherapeutic regimens followed by chemoradiotherapy in order to improve on DFS and OS. The NEOFIRINOX trial (NCT01804790) is randomizing patients with rectal cancer to intensive chemotherapy with irinotecan, oxaliplatin, and 5-FU (FOLFIRINOX) followed by chemoradiotherapy, surgery, and further adjuvant chemotherapy (capecitabine or FOLFOX) vs. a control arm of chemoradiotherapy followed by surgery and adjuvant chemotherapy (capecitabine or FOLFOX).

In order to maximize systemic therapy exposure, clinical trials are evaluating the administration of the all systemic chemotherapy prior to surgical resection. For example, the RAPIDO clinical trial (NCT01558921) is randomizing rectal cancer patients to 5×5 Gy of radiotherapy followed by 6 cycles of CAPOX and then surgery vs. standard chemoradiotherapy and further adjuvant therapy (at the treating physician's discretion). Finally, several studies are investigating nonsurgical approaches to patients with rectal cancer who have a complete clinical response to chemoradiotherapy. The Cancer Institute of San Paulo is leading a randomized clinical trial (NCT02052921) that randomizes rectal cancer patients with complete clinical response following neoadjuvant chemoradiotherapy to observation vs. surgical resection with a primary end point of 3 year DFS.

Colorectal Cancer: Surveillance After Curative-Intent Therapy

Scott E. Regenbogen and Karin M. Hardiman

Key Concepts

- Liver metastases and locoregional recurrence are more likely to be amenable to curative-intent salvage resection when detected in asymptomatic patients. Therefore, active surveillance is indicated for patients who are candidates for liver and/or intestinal resection.
- Use of carcinoembryonic antigen testing and computed tomography (CT) scans is associated with increased detection of asymptomatic recurrence after curative resection for colorectal cancer. There is no evidence to support the use of any other laboratory testing or positron emission tomography (PET) scans in routine surveillance.
- Patients with advanced age and comorbidity, who would not be fit to undergo therapy for recurrence, should not be subjected to active surveillance. They should, however, receive evaluation and treatment for symptoms suggestive of recurrence.
- Patients with resected rectal cancers are at greater risk for locoregional recurrence. This risk is increased by omission of chemoradiotherapy for locally advanced tumors, close or positive margins, T4 and N2 histology. Consideration should therefore be given to local pelvic surveillance both endoluminally and extraluminally in these patients at highest risk.
- Surveillance after resection of Stage I colorectal cancer remains controversial. While the recurrence rates are low, in general, there are markers of relatively greater risk, including margin positivity, unknown lymph node status (e.g., local excision), inadequate lymph node sampling, lymphovascular invasion, poorly differentiated histology, and/or T2 disease. Active surveillance may be considered for patients with one or more of these risk factors.

Introduction

With improvements in screening, diagnosis, surgical technique, and adjuvant therapy for colon and rectal cancers, nearly two-thirds of patients who undergo surgical resection survive 5 years or more [1]. As a result, there is a rapidly growing population of colorectal cancer survivors, exceeding 1.2 million in the United States alone [2]. These individuals face varying risk for subsequent colorectal cancer throughout their lifetime, yet there is little consensus on optimal regimens for surveillance and survivorship care [3, 4].

The primary goal of colorectal cancer surveillance is to detect treatable recurrent, metastatic or metachronous colorectal malignancy and optimize the opportunities for potentially curative intervention. Thus, surveillance strategies must include not only evaluation for local recurrence and distant metastasis from the treated cancer, but also the increased personal risk for subsequent primary colorectal cancers. For patients with suspected or known genetic colorectal cancer syndromes, these strategies must also take into account the risk of other associated cancers, and the screening needs of potentially affected family members [5]. Ultimately, the success of colorectal cancer surveillance may be measured by improvements in overall survival, cancer-specific survival, disability or quality of life. Some studies have evaluated proxy measures, such as the rate of curative-intent metastasectomy or resection of colorectal neoplasia, but it is not clear to what degree these additional interventions benefit colorectal cancer survivors more broadly.

In order to demonstrate benefits from active surveillance, there must be evidence of improved detection of recurrence in patients amenable to curative-intent salvage therapy that itself is efficacious in improving outcome after recurrence. It has proven challenging to support with real data each of the steps in this chain of logic [6]. In addition, interpretation and synthesis of

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_34

findings of published studies are complicated by the heterogeneity of the interventions and comparisons—the surveillance intervention in one trial may be no more intensive than the control group regimen of another—and the challenges of obtaining adequate power to detect meaningful differences in survival and other objective oncologic outcomes in such studies.

It is also important to consider the appropriateness of surveillance for patients who might not be eligible for, or willing to undergo, treatment for recurrence. Recognizing that older adults account for the majority of colorectal cancer patients [7], patient preferences, age, comorbidities, and functional status must all contribute to the decision to pursue active surveillance. There is little need, for example, to conduct surveillance for asymptomatic liver metastases for a patient unwilling or unable to undergo hepatic resection and/or chemotherapy. For such patients, symptom-driven evaluations may suffice.

At the same time, the landscape around both the detection and treatment of recurrence continues to evolve. Compared with two decades ago, when some of the first randomized trials of intensive surveillance were conducted, the sensitivity of radiographic surveillance has increased severalfold, allowing detection of earlier metastatic disease in the liver and lungs. The advent of pelvic and liver MRI, endorectal ultrasound, and PET scanning offers new modalities for the detection of recurrent disease. Meanwhile, second- and third-line chemotherapeutic regimens, and ablative techniques for liver and lung metastases, have increased the options for both curative-intent and palliative-intent therapy for recurrent disease. More than a third of patients with recurrence undergo salvage resection, with median survival among these highly selected patients in excess of 3–5 years [8–11].

Timing and Choice of Surveillance Modalities

Intensity of Surveillance

There are various clinical, laboratory, radiographic, and endoscopic methods available for surveillance after treatment of colorectal cancer. Recommendations regarding their application and frequency of use vary between agencies involved in scripting guidelines for colorectal cancer care, and are summarized in Table 34-1. Most guidelines include more intensive early surveillance, with diminishing frequency after 2–5 years, due to the recognition that 80% of recurrences are detected within 3 years after initial curative-intent surgical therapy, and at least 95% are evident within 5 years [10, 12–14]. After 3 years without evidence of disease, cancer-specific mortality declines significantly and conditional survival thereafter is very high [15].

There have been eight prospective randomized trials addressing outcomes of surveillance after curative resection [16–23]. Overall, there is a lack of high-level evidence to support specific choices among surveillance regimens [24], but their interpretation is complicated by the heterogeneity of surveillance regimens, changes in diagnostic and therapeutic technologies available at the times they were conducted, and limitations of sample size and duration of follow-up [25].

Older trials, without intensive radiographic surveillance, have tended to show less benefit. For example, Ohlsson et al. [16] randomized 107 patients from 1983 to 1986 to either no follow-up or a surveillance regimen including CEA, colonoscopy, and chest X-rays, and found no meaningful differences in survival or recurrence patterns. Makela et al. [17] randomized 54 patients from 1988 to 1990 to yearly barium enema versus endoscopic surveillance plus liver ultrasonography and annual CT, with both groups receiving CEA testing and chest X-rays. In the intervention group, recurrences were found earlier (median 10 vs. 15 months, $p=0.002$), but patients were not significantly more likely to undergo salvage resection (19% vs. 14%, $p=0.67$) and 5-year overall survival was not significantly different (54% vs. 59%, $p=0.50$). In study of nearly 600 patients from 1983 to 1994, Kjeldsen et al. [18] applied the same modalities (clinical examination, colonoscopy, chest X-ray, hemoglobin, sedimentation rate, and liver enzymes) to the treatment and control arms, but varied the frequency of exams (every 6 months versus every 5 years). Recurrences in the every 6 months group were more likely to be asymptomatic (50% vs. 16%, $p=0.02$), and were subjected to more salvage resections (22% vs. 7%, $p=0.15$), but there was no difference in overall survival (70% vs. 68%, $p=0.48$) or cancer-specific survival (79% vs. 79%, $p=0.9$) between groups. And Schoemaker [19] et al. randomized 325 patients to clinical evaluation only versus additional chest X-ray, liver CT, and colonoscopy annually, and found only three resectable, asymptomatic recurrences (one each in the colon, liver and lung), without significant improvement in 5-year survival ($p=0.20$).

In contrast, more recent trials, incorporating more frequent endoscopy and modern imaging techniques, have been more likely to demonstrate benefit. In a study of 259 patients between 1997 and 2001, Rodriguez-Moranta et al. [20] compared routine clinical examination, colonoscopy, and CEA alone versus intensive surveillance with the addition of semi-annual abdominal CT or ultrasound, annual chest X-ray, and annual colonoscopy. They found improved survival for patients with Stage II cancers and rectal lesions, primarily due to the detection of resectable metachronous and locally-recurrent tumors. Pietra et al. [21] compared a regimen of annual CEA, ultrasound, chest X-ray, and colonoscopy against more frequent CEA and ultrasound, annual chest X-ray and colonoscopy, and the addition of annual abdominal CT. They found no difference in recurrence rates, but a significantly higher rate of salvage resection in the intensive surveillance group (65% vs. 10%, $p<0.01$), which translated into improved survival at 5 years (73% vs. 58%, $p=0.02$), particularly among those with recurrence (38% vs. 0%, $p<0.01$). Secco et al. [22] stratified patients into high and low risk of recurrence (based on primary tumor location, T stage, differentiation histology, and preoperative CEA level) then randomized to minimal surveillance versus active surveillance, with frequency of abdominopelvic ultrasound,

Modality	American Society of Colon and Rectal Surgeons [37]	National Comprehensive Cancer Network [48, 49]	American Cancer Society, US Multisociety Task Force on Colorectal Cancer [70]	American Society of Clinical Oncology [55]	Cancer Care Ontario [51]	European Society of Medical Oncology [52, 79]	British Society of Gastroenterology, Association of Coloproctology for Great Britain and Ireland [72, 73]
History and physical exam	Every 3–6 months for 2 years, then every 6 months to 5 years	Every 3–6 months for 2 years, then every 6 months to 5 years	Not addressed	Every 3–6 months for 5 years	Every 6 months for 5 years	Every 3–6 months for 3 years, then every 6 months to 5 years	Not addressed
CEA	Every 3–6 months for 2 years, then every 6 months to 5 years	Every 3–6 months for 2 years, then every 6 months to 5 years	Not addressed	Every 3–6 months for 5 years	Every 6 months for 5 years	Every 3–6 months for 3 years, then every 6 months to 5 years	"Role of CEA is uncertain"
Other laboratory testing	Not recommended	Not recommended	Not addressed	Not recommended	Not recommended	Not recommended	Not recommended
Abdominal Imaging	CT scan annually for 5 years. Consider more frequent for highest risk[a]	CT scan annually for 5 years	Not addressed	CT scan annually for 3 years. Consider 6–12 months for high risk	CT scan annually for 3 years. US every 6–12 months may be substituted	CT scan or contrast-enhanced ultrasound every 6–12 months for 3 years for patients at higher risk of recurrence	"Reasonable to offer" CT of the liver within 2 years of resection
Pelvic imaging	CT scan annually for 5 years. Consider more frequent for highest risk[a]	CT scan annually for 5 years	Not addressed	CT scans every 6–12 months for 2–3 years, then annually up to 5 years	CT scan annually for 3 years for rectal cancers only	Not specifically recommended	Not specifically recommended
Chest imaging	CT scan annually for 5 years. Consider more frequent for highest risk[a]	CT scan annually for 5 years	Not addressed	CT scan annually for 3 years. Consider 6–12 months for high risk	CT scan annually for 3 years. CXR every 6–12 months may be substituted	CT scan every 6–12 months for 3 years for patients at higher risk of recurrence	Not specifically recommended
PET scan	Not recommended for routine surveillance	Not recommended for routine surveillance	Not addressed	Not recommended for routine surveillance	Not recommended for routine surveillance	Not recommended for routine surveillance	Not recommended
Colonoscopy	1 Year after resection (or within 6 months if previously incomplete). If normal, repeat in 3 years. If adenomas, repeat in 1 year. Annual colonoscopy for patients with suspected familial syndromes who have not undergone proctocolectomy	1 Year after resection (or within 6 months if previously incomplete). If normal, repeat in 3 years, then 5 years. If advanced adenoma, repeat in 1 year. Annual colonoscopy for patients with suspected familial syndromes who have not undergone proctocolectomy	1 Year after resection (or 1 year after colonoscopy that cleared synchronous disease before primary treatment). If normal, repeat in 3 years, then 5 years. More frequent if high-risk adenoma (s) or suspicion for Lynch syndrome	1 Year after resection, or upon completion of adjuvant therapy if previously incomplete. If normal, repeat in 5 years. Otherwise, according to endoscopic findings	1 Year after resection (or within 6 months if previously incomplete). If normal, repeat in 5 years	1 Year after resection, then every 3–5 years thereafter	Every 5 years after resection, until benefits outweighed by comorbidity

Stage-specific recommendations	Stage 1: high risk only[b] Stage 2: all Stage 3: all Stage 4: when metastases are resected for cure	Stage 1: colonoscopic surveillance only Stage 2: all Stage 3: all Stage 4: when metastases are resected for cure, CT scan every 3–6 months for 2 years, then every 6–12 months to 5 years	Not addressed	Recommendations apply to Stage II and III disease only. Insufficient data to make recommendations for Stage I	Recommendations apply to Stage II and III disease only	Not addressed	Not addressed
Rectal surveillance	Proctoscopy every 6–12 months for patients with anastomosis, every 6 months after local excision, for 3–5 years. Endorectal ultrasound for high risk[c]	No additional testing specifically recommended	Proctoscopy, flexible sigmoidoscopy or endorectal ultrasound every 3–6 months for patients with anastomosis	Proctosigmoidoscopy every 6 months for 2–5 years for patients who did not receive radiotherapy, those with T4 or N2 tumors. Pelvic imaging for rectal tumors only	Proctosigmoidoscopy every 6 months for 2–5 years for patients who did not receive radiotherapy. Pelvic imaging for rectal tumors only	No additional testing specifically recommended	Not addressed

CEA Carcinoembryonic antigen, *CT* Computed tomography, *PET* Positron emission tomography

[a]Highest risk for systemic recurrence includes patients with N2 disease or after curative-intent metastasectomy

[b]High risk of recurrence in Stage I disease is to be defined by provider(s) according to features such as margin positivity, unknown lymph node status (e.g., local excision), inadequate lymph node sampling, lymphovascular invasion, poorly differentiated histology, and/or T2 disease

[c]High risk for local recurrence include local excisions with poor histology (T2+, poorly differentiated), positive margins, T4 or N2 disease

chest X-ray, and proctoscopy (for rectal cancers only) adapted to risk class. Recurrence rates were similar between regimens, but the likelihood of salvage reoperation for recurrence was higher with active surveillance among the high-risk (34% vs. 12%, $p<0.01$) but not low-risk (22% vs. 24%) patients. Survival at 5 years was improved with surveillance in both risk groups (both $p<0.01$, proportions were not presented in the manuscript).

In the Follow-up After Colorectal Surgery (FACS) trial, the only factorial-design randomized study to evaluate the role of CT scans of the chest, abdomen, and pelvis, Primrose et al. [23] compared four groups: minimum follow-up, CEA only (every 3 months for 2 years, then semiannually to 5 years), CT only (every 6 months for 2 years, then annually to 5 years), and both CEA and CT. Colonoscopy was performed at 5 years in the non-CT groups, and at 2 and 5 years in the CT groups. Between 2003 and 2009, they randomized over 1200 patients in 39 hospitals in the United Kingdom. Again, more curative-intent salvage operations were performed in the active surveillance groups (6.7% CEA alone, 8.0% CT alone, 6.6% CEA + CT) than the minimal follow-up group (2.3%, $p=0.02$), but there was no difference in survival (82% active vs. 84% minimal), and the addition of CT to CEA did not increase the detection of resectable recurrences.

Several meta-analyses have attempted to synthesize these and other non-randomized trials and have generally corroborated the findings of the trials described above. Tjandra and Chan [26] analyzed the seven pre-FACS studies above [16–20, 22, 27] and interim data from an ongoing study [4] and found that intensive surveillance resulted in more frequent and earlier detection of asymptomatic, resectable recurrence, with a small but statistically significant improvement in survival during follow-up (78% vs. 74%, $p=0.01$). Pita-Fernández et al. [28] evaluated 11 trials, including more than 4000 patients, randomized according to a variety of different protocols and regimens, and found a small improvement in overall survival with more intensive surveillance (74% vs. 71%, p value not reported). Survival was significantly improved among patients subjected to colonoscopy, chest X-ray, liver ultrasonography, CT, and clinical assessment. There was also improvement in survival associated with increased frequency of CEA testing, liver ultrasonography, and clinical assessment. Findings and conclusions were similar in a meta-analysis by Renehan et al. [29]. Further, a Cochrane Collaborative meta-analysis of the pre-FACS trials found that intensive surveillance more than doubled the odds of salvage surgery and was associated with approximately 27% reduced odds of mortality. Particular benefit was found in trails that increased frequency of testing and use liver imaging [25].

There are two ongoing randomized trials whose results have not yet been reported. The COLOFOL trial [30] in Denmark, Sweden, Poland, Ireland, and Uruguay is comparing semiannual CT or MRI against imaging performed at 12 and 36 months after resection. And the GILDA trial [4], in Italy, Spain, and the United States, evaluates increased frequency of colonoscopy, chest X-ray, liver ultrasound, and abdominopelvic CT (for rectal cancers only). As of 2004, GILDA had enrolled nearly 1000 patients and interim results demonstrated no improvement in mortality (7% in the intensive arms, 5% in the minimal surveillance arm).

Ultimately, high-level evidence to support each component of any of the guidelines included herein is lacking. Nevertheless, we can likely conclude that more frequent testing and the use of advanced imaging will result in more potentially curative surgery for recurrence and a measurable, but small, improvement in survival.

Physical Examination

Most of the major societies' guidelines include periodic clinical evaluation, including assessment of symptoms and physical examination. Findings suggestive of disease recurrence may include weight loss, fatigue, anemia, cough, abdominal pain, rectal bleeding, or changes in bowel habits. Physical examination should focus on the abdomen, including evaluation for wound implants, lymph nodes, and rectal exam (or perineal wound exam after abdominoperineal resection).

In addition to their role in colorectal cancer surveillance, these visits also serve an important survivorship role in overall health maintenance and management of physical and psychosocial function after colorectal resections. More than half of rectal cancer patients who undergo low anterior resection suffer bowel dysfunction [31, 32]. And high rates of depression persist among colorectal cancer survivors even more than 5 years beyond their diagnosis [33]. Additionally, health behavior promotion can improve cancer outcomes as well. High intake of red meat and saturated fat has been associated with worse survival after treatment of colorectal cancer [34, 35], whereas regular weekly exercise is associated with significantly increased disease-free survival [36]. Interventions to improve these preventive health-related behaviors may thus improve outcomes from both the cancer and comorbid disease.

American Society of Colon and Rectal Surgeons (ASCRS) recommends visits every 3–6 months for 2 years, followed by every 6 months until 5 years [37]. Recognizing that many patients who present with recurrence are symptomatic [18, 38], a detailed history and physical examination may be sufficient to detect recurrent disease in many instances. Symptomatic recurrences, however, are far less likely to be amenable to curative-intent therapy [38, 39].

Laboratory Testing

None of the major guidelines currently endorse the routine evaluation of complete blood count, liver function tests, fecal occult blood testing, or blood chemistries. However, most recommend checking levels of carcinoembryonic

antigen (CEA), an oncofetal protein that may be elevated in patients with recurrent colorectal cancer. CEA detects only about 30–60% of recurrences [10, 38, 40–43], the positive predictive value of CEA is only about 65% [44], and more than 15% of patients in surveillance have falsely elevated CEA in the absence of recurrence [40]. Yet, elevations in CEA may precede symptomatic presentation of metastasis [45], and the trials showing greatest benefit to intensive surveillance [21, 23] have included regular CEA evaluations. CEA elevations identify disease in the absence of abnormal imaging in up to 23% of patients with recurrent colorectal cancer [46], but may be more commonly elevated with metachronous liver metastases than with pulmonary metastases, luminal or locoregional recurrences [40, 42]. About a third of colorectal cancers do not produce CEA [47], but the significance of CEA elevation during surveillance seems to be independent of the preoperative CEA level [45]. Still, no studies have formally addressed the accuracy of surveillance CEA testing among patients with normal CEA at time of diagnosis.

Recommendations for management of asymptomatic CEA elevation are outlined in guidelines from both NCCN [48, 49] and ASCRS [37]. After confirmation of serial elevation in CEA level, a complete physical examination, endoscopy, and CT imaging of the chest, abdomen, and pelvis are performed. If these are all negative, consideration is given to PET-CT and/or repeat imaging every 3 months until levels decline or recurrence is detected.

Abdominal Imaging

The most common site of metachronous metastatic colorectal cancer is the liver [50]. Recommendations for routine imaging to detect liver metastases have, therefore, broadened substantially in the past decade. The Cochrane Collaborative meta-analysis [25] concluded that there was a survival benefit associated with liver imaging, with hazard ratio for mortality of 0.64 (95% confidence interval 0.49–0.85). This conclusion was derived from the results of five randomized trials [16, 17, 19–21], which used varying combinations of liver ultrasonography, abdominal CT, or both.

Observational studies have strongly supported the use of more frequent advanced liver imaging due to increased detection of resectable metastases. In a single-institution study, Fora et al. [14] reported results from their practice of CEA testing plus chest and abdominopelvic CTs every 6 months for the first 2 years, then annually to 5 years for patients with resected Stage II and III colorectal cancer. Among the 44 of 177 (25%) patients diagnosed with recurrence, CT detected the recurrence in 30 (68%). Half of patients diagnosed with recurrence had elevated CEA, but CEA was responsible for the diagnosis in only 8 (18%), and symptoms preceded diagnosis in only 3 patients (7%). Curative-intent salvage surgery was undertaken for 25 of the 44 recurrences (57%). Likewise, Arriola et al. [9] found that recurrences diagnosed by CT were far more likely to undergo curative-intent resection than those detected by CEA alone. In a meta-analysis of five surveillance trials, Renehan et al. [29] concluded that the regimens most consistently associated with improved survival included both CT scanning and frequent CEA testing.

Canadian [51] and European [52] guidelines provide the option of either CT or ultrasound, and as recently as 2004, ASCRS practice parameters for colorectal cancer [53] surveillance did not recommend routine liver imaging, because of the unclear survival benefit associated with salvage resection, the lack of evidence for incremental benefit of imaging in patients undergoing CEA testing, and the cost of CT. Since then, however, improvements in the detection and management of hepatic and pulmonary metastases have altered this calculus [54], and the current ASCRS practice parameter [37] and recommendations from other US-based agencies [48, 49, 55] recommend routine CT imaging, due to increased sensitivity for identifying early liver lesions, and the opportunity to evaluate the remainder of the abdomen and pelvis for other sites of metastasis (such as retroperitoneal lymph nodes and ovaries), and to identify local recurrence in the resection bed [37]. Despite a lack of controlled studies comparing different imaging intervals, the ASCRS guideline suggests consideration of semiannual imaging for patients at highest risk of recurrence, including those with resected N2 or Stage IV disease.

There is currently no organization that endorses routine use of PET-CT scans or liver MRI. One randomized trial compared addition of PET to a surveillance regimen including CTs at 9 and 15 months after surgery, and found shorter time to diagnosis (12.1 vs. 15.4 months, $p=0.01$) and a higher rate of resection for recurrence (44% vs. 10%, $p<0.01$) in the PET+CT group [56]. Nevertheless, a meta-analysis of the use of PET in surveillance regimens noted inadequate evidence to support its use in routine surveillance [57]. In the evaluation of unexplained CEA elevation, observational studies find that PET and PET-CT have sensitivity for detecting metastasis in excess of 90% despite somewhat lower specificity, from 70 to 80%, due to false positive findings [58–63]. In routine surveillance, however, PET does not improve sensitivity over CT due to its lower spatial resolution and the use of non-diagnostic quality CT imaging without contrast enhancement in combined PET-CT exams.

Chest Imaging

Whereas plain radiography was the mainstay of surveillance for pulmonary metastasis in the past, most of the major guidelines now recommend the use of cross-sectional thoracic imaging at least annually. This change has come with the recognition that pulmonary metastasis may present as a solitary site of disease recurrence [8, 50, 64, 65], and may

even represent the most common site of distant metastasis for distal rectal cancers [66, 67]. Unfortunately, among the published randomized studies, only the FACS trial [23] has included chest CT scans in the regimen, and this study did not find a statistically significant incremental benefit to CT scan over CEA alone (though the study was not powered to examine this comparison). In an observational study of 530 patients with resected Stage II or III colorectal cancers, Chau et al. [38] found that chest CT was responsible for 35% of the diagnosed metastases, and 73% of patients found to have isolated pulmonary recurrence underwent curative-intent resection. Thus, for now, chest imaging is recommended in spite of a lack of high-level evidence to support its effectiveness in practice.

Colonoscopy

Surveillance endoscopy after colorectal cancer resection can serve three important purposes: clearance of remaining colon when preoperative colonoscopy was incomplete, anastomotic surveillance for detection of local luminal recurrence, and detection of metachronous neoplasia. For patients who did not have complete colonoscopy before resection of the primary tumor (because of an obstructing tumor for example) complete colonoscopy should be performed within 3–6 months after surgery [37], because the estimated incidence of synchronous neoplasia exceeds 30% [68–70]. Anastomotic recurrence after resection of colon cancers is rare [29, 71], representing only about 4% of recurrences [65]. On the other hand, local recurrence is a common concern after low anterior rectal resections—local surveillance for rectal cancer is discussed in more detail below.

For patients who had complete colon evaluation before their primary resection, the primary goal of surveillance colonoscopy is the detection of metachronous neoplasia, or polyps that were missed on the preoperative evaluation. The BSG/ACPGBI guidelines suggest waiting until 5 years after resection [72, 73], whereas all of the other guidelines include a complete colonoscopy at 1 year, though the rate of clinically significant findings may be quite low. In a meta-analysis of 17 studies including nearly 8000 patients followed after curative colorectal cancer resections, there were only 57 metachronous cancers found with the first 2 years—an incidence of 0.7% [70], consistent with the incidence in other studies [74–76]. In a recent single-institution study, Cone et al. [71] found that 15% of patients had polyps on their 1-year colonoscopy, but only 3% of these were greater than 1 cm in diameter. Nevertheless, these detection rates, both for malignancy and for high-risk adenomas, are at least as high as those of average-risk screening exams. Combined with the recognition that more than half of metachronous cancers are detected in the first 2 years after resection [77, 78], these data have been considered reasonable justification for the recommendation for colonoscopy at 1 year in most guidelines [37, 48, 51, 52, 55, 70, 79, 80].

In a randomized trial, Wang et al. [75] evaluated even more frequent colonoscopy, comparing a regimen of exams every 3 months for 1 year, then every 6 months for 2 more years, then yearly to 5 years versus colonoscopy at 6, 30, and 60 months only. The overall incidence of anastomotic recurrence was 6.9% and metachronous cancers were found in 2.8%. There was a higher rate of asymptomatic recurrences and curative-intent salvage operations in the more frequent group, but no statistically significant difference in 5-year survival (77% vs. 72%, $p=0.25$). Likewise, in their meta-analysis of surveillance trials, Tjandra and Chan [26] concluded that there was an increase in the curative reoperation rate among studies with increased frequency of colonoscopy, but a mortality benefit to colonoscopy only when compared against no surveillance at all.

After the initial 1-year colonoscopy, patients with a personal history of colorectal cancer remain at increased risk for metachronous neoplasia for the rest of their lives. The annual incidence of a second primary colorectal cancer is about 0.3%, resulting in an incidence of 1.5–3.1% within 5–10 years [74, 78, 81, 82]. Up to half of patients develop metachronous polyps after resection of a primary colorectal cancer [83]. Thus, even after the first year, patients with a personal history of colorectal cancer still require more frequent endoscopic surveillance than average-risk individuals or those with a history of adenomas alone. The ASCRS guideline [37] recommends that the subsequent colonoscopy schedule be tailored to the findings at the 1-year examination, and to other patient specific risk factors and circumstances. Patients with high-risk adenomas (high-grade dysplasia, size greater than 1 cm or more than three adenomas) and those with a diagnosed or suspected hereditary colorectal cancer syndrome may require annual colonoscopy for more intensive surveillance [5]. On the other hand, patients with limited life expectancy are unlikely to benefit from the detection of an asymptomatic cancer, and may be selected for less frequent, or no, endoscopic surveillance [84–86].

Other methods of luminal surveillance are not formally recommended at this time. Air-contrast barium enema is a less effective means of surveillance after colonoscopic polypectomy [87], and would be expected to compare similarly among patients after cancer resections. CT colonography has been advocated elsewhere as a technique for simultaneous assessment of both luminal and distant disease [88, 89], but it has not been satisfactorily evaluated in the setting of colorectal cancer surveillance, and its sensitivity has not been satisfactory to replace optical colonoscopy in this setting [70, 90].

Stage I Disease

Most of the major guidelines for and studies of colorectal cancer surveillance pertain primarily to Stage II–III disease, and to Stage IV tumors that have been resected with curative intent. Stage I patients have been largely excluded from many of the randomized trials. As a *result*, there remains controversy regarding approaches to the surveillance of resected Stage I colon cancers (see Table 34-1). Several of the guidelines specifically recommend against routine imaging. For example, NCCN [48] and ASCO [55] recommend only endoscopic surveillance for anastomotic recurrence or metachronous cancers. Further, there is presumed to be low incidence of systemic recurrence, as 5-year colon cancer survival rates exceed 90%, and very few operations for metachronous metastatic recurrence occur in patients who initially presented with a Stage I tumor [91]. Thus, there is concern that surveillance will identify more incidental findings than treatable recurrences. Chao and Gibbs [92] estimated it would take nearly 200 patients with Stage I disease in surveillance to detect each curable metastasis, and cautioned against over-testing in this setting.

On the other hand, in a secondary analysis [8] of the Clinical Outcomes of Surgical Therapy trial [93], which compared laparoscopic and open colectomy for colon cancer, the 5-year recurrence rate was 9.5% for early stage patients (including Stage I and IIa), occurring at a median of 1.8 years after primary resection. More than a third of patients with recurrence underwent salvage resection, with no difference in salvage rates between initially early and late stage patients. Median survival after salvage surgery for early stage patients was 51 months. Finding equivalent rates of salvage and better survival for recurrences after resection of early stage disease, Tsikitis et al. [8] recommended active survival for these patients, though they did not distinguish between Stage I (T1-2, N0) and Stage 2a (T3N0) in the study. Accordingly, the most recent ASCRS [37] Practice Guideline recommends consideration of active surveillance for Stage I patients, but limits the recommendation to those designated at higher risk—for example, close or positive margins, unknown lymph node status (e.g., local or endoscopic excision), inadequate lymph node sampling, lymphovascular invasion, poorly differentiated histology, and/or T2 disease.

Local Surveillance for Rectal Cancer

Additional surveillance recommendations for rectal cancer are predicated on the greater risk of locoregional recurrence, compared with colon cancers [70], due to both anatomic and biologic differences between the tumors [94–96]. Locoregional recurrence of rectal cancer can occur either intraluminally, typically at the site of anastomosis, or extraluminally, likely associated with residual lymphatic disease, close radial margins, or tumor shed during resection. Although the use of total mesorectal excision (TME) and chemoradiotherapy for locally advanced rectal cancers have substantially reduced local failure after primary resection [97–100], between 4 and 22% of patients still experience local recurrence [98, 99, 101–103]. The resulting downstaging that may occur with the use of preoperative therapy for rectal cancer also may creates confusion about how to classify future risk of recurrence. In the ASCRS practice guidelines, it is recommended that pretreatment clinical staging be used to guide surveillance intensity unless the pathologic staging exceeds the preoperative assessment [37].

Early identification of local recurrence may offer the opportunity for curative-intent salvage resection. Therefore, surveillance of colorectal anastomoses and pelvic imaging are recommended beyond what is performed for colon cancer surveillance. Physical assessment including meticulous pelvic and groin examinations should be performed every 6 months. For patients with a low anastomosis or distal tumor with local excision or non-operative management, digital exam of the anastomosis or tumor site should be included. For patients who have undergone abdominoperineal resection (APR), careful palpation of the perineum and, in women, the posterior wall of the vagina is recommended. Special attention should be paid to areas of nodularity or changes over time. Any suspicious lesions should undergo biopsy as local recurrences after APR are frequently perineal or pre-sacral [100].

Proctosigmoidoscopy is recommended in the most recent ASCRS practice parameters [37] every 6–12 months for 3–5 years for those who have undergone a low anterior resection with anastomosis, and more frequently for those considered to be at higher risk of local recurrence. These higher risk patients and tumors might include men, distal lesions, close margins, incomplete TME, positive lymph nodes, lack of treatment response, lymphovascular invasion, and/or poor differentiation [98, 103–108]. On the other hand, in recognition of the substantially lower recurrence rate associated with TME and chemoradiotherapy, some guidelines have suggested limiting additional endoscopic surveillance only to patients who did not receive guideline-concordant multimodality therapy [51, 55]. To date, however, there have been no high-quality trials evaluating the effect of proctosigmoidoscopy on detection of recurrence, salvage resection, or survival after low anterior resection.

Recognizing that proctosigmoidoscopy only evaluates endoluminal surfaces, and thus may not detect early disease in residual mesorectum or other extraluminal tissues, the most recent ASCRS [37] and ACS/MSTF [70] guidelines also suggest consideration of endorectal ultrasonography (ERUS) for patients considered to be at high-risk for local recurrence. In three studies, ERUS identified asymptomatic rectal cancer recurrence that was otherwise undetected by digital exam, endoscopy, CT, or CEA in about 30% of cases [109–111]. Surgically resectable recurrences were more common in the ERUS-detected group, suggesting it may identify earlier

recurrent disease [111]. Further, ERUS-guided biopsy may provide the best opportunity to obtain histologic evaluation of extraluminal abnormalities [112–114]. Extraluminal pelvic disease may otherwise be evaluated by cross-sectional imaging. ASCO [55] and CCO [51] both recommend pelvic CT imaging for rectal cancers only, as a means of detection of local recurrence. MRI of the pelvis can also be used and is highly accurate for the diagnosis of pelvic recurrence [115], but its use in routine surveillance did not improve the detection of resectable recurrence in a single trial [116], and its cost-effectiveness has not been evaluated.

For rectal cancers treated by local excision, rather than radical resection, particular attention must be paid to both endoluminal and mesorectal surveillance. Even among the best candidates—those with T1 cancers and no high-risk histologic features—there is a significantly higher risk of local recurrence compared with resection with TME, ranging from 4 to 33% [117–119]. Outcomes of local excision for higher stage tumors are even worse [120]. Thus, at least semiannual endoscopic surveillance after local excision is highly recommended, and consideration may be given to the use of ERUS for these patients, especially.

As there is increasing interest in and application of non-operative approaches for patients who experience complete clinical response after chemoradiotherapy [121, 122], surveillance regimens for these patients will need to be defined as well. Because non-operative treatment is currently limited to clinical trials [123], none of the guidelines include formal recommendations for such patients. However, the non-operative trials reported to date have employed remarkably intensive surveillance, including very frequent physical examination, endoscopy, and imaging, often with pelvic MRI [122–125].

Compliance with Guidelines

Despite published recommendations for surveillance after resection for colorectal cancer, compliance with surveillance remains challenging both for patients and their physicians. There is evidence that patients who adhere to recommended surveillance have a greater likelihood of curative-intent reoperation for recurrence and improved overall and disease-specific 5-year survival [126, 127]. Yet anywhere from 25 to 42% of patients have poor completion of recommended surveillance, and 11–21% have no surveillance at all [126–129]. Studies in Canada [130], the Netherlands [131, 132], and Norway [133] have found substantial differences in the surveillance patterns between providers, and noted that routines are commonly inconsistent with published guidelines. Among US Medicare beneficiaries, there is substantial geographic variation in the intensity of surveillance, with about 60% of patients failing to complete recommended testing, while 23% undergo testing more intensive than recommended by guidelines [134]. Similarly, a survey of ASCRS membership revealed that colon and rectal surgeons employ a wide variety of surveillance approaches, and only 30% performed surveillance in accordance with a formal national or local guideline [135].

There is also little consensus regarding who should manage cancer surveillance—the operating surgeon, medical oncologist, gastroenterologist, or primary care doctor. This ambiguity may contribute to nonadherence in many patients, as responsibility for ordering and managing testing can be undefined [136]. In a survey of Canadian colorectal cancer specialists, Earle et al. found high levels of endorsement of recommended surveillance, and a belief that specialty physicians are more capable of effective surveillance. Similarly, in a Texas study, patients who saw a medical oncologist as part of surveillance were significantly more likely to exhibit compliance with minimal recommendations for office visits, CEA testing, and colonoscopy [128]. Two randomized trials have compared surveillance by general practitioners and surgeons. In both studies, surveillance by surgeons was associated with more costly and intensive diagnostic testing, but no difference in recurrence rates, time to diagnosis, survival, or quality of life [137, 138] Patients seeing general practitioners received more fecal occult blood testing, whereas those followed by surgeons had more ultrasounds and colonoscopies [137]. Patients followed by primary care doctors report that greater attention is paid to preventive health maintenance for comorbidities [139].

In a single-institution study, Standeven et al. [140] found that, compared with community-based primary care follow-up, the establishment of a formal surveillance program in a referral center improved adherence to surveillance guidelines. Strand et al. [141] trained specialty nurses to conduct surveillance and found similar patient satisfaction and detection of recurrence among patients randomized patients to visits with either the nurse or a surgeon. It remains unclear, however, whether such a model—a multidisciplinary team with a clinic dedicated to colorectal cancer surveillance—could be replicated more widely.

Quality of Life

Apart from the cancer-specific outcomes of surveillance, an essential question is the effect of intensive surveillance on psychological health and quality of life. While reassuring surveillance examinations may allay fears of cancer recurrence for some patients, there could be others for whom surveillance examinations create additional unwarranted worry and result in investigations for false positive or incidental findings.

Most patients in surveillance report, however, that these anxieties and inconveniences are outweighed by the reassurance and optimism imparted by negative results [142]. In the randomized trial by Kjeldsen et al. [143] patients randomized to more frequent evaluations reported greater confidence in

the surveillance process, and somewhat less worry about test results, even in this trial which showed no effect of surveillance intensity on survival. Likewise, Stiggelbout et al. [144] interviewed more than 212 patients undergoing surveillance for colorectal cancer and found generally positive attitudes toward surveillance, with relatively little worry regarding testing. Even when asked to consider the possibility that testing would not improve the detection of recurrence, 64% of patients in that study still expressed a preference for active surveillance.

Cost

As recommendations for surveillance imaging have expanded in recent guidelines, another important consideration will be the costs of surveillance. Total costs of the surveillance regimens in published studies vary 28-fold [145], without a clear correlation between cost and efficacy. Meanwhile, between 1999 and 2006, the use of CT and MRI scans in the follow-up of patients with colorectal cancer increased at an annual rate of more than 5%, and the use of PET scans more than tripled [146].

Among a cohort of Italian patients undergoing surveillance with clinical examination, CEA, abdominal ultrasonography, chest X-ray, and colonoscopy, the 5-year cost of surveillance averaged $5400 per patient, but more than $100,000 per detected case of potentially curable recurrence [147]. Similarly, in a meta-analysis of five randomized trials [16–19, 21], Renehan et al. [148] estimated the average costs of surveillance at almost £2500 per patient, or about £3000 per year of life saved—within the range of acceptable cost-effectiveness for the UK's National Health Service. And a comparative study in France estimated that intensive surveillance cost an additional 3144€ per quality-adjusted life year gained over a minimal surveillance strategy [149].

We can conclude from these limited data that the cost-effectiveness of colorectal cancer surveillance is likely to be within the range of other interventions considered acceptably costly. Caution must be taken, however, if an increase in the cost, complexity, and frequency of recommended testing is contemplated.

Conclusions

There continues to be substantial uncertainty about the magnitude of benefits from active surveillance and the content of optimal surveillance regimens after curative resection for colorectal cancer. With improved imaging technology and a growing array of management options for recurrence, however, active surveillance is recommended for patients eligible for treatment of recurrent disease. Although there is likely great value to standardization of surveillance regimens, optimal approaches will require tailoring of surveillance strategies to individual patient risk factors. Perhaps the introduction of biomarkers [150] or simulation models [151, 152] to estimate individual risk will inform choices about surveillance modalities in the future [153]. In coming years, the GILDA [4, 154] and COLOFOL [30] trials should contribute important data on the cancer-related outcomes of surveillance and will also report on health-related quality of life and the cost-effectiveness of intensive surveillance. For now, however, decisions must be based largely on clinicopathologic risk factors, preferences for intensity of testing, and willingness to pursue further investigation and active treatment for abnormalities detected by testing.

Colorectal Cancer: Management of Local Recurrence

Eric J. Dozois and Dorin T. Colibaseanu

Key Concepts

- Patients with colorectal cancer at the highest risk for local recurrence are those who present with obstruction or perforation, higher-stage disease, and adverse pathologic features, or undergo an operation that does not adhere to standard oncologic principles.
- The most significant predictor of survival following surgery for local recurrence is the ability to achieve a negative-margin (R0) resection.
- The probability of achieving an R0 resection is much greater in patients with recurrences involving an anastomosis or urogynecologic structures compared with those involving para-aortic tissue, sacrum, or lateral pelvic sidewall.
- A dedicated multidisciplinary team at an institution experienced in the management of patients with local colorectal cancer recurrence can facilitate complex surgical decision-making and greatly enhance patient outcomes.
- A multimodality approach that includes chemotherapy and radiotherapy improves local control and improves 5-year survival in patients with local recurrence.

Introduction

The medical and surgical management of colorectal cancer has a rich history, and treatment paradigms have evolved significantly over the last 100 years [1–6]. Major advances have been made in our understanding of tumor biology, the role of chemoradiotherapy, and most importantly, the significance of precise surgical technique. These advances have dramatically decreased local recurrence and increased 5-year survival in patients with primary colorectal cancer [1, 6–9]. Despite these advances, local recurrence following surgery remains a significant problem [4, 10–18]. In addition to its impact on survival, major morbidity from local recurrence can have a dramatic detrimental impact on quality of life [19–21].

In the United States, approximately 90,000 patients are diagnosed with colon cancer each year, and in those that undergo surgery, somewhere between 8 and 12 % will develop a local recurrence [22, 23]. Of the 40,000 patients diagnosed with rectal cancer each year, approximately 5–30 % will develop a local recurrence [24–28]. Patients with colorectal cancer at the highest risk for local recurrence are those that have higher-stage disease, high-grade tumors, and lymphovascular involvement or present with obstruction, perforation, or a locally advanced tumor at the time of presentation [29–34]. Operations done by noncolorectal-trained surgeons, or by surgeons who perform less than 20 rectal cancer resections per year, have been reported to have higher local recurrence rates [30]. Recently, the importance of a threatened or violated circumferential margin as an independent predictor of future recurrence has reinforced the importance of meticulous surgical technique [15, 35, 36]. All efforts to reduce the risk of local recurrence should be made when managing primary colorectal cancer, and the best results are achieved when patients are managed by experienced teams [37, 38].

When patients with colorectal cancer develop local recurrence, surgery offers the best opportunity for cure [15, 24, 39]. In the last 20 years, surgery for local recurrence has become safer, indications have expanded, and better results are being achieved leading to meaningful survival for many patients [17, 18, 40–42]. This chapter will review all aspects of management in patients with local recurrence as well as outcomes of surgery. Due to the complexity of medical and surgical decision-making, in addition to the surgical expertise required to perform these technically challenging operations, the treatment of patients with local recurrence should preferentially occur at centers that have a dedicated and experienced multidisciplinary team.

Preoperative Evaluation and Patient Selection

The majority of colorectal cancer relapses following surgery occur within 3 years of resection [7, 16, 26, 28, 43]. Most but not all patients will have symptoms from recurrent disease, and these will include pain, malaise, bleeding, and symptoms of partial obstruction [21]. In some patients, carcinoembryonic antigen (CEA) levels will be elevated, and this finding in the asymptomatic patient should trigger a workup for recurrence.

In patients with suspected local recurrence, every attempt should be made to obtain tissue for confirmation. Patients with luminal local recurrences can undergo endoscopy to obtain tissue. In patients with suspicious radiographic findings, obtaining tissue confirmation may be more challenging. Most patients with recurrent colon cancer will have obvious findings on imaging to confidently diagnose them with recurrence, and a transabdominal biopsy should be avoided. In contrast, every attempt should be made to obtain tissue confirmation in patients with suspected pelvic recurrence. One should be hesitant to undertake a major pelvic resection without tissue confirmation of recurrence. In our experience, computed tomography (CT)-guided percutaneous biopsy has been very useful to confirm or refute the presence of recurrence. In some cases, it may be very difficult to differentiate postoperative changes from recurrent tumor based on imaging alone. CT-guided percutaneous biopsy can confirm recurrence, but a negative result does not rule it out. In the absence of a tissue diagnosis, a rising CEA, with a notable change in the size of the lesion on serial imaging, and lesions that are positron emission tomography (PET) avid can be considered consistent with recurrent disease.

Patients with recurrent colorectal cancer being considered for curative-intent resection undergo imaging studies to assess the local-regional characteristics of the recurrence and to exclude metastatic disease [17, 18, 40]. Our protocol includes fusion PET-CT imaging of the chest, abdomen, and pelvis and magnetic resonance imaging (MRI) of the pelvis for recurrent rectal cancers. Several studies have confirmed that 18-fluorodeoxyglucose PET imaging has a high sensitivity for the detection of locoregional and distant recurrences in patients with colorectal cancer [44–46]. In the evaluation of 58 patients for advanced or recurrent colorectal cancer, Ogunbiyi et al. found that PET imaging had a sensitivity and specificity of 91 % and 100 %, respectively [47]. Chessin et al. showed that fusion imaging that combines CT and PET imaging has an enhanced sensitivity of 98 % as compared to 64 % with standard CT for the detection of rectal recurrence; in other studies, fusion imaging led to altered management in 58 % of patients [48, 49]. Moreover, PET retains its diagnostic ability even after irradiation, and because of this, we believe that all patients being considered for resection should undergo this study.

When seeing patients with local recurrence, it is important to obtain a complete history and physical examination. All records of previous treatments (surgical and chemoradiotherapy) should be reviewed. Pain and neurologic dysfunction may be a sign of advanced pelvic disease [15]. Bilateral lower extremity edema is an indicator of venous or lymphatic obstruction. A full colonoscopy should be done to rule out any synchronous lesions. If the rectum is intact, a digital rectal exam can assess the relationship of the recurrent cancer to the sphincter complex, prostate, or posterior vaginal wall. Cystoscopy may be useful to assess transmural invasion of the bladder.

Laboratory tests should be obtained by looking particularly for anemia and the nutritional state of the patient. The patient's albumin, prealbumin, and transferrin levels will give an idea of the protein reserves of the patient. If required, nutritional supplementation should be instituted to strengthen the immune system and optimize wound healing. A significantly elevated CEA should raise concern for occult metastatic disease [50].

Operations for local recurrence are often long and can be associated with significant blood loss, systemic inflammation, and tissue trauma, and the overall stress response associated with these big operations can pose significant risk to patients [51, 52]. Despite this, recent series have demonstrated a very low mortality following these major resections [17, 18, 40]. Patients with significant chronic obstructive pulmonary disease and cardiovascular conditions should be carefully evaluated and optimized preoperatively. Patients with ASA classifications of IV or V will be at the highest surgical risk and are generally not candidates for a major resection.

The decision to go ahead with a major, potentially morbid operation for local recurrence requires that the patient is fully informed regarding the risks and life-changing impact on quality of life. Ultimately, it should be the well-informed patient who decides what disability that might arise from surgery they are willing to live with. The likelihood of a stoma is high, and patients should be counseled by a stoma therapist preoperatively [53–55]. Patients undergoing multivisceral and musculoskeletal resections will require the most intense counseling regarding their postoperative recovery, limitations, and potential morbidity and mortality [14, 27, 42, 56].

The inclusion criteria for surgery in patients with recurrence have expanded significantly in the last 10 years [57]. In determining who should be offered surgery, one must consider the goals of the operation. If palliation is the goal, surgery must have a high probability of symptomatic relief and not be significantly morbid. If oncologic cure is the goal, the ability to confidently achieve a margin-negative (R0) resection must be highly probable. Based on multiple studies in patients with recurrent colorectal cancer, the number one determinant of oncologic benefit is the ability to achieve an

R0 resection. Multiple points of tumor fixation may limit the surgeon's ability to achieve an R0 resection, and this finding on evaluation has been associated with poor outcomes [15]. Patients operated for central recurrences that extend anteriorly (urogenital, gynecologic organs) have the best opportunity for an R0 resection and, therefore, good outcomes following surgery [15, 16, 58]. When a recurrence in the pelvis extends posteriorly to the sacrum or lateral to the pelvic sidewall, the ability to achieve an R0 resection becomes much less certain. In cases where there is significant lateral extension of the tumor, specifically through the sciatic notch, a positive margin is almost certain unless an extended resection such as a hemipelvectomy is done [41].

Contraindications to surgery will vary from institution to institution and from surgeon to surgeon. Local recurrences that involve major vascular structures, the high sacrum, or extensive pelvic sidewall disease were frequently listed in publications as contraindications to surgery in the past [16, 59, 60]. In the modern era, several well-recognized and respected centers have expanded their indications in light of increasing data demonstrating meaningful survival in patients undergoing extended resections [17, 18, 40, 42, 57]. In the author's view, contraindications to surgery should be based primarily on the inability to completely clear the tumor with the understanding that limited survival benefit is achieved if gross residual tumor remains.

Classification of Local Recurrence and Determining Resectability

Classification schemes for both recurrent colon cancer and rectal cancer have been proposed and are used not only to characterize patterns of recurrence but also to predict R0 resectability and oncologic outcomes [61].

Locoregional recurrence in patients with colon cancer can be classified as four distinct groups and include peri-anastomotic (mural disease), mesenteric (regional nodal disease), retroperitoneal or pelvic (drop metastases, distant nodal disease, or residual disease transmural disease), and peritoneal. In a study from the Memorial Sloan Kettering Cancer Center, Bowne et al. demonstrated that the most common site of recurrence was peri-anastomotic (36 %), followed by peritoneal (16 %), mesenteric (15 %), and retroperitoneal (12 %) [62]. In our experience, some cases of recurrence were directly attributed to inadequate mesenteric resections at the time of original surgery. However, most nodal-based relapses were found at nodal sites (iliac, para-aortic) not typically removed during standard oncologic resection [63].

Pelvic recurrences can be broadly categorized in terms of what resection would be necessary for complete tumor removal. With this in mind, the authors have generally classified recurrences as those requiring an anterior, posterior, lateral, or combined resection (Figure 35-1). In anterior resections, the rectum and urogynecologic structures are removed. A posterior resection involves removing the rectum and a portion of the sacrum. A lateral resection involves removal of the rectum and iliac vessels and/or components of the lumbosacral plexus. The term "combined resection" or "composite resection" includes any combination of anterior, posterior, or lateral structures.

For recurrent colon cancer, CT imaging is our study of choice to make decisions regarding resectability. For recurrent rectal cancer, MRI of the pelvis is our study of choice to assess neuromuscular and bony involvement and for surgical planning. We use a musculoskeletal protocol that is done with and without gadolinium and includes sagittal, axial, and coronal oblique views (Figure 35-2). MRI has highly detailed soft-tissue resolution, which is helpful in planning lines of resection as it pertains to adjacent structures. Specifically, for tumors with posterior and lateral extension, MRI can determine proximal sacral extent, involvement of lumbosacral nerves, and whether or not a margin can be obtained on the lateral pelvic sidewall. Computerized tomography or MR angiogram or venogram may add additional information regarding vascular involvement and indicate the need for a vascular surgeon to be a member of the multidisciplinary surgical team.

A major challenge from a surgical planning perspective in many cases of local recurrence is the fact that the borders of recurrences can be indiscrete and ill defined on imaging. Recurrences may be infiltrative and sheetlike and sometimes have islands of intervening normal tissue. This makes it difficult to preoperatively determine where the "true margins" are. Because of this, one must be prepared to alter the surgical plan intraoperatively as findings may differ significantly from what the preoperative imaging suggested. Intraoperative frozen section pathologic analysis can be very useful to ensure that further resection can be done if there is a persistent microscopic margin discovered at the time of surgery.

Another challenge in management of local recurrence is differentiating both postoperative and radiation-induced fibrosis from actual tumor. MRI with T2-weighted imaging can assist because fibrosis and tumor demonstrate different signal intensities [64]. Gadolinium-enhanced MRI is reported to have an 88 % and 95 % sensitivity and specificity, for the detection of pelvic recurrences in the setting of previous surgery and radiation [65].

Multimodal Therapy Including Intraoperative Radiation

Multimodal therapy in the management of locally recurrent colorectal cancer refers to a treatment approach that includes pre- and postoperative systemic chemotherapy, preoperative external beam radiotherapy (EBRT), and, in some protocols, intraoperative radiation therapy (IORT). The authors have used this approach very selectively in patients with recurrent

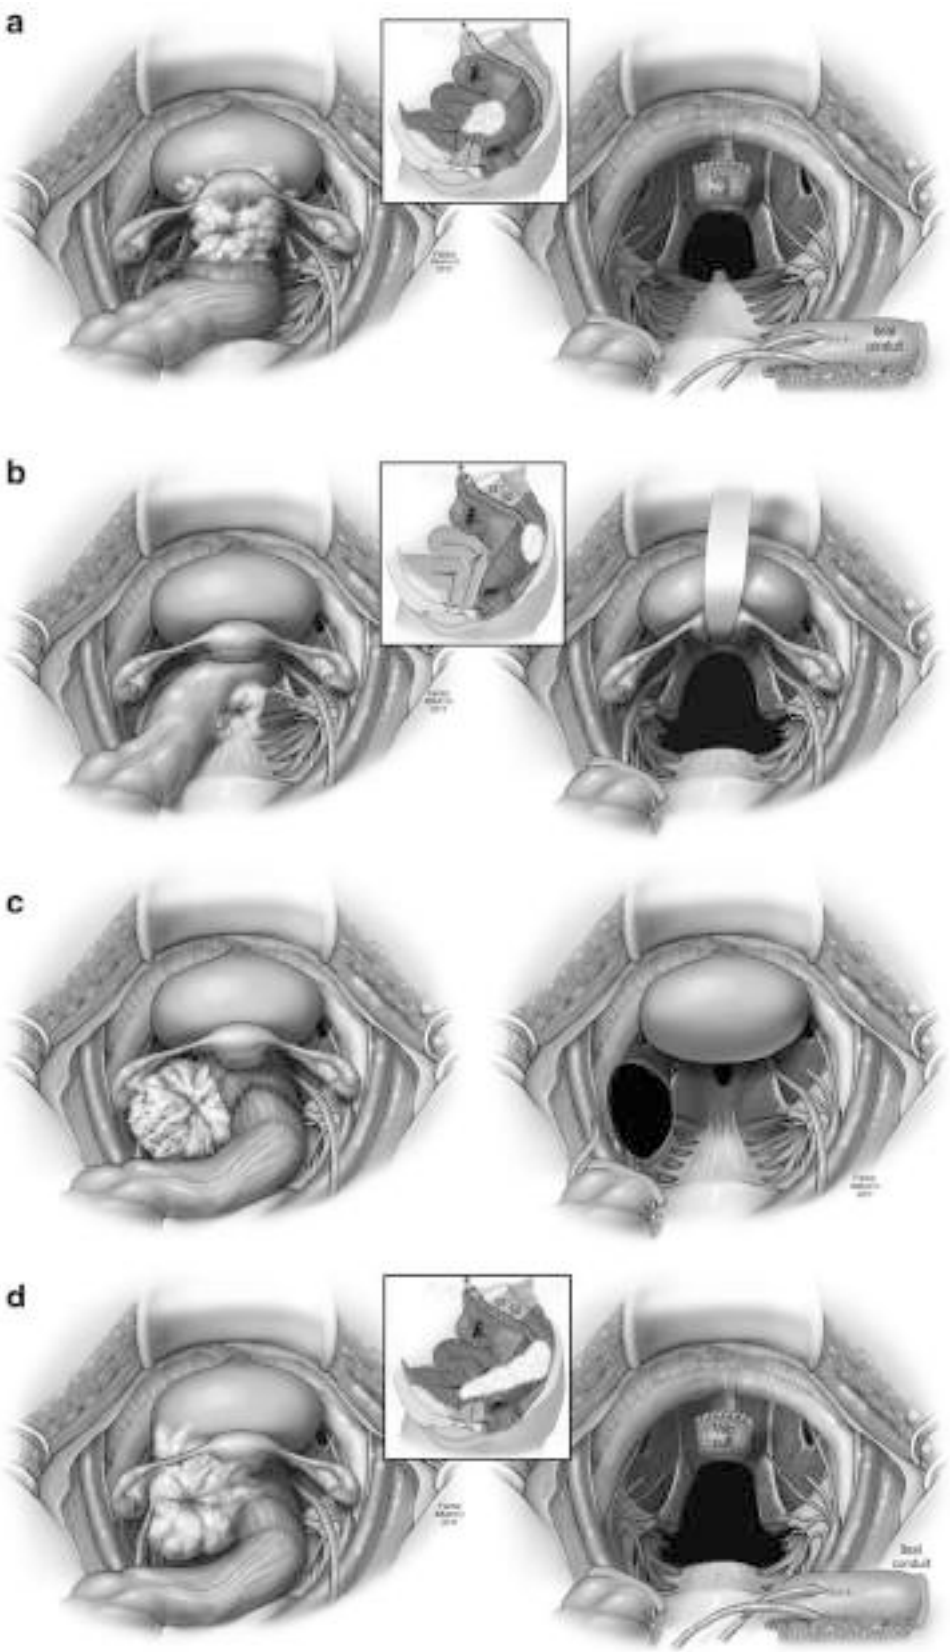

FIGURE 35-1. Classification of recurrence. (**a**) *Anterior*: involves structures anterior to the neorectum. (**b**) *Posterior*: involves structures posterior to the neorectum. (**c**) *Lateral*: involves pelvic sidewall and associated structures. (**d**) *Combined anterior-posterior*: tumor includes anterior and posterior structures.

colon cancer and in almost all cases of recurrent rectal cancer. In patients with locally recurrent colon cancer, there is usually less concern about the ability to get a wide surgical resection unless tumor abuts fixed critical structures (e.g., lumbar spine, aorta, vena cava). In these cases, we will employ a full multimodality approach that included IORT [63]. Since 1981, curative-intent therapy at our institution has included IORT for locally advanced and locally recurrent rectal cancer. Our protocol includes neoadjuvant chemotherapy and EBRT, IORT, and postoperative chemotherapy [13, 21, 66]. Patients who are radiation naïve receive 50.4 Gy of EBRT with concurrent five FU-based chemotherapies over 5 weeks followed by a 6–8-week recovery period before surgery. In patients who have received previous irradiation, we give 20–30 Gy with concurrent five FU-based chemotherapies, over a 3-week period followed by surgery within 7 days of the last dose of radiation. The amount of radiation given intraoperatively to the tumor resection bed depends on the margin status at the time of resection. For wide margins (500–750 cGy), R1 (1000–1250 cGy), <2 cm of gross residual (1500 cGy) and for >2 cm gross residual (1750–2000 cGy) [66]. Given that distant relapse of disease is the most common cause of death following surgery for local recurrence, systemic chemotherapy is part of our multimodality protocol. In a series of 607 patients with locally recurrent colorectal cancer treated at our institution with a multimodality approach that included IORT, the cumulative incidence of distant relapse was 53 % at 5 years. Distant relapse was less common in patients who had R0 vs. R1 or R2 resections and in those treated with postoperative chemotherapy [66]. Significant advances in chemotherapeutic regimens over the last 20 years have likely decreased the incidence of distant failures following surgery for local recurrence, but the optimal regimen and length of treatment are still debated.

Though there is a paucity of randomized data, many authors agree that a multimodality approach can significantly decrease local relapse and improve 5-year survival in

colorectal cancer patients with local recurrence [15, 67, 68]. Several centers have shown good results with the use of IORT in patients with recurrent colorectal cancer, and 5-year survival rates range from 29 to 60 % in patients undergoing R0 resection (Table 35-1). Five-year survival rates after IORT in patients having R1 or R2 resection can be as high as 16 % and 27 %, respectively (Table 35-2). In most series where IORT is not included in the management of patients who had an R2 resection, no long-term survival is seen [66].

Radiation-induced toxicity is a significant concern in patients receiving multimodality therapy that includes IORT. In many cases, it may be hard to separate IORT-related complications from surgical ones. In a published series of 607 patients from our institution with recurrent colorectal cancer treated with EBRT and IORT, we attributed radiation specifically as the cause for some septic complications (wound related, enterocutaneous fistulas), small bowel and ureteral obstructions, as well as neuropathy [66]. Both the incidence and severity of neuropathy were related to IORT dose. Doses that exceeded 12.5 Gy were associated with a higher rate and severity. In total, 15 % of patients experienced some grade of neuropathy, with only 3 % of patients suffering from grade 3 neuropathy defined as severe weakness or intractable pain.

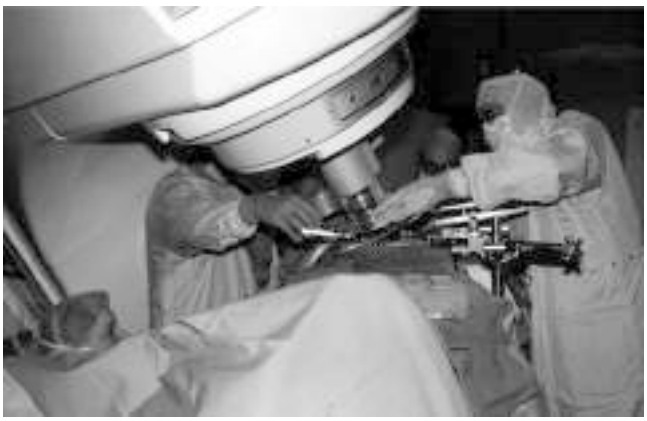

FIGURE 35-3. The IORT suite; the operating table is positioned under the linear accelerator by the radiation oncologist and the appropriate Lucite cone is affixed to direct the beam.

Technical Aspects of Surgical Resection

General Considerations

We use ureteral stents for all operations in patients with local recurrence in the pelvis. The Lloyd-Davies position is used to allow access to the perineum. Care is taken to protect the extremities from nerve injury with adequate padding of both the tucked arms and lateral lower extremities in the stirrups. An exploratory laparotomy is carried out through a midline incision to confirm absence of extra-pelvic disease and determine local resectability. Any lesions suspicious for metastatic disease are biopsied and sent for frozen section analysis. The presence of metastatic disease typically precludes resection for cure, and proceeding on to resection of the local recurrence has to be weighed carefully. All adherent tissue to the recurrence tumor should be resected en bloc. In general, the technical approach to local recurrence in the abdomen or in the pelvis is carried out by widely mobilizing normal surrounding tissues and organs in preserved embryologic planes when feasible and working toward the distorted anatomy and malignant pathology. This allows exposure of structures that are close to the recurrence but will be preserved if not invaded. In addition, vascular pedicles and collateral vasculature should be well delineated prior to ultimate mobilization of the recurrence and surrounding adherent tissue or organs, so that when significant bleeding is encountered, proximal and distal vascular control can be achieved safely.

Most cases for recurrence at our institution are done in a dedicated IORT operating room. This suite houses our linear accelerator and mobile anesthesia equipment that allows the patient to move into the optimal position for IORT (Figure 35-3). The radiation dose and field are selected based on tumor margin status. At our institution, Lucite cones are used to focus the beam of radiation delivered by the linear accelerator and protect the small bowel and other organs from radiation injury (Figure 35-4). The radiation oncologist and surgeon position the cone together for optimal radiation delivery.

Recurrent Colon Cancer

As previously stated, local recurrence in patients with colon cancer typically occurs in one of three patterns, luminal, locoregional, or para-aortic lymphatics, and in the resection bed of the previous index colectomy. Luminal and locoregional nodal recurrences are generally straightforward technically, and surgery involves resection of additional colon and adjacent mesentery. During operations in patients with retained mesentery from incomplete previous surgery, it is the author's experience that isolation and ligation of the vascular pedicles of the original tumor (that should have been removed during the index operation) is a good initial step to allow safe mobilization of the recurrence that lies within the retained mesentery. In cases where para-aortic or para-iliac nodes are involved, major vascular reconstruction may be necessary in addition to en bloc resection of surrounding structures (Figure 35-5) [69].

In cases where recurrence occurs in the previous resection bed, locoregional structures associated with the course of the colon are often involved (kidney, ureters, psoas muscle, stomach, spleen, duodenum, and pancreas). The most complex resections done for local recurrence after right colon resection are those that involve the duodenum and the head of the pancreas. When a Whipple operation is required, we involve a hepatobiliary surgeon to assist with resection and reconstruction. In cases where IORT will be used, radiation is delivered to the at-risk tumor bed just prior to closure.

Recurrent Rectal Cancer

Recurrences That Extend Anteriorly

After ruling out metastatic disease, the left colon is fully mobilized and transected at the appropriate level for subsequent end colostomy (in patients who have intestinal continuity). The entrance to the pelvis is cleared of loops of small bowel for optimal pelvic exposure. Dissection begins in the lower abdomen before entering the presacral space along the lower aorta and continues distally over the iliac vessels and ureters. Vasiloops are used to retract the ureters and vascular structures. In the re-operative pelvis, dense fibrosis and distorted anatomy require careful, meticulous dissection to avoid inadvertent injuries and major bleeding complications. In the author's experience, the most at-risk region for significant bleeding occurs during mobilization of the left common iliac vein, and this dissection should proceed with caution. Posterior lumbar branches, if not identified and injured, can lead to significant blood loss if avulsed.

The anterior and lateral lines of resection (decided upon during preoperative review of imaging) are delineated and confirmed, and the involved structures and organs are mobilized widely for subsequent en bloc resection. The presacral space is further developed, and the dissection is

carried down along the anterior sacrum being careful to stay anterior to Waldeyer's fascia to avoid the presacral venous plexus. The dissection is then carried laterally along the pelvic sidewall on each side with careful protection of the lumbosacral plexus and internal iliac vessels. The deepest part of the pelvic dissection will be the pelvic floor musculature, which can be incised during the abdominal portion of the procedure. When the transabdominal portion reaches this point, a combined transperineal approach facilitates final tumor removal. The transperineal portion begins with purse-string closure of the anus (if present), and then a wide, elliptical incision is made to include the sphincter complex and as much pelvic floor musculature as possible. With a surgeon working above, the two dissection planes can be joined safely and with careful attention to the tumor margins.

In women, anterior involvement may require resection of the posterior wall of vagina, and this portion of the operation is approached transvaginally and transabdominally simultaneously. In men, anterior fixation often requires cystoprostatectomy due to invasion of the trigone and prostate. Partial cystectomy may be sufficient in rare cases. When a urinary conduit is necessary, the ureters are mobilized as close to the bladder as possible to provide adequate length to reach the conduit. To mobilize the bladder, the space of Retzius is entered to fully mobilize the anterior portion of the bladder. The blood supply to the bladder (superior and inferior pedicles) is taken serially along the pelvic sidewall off the internal iliac vessels. The wings of peritoneum to the bladder are then taken down until the bilateral vasa are identified and clipped. The endopelvic fascia is opened bilaterally. The dorsal venous complex is subsequently ligated. The urethra is then delivered into the wound and transected.

Once the tumor is out, the surgeon orients the specimen for the pathologist and frozen section margins are assessed. If margins are not clear, further resection is undertaken when safe to achieve an R0 resection. At this point, IORT is given to the at-risk resection bed. Creation of end colostomy and urinary conduit completes the procedure. In women in whom a large portion of the posterior vaginal wall is removed, a vertical rectus abdominis flap (VRAM) is used for vaginal reconstruction.

Resection That Includes Sacrectomy

Stage I: Anterior Component

This dissection begins as outlined above for anterior recurrences. Once the deep pelvic portion of the operation begins, the anterior, lateral, and superior (along the spine) lines of resection are delineated, and the involved neuromuscular structures and organs are mobilized widely for subsequent en bloc resection. Frozen section biopsies are taken as needed to establish that final margins will be negative.

Vascular exposure often requires mobilization of the lower aorta and vena cava, in addition to the iliac arteries and veins. If vascular structures need to be resected en bloc with the tumor, the decision to do so is made here. If the resection does not require aortoiliac reconstruction, circumferential mobilization of the common and external iliac arteries will facilitate exposure of the veins. The internal iliac artery branches are ligated and divided first, distal to the takeoff of the posterior division superior gluteal artery branch, to preserve blood flow to the gluteal muscles and soft tissue of the perineum. Multiple internal iliac vein branches are then ligated after control of the main trunk(s) of the internal iliac vein has been achieved. The branches are ligated and divided before ligation of the main trunk to avoid venous distention of the branches, which can lead to troublesome bleeding (Figure 35-6). Lateral and middle sacral vein branches, which drain into the posterior aspect of the left common iliac vein and caval confluence, are ligated and divided. Suture ligature is preferable for short, broad-based internal iliac vein branches. The vascular dissection is carried along both sides of the sacrum onto the pelvic floor. In general, the internal iliac vessels are taken at their confluence as part of any sacrectomy above the third sacral body. For sacrectomy at or below the third sacral body, we generally preserve the internal iliac vessels.

Once the most proximal lumbosacral level of transection is determined, unicortical anterior osteotomies are performed at the bony level of resection (Figure 35-7). Prior to closing the abdomen, a thick Silastic mesh is placed anterior to the sacrum and posterior to the ureters, aorta, iliac vessels, and soft-tissue structures to protect against injury when blind osteotomies are performed during the second stage of the procedure, at which point the patient is in prone position. A titanium screw is also placed at the level of the osteotomy site to facilitate performing the posterior osteotomies by using intraoperative fluoroscopy (Figure 35-8).

During the anterior stage of the operation, IORT may be delivered prior to final tumor resection if orientation of the Lucite cone in the prone position will not be feasible to radiate the at-risk tumor bed. A colostomy and ileal or colonic urinary conduit are fashioned as needed, and a VRAM flap is then elevated for subsequent perineal reconstruction.

Stage II: Posterior Component

The second stage of the procedure is typically carried out 2 days after the anterior portion. With the patient in the prone position, a posterior midline incision is made along the middle

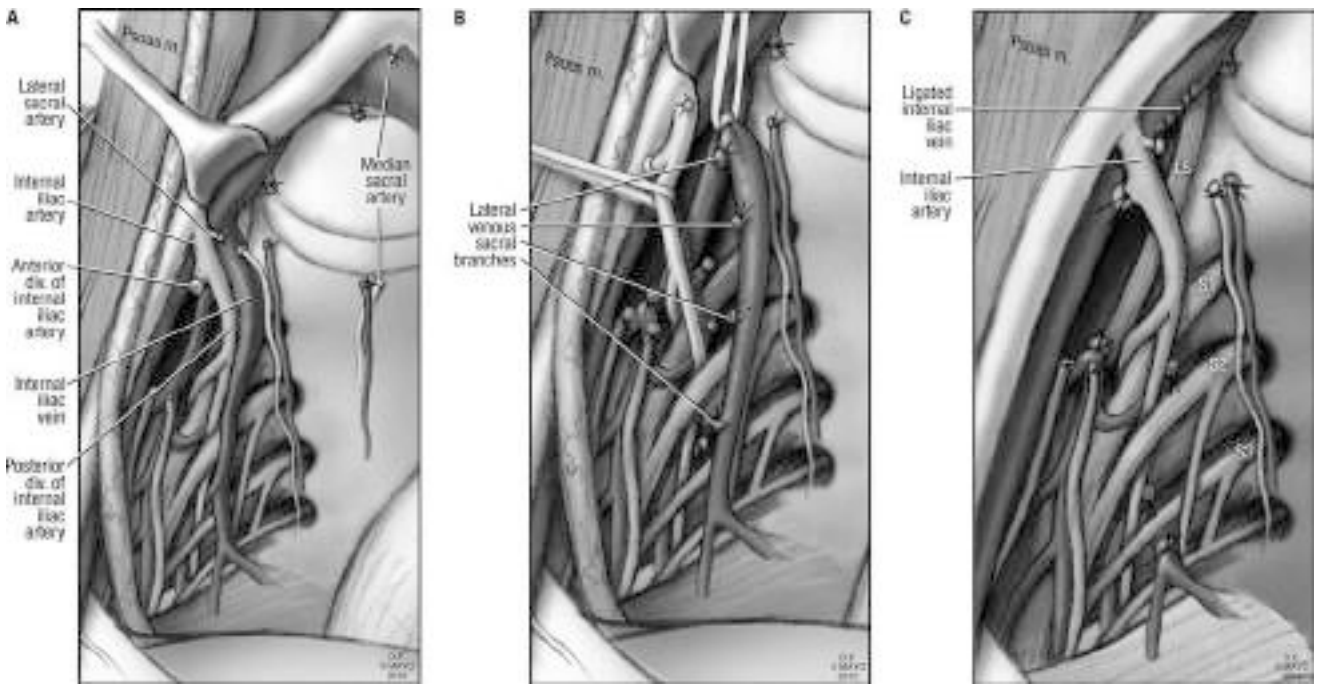

FIGURE 35-6. (**a**) Pelvic vascular anatomy. Ligation of anterior division of internal iliac artery, lateral sacral arteries and veins, and sacral artery and vein. (**b**) Ligation of lateral venous sacral branches. (**c**) Ligation of internal iliac vein.

portion of the sacrum, and the gluteus maximus muscles are dissected away from the sacral attachments. The sacrospinous and sacrotuberous ligaments are divided to access the pelvic cavity posteriorly. The piriformis muscles are divided while protecting the sciatic and pudendal nerves. Laminectomy, dural sac ligation, and posterior sacral osteotomies are then carried out (Figure 35-9). Final osteotomies are performed based on the preoperative MRI imaging studies and intraoperative fluoroscopy to identify the anterior positioned titanium screw. After resection, the surgical team meets with the pathologist to accurately orient the specimen, and together they assess the completeness of resection. If frozen section analysis demonstrates an R1 or R2 margin, wider resection is undertaken as it can be done safely. Before soft-tissue wound reconstruction is done, IORT is given (if not given during stage I) and the dose is based on tumor margin status, as discussed above.

Stage III: Spinal Reconstructive Component

In cases where the lumbosacral line is transected, spinopelvic stability is compromised and patients will require instrumented reconstruction. For resections above the level of the S1 neuroforamen but below the lumbosacral junction, clinical experience and biomechanical studies have shown that in situ spinopelvic stabilization is beneficial to avoid collapse of the residual sacrum [70]. In these cases, an instrumented posterior spinopelvic fusion is made from the lower lumbar spine to the remaining pelvis.

Resections done through the lumbosacral junction, or higher, disrupt spinopelvic continuity. These patients undergo reconstruction using a combination of dual fibula grafts and instrumented stabilization from the lower lumbar spine to the remaining pelvis (Figure 35-10) [71]. The decision to use fibula allo- or autografts is individualized.

A concurrent hemipelvectomy is considered if the local extent of disease leads to sacrifice of both the femoral nerve and the lumbosacral plexus/sciatic nerve or the hip joint and the femoral or sciatic nerves. Resections of this magnitude would otherwise leave a nonfunctional limb. In addition, patients will have such a large soft-tissue defect that a pedicled quadriceps apron flap is necessary for closure. In these cases, the fibula from the amputated limb can be preserved on a pedicle at the end of the quadriceps flap for reconstruction. This is then used to restore spinopelvic continuity.

Soft-Tissue Reconstruction

Nonhealing perineal wounds following an abdominal perineal approach to complex pelvic tumors are reported to occur in 7–66 % of patients [72]. We, as well as others, have found that the use of a VRAM flap is associated with fewer perineal wound complications [72, 73]. The VRAM provides a well-vascularized, bulky tissue paddle that not only fills dead space but also can be used to reconstruct the perineal skin defect. Our technique is described elsewhere, but in essence, the VRAM is mobilized en bloc with the overlying fat and

FIGURE 35-10. Intraoperative photograph of fibula grafts and instrumented spinopelvic reconstruction following total sacrectomy.

skin [74]. Particular attention is paid to the blood supply, especially the deep inferior epigastric artery and vein. Once mobilized, it is rotated transabdominally in the perineum keeping the overlying skin and fat intact, which helps bridge the significant defects that these resections leave behind. In cases where the rectus is not available, a pedicled omental flap can be a good second choice if it is robust. It can fill the pelvic dead space providing vascularized tissue and has been shown to decrease risk of pelvic sepsis following surgery [75]. Moreover, the omentum can line the raw surfaces of the pelvis, preventing the small bowel from getting trapped in the deep pelvis, which is a common cause of small bowel obstruction following exenteration.

Thigh fillet flaps are used after hindquarter amputation and are based on the superior and inferior gluteal vessels. This flap allows one to take advantage of the bulky gluteal muscle, which can cover large defects after the ipsilateral pelvis has been resected. Long anterior hemipelvectomy flaps are based on the vascular muscle distribution supplied by the superficial femoral artery. This flap includes the bulk of the quadriceps femoris and—like the posterior hemipelvectomy flap—can provide significant coverage of very large pelvic and soft-tissue defects.

Results of Surgery

Recurrent Colon Cancer

Limited data exists on surgical and oncologic outcomes in patients with locally advanced recurrent colon cancer. Few centers have published their experience, and patient groups are small and heterogeneous, making definitive conclusions regarding management difficult. In a series from the Mayo Clinic, 73 patients underwent a multimodality approach that included IORT for recurrent colon cancer [63]. In this cohort, an R0 resection was achieved in 52 % and led to a 5-year survival of 37 %. In a series from Leeds, Harji et al. reported on 42 patients with recurrent colon cancer [76]. An R0 resection was achieved in 64 %, and mean survival did not differ between R0 vs. R1 resected patients (29 months vs. 26 months). Survival outcomes were dependent on location of recurrence, and median survival after resection was 33 months for anastomotic, 26 months for pelvic, and 19 months for abdominal recurrences. In the largest series published, Bowne et al. from the Memorial Sloan Kettering Cancer Center reported on 100 patients operated on for curative-intent resection for locally recurrent colon cancer [62]. Fourteen patients were found to have unresectable disease at the time of surgery and 65 % had an R0 resection. Multivisceral resection was common, and the best oncologic outcomes were achieved in patients undergoing R0 resection. Actuarial 5-year survival was 35 % for their entire cohort but was 58 % in those undergoing R0 resection.

In all three of these series, surgery could be performed safely, but multivisceral en bloc resection was required in many patients in attempts to reach a negative-margin resection. Margin status and location of recurrence appear to be the most important predictors of outcome in patients with recurrent colon cancer.

Recurrent Rectal Cancer

In the past, published series of surgery for locally recurrent rectal cancer were limited by small numbers and heterogeneous patient groups. In 2015, we now have robust data that confirms that an R0 resection, the ultimate goal for these operations, is achievable in 70–93 % [17, 18, 42] and overall 5-year survival can be as high as 40 %. Moreover, in series published where IORT is a component of multimodality therapy, meaningful survival can also be achieved in patients who have R1 or R2 resections [40]. Aggressive surgery that includes more lateral pelvic resections (pelvic sidewall tumors) and higher sacral resection (above the third sacral body) is increasingly reported by experienced centers with good results [17, 18, 56, 57].

In a Mayo Clinic series, Hahnloser et al. reported outcomes in 394 patients that underwent a curative-intent resection for locally recurrent cancer [15]. Operative mortality was 0.3 % (1 patient with uncontrolled hemorrhage), and significant morbidities were seen in 26 % of patients (most common was pelvic sepsis). Margin status for this cohort was R0 (45 %), R1 (9 %), and R2 (46 %). Survival was clearly impacted by margin status, 37 % for R0 and 16 % for R1/R2 patients. Other significant findings in this study were that symptomatic pain at presentation and >1 fixation point of the recurrence was associated with margin-positive resection and therefore a poor outcome. Patient demographics, factors related to the initial rectal cancer, and extended vs. limited resection did not impact overall oncologic outcomes. In a series from the Leeds General Infirmary, Boyle et al. reviewed outcomes in 64 patients with locally recurrent rec-

tal cancer, 57 of which underwent curative-intent resection [39]. Pelvic exenteration or sacrectomy was required in 32 %. An R0 resection was achieved in 37 %, perioperative mortality was 1.6 %, and morbidity was 40 %. Overall median survival was 34 months, and R0 resected patients had a significantly longer survival compared to R1 or R2 patients (median survival for R2 was 8 months). In a recent report from Denmark, Nielsen et al. published results on early and late outcomes of surgery for locally recurrent rectal cancer [77]. In their series, 115 patients underwent curative-intent resection. 30-day mortality was 0.8 % and an R0 resection was achieved in 61 %. The 3- and 5-year survival rates for R0 resections were 55 % and 42 %, respectively. No patients with R2 resection lived past 3 years.

Local excision for early rectal cancers has gained wider acceptance in the last 10 years [78]. The risk of local recurrence following local excision remains elevated, especially for high-risk T1 and T2 cancers. When local recurrence occurs following local excision, surgical salvage is the only treatment that has the potential to achieve meaningful survival. In a recent report, Bikhchandani et al. found that R0 resection was possible in 93 % and 5-year survival rate and DFS were 50 % and 47 %, respectively [79]. Metastatic disease following salvage surgery was the most common cause of death in this cohort. You et al. from the MD Anderson Cancer Center reported on 40 patients undergoing surgical salvage following local excision for rectal cancer [80]. A multimodality approach was used and R0 resection was achieved in 80 %. Multivisceral resection was required in 33 % and perioperative morbidity was 50 %. The 5-year overall and 3-year recurrence-free survival was 63 % and 43 %. Pathological stage at initial local excision, receipt of neoadjuvant chemoradiotherapy before local excision, pathological stage at salvage, and R0 resection at salvage significantly influenced re-recurrence-free survival.

The importance of an R0 resection in patients undergoing surgery for recurrent rectal cancer cannot be overstated. A recent meta-analysis of survival based on resection margin status following surgery for recurrent rectal cancer was published by Bhangu and colleagues [81]. In their analysis, they reviewed 22 studies that included 1460 patients and found that 57 % underwent R0 resection, 25 % R1, and 11 % R2. The range of median survival was 28–92 months for R0 resections, 12–50 months for R1, and 6–17 months for R2. Patients undergoing an R0 resection survived on average for 28 months longer than those undergoing R1 resection and 53 months longer than those undergoing R2 resection.

Surgery for Re-recurrent Disease

In the author's view, a second colorectal cancer recurrence is not a contraindication to curative resection as long as the principles of determining resectability for primary recurrence are followed. In a study by Colibaseanu et al., 47 patients underwent surgery for locally re-recurrent colorectal cancer [40]. An R0 resection was achieved in 60 % and 30-day mortality was nil. Overall 2- and 5-year survival was 83 and 33 %. Disease-free survival at 2 and 5 years was 55 and 27 %. In another study by Harji et al., 30 patients underwent resection for a second-time locally recurrent rectal cancer [82]. In their series, an R0 resection was achieved in 30 %, and they achieved a 1- and 3-year survival rate of 77 % and 27 %, respectively. It was the conclusion of both studies that in patients where R0 resection was possible, surgical resection for re-recurrent colorectal cancer had comparable oncologic outcomes than those patients undergoing surgery for first-time recurrences.

Resection That Includes the Aortoiliac Axis

The safety and feasibility of aortoiliac axis reconstruction in the course of complex tumor resections has been well described [83]. Small series have been published that specifically evaluate outcomes following resection in patients with locally recurrent colorectal cancers that involve the aortoiliac axis. In a study by Abdelsattar et al., 12 patients underwent major vessel resection that included the internal and external iliac arteries and veins and in some cases the aorta [69]. An R0 resection was achieved in 7 patients and R1 in 5. No graft complications were seen in long-term follow-up and 30-day mortality was nil. Overall survival and DFS at 4 years were 55 and 45 %. In another study by Austin et al., en bloc vascular resection was done as part of pelvic exenteration for pelvic malignancies in 36 patients (69 % were rectal cancers) [84]. An R0 resection was achieved in 60 % of the locally advanced primary and recurrent rectal cancer cases. For the overall cohort, 46 % of patients were disease-free with the average disease-free interval being 30 months. Both studies concluded that despite the complexity of the technique, the surgery can be performed safely when done by expert multidisciplinary teams, and overall survival and DFS are comparable to outcomes seen with locally advanced disease to nonvascular structures.

Sacropelvic Resections

Owing to the complex anatomical relationships of the pelvic structures, some local recurrences involve multiple fixation points and will require both multivisceral and neuromusculoskeletal resection to achieve a negative-margin resection. Operations for recurrences involving the lateral pelvic sidewall or high lumbosacral skeletal components are among the most technically challenging to perform. In the past, limited data existed regarding both the safety and the oncologic benefits of surgery in these patients. Once thought to be a common contraindication to surgery for recurrent colorectal cancer, high sacral and other complex sacropelvic resections are being done by an increasing number of centers around the world [57]. In most recent series from

specialized centers, authors have shown that surgery in these complex patients can be done safely and with meaningful oncologic outcomes.

In a small series of 9 patients who had sacral resection at the level of the second sacral body or higher (up to fifth lumbar space), Dozois et al. reported an R0 rate of 100 %, no 30-day mortality, and an overall median survival of 31 months [41]. Three patients were long-term survivors at 40, 76, and 101 months. In another study from the same institution, Colibaseanu et al. reviewed 30 patients that had undergone curative-intent extended sacropelvic resections [17]. Four patients in this series underwent hindquarter amputations and over 50 % had sacral resections above the third sacral body. There were no 30-day mortalities and R0 resection was achieved in 93 %. Overall survival and DFS at 2 and 5 years were 79 and 43 %. Overall survival in this series was not different in patients undergoing high (>3rd sacral body) vs. low sacral resection.

In a study from the Royal Prince Alfred Hospital in Sydney, Australia, Milne et al. reported on 100 patients undergoing sacropelvic resection for advanced pelvic malignancies, of which 18 were primary rectal cancers and 61 were recurrent rectal cancers [18]. In the entire cohort, an R0 resection was achieved in 72 %, no 30-day mortality was seen, and overall survival and DFS were 38 % and 30 %, respectively. In a study by Sagar et al. from the Leeds General Infirmary, 40 patients underwent composite sacropelvic resection [56]. An R0 resection was achieved in 50 %, and the mean disease-free interval was 55.6 months for R0 and 32 months for R2 patients.

Postoperative Complications and Quality of Life

Despite the complex nature and magnitude of surgery for local recurrence, several recent series have demonstrated that these cases can be done with an operative mortality rate that ranges from 0 to 3 % [17, 18, 40, 42]. When it does occur, 30-day mortality is usually a result of uncontrolled sepsis. This is a dramatic improvement compared to series published 20 years ago, where operative mortality could be as high as 8.5 % [14]. Several factors are responsible for the significant decrease in operative mortality, better patient selection, improved surgical technique by experienced specialists, better anesthesia, and better postoperative ICU management.

Early and late complications following surgery for local recurrence remain a significant challenge. Most series report intra-abdominal/pelvic sepsis and wound-related complications as the most significant causes of morbidity [17, 18, 56, 60, 67, 85]. Other common complications are postoperative bleeding requiring transfusion, voiding dysfunction, prolonged ileus, delayed small bowel perforation, and late fistulas. Universally, higher complications are associated with extended resections such a sacrectomy and exenteration [15, 17]. Urologic complications both early (ureteral obstruction, leak) and late (ureteral stricture) are reported in many series. In a study by Rahbari et al., risk factors associated with postoperative complications were analyzed [86]. In their series, 92 patients underwent curative-intent surgery for recurrent rectal cancer. To identify predictors of complications after resection, univariate and multivariate analysis was done. On univariate analysis, partial sacrectomy ($p=0.0001$), intraoperative blood loss ($p=0.005$), amount of transfusion ($p=0.02$), and operating time ($p=0.006$) were associated significantly with surgical complications. Multivariate logistic regression analysis of ASA score, BMI, partial sacrectomy (yes or no), blood loss, operating time, and the use of IORT (yes or no) revealed that partial sacrectomy is the only independent predictor of surgical morbidity. It is the author's perspective that careful surgical planning, reducing blood loss, reducing operating time, and the judicious use of soft-tissue flaps can significantly decrease postoperative morbidity.

Little information exists about the impact of major surgical intervention on quality of life in patients with recurrent colorectal cancer. While oncologic outcomes remain the most important outcome measure for patients and physicians deciding on an aggressive surgical approach, quality of life after surgery must be considered and discussed with patients so that they are well informed. In the modern era, advances in surgical technique and expertise allow surgeons to perform increasingly more complex operations, and how these operations impact quality of life is a relevant and growing area of interest to both patients and surgeons.

In a study by Austin and colleagues at the Royal Prince Alfred Hospital in Sydney, Australia, quality of life in 75 patients undergoing pelvic exenteration for advanced rectal cancer was assessed using the Short Form 36 version 2 (SF-36v2) and Functional Assessment of Cancer Therapy-Colorectal (FACT-C) instruments [87]. They found that FACT-C scores in survivors were good and comparable to those of patients who had low anterior resections or abdominal perineal resections. Though the summary scale of the SF-36v2 form was lower in exenteration patients than the general Australian population, the mental component summary scale was high and comparable. In a systematic review of health-related quality of life (HRQoL) in patients with locally recurrent rectal cancer, Harji et al. reviewed a total of 14 studies compromising 501 patients [88]. This study (the first published study to focus exclusively on HRQoL in patients with locally recurrent rectal cancer) identified several consistent themes. There are few studies of variable quality, reporting on a large number of HRQoL domains. Moreover, the heterogeneous treatment approach and patient population make study comparisons difficult. Harji and colleagues conclude that a disease-specific, validated, and reliable outcome measures are both lacking and required to provide meaningful data in patients who undergo surgery for locally recurrent rectal cancer. This tool, once developed,

could then be used to prospectively measure HRQoL. This data would be very useful in assisting in surgical decision-making for both the physician and the patient.

Palliative Approach

Patients with an asymptomatic recurrence which is unresectable, either due to the presence of concurrent metastases or because of local factors, do not warrant surgical intervention [89]. In symptomatic patients, EBRT can sometimes relieve obstruction, decrease bleeding, and reduce pain [90]. Endoscopic stenting is especially helpful with malignant obstructions and can in some cases be used to palliate malignant fistulas that are inoperable [91, 92]. Patients not candidates for stents may need a colostomy for symptomatic relief.

Chemotherapy has been shown to prolong survival and palliate symptoms in patients with primary metastatic colorectal cancer, and in large, the treatment of unresectable recurrent colorectal cancer is based on extrapolations from this data. FOLFOX and FOLFIRI are the most commonly used chemotherapy protocols in patients with unresectable metastatic disease. The three most prominent trials comparing the two regimens did not distinguish which is superior, though both regimens prolong survival [93–95]. Newer agents such as bevacizumab, cetuximab, and panitumumab have and continue to be studied as monotherapy or as part of multidrug regimens [96–98].

Patients in whom a palliative approach is taken will benefit greatly by meeting with a palliative medicine team to discuss treatment goals and assist with end-of-life decisions. In addition, a cancer pain specialist can assist in reducing suffering through optimal pain management, and this should be the goal in patients undergoing a palliative approach.

Colorectal Cancer: Management of Stage IV Disease

Glenn T. Ault and Kyle G. Cologne

Key Concepts

- Multidisciplinary evaluation is of paramount importance in the treatment of metastatic colorectal cancer.
- Positron emission tomography (PET) scan should be used in the evaluation of metastatic disease prior to potentially curative surgical therapy, or in cases of equivocal disease, but not for routine detection of metastatic disease.
- Patients with incurable metastatic disease and asymptomatic primary tumors should be considered for initial treatment with chemotherapy.
- For metastatic colorectal liver lesions, synchronous resection, liver-first, or colon-first strategies are all acceptable means of surgical treatment.
- Resection, ablation, or a combination of ablative and resection techniques can be used to minimize parenchymal liver resection and preserve function when treating metastatic colorectal metastases.
- Cytoreduction and hyperthermic intraperitoneal chemotherapy (HIPEC) may be considered in appropriately selected patients treated at specialized centers with expertise in this technique, although it has not been demonstrated to be superior to modern systemic chemotherapy.
- Metastases to organs other than the liver, lung, ovary, or peritoneum are uncommon and commonly occur in conjunction with widely metastatic disease. Thus, resection rarely has an impact on overall survival and should only be undertaken in select circumstances after multidisciplinary evaluation.
- Treatment of metastatic disease in the elderly requires consideration of the performance status, frailty, and impact of various treatments on quality of life.

Introduction

Despite screening protocols, approximately 20% of colorectal cancer patients present with established distant metastasis [1]. Computed tomography (CT) scan or magnetic resonance imaging (MRI) generally detects this metastasis at the time of the initial staging of the cancer. Once the diagnosis of stage IV disease is made, a multidisciplinary team should plan appropriate curative or palliative therapy. Unfortunately for the clinician, there is enormous heterogeneity with respect to sites of disease, extent of disease and symptoms, performance status, and comorbidities in these patients. Stage IV patients have a range of presentation from the asymptomatic patient with a single metastatic lesion to the rapidly deteriorating patient with colon obstruction and advanced multiorgan metastases. While treatment algorithms may exist for some forms of metastatic disease such as a solitary liver lesion, others, especially for those with multiple sites of metastases, are still being defined. This chapter aims to provide a reference source for colorectal surgeons managing patients who present with metastatic stage IV colorectal cancer.

While there has been considerable progress in the treatment of advanced colorectal cancer, the vast majority of stage IV patients are unfortunately not curable by current treatment protocols. An evaluation of data from the SEER population-based database estimates that the 5-year survival rate for stage IV patients diagnosed between 1991 and 2000 was 8% [2]. Even with this low overall cure rate, there are treatment options available to extend survival and enhance quality of life. Oncologic teams have several tools to utilize including systemic chemotherapy, radiotherapy, endoscopic treatments to palliate obstruction, surgical diversion, and surgical resection, all of which can play important roles in the treatment of these patients. Treatment approaches must be individualized based on the extent of resectability of local and distant disease, the presence or absence of bowel obstruction, performance status, and comorbidities. For patients with good performance status and minimal symptoms from the primary site of the cancer, standard treatment is systemic chemotherapy, which has been proven to prolong survival and quality of life [3, 4]. Surgical resection of the primary tumor and, if indicated, of the metastatic lesions can provide excellent palliation and in a limited number of cases can provide lasting cure.

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_36

First-line therapy with either FOLFOX or FOLFIRI now has been shown to yield major responses in up to 50% of previously untreated patients and achieves minor responses or stable disease in an additional 20% of patients [5]. Multiple effective drug combinations are available as well, and second and third line chemotherapy is becoming more effective and more likely to impact survival. Over the past 15 years, the median survival for patients with metastatic disease who are treated with chemotherapy has improved from 9 to 12 months and is currently greater than 24 months and may be as long as 36 months [6–8]. Although cure from chemotherapy alone remains extremely rare, effective chemotherapy combined with aggressive surgery may be increasing the overall cure rate. In this setting, the care of patients with advanced disease has become quite complex. In this chapter the aim is to provide a reference source for colorectal surgeons managing patients who present with metastatic stage IV colorectal cancer.

Biology of Metastatic Disease

Metastasis is defined as the spread of malignant cells from a primary tumor to a distant organ. It is estimated that 90% of all cancer deaths are the result of metastatic spread [9]. The biologic process of metastasis is poorly understood. Numerous clinical and laboratory studies have attempted to define the complex process of metastasis formation. The process relies on properties of the tumor cells, as well as the microenvironment of the primary and secondary sites [10, 11]. A series of major events must occur (Figure 36-1).

The first step is tumorigenesis, which occurs after the initial malignant transformation. The tumor proliferates into a small mass of heterogeneous cells that are of varying metastatic or malignant potential. These tumor cells undergo multiple and sequential genetic changes, characterized by the appearance of oncogenes and a decrease in tumor suppressor genes. As a tumor grows beyond 1 mm in diameter and becomes relatively hypoxic, angiogenesis is initiated. The process of tumor angiogenesis is tightly regulated by pro- and antiangiogenic factors secreted by both the tumor and its environment. As tumors successfully grow, suppressors of angiogenesis are inhibited, and proangiogenic factors predominate, resulting in neovascularity and further growth of the tumor [12]. Some tumors may grow by utilizing other existing blood vessels in nearby tissues.

In the next step, some cells will develop an invasive phenotype. Most researchers believe that there is a selection process resulting in the clonal expansion of certain cell subpopulations with growth advantage and invasive properties. Whether this process represents a property of the whole tumor cell mass or true clonal selection of more invasive cell subpopulation is not known, and it is a subject of intense research [13]. Malignant invasion is characterized by down-regulation of cell adhesion, resulting in detachment of the cell from the primary tumor mass and the extracellular matrix. Stromal invasion is accomplished through interactions with the basement membrane, including adhesion,

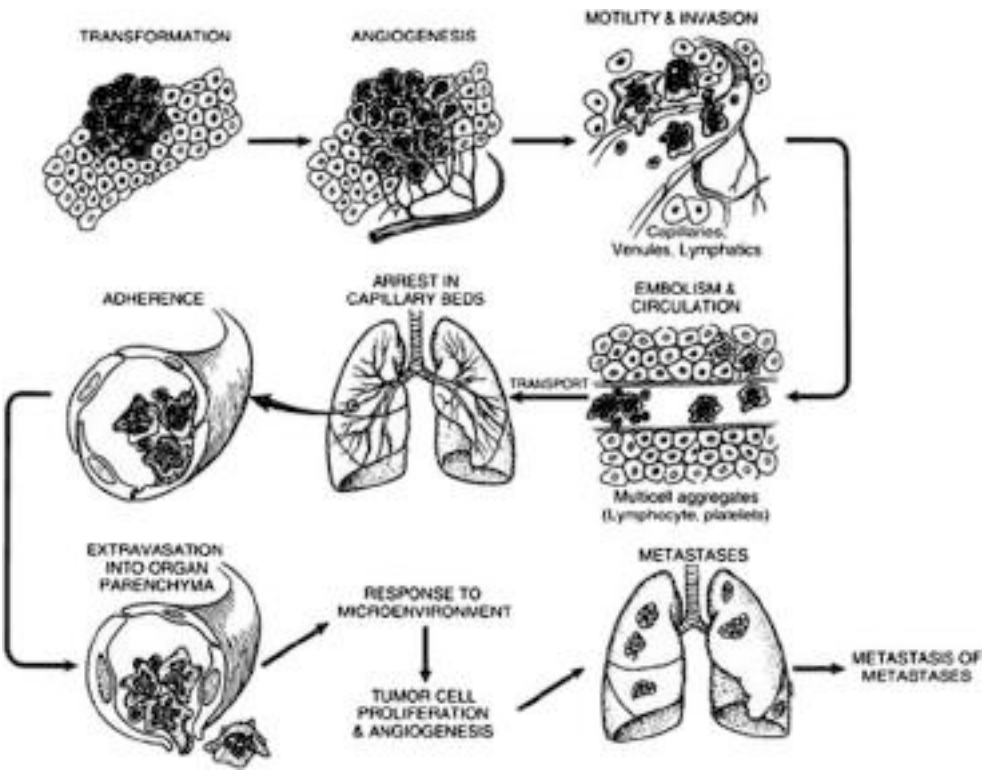

FIGURE 36-1. Schematic illustrating the multistep process involved in the development of metastasis. With permission from DeVita VT Jr., Hellman S, Rosenberg SA. Cancer: Principles and Practice of Oncology, 6th ed., Lippincott Williams and Wilkins, copyright 2001 [303].

proteolysis, and migration, ultimately resulting in detachment and invasion through the basement membrane. This invasive phenotype also enables these cells to enter thin-walled lymphatics and vasculatures, allowing access to systemic circulation [14, 15]. Once inside the vascular system, cells or cell clumps (emboli) are circulated and must survive hemodynamic filtering as well as immune surveillance. They must then arrest in distant organ. There is likely a complex interaction between the malignant cell and the endothelium or exposed basement membrane, allowing cell arrest. Once arrested in a tissue bed, the cells extravasate into the tissue, enabling formation of the metastatic focus. These metastatic cells can become dormant or proliferate; what determines this fate is not fully understood. Growth in the distant organ after deposition is a major limiting factor in the formation of metastasis. Some metastatic cells can remain dormant while others proliferate and must again go through tumor genesis, angiogenesis, and evasion of the immune system. This complex multistep process of metastasis formation is related to multiple genetic changes among malignant cells. Recent studies have shown differences in the genetic fingerprints of matched primary tumors and their lymph node metastasis suggesting that tumors may undergo continual mutagenesis. The metastatic tumor cells may genetically look very different from its parent primary cells [16]. This finding appears to confirm that there are genes specific to tumorigenesis, invasion, angiogenesis, and other steps. A number of genes have been identified that suppress metastatic potential and, by their downregulation, affect a cell's ability to metastasize without affecting tumorigenicity [16].

These discoveries provide a sense of the future challenge in elucidating the multiple, stepwise, and specific changes that regulate a cell's ability to metastasize. Advances in this field will have obvious and profound implications for the treatment of cancer.

Diagnostic Strategies

Part of the evaluation of newly diagnosed colorectal cancer includes systemic staging with cross-sectional imaging of the chest, abdomen, and pelvis. Rectal cancers will also include additional local staging with an endorectal ultrasound or pelvic MRI [17]. Twenty to thirty percentages of patients will present with evidence of metastatic disease on this staging workup [17, 18]. Increased suspicion should be given to the presence of metastatic disease when the CEA level is greater than 20 ng/mL [19].

There is the potential for some diagnostic uncertainty, as some lesions detected on staging workup may represent entities other than metastatic cancer (such as cysts, hemangiomas, granulomatous or infectious lesions, focal nodular hyperplasia, etc.). Hemangiomas have a prevalence of 7–21% and have characteristic imaging findings including a hyper-enhancing ring. Focal nodular hyperplasia is present in up to 3% of patients [18]. There are several imaging modalities that can be used to help identify true metastatic disease from other possibilities in the differential diagnosis, and each has unique characteristics. None is infallible, and in cases of uncertainty, multiple imaging modalities or tissue biopsy may be required to confirm the diagnosis, as it dramatically changes the prognosis and perhaps the treatment strategy as well. Consultation with a radiologist specializing in these imaging techniques is also helpful.

Computed Tomography

Computed tomography has been the mainstay of distant staging workup for colorectal cancer. Technology now allows high resolution, subcentimeter slice thickness with multiplane reformatting. This allows vascular reconstruction and volumetric analysis, which can be particularly important for operative planning for large liver resections [20–22]. Triple phase scans allow improved delineation of hepatic metastases (Figure 36-2). Though enhancement characteristics differ, most metastatic lesions are hypoattenuating on portal venous phases of an abdominal CT. Numerous studies have failed to gain significant value in routine use of four-phase CT to detect hepatic metastases, and portal venous phases are the most important to detect hypoattenuating liver lesions suggestive of metastases [23–25]. Despite this, up to 25% of hepatic liver metastases may be missed on high-quality CT, due mostly either to size or confusion with other disease processes [26, 27].

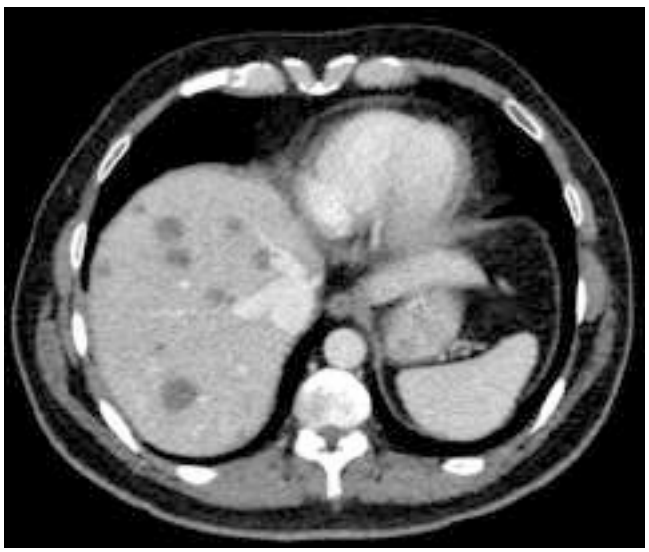

FIGURE 36-2. CT of the abdomen demonstrating liver metastases involving multiple segments of the liver. Treatment of these requires advanced planning and input in a multidisciplinary setting involving hepatobiliary, interventional radiology, oncology, and other specialties to determine planned interventions and timing.

Positron Emission Tomography

PET and PET-CT scans are a modality used both for initial staging and for follow-up imaging. The technology has dramatically improved recently and can now provide very clear pictures of tumor deposits in distant locations (Figure 36-3) [28]. Sensitivity of PET-CT for detecting metastatic lesions ranges from 87 to 100%, which compares favorably with regular CT (where sensitivities range from 52 to 69%) [29]. Specificity of PET-CT is also good and ranges from 94 to 100% (compared with 80–94% for regular CT). Limitations include a size resolution of about 1 cm and limited ability to detect mucinous tumors. Some studies suggest that the ability of PET-CT to detect subcentimeter lesions may be less than 50% [30–32]. Most protocols include a lack of intravenous contrast, which may limit the ability to evaluate some smaller lesions. National Comprehensive Cancer Network (NCCN) guidelines do not recommend routine use of PET-CT to evaluate metastatic lesions except in equivocal findings or in cases where patients are allergic to IV contrast which would otherwise limit the usefulness of regular CT [33]. In cases where patients are being considered for liver resection of metastatic tumor, there is some evidence that PET-CT can detect extrahepatic disease that is missed in up to one third of patients evaluated by CT scan alone. This changed management strategy in 8–21% of patients [34].

Magnetic Resonance Imaging

While MRI is used to perform the initial staging of rectal cancers, it can also be useful for characterizing equivocal lesions of the liver, as it is particularly good at soft tissue characteristics, especially those that fall below the resolution of PET [35, 36]. The soft tissue delineation is also better than CT scan and can help with tumor identification [34]. MRI of the liver with contrast using a liver-specific protocol can help define lesions that are potentially resectable. Sensitivity of MRI at detecting response of liver lesions to neoadjuvant treatments may be better than PET [37]. MRI cannot be used in patients with pacemakers, implantable cardiac defibrillators, cochlear implants, and other orbital foreign bodies [18]. Cost remains a significant factor that also limits routine use of MRI in the evaluation of liver lesions.

Contrast-Enhanced Ultrasound

Contrast-enhanced ultrasound (CEUS) is the newest imaging modality to gain popularity. It is highly operator dependent but highly effective (one study demonstrated 97% of lesions seen on CT were also detected on CEUS) [38]. As centers gain expertise in this modality, its use may increase in the future. Another potential limitation is that chemotherapy-induced fatty infiltration of the liver may limit diagnostic accuracy.

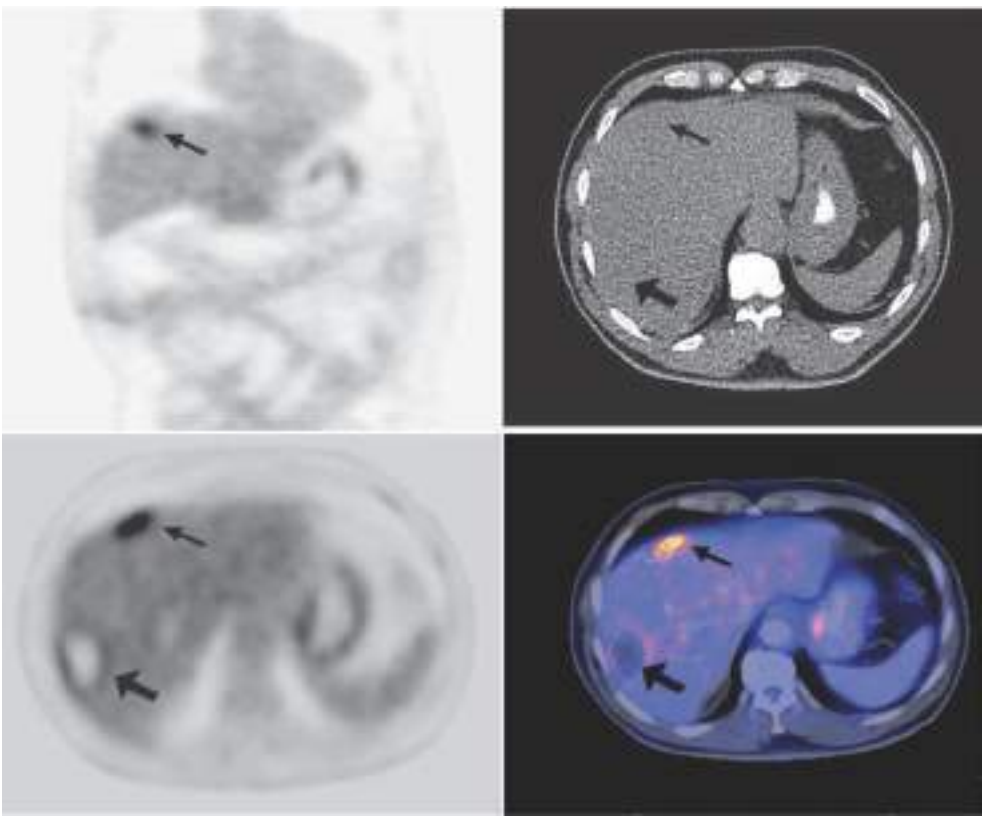

FIGURE 36-3. PET-CT scan and various phases. Lesions may not always show up or appear active on all phases of imaging.

Biopsy

In equivocal cases where imaging characteristics are not suspicious of colorectal metastases, tissue biopsy confirmation remains an option. A small percentage of patients will have a histologic process other than the primary malignancy [39, 40].

Multidisciplinary Evaluation

Multidisciplinary evaluation is of critical importance to caring for patients with metastatic disease. As there is often no one agreed-upon absolute treatment strategy, it is important to have consensus from treating oncologists, radiation oncologists, and various surgical disciplines such as colorectal, hepatobiliary, thoracic, and gynecology [41, 42]. Of particular value is whether or not an organ can be rendered disease-free. This allows surgery for cure, which has a different end point than surgery for palliation [43]. It is estimated that only 20–30% of patients with identified metastatic disease will have potentially resectable disease [44]. Goals of multidisciplinary evaluation should include relief of symptoms and quality of life improvement and determine the best means of prolonging life expectancy. In some cases, this may include chemotherapy alone. Consideration must be given to multiple variables including performance status, tumor burden, patient's expectations of treatment, and overall care goals.

If disease is determined to be resectable, common considerations are whether to perform sequential or simultaneous resections, use of chemotherapy or radiation in a neoadjuvant or adjuvant setting, and whether or not to perform an anastomosis. If the disease is not resectable, there are a few common scenarios that deserve some additional attention. A typical algorithm can be found in Figure 36-4.

Surgical Emergency

Tumors at the primary site may cause a surgical emergency, even in the setting of metastatic disease. In these cases, surgical intervention should be undertaken to relieve the immediate, life threatening issue, such as perforation with peritonitis, lower GI bleeding, or large-bowel obstruction. If possible, and if it can be performed with limited morbidity, an oncologic surgical resection should be performed [17, 45]. A primary anastomosis can be performed in select, low risk patients, but carries the potential it may delay chemotherapy and other life-sustaining treatments if an anastomotic leak should occur [46]. This should be weighed very carefully when performing surgery in the emergent setting.

Palliative Management of Primary Cancer: Laser, Fulguration, and Stents

Incidence and Presentation

Approximately 8–29% of patients with colorectal cancer initially present with symptoms of partial or complete bowel obstruction [47]. In a review of 713 obstructing carcinomas, 77% were left-sided and 23% were right-sided cases [48]. The majority of patients with obstructing colorectal carcinomas have either stage III or stage IV disease [49]. Acute malignant colon or rectal obstruction is an indication for emergent surgical intervention. However, these emergency operations are associated with a mortality rate of 15–34% and a morbidity rate of 32–64% despite advances in perioperative care [49, 50]. Therefore, alternative palliative endoluminal strategies aimed at relieving obstruction have gained increasing popularity over the past decades.

The initial symptoms of bowel obstruction may include mild discomfort and a change in bowel habits. With disease progression and luminal narrowing, the symptoms may worsen ranging from crampy abdominal pain, abdominal distension, nausea, abdominal tenderness, and obstipation. Vomiting is a late symptom unless there is an associated small bowel obstruction. Leukocytosis is a concerning finding and may indicate near or complete obstruction. Without treatment, the process can progress to complete obstruction, ischemia, and perforation. The risk of cecal perforation is greatest in patients who have a competent ileocecal valve that does not allow decompression of the large intestine into the proximal small intestine.

In the setting of metastatic cancer, the clinician must first answer the following critical question, "is the colon or rectal

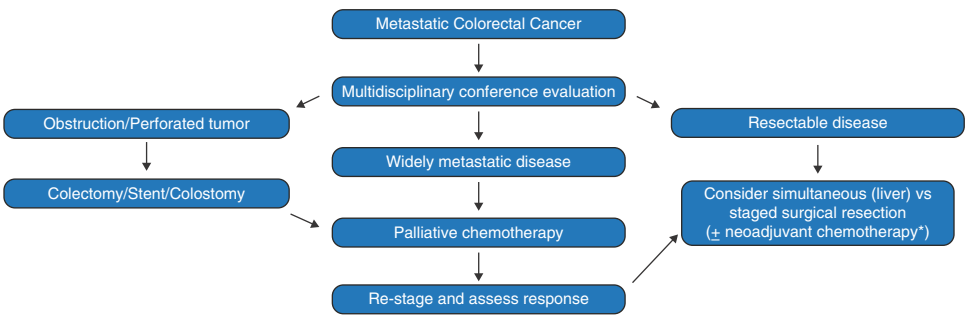

FIGURE 36-4. Treatment algorithm for metastatic colorectal cancer.

obstruction a contraindication for system chemotherapy or radiotherapy?" The degree of obstructive symptoms and endoscopic and radiographic findings are key elements to consider when answering this question. If the patient has minimal symptoms and there is no radiographic evidence of high-grade obstruction, many patients with partially obstructing colon and rectal cancers will tolerate aggressive chemotherapy as described previously in this chapter. In those patients with partially obstructing rectal cancers, the addition of radiation therapy is also well tolerated and can be highly effective. Patients must be instructed to monitor their symptoms closely and to report any signs of worsening obstruction immediately. A liquid diet or pureed diet with adequate protein and calorie intake taken in small portions may help reduce obstructive symptoms. For patients with advanced obstruction, nonsurgical palliative options include laser therapy, fulguration, and colonic self-expanding metal stents. If less-invasive endoluminal strategies are not successful in patients with nonresectable malignant obstruction of the colon and rectum, surgical creation of palliative proximal diverting stoma or intestinal bypass should be performed.

Laser Therapy and Fulguration

Laser therapy has been utilized for palliation of obstructing rectal cancers [51–54]. In a large series of 272 patients who underwent palliative laser therapy for rectosigmoid cancers, the immediate success rate in treating obstructive symptoms was 85% [55]. Other studies have shown similar success rates in the range of 80–90% [53, 54]. However, laser therapy is practical only for treating cancers of the distal colon and rectum and is rarely used to treat proximal lesions. In addition, multiple sessions are often required in order to achieve lasting relief of symptom. Serious complications like bleeding, perforation, and sever pain have been reported in 5–15% of patients, especially those undergoing multiple treatment sessions [52, 54–56]. While laser therapy has been shown to be practical and feasible to other palliative treatment modalities in the management of these unfortunate stage IV patients and has low morbidity and mortality [57], it does not affect overall survival of stage IV patients.

Surgical fulguration of rectal cancers is another method of opening the rectal lumen and relieving obstruction [58, 59]. Fulguration, in combination with endoluminal debulking, can remove a large volume of tumor. However, unlike laser therapy, fulguration and debulking require hospital admission and regional or general anesthesia. Both fulguration and laser therapy have given way to stenting.

Self-Expanding Metal Stents

Since their introduction in 1991, colonic stents have become an effective method of palliation for obstruction in colorectal cancer patients, especially those with unresectable metastatic disease, or used in an effort to decompress an obstructed patient preoperatively [60]. Especially in nonoperative stage IV patients or those that have significant comorbidities, these self-expanding metallic stents can potentially dilate the lumen to a near-normal diameter, providing quick relief of symptoms. Stents can be placed in patients using minimal sedation in the endoscopy suite with the aid of fluoroscopy. Moreover, these stents can be placed across relatively long lesions by overlapping stents in a "stent-within-stent" fashion. Laser therapy has also been used in certain situations, in conjunction with colonic stents, to recanalize and decompress large bowel or when tumor ingrowth occurs in patients who have had long-term stents in place. It should be noted the emergency surgery is recommended over stent placement in those patients with evidence of colonic obstruction and systemic toxicity. Presence of systemic toxicity may indicate the presence of ischemia and/or perforation which requires immediate evaluation and the potential for emergency surgery.

Stenting can achieve long-term palliation in patients who are not operative candidates. More than 75% of patients can achieve adequate palliation with stenting, although tumor ingrowth, stent migration, and perforation, especially those receiving bevacizumab, may occur [61]. If these stent-related complications occur, it may necessitate reintervention either with an additional stent or with other palliative measures such as laser or argon plasma coagulation therapy or surgery [62].

A systematic review from 1990 to 2000 of the published data on stenting of colorectal obstruction included 29 case series in the analysis [63]. The review evaluated technical and clinical success, complications, and reobstruction. Cases involving stent replacement for palliation and stent placement as a "bridge to surgery" were both assessed. Stent insertion was attempted in 598 cases. Stent deployment was technically feasible in 551 (92%) cases and clinically successful in relieving obstruction in 525 (88%) cases. Palliation of obstruction was achieved in 302 (90%) of 336 cases. Stent placement as a "bridge to surgery" was successful in 223 (88%) of 262 insertions of which 95% had a one-stage surgical procedure. There were three deaths (1%). Perforation occurred in 22 cases (4%). Stent migration was reported in 54 (1%) of the 551 technically successful cases. Stent reobstruction occurred in 52 (10%) of the 525 clinically successful cases and trended toward a higher incidence of reobstruction in the palliative treatment group. The reviewers concluded that "stent usage can avoid the need for a stoma and is associated with low rates of mortality and morbidity" [63]. A series of 52 patients with malignant obstruction secondary to either primary or recurrent colon or rectal carcinoma, who underwent stent replacement by colorectal surgeons, reported that 50 out of 52 were successfully palliated [64]. One patient had a perforation, and in another patient obstruction was not relieved because of multiple sites of obstruction. The overall complication rate in this series was 25%. Stent migration was the most common complication (15%), followed by reobstruction secondary to tumor ingrowth (4%), perforation (2%), colovesical fistula

(2%), and sever tenesmus (2%). Surgical intervention was required in 17% of cases due primarily to one of the above complications or recurrent obstruction.

There are limited data evaluating stent placement proximal to the splenic flexure. In a recent publication, colonic stenting was attempted in 97 patients with malignant large-bowel obstruction [65]. Sixteen (17%) patients had lesions proximal to the splenic flexure (eight ascending, eight transverse colon). Stenting was successful in relieving obstruction in 14 (88%) of these patients. Stenting was performed for definitive palliation in nine of these patients and as a bridge to elective surgery in the other seven patients. One patient developed gastrointestinal bleeding that was managed conservatively. No perforations or stent migrations were reported [65].

Complications reported in the literature for colonic and rectal stents include stent malpositioning, perforation, stent migration, tumor ingrowth (through the stent interstices), tumor overgrowth (beyond the ends of a stent), stool impaction, bleeding, tenesmus, and postprocedure pain (Figure 36-5). Perforation and stent migration occur with the highest frequency. The rate of perforation however appears to be decreasing overall as the technique and technology have improved and in experienced hands is now approximately 5% [66]. Stent migration has been described to occur in a median of 11% of patients in a systematic review [67]. Migrations tend to occur with stents that are too narrow or too short in relation to the obstructing lesion or in the presence of tumor shrinkage following therapy [68]. Stenting of cancers in the mid to low rectum may result in urgency, pain, and incontinence. While the complications associated with stents and other less-invasive endoluminal strategies should not be taken lightly, one must keep in mind that emergency operations for malignant colon and rectal obstruction have a significant mortality rate of 15–34% and a high morbidity rate of 32–64%. Taken in the correct context, these endoluminal palliative strategies provide increasingly effective and durable relief for patients with malignant obstruction.

The Challenge of Primary Tumor Management in Asymptomatic Stage IV Colorectal Cancer: To Resect or Not to Resect?

Optimal first-line therapy for patients who present initially with unresectable stage IV disease remains controversial. Some advocate initial resection of the primary, while others recommend initial chemotherapy if the primary tumor is asymptomatic.

In the era of modern chemotherapy, patients can experience increased length and quality of life with 5-FU-based multiagent chemotherapy [69]. Prophylactic resection of the primary tumor can provide long-term local control and may benefit select patients [70]. This must be weighed against the risk of surgical complications resulting in delay in chemotherapy and other palliative treatments. Particularly in rectal cancer, complications arising from surgery have been shown to delay initiation of chemotherapy beyond 8 weeks postoperatively. As these patients have worse overall survival, the risk of these complications may not be inconsequential [71]. As there are no randomized, controlled trials for this topic, some information on the natural history of the disease can aid management decisions.

Poultsides et al. [72] examined the natural history of patients receiving primary chemotherapy without surgical intervention for stage IV colorectal cancer. Left untreated, only 7% of primary lesions progressed to require emergency surgery for obstruction or perforation while receiving palliative multiagent chemotherapy. An additional 4% required a nonoperative intervention (e.g., stent or radiotherapy). The remaining 89% never required any further intervention on the primary tumor. Twenty percent responded well enough to undergo combined resection at the time of subsequent metastasectomy. Matsumoto et al. [73] reported that 75% of patients with unresectable disease could be spared primary tumor intervention. An endoscopically nontraversable primary lesion at the time of diagnosis was predictive of subsequent need for intervention (which occurred 64% of the time within the next year). Other studies suggest that 68–90.7% of patients will not require surgical intervention on the primary tumor [69, 74–76]. As there are some high-risk features that may predispose to perforation or obstruction, some oncologists will request initial surgical diversion for locally advanced, near-obstructing lesions or those that display signs of impending perforation or abscess on imaging.

Indeed, the argument for up-front primary tumor resection is based on the desire to avoid potential complications from the primary tumor during treatment. This concern may be greatest when the agent bevacizumab is utilized—which has led both surgical and medical oncologists to advocate primary tumor resection at the time of diagnosis prior to the institution of the drug [77, 78]. In fact, the majority of US patients presenting with stage IV disease will still undergo

noncurative primary tumor resection, perhaps partially for this reason. However, during the past decade, several highly active systemic agents, both cytotoxic and biologic, have become available for the treatment of patients with metastatic colorectal cancer. As a result the median survival of patients with unresectable metastatic disease has increased from 9 to 12 months with fluorouracil alone to up to 24 months with sequential modern cytotoxic and biologic treatments [8]. Therefore, it may be generally accepted that, in these stage IV patients, systemic chemotherapy with or without primary resection is the essential treatment modality to prolong survival. These modern agents also have increased activity on the primary tumor and can even induce a complete response [79–81]. Thus the old question of how best to manage the primary tumor continues to be debated. It is agreed upon that resection of a lymph node basin outside the primary vascular pedicle is rarely indicated [82].

While there was some initial evidence in the literature that resection of the primary tumor was associated with a survival benefit [83], this finding was most likely the effect of selection bias. Patients with less extensive disease, or better performance status, were selected for resection [74, 84, 85]. Currently, routine surgery for the asymptomatic primary tumor in the setting of unresectable metastatic disease is not recommended. This recommendation stems in part from a Cochrane review of 798 studies involving 1086 patients that suggests there is not enough evidence to justify routine resection of primary tumors. Furthermore, survival was not consistently improved with primary tumor resection, nor was morbidity of complications from tumor complications reduced by initial resection. However, further study was recommended as there is a paucity of randomized trials on this matter [17, 86].

Investigators from the National Surgical Adjuvant Breast and Bowel Project (NSABP) have reported results of a phase II prospective single-arm study or primary systemic chemotherapy with fluorouracil, oxaliplatin (mFOLFOX6), and bevacizumab for patients with asymptomatic primary intact unresectable stage IV colorectal cancer (NSABP C-10) [87]. The investigators aimed to directly address the concerns for both primary tumor-related complications associated with first-line systemic therapy in patients with asymptomatic disease and the risk of tumor complications with the use of bevacizumab in this setting. A total of 86 patients form 29 institutions were evaluated with the primary eligibility criteria being that the treating clinician identified the patient to be asymptomatic with respect to his or her primary tumor. After a median follow-up of 20.7 months, the majority of the patients could be successfully managed nonoperatively without the need for primary tumor intervention, meeting the study's primary end point. Median overall survival was 19.9 months, and the overall rate of major morbidity related to the intact primary tumor was 16.3% (95% CI, 7.6–25.1%) at 24 months.

The investigators concluded that the first-line combination therapy with mFOLFOX6 and bevacizumab did not result in an unacceptable rate of primary tumor-related complications and that noncurative resection of the asymptomatic primary tumor in these patients could be avoided. These findings confirm prior retrospective reports demonstrating low rates of intestinal complications with either fluorouracil-based or more modern systemic chemotherapies [72, 88, 89]. In their prospective evaluation, however, the NSABP investigators [87] have further demonstrated the safety of first-line chemotherapy with bevacizumab in patients with intact but asymptomatic tumors. Indeed, 73.3% of the patients still had not required primary tumor resection at the time of death or last follow-up.

This study has moved clinical treatment decision-making forward and provides prospective evidence that routine noncurative resection may be unnecessary. This relatively small study also highlights a key question in determining which patients may be eligible for this approach. Establishing a patient as "asymptomatic" was a key eligibility criteria. In this study, asymptomatic was defined as having no bowel perforation or obstruction and no active bleeding requiring a transfusion [87]. It was at the treating physician's discretion to define whether a patient exhibited signs of obstruction. The key issue of understanding which patients are eligible for this approach can also influence the true incidence of primary tumor-related morbidity (i.e., not all patients with asymptomatic disease are the same.) Despite some limitations of the study, the results were reassuring for the safety of first-line systemic chemotherapy with bevacizumab. There will remain a group of patients who will still require subsequent primary tumor resection. The challenge of identifying these patients for planned elective resection to avoid the higher mortality and morbidity risks of emergent resection while sparing the morbidity of resection still needs to be defined.

It also needs to be acknowledged that retrospective comparative studies, even in the era of modern systemic therapies, have demonstrated survival benefits associated with resection of the primary tumor, although the individual contributions of the multiple factors of patient selection, location and extent of tumor burden, tumor biology, ability to tolerate, and availability of systemic therapy and aggressiveness of surveillance are unknown. A comparative multi-institutional study of patients with stage IV cancer at diagnosis remarkably demonstrated a median survival of 30.7 months with primary tumor resection compared with 21.9 months ($p=0.031$), raising the question of whether primary tumor resection has the potential to further improve median survival beyond what can be achieve by even modern systemic therapy alone [90]. Perhaps there is a group of patients with putatively asymptomatic circumferential or locally advance primary tumors who might derive a survival benefit from either up-front or interval resection with the potential to avoid the need for emergent intervention or

permanent ostomy. Performing a randomized study in an unselected stage IV population may indeed prove to be difficult.

The NSABP C-10 trail is the only modern prospective multi-institutional study that specifically addresses the issue of primary tumor resection in patients with asymptomatic stage IV colorectal cancer. Current treatment patterns are influenced by strong patient and provider biases but with this trial there is no additional evidence supporting the safety of systemic chemotherapy as the initial primary treatment approach for carefully selected asymptomatic patients avoiding the need for and the morbidity risk of noncurative resection. Unfortunately more questions remain and additional study is needed to help us understand how best to select patients and optimize the available treatment modalities, including surgery to improve outcomes and prevent subsequent morbidity.

Surgical Therapy of Liver Metastases

Liver metastases are a common occurrence, and surgical resection represents the best opportunity for long-term cure. Approximately 20–30% of patients have potentially resectable lesions at the time of diagnosis. With appropriate selection, 5-year survival has been reported around 30% (range 15–67%) [91–94]. Even with modern chemotherapy for colorectal cancer, surgery for metastatic cancer (if possible) has consistently been shown to improve 5-year survival and quality of life and should be considered when possible. This may require referral to a specialized center [92, 95, 96].

Untreated, potentially resectable liver lesions have a median survival of 8 months, with 5-year survival of <5% [43, 97]. With modern forms of chemotherapy, median survival can be extended to greater than 24 months and in rare cases can be up to 34 months [7, 8]. In addition, newer liver strategies may allow a staged resection, portal vein embolization, or a combination of resection, embolization, and other strategies to ablate or otherwise treat or downsize liver lesions, which may allow a greater percentage of patients to undergo some form of treatment [98]. This has allowed some centers to see overall 5-year survival rates among patients with metastatic colorectal cancer at the time of diagnosis to be as much as 19% [99]. This underscores the importance of multidisciplinary evaluation of these patients. The main reason for failure in treated patients is intrahepatic recurrence of the tumor, which occurs in 60–70% of patients, one third of whom die within 2 years of surgery for hepatic metastases [99].

For patients with resectable lesions, there are several strategies that can be utilized to treat these lesions. Each has its own merits and they will be reviewed here. Multidisciplinary evaluation and local expertise are again key to determining the appropriate strategy, as there is a paucity of data to evaluate the various treatment strategies.

Combination Liver and Colon Resection

Combination resection involves simultaneous resection of liver and colonic lesions. This allows a single operation to treat both disease foci without delay between procedures. There is evidence to suggest that this approach results in a similar long-term outcome when compared to those undergoing staged therapy. Similarly, simultaneous resection does not increase overall morbidity, though there is an inherent selection bias in trials examining this issue [92, 100–102]. This approach is typically done for relatively minor resections which can include lobectomy. Larger liver resections may result in increased morbidity when combined with other procedures and may not be appropriate candidates for this strategy [103, 104]. A meta-analysis of 2880 patients suggested that simultaneous resection was safe provided patients were less than 70 years old and did not have severe comorbidity [105, 106]. An additional meta-analysis of 18 studies including 3605 patients did not show a survival advantage to any strategy, though there is the potential for considerable selection bias toward smaller lesions in the patients undergoing a combined approach strategy [107].

Liver-First Strategy

In patients with liver metastases from colorectal cancer, it is the metastatic disease in the liver (particularly if >3 cm in size) that is the primary determinant of overall survival [108, 109]. This is a potential reason for addressing the liver disease first, particularly in the setting of larger metastatic lesions where the primary lesion is asymptomatic. As there is some evidence to suggest the primary lesion has a low chance of becoming symptomatic during follow-up, it is reasonable to proceed with treatment of the metastatic disease first [72]. This also may avoid unnecessary colorectal surgery (and its associated morbidity) in patients who go on to develop incurable metastatic disease. There is evidence to suggest that a “liver-first” strategy may still allow patients with potentially curable disease to undergo both liver and colon resection over time [109].

It is unclear whether the development of additional metastatic disease is stimulated by the liver metastases vs. the primary tumor [110–114]. This has generated considerable debate between hepatobiliary and colorectal surgeons as well as oncologists. As no randomized trials exist, this is a philosophic discussion that occurs at many tumor board interactions. The answer remains unclear, but it may affect the opinions of those involved in making recommendations.

The liver-first approach can be combined with neoadjuvant chemotherapy for borderline resectable lesions or to allow tumor biology to dictate those lesions that are likely to progress rapidly prior to surgery. While this has been recommended as standard of care by some, others have disputed this and still recommend surgical resection followed by adjuvant chemotherapy due to the effect of chemotherapy-associated steatosis

that can increase surgical morbidity [115–118]. The liver-first strategy has a particular advantage in the setting or rectal cancer, where the process of neoadjuvant chemoradiotherapy can potentially take up to 3 months. This may allow surgery on the metastatic disease while treatment for the primary lesion is still ongoing. Alternatively, radiotherapy on rectal lesions can be reserved for overall disease that responds favorably to initial treatments—particularly the short course variety. The data for the liver-first approach is limited and largely based on non-randomized data, but seems to remain a viable method with good long-term results [119–125]. An international multidisciplinary consensus conference [126] suggested the liver-first strategy is as good as the conventional approach. The recommendation is to perform resection as soon as technically possible with a course of chemotherapy (if used) as short as possible in the absence of tumor progression. Furthermore age and total number of hepatic metastases should not be an absolute contraindication to surgery. The importance of a multidisciplinary approach remains crucial to ensuring long-term survival.

Colon-First Strategy

Proponents of the colon-first strategy hypothesize that the colon or rectum acts as an ongoing source of seeding metastatic disease. Additionally, the primary tumor represents a potential source of bowel-related morbidity in the form of bleeding, obstruction, or perforation. Some authors suggest the rates of this can be as high as 20%, but others suggest it is much lower than this [72, 87]. Additionally, the risk of morbidity associated with a colorectal anastomosis may be increased by addition of a liver procedure, where anesthesia and surgical techniques may include a low flow state or temporary alteration in portal blood circulation (e.g., a Pringle maneuver), which may affect blood flow to the bowel [127, 128]. Along similar lines, removal of the colon or rectum first may allow subsequent, more advanced, or aggressive strategies such as portal vein embolization to be used without compromising a future bowel procedure. Finally, resection of the colon first may allow detection of new or occult liver metastases which can then be removed with definitive surgery [129, 130].

Evidence to support each of these strategies is very limited and largely based on small, single institution series. Survival analyses across multiple studies suggest there is little difference between simultaneous, colon-, or liver-first strategies [105, 131–133]. As such, the agreed-upon treatment strategy should depend on the local expertise at an individual institution. The colon-first strategy may allow removal of the primary lesion with subsequent referral to a higher level of care or specialized center for definitive hepatectomy/metastasectomy. In counseling patients on the risk of recurrence, there have been identified factors to help determine prognosis. The Fong score is a series of five factors identified to have the greatest influence on outcome based on an analysis of 1001 patients undergoing potentially curative hepatectomy [134]. These included size >5 cm, disease-free survival less than 1 year, more than one tumor, lymph node-positive primary, and CEA >200 ng/mL.

Margin Status

Excision to negative margins in hepatic resection results in improved disease-free and overall survival. One study revealed an overall survival of 46 months was reduced to 24 months in patients with positive margins [135]. Furthermore, recurrence rates were significantly higher (28% with R1 resection vs. 17% with R0 resection, $p=0.004$) in a study of 436 patients comparing margin status of hepatectomy specimens [136]. A consensus statement from the Society of Surgical Oncology concluded that while wide margins of >1 cm are desirable, a close margin should not preclude resection. Another study suggested that a margin <5 mm is a risk factor for local recurrence [137].

Ablation of Liver Metastases

There are a variety of techniques for ablation of liver metastases that do not require tissue resection. These include percutaneous ethanol ablation, radiofrequency ablation (RFA), microwave ablation, cryoablation, and irreversible electroporation (or NanoKnife). RFA is the most commonly employed technique, though all can be used successfully and also used in conjunction with other forms of therapy (e.g., surgical resection) [138]. As patients may develop a future recurrence, preservation of liver parenchyma may be important, especially with a larger burden of disease. This is the typical place for use of these ablative therapies. In selecting what treatment modality to use, the overarching goals of minimal morbidity with maximum treatment effect and prolongation of life remain a guiding principle during multidisciplinary evaluation. Several different treatments may be used simultaneously or in a staged approach. Recently, these combined ablation and resection (CARe) techniques have shown promising results. A four-center retrospective study showed disease-free 1- and 5-year survival rates of 87.9% and 78%, respectively [139].

RFA has been the most widely applied ablative technique, used primarily for metastatic liver tumors that are not amenable to surgical resection. Patients may not be candidates for surgery for various reasons including that the lesions are anatomically difficult for surgical resection (adjacent to the confluence of the hepatic or portal veins), the functional hepatic reserve after resection would be insufficient, there are significant comorbidities that preclude an operation, or extrahepatic metastases are present, further decreasing the likelihood of cure. RFA uses heat generated from high frequency alternating current (generally in the range of 350–500 kHz) to ablate diseased tissue. RFA can be performed with open, laparoscopic, or percutaneous approaches. Studies have reported that the approach by which RFA is

performed has an impact on tumor recurrence rates, with the fewest local recurrences after open RFA, followed by laparoscopy, and finally percutaneous RFA [140–143]. However, local tumor recurrence rates overlap broadly with each technique, and physician experience as well as the type of RFA equipment is also inversely related to local recurrence rates [144, 145]. An expert panel convened by the American Society of Clinical Oncology (ASCO) to review the evidence on RFA for colorectal cancer liver metastases concluded that there is insufficient evidence to resolve the issue of optimal approach [146].

The vast majority of published data on efficacy of RFA for colorectal cancer liver metastases comes from retrospective series, many of which have limited follow-up (20 months or less), and there are few published randomized trials [140, 147–152]. A systematic review of the literature reported a wide range of 5-year survival (14–55%) and local recurrence rates (3.6–60%) [146]. However, both the retrospective series and the limited number of prospective trials consist of a variable mix of patients with potentially resectable liver-isolated disease and unresectable liver metastases with or without extrahepatic disease involvement. Finally, few series provide data on the use of chemotherapy concurrent with or following RFA, and as outcome measures differ between studies, a comparison is not always possible.

How the timing and use of RFA play into the overall treatment strategy remains an unanswered question. While many retrospective comparative series suggest RFA has higher local recurrence rates and worse progression-free survival (compared with resection), there are inherent limitations in these studies [153–159]. Given the evidence from retrospective reports that resection improves overall survival, particularly in the absence of extrahepatic disease, a systematic review of the literature by an expert panel from ASCO concluded that there is not enough evidence to support the use of RFA over resection in patients with potentially resectable colorectal cancer liver metastases [146]. A similar conclusion was reached in a 2012 Cochrane review [160].

RFA is a relatively well-tolerated technique, with a mortality rate of 0–2% and the major complication rate between 6 and 9% in most studies [146]. Complications can include liver abscess, pleural effusion, skin burns, and pneumothorax from diaphragm injury [161]. In summary, the place of RFA in the management of colorectal cancer liver metastases is still evolving, particularly in patients who have extrahepatic disease involvement. It is a potential option for patients with potentially resectable isolated liver metastases who are not surgical candidates.

Other Liver Metastasis Strategies: Hepatic Intra-arterial Chemotherapy/Chemoembolization

Regional chemotherapy through the hepatic artery is a therapeutic option for patients with isolated liver metastasis that are not amenable to surgical resection or local ablation. This method can also be combined with other forms of treatment. This mode of therapy is based upon the fact that liver macrometastases derive more than 80% of their blood supply from the hepatic arterial circulation, while normal hepatocytes are supplied primarily by the portal circulation [162]. This allows selective delivery of drug to the tumor with relative sparing of the normal hepatocytes. There is also a marked increase in the local concentration of the chemotherapy that is achieved by injection into the hepatic artery. Regional administration of agents that are rapidly metabolized in the liver by a first-pass effect leads to higher levels of drug exposure and minimizes side effects [163].

Transarterial embolization with or without chemotherapy (transarterial chemoembolization, TACE) has been investigated in patients with colorectal cancer liver metastases using both conventional techniques and drug-eluting beads. Response rates vary from 29 to 88%, which is based on limited experience. Most reported studies lack a control group, and the results from the two small-randomized controlled trials had conflicting results [164–166].

Most series of colorectal liver metastases have studied infusional hepatic artery chemotherapy without embolization. While there has been extensive clinical investigation of hepatic infusional chemotherapy in the past 30 years, there are fewer studies evaluating modern chemotherapeutic agents. A number of strategies have been explored in an attempt to overcome treatment-limiting toxicity and to maximize the safety and efficacy of HIA treatment. The majority of reports have evaluated modifications of 5-FU-based therapy, while more recent studies have explored other agents such as irinotecan and oxaliplatin. It has been shown that both oxaliplatin and irinotecan can be safely delivered and result in a high response rate in patients with unresectable disease [167–171]. A review of trials in the 1990s demonstrated that while response rates of tumors may be improved over systemic chemotherapy, the effect on survival was modest (overall survival 22.7 vs. 19.8 months). Other randomized trials have not seen any survival advantage [172, 173]. With improvements in chemotherapy, there is a paucity of high-quality data on the effectiveness of this treatment methodology. A recent review of nine studies and 1057 patients [174] did demonstrate improved 5-year disease-free survival rates (hazard ratio 0.61) when compared with systemic chemotherapy alone. A modest improvement in overall survival was also seen. This suggests it may have a role in the treatment of patients at high risk for recurrence, but this will require corroborative studies and should at present be restricted to centers with expertise in the technical aspects of its use.

Pulmonary Metastasis

Approximately 10% of patients with colorectal cancer develop pulmonary metastasis. The vast majority of patients with metastatic colorectal cancer to the lungs have advanced

disease and are therefore treated with systemic chemotherapy or best supportive care. Due to differences in blood supply, pulmonary metastases may be more common after rectal (vs. colon) cancer due to the dual blood supply of the rectum (portal and systemic). A limited number of studies have reviewed the incidence of pulmonary metastases after resection of rectal cancer and have estimated that approximately 1–12% of patients develop isolated pulmonary metastases [175–178]. Of those patients with isolated pulmonary metastases, approximately 7–14% of patients would be considered as candidates for pulmonary metastasectomy [175, 178, 179].

There may be some tumor-related factors that give a predisposition to pulmonary metastasis. A recent study investigated predictive factors for pulmonary metastases after R0 resection of rectal cancer without preoperative chemoradiotherapy. Actuarial incidence of pulmonary metastases was significantly related to the number of risk factors present. Tumor depth (T2–T3), lymph node ratio >0.091, and tumor location in the anal canal were the independent risk factors for pulmonary metastases in patients with rectal cancer [180]. Another study demonstrated that adjuvant chemotherapy, extrapulmonary metastases, and prelaparotomy CEA value were independent prognostic factors for overall survival of patients with pulmonary metastases after a resection for colorectal cancer with curative intent [181].

Due to the retrospective nature of the reported information in the literature, clinical outcome data after metastasectomy for colorectal lung metastases must be interpreted with caution. Improved clinical outcome and survival data is more likely due to ideal patient selection and tumor biology rather than the surgical intervention in and of itself. In addition, there are no adequate control groups in these reports; therefore, survival statistics are difficult to interpret. However, there are patients who undergo pulmonary metastasectomy with no evidence of disease after long-term follow-up [179, 181]. In addition, long-term survival without complete resection is very rare, suggesting that select patients do occasionally benefit from pulmonary metastasectomy. Input on the resectability of lung lesions by a thoracic surgeon at multidisciplinary evaluation is essential.

Modern series of lung resection for metastatic colorectal cancer report operative mortalities of less than 2% (Table 36-1). Five-year survival rates range from 16 to 64%, but generally cluster around 30–40%. Most studies evaluate factors associated with outcome; however, given the limited number of cases, the statistical power of these studies to detect significant factors is limited. In general, the pathology of the primary tumor (grade, location, stage) has not been shown to impact clinical outcome. The most commonly cited significant factors associated with adverse outcomes include the number and size of pulmonary metastasis, short disease-free interval, elevated CEA, and incomplete resection.

A recently published series of 94 patients from a single institution who underwent complete resection of pulmonary metastases from colorectal cancer was analyzed for survival rates as well as prognostic indicators for long-term survival. The cumulative survival rate was 45.5% after pulmonary metastasectomy [182]. Multivariate analysis revealed that an elevated preoperative CEA level was an independent prognostic indicator as shown in other studies. The study concluded that surgical resection offers a chance to prolong survival in colorectal cancer patients with resectable pulmonary metastases. However, there was a high recurrence rate (69.1%) and careful postoperative follow-up was advocated by the authors. Critiques of this study include the lack of randomization, appopriate controls, and failure to address the role of adjuvant chemotherapy.

While a majority of series have evaluated metastatic disease limited to the lungs, several series have evaluated patients with both liver and lung metastases. The majority of studies that have analyzed synchronous liver and lung metastases report a uniformly poor outcome following combined resections. Long-term survival is very uncommon in this situation [182–185]. In the setting of isolated pulmonary recurrence after partial hepatectomy, pulmonary metastasectomy appears to have more favorable outcomes similar to those for the initial hepatectomy [183, 184, 186].

TABLE 36-1. Outcome of patients undergoing pulmonary metastasectomy for colorectal cancer

Study	*n*	Operative mortality (%)	5-year survival (%)	Significant risk factors
Mori et al. [293]	35	–	38	None found
McCormack et al. [294]	144	0	44	Margin

The surgical approach to patients who are potential candidates for pulmonary metastasectomy has been somewhat controversial. Based on older studies reported in the 1980s citing a 38% yield of contralateral thoracotomy in finding radiographically occult disease, routine bilateral thoracotomy had been advocated previously [187]. With modern-day imaging, routine bilateral thoracotomy is no longer justified. The use of video-assisted thoracoscopic surgery (VATS) has increased significantly and is often used in metastasectomy when a minimal parenchymal resection is necessary. Initially, VATS was deemed substandard to thoracotomy due to the inability to palpate the lung parenchyma; a prospective study evaluating confirmatory thoracotomy after VATS showed that 22% of lesions were missed [187, 188]. However, with improvements in modern imaging and VATS techniques, a minimally invasive approach can now be employed.

Radiation therapy for colorectal cancer pulmonary metastasis has been of limited utility in the past due to radiation-induced pneumonitis, rib and spinal fractures, and skin toxicities. However, these toxicities can be minimized with the advent of robotic-assisted Gamma Knife radiotherapy or "CyberKnife" [189]. Initial reports appear to have minimal toxicity associated with single-session lung radiotherapy using robotic image-guided real-time respiratory and tumor tracking. This is an exciting field of research and may become an additional therapeutic modality in the future. However, the outcome and efficacy data is limited at this time, and the associated cost of robotic image-guided radiotherapy will be a limiting factor in widespread availability.

While it appears that certain colorectal cancer patients would benefit from pulmonary metastasectomy even in the presence of liver metastases, no randomized controlled trials have been conducted and reported, and the effectiveness of pulmonary metastasectomy has been suggested mostly by results of retrospective analyses. A randomized trial to investigate the effectiveness of pulmonary metastasectomy in colorectal cancer is currently in progress [190], and we will need to look to those results which hopefully will give clear evidences on the benefits of and to establish standard guidelines for pulmonary metastasectomy.

Peritoneal Metastasis

Peritoneal carcinomatosis represents one of the most challenging aspects of metastatic colorectal cancer. The peritoneal surface is involved in approximately 10–15% of colorectal cancer patients at time of initial presentation (synchronous metastases) and in 20–50% of patients who develop recurrence (metachronous metastases) [191–193]. As a site of colorectal cancer metastasis, the peritoneal surface ranks second only to the liver. It is characterized by intraperitoneal spread of metastatic nodules. Peritoneal metastasis occurs by direct implantation of cancer cells via one of four mechanisms: (1) spontaneous intraperitoneal seeding from a T4 colorectal cancer that has penetrated the serosal surface of the colon, (2) extravasation of tumor cells at the time of colon perforation from an obstructing cancer, (3) iatrogenic tumor perforation through an area of serosal injury or enterotomy at the time of colon resection, and (4) leakage of tumor cells from transected lymphatics or veins at the time of colon resection [192]. The risk of peritoneal metastasis is therefore highest in the setting of locally advanced cancers, and, until recently, most oncologists viewed peritoneal carcinomatosis as a terminal condition, to be palliated only with systemic chemotherapy.

However, in a small set of cases, the peritoneal cavity is determined to be the only site of metastatic disease after a detailed workup of the lungs and liver. This has led some to hypothesize that in some cases, peritoneal carcinomatosis may represent a first site of dissemination and, therefore, not necessarily indicative of generalized disease [194–196]. This scenario appears to be rare overall. In a combined series of 2095 patients with metastatic colorectal cancer (CRC) who were enrolled in two chemotherapy trials, 364 (17%) had peritoneal carcinomatosis, but only 44 (2.1%) had peritoneal carcinomatosis as the sole presentation of metastatic disease [197].

A similar paradigm is hypothesized for appendiceal cancer, which also has a propensity to spread intraperitoneally. Radical surgical cytoreduction and intraperitoneal (IP) chemotherapy has gained acceptance for the treatment of diffuse peritoneal adenomucinosis (pseudomyxoma peritonei) and selected patients with peritoneal dissemination of an appendiceal adenocarcinoma (mucinous peritoneal carcinomatosis). This topic is covered in the chapter devoted to appendiceal neoplasms.

Peritoneal metastases are clinically important because of their frequent progression to malignant ascites and/or malignant bowel obstruction [193, 198–201]. When patients present with peritoneal metastases, the most frequent symptoms were ascites (29.7%) and bowel obstruction (19.5%). Preoperative detection of peritoneal metastases is not reliable. Noninvasive imaging frequently misses small peritoneal lesions, even when these are widely disseminated. The sensitivity of CT scanning for lesions smaller than 5 mm is only 28% as compared to 70% for lesions 2 cm or greater [202]. Thus, indirect signs such as bulky primary tumor, ascites, or bowel obstruction are important clues. The utility of MRI in diagnosis of peritoneal carcinomatosis beyond that of CT is largely unknown and PET scans are of limited value. Unfortunately, in the majority of cases, diagnosis is made at the time of primary resection [203]. There are several approaches to treatment if peritoneal involvement is discovered.

The extent of carcinomatosis is a major prognostic factor and is best assessed by either laparoscopic or open exploration. Two different peritoneal carcinomatosis staging systems (Gilly's classification and Peritoneal Cancer Index of Sugarbaker) can be used to assess the extent of carcinomatosis

[204, 205]. These staging systems have both shown utility in determining the prognosis and treatment of patients with peritoneal carcinomatosis. By Gilly's classification, carcinomatosis is classified principally by the dimensions of the peritoneal tumor implants: stage I, tumor nodules less than 5 mm in diameter localized in one part of the abdomen; stage II, tumor nodules less than 5 mm disseminated widely through the abdomen; stage III, tumor nodules 5–2 cm in diameter; and stage IV, tumor nodules greater than 2 cm. The Peritoneal Cancer Index scores the extent of carcinomatosis on the basis of tumor size and location within 13 regions of the abdomen and pelvis with the largest size in each abdominopelvic region is scored on a scale of 0–3 (0, no tumor; 1, tumor up to 0.5 cm; 2, tumor up to 5.0 cm; 3, >5 cm or confluence). The total score of the Peritoneal Cancer Index is shown to correlate with survival. Median survival and 5-year survival after surgical debulking and intraperitoneal chemotherapy were 48 months and 50% for peritoneal index <10, compared to 12 months and 0% for index >20.

Standard management of patients known to have peritoneal metastases at initial presentation (if known preoperatively) is systemic chemotherapy. Colon resection plays an important role for patients with obstructing primary cancers and also for patients with occult metastases that are first detected in the operating room. Historically, the median survival for patients with unresected peritoneal metastasis treated with 5-fluorouracil-based systemic chemotherapy was very poor (6–8 months) [194, 206, 207]. However, patient survival is highly variable, depending on the extent of metastatic disease and response to chemotherapy [194, 207]. Contemporary combination chemotherapy regimens have significantly greater efficacy and can produce long periods of disease control in certain patients.

Despite the grim prognosis for patients with peritoneal carcinomatosis from colorectal cancer, a subset of patients once thought unsalvageable are now being considered for surgery with curative intent. Pioneered by Sugarbaker, the goal of cytoreductive surgery and intraperitoneal (IP) chemotherapy is to remove all macroscopic disease with peritonectomy procedures and visceral resections followed by perioperative IP chemotherapy to destroy residual microscopic disease. IP delivery offers pharmacokinetic advantage over standard intravenous delivery by producing high regional concentrations of drug while simultaneously minimizing systemic toxicities [208–210]. For patients with isolated peritoneal carcinomatosis from colorectal cancer, radical surgery to achieve an R0 resection (if it can be accomplished) remains the mainstay of treatment. Benefit from cytoreductive surgery with heated intraperitoneal chemotherapy has been suggested in several retrospective case series, a multi-institutional registry review [211], two randomized trials, and a systematic review.

These randomized trials must be interpreted with caution as neither used modern combination chemotherapy as the control arm [212, 213]. In the first trial, 105 patients with established peritoneal carcinomatosis of colorectal ($n=87$) or appendiceal ($n=18$) origin were randomly assigned to (A) cytoreductive surgery and HIPEC (with intraoperative mitomycin C) followed by systemic chemotherapy (5-FU and leucovorin only) or (B) systemic 5-FU and leucovorin alone with palliative surgery as needed [212]. Despite the high postoperative mortality rate (8%), the median disease-specific survival in the IP treatment group was significantly longer (22 versus 13 months). At a median follow-up of 8 years, 45% of patients in the IP chemotherapy arm who underwent complete cytoreduction (no residual tumor nodules) were still alive [214]. It should be noted that the use of a modern systemic oxaliplatin or irinotecan containing regimens in the control arm could potentially have narrowed and even eliminated the survival difference between the groups, since median survival durations in contemporary reports approximate 20 months.

The second trial, which also randomly assigned patients following aggressive surgical cytoreduction to systemic therapy (5-FU-based) with or without hyperthermic IP chemotherapy, only accrued 35 of the planned cohort of 90 patients (30 CRC, 5 appendiceal cancers) [213]. Although the 2-year survival rate of patients undergoing IP chemotherapy was 60% (much higher than would be expected among patients treated with systemic 5-FU/leucovorin chemotherapy), the difference in survival between the experimental and control groups was not statistically significant.

A systematic review of published data of cytoreductive surgery and IP chemotherapy for peritoneal dissemination of colorectal cancer, including the two randomized trials described above [212, 213], one comparative study [215], a multi-institutional registry series (an earlier report than described above) [216], and several case series, came to the following conclusions [217]:

- Median survival varied from 13 to 29 months, and 5-year survival rates ranged from 11 to 19%.
- Patients who underwent complete surgical cytoreduction appeared to benefit the most, with median survival 28–60 months and 5-year survival from 22 to 49%.
- This survival benefit was achieved at a cost of overall treatment-related morbidity rates between 23 and 44% and mortality rates from 0 to 12%.

Although these results seem promising, many important unanswered questions remain, including which patients with colorectal cancer peritoneal carcinomatosis have a higher or considerably lower likelihood of long-term survival after cytoreductive surgery and HIPEC [218] (Figure 36-6) and whether results in any population are better than could be achieved using modern oxaliplatin and/or irinotecan-based systemic chemotherapy with or without biologic agents. These regimens have greater activity as compared with 5-FU and leucovorin alone. Median survival durations in unselected patients with metastatic disease are 22–24 months, and approximately 10% of patients remain alive at 5 years.

FIGURE 36-6. Hyperthermic intraperitoneal chemotherapy (HIPEC). Courtesy of Eric K. Johnson, M.D.

The only data that specifically address the efficacy of modern systemic chemotherapy in patients with isolated peritoneal carcinomatosis come from a retrospective analysis of 48 highly selected patients with peritoneal carcinomatosis from colorectal cancer who were treated with an oxaliplatin- or irinotecan-based palliative chemotherapy regimen at one of five French comprehensive cancer centers (where cytoreductive surgery and HIPEC were not available) over a 5-year period [219]. These patients were selected as the control group on the basis of their meeting clinicopathologic criteria defined as good prognostic factors for HIPEC [213]. The 2- and 5-year survival rates were 65 and 13%, respectively, and the median survival was 24 months. In contrast, the median and 2- and 5-year survival rates for a separate group of 48 patients who underwent cytoreductive surgery and HIPEC for colorectal cancer peritoneal carcinomatosis during the same time period at the Gustave Roussy Institute were 63 months and 81 and 51%, respectively. The authors concluded that, in appropriately selected patients with isolated peritoneal carcinomatosis, results with cytoreductive surgery and HIPEC are superior to those that can be achieved with modern combination chemotherapy regimens. The retrospective nature of this analysis and the inherent bias in comparing nonrandomly assigned patients limit the confidence with which this conclusion can be judged.

While patients who undergo complete cytoreduction followed by HIPEC seem to have a more favorable prognosis than can be achieved with systemic chemotherapy alone, there remains insufficient evidence to conclude whether the survival advantage is due to treatment or to biologic features that allow these patients to undergo complete cytoreductive surgery. Furthermore, the quality of the cytoreductive surgery is dependent upon the skills and level of experience of the surgeon. The favorable results (particularly with regard to treatment-related toxicity) [211, 220] achieved by international experts in the field may not be replicated in routine clinical practice. Finally, the independent contribution of HIPEC to the success of this approach has not been proven. Randomized trials are needed.

Based upon all of these issues, the NCCN believes [221] this approach should not be considered standard at present and only pursued in centers with demonstrated expertise [222], preferably in the context of a clinical trial. Such a trial, USMCI 8214/ACOSOG Z6091, in which patients with peritoneal carcinomatosis from colorectal cancer were randomized to standard systemic chemotherapy or surgical cytoreduction with heated intraperitoneal chemotherapy followed by systemic chemotherapy, was closed for lack of accrual. Another trial, Prodige 7, in which patients with isolated intraperitoneal metastases from colorectal cancer are randomly assigned to cytoreductive surgery with or without HIPEC, is underway in France.

In summary, the standard therapy for patients with peritoneal metastases is systemic chemotherapy. However, there is some evidence that aggressive surgical cytoreduction and IP chemotherapy may benefit highly select patients with limited peritoneal tumor burden. Additional clinical trials are needed to define optimal use of this aggressive treatment approach. As a result, if unexpected, diffuse carcinomatosis is found at the time of operative intervention, consideration should be given to referral to a specialized center prior to further operative intervention other than a possible proximal diversion or relief of any immediate surgical emergency.

Ovarian Metastases

Approximately 4–30% of ovarian neoplasms are metastatic cancers with the most common being colorectal and breast cancer [223]. A recent autopsy study demonstrated that of all women dying with colorectal cancer, between 6 and 14% were found to have ovarian metastasis at the time of death [224]. For those women with stage IV disease, the risk of developing ovarian metastases is substantially higher and approaches 90% for those with established peritoneal metastasis. Therefore, in a woman with a recent diagnosis of advanced colorectal cancer, any ovarian mass should be considered a metastasis from colorectal cancer until proven otherwise.

The pathogenesis of ovarian metastasis from colorectal cancer is multifactorial. While metastatic spread occurs primarily through the peritoneum, it can also occur by direct extension, hematogenously or lymphatically. It is imperative that careful intraoperative assessment of the ovaries is undertaken at the time of primary resection of the colon cancer. Depending on the study, synchronous metastases can occur in 0–8.6% of patients [225–228], while metachronous metastases develop in 1.4–6.8% of cases [223, 224], usually within 2 years after the primary resection [226–233]. At least half of the cases have bilateral ovarian involvement [234, 235], and 40% of these patients have associated extra-ovarian

pelvic metastasis [234] and if large enough can be palpated on physical exam or with peritoneal drop metastasis known as the "Blumer's shelf." It is extremely difficult to determine a primary ovarian tumor from a metastatic colorectal tumor by gross examination alone, but through the integration of pathologic, cytogenic, and immunohistochemical features, a correct diagnosis can be generally arrived at. Most metastatic colorectal lesions are CK20+/CEA+/CK7− on immunohistochemical staining, while primary ovarian neoplasms are CK20−/CEA−/CK7+ [235–238].

The decision to perform an oophorectomy at the time of surgery requires some in-depth reasoning. Primary en bloc resection of colorectal cancer with direct extension to the ovary (T4) or resection of macroscopic metastatic disease to the ovary with prophylactic bilateral resection has been suggested to offer survival benefit and should be performed with curative intent in the absence of other significant metastatic disease. However, the removal of macroscopically normal ovaries (prophylactic oophorectomy) in women with colorectal cancer is controversial and remains the subject of much debate. Proponents of removal argue that resection improves the cure rate by removing potential microscopic "undetectable" synchronous disease, eliminates the risk of ovarian cancer, and removes the risk of future metachronous ovarian metastatic disease. Others argue that the low incidence of ovarian metastasis, the small amount of supportive data, and few clinical correlations with predictive value make the additional resection of the ovaries unnecessary [224]. Clinical studies attempting to document the benefit of ovarian metastasectomy in patients with colorectal cancer are small and retrospective [225, 239, 240]. The majority of studies to date, however, fail to show any survival benefit for prophylactic oophorectomy, and most studies demonstrate that when ovarian metastases are present, it is a very poor prognostic sign [224]. Based on available information, it is reasonable to offer prophylactic oophorectomy to all postmenopausal patients, in particular to those women who have undergone pelvic radiation as part of their treatment for rectal cancer. For premenopausal patients, only those with established peritoneal metastases, those that are proven to have an increased risk of developing ovarian carcinoma (strong family history, known carriers of breast cancer (BRCA), or those with an HNPCC mutation), or those who have already completed their families should be considered for prophylactic oophorectomy.

Most ovarian metastases are asymptomatic and are only detected at the time of surgery; however, larger metastatic lesions can compress or invade adjacent organs, rupture, and on rare occasions bleed. Larger ovarian lesions are usually visualized on initial staging imaging and should be part of the decision-making regarding surgical resection and informed consent. Survival of women with synchronous ovarian colorectal metastases is significantly worse than that of patients without such metastases [223, 241]. Ovarian metastases are frequently resistant to systemic chemotherapy even when other sites of metastatic disease are responding, and therefore, resection of these synchronous metastases including bilateral oophorectomy and resection of gross disease should be performed at the index operation [242–245]. Reoperation for metachronous metastases should be considered in select patients with good performance status and limited tumor burden elsewhere. Discussion of these patients in a multidisciplinary fashion is imperative. To prevent local tumor progression, an aggressive surgical approach should be undertaken to achieve complete resection. The survival benefit of removing ovarian metastases had never been well documented, although complete metastasectomy is associated with significantly better outcome when compared to palliative debulking, especially in the setting of metastatic disease confined to the pelvis [246, 247]. It should be noted that complete resection is possible in 50% of these cases. The median post-resection survival for women with isolated ovarian metastases is 18 months [242]. Women with other sites have significantly shorter survival, and 5-year survival after resection of established metastasis is rare [243, 244]. In these cases, systemic chemotherapy should be strongly considered, particularly when residual disease is present. With the constant evolution and improvement of chemotherapeutic regimens, containing oxaliplatin, irinotecan, and/or bevacizumab, better survival can be expected [248–251]. See Figure 36-7 for an algorithm outlining the treatment of ovarian metastases.

Other Sites of Metastasis

Bone

Before the introduction of modern chemotherapy and targeted treatment options, bone metastases were reported in as high as 24% of cases [252, 253]. With modern therapies, bone metastases from colorectal cancer reportedly occur now in 7–9% of cases, and most often present in the context of widespread metastatic disease [254–257]. Routine diagnostic bone imaging is not indicated in colorectal cancer patients, unless there are specific bone-related symptoms. When bone metastases occur, they most commonly occur in the spine (65%), followed by hip/pelvis (34%) and long bones (17%). There are no curative modalities, but palliation of pain, fractures, or spinal cord involvement are important issues for these patients. Symptomatic relief from bony metastases can usually be accomplished with radiation, chemotherapy, as well as bisphosphonate therapy with zoledronic acid [253]. However, pathologic fractures are best treated by operative internal fixation. The systemic issues related to bone metastases are serious and include debilitation, immobility, hypercalcemia, and thromboembolic disease.

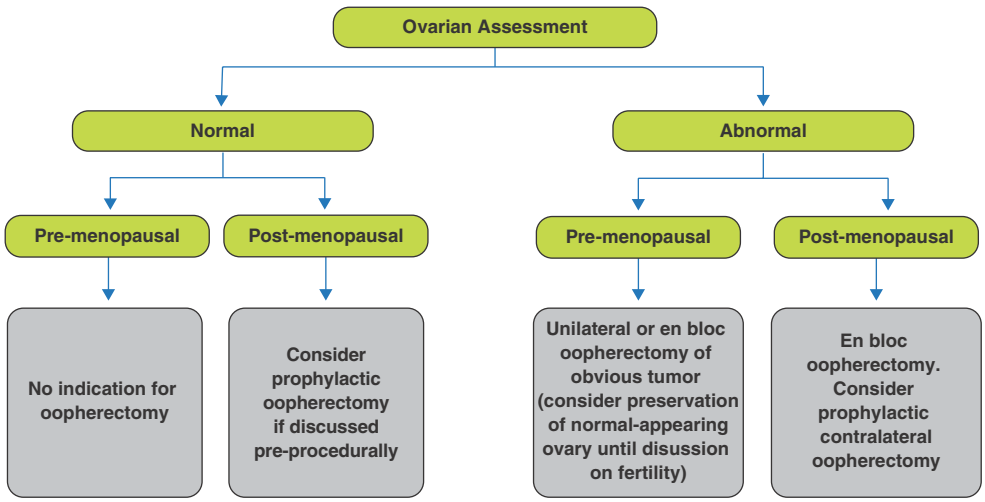

FIGURE 36-7. Treatment algorithm for ovarian metastases.

Brain

Cerebral metastases from colorectal cancer are uncommon, occurring in 1–4% of colorectal cancer cases [254–256]. Colorectal tumors account for approximately 3% of all metastatic brain tumors [257]. These are generally found in the context of widespread metastases to multiple organ sites, but on rare occasion can present as an isolated brain metastasis [258]. There is no role for routine brain imaging at primary presentation or at presentation with metastases elsewhere, unless there are specific neurologic symptoms. Once brain metastases occur, symptoms are common; palliative therapies include steroids to decrease swelling and anticonvulsants to control seizures. Definitive therapy of colorectal brain metastases usually involves surgery, radiation, or a combination of the two. For isolated, single brain metastases, resection can result in survival beyond 1–2 years; however, because brain metastases are infrequently the sole site of metastatic disease and because survival is dismal regardless of therapy chosen, craniotomy is rarely indicated [256–260]. As with pulmonary metastasis, there is increasing interest and data in the literature regarding Gamma Knife and CyberKnife radiotherapy for bone and brain metastasis [261, 262]. The outcome and efficacy data is limited at this time and the associated cost of robotic real-time image-guided radiotherapy may be a limiting factor in widespread applicability.

Pancreas

The pancreas is an uncommon location for solitary metastases from other primary cancers [263]. While the prevalence of pancreatic metastases has been described as high as 6–11% [264], reports of solitary resectable pancreatic metastases from colorectal cancer are extremely rare [265, 266]. Although long-term survival is rare, surgical resection can be performed safely in patients with isolated pancreatic metastases from colorectal cancer and in selected patients with extrapancreatic disease [265]. As with other sites of multiorgan metastases, a multimodality approach is strongly recommended and consideration for surgical resection should be taken in context with an overall treatment plan and chances for improving survival while maintaining quality of life.

Adrenal

Adrenal metastases are uncommon with 14% found in one autopsy series [267]. Isolated adrenal metastases are even rarer. Aggressive surgical resection for isolated adrenal metastases is described in only a few case reports or small series [268–273]. In the largest series of eight patients with apparently isolated adrenal metastasis from colorectal cancer, all of whom received adjuvant chemotherapy, or remained alive and disease-free 12 months after adrenalectomy, one was lost to follow-up and six died of their malignancy. The mean survival of patients who died was 32 (range 12–60 months) [268]. In contrast to the situation with isolated adrenal metastases, the development of adrenal metastases after liver resection for colorectal cancer is associated with a poor prognosis, and adrenalectomy is not warranted [274].

Retroperitoneal Lymph Nodes

Isolated retroperitoneal nodal recurrence occurs in less than 2% of patients following a colorectal cancer resection with curative intent [275–277]. Salvage surgery has been previously avoided due to the poor prognosis; however, this concept is being challenged [278, 279]. A retrospective review of nine studies including case reports, case series, and case-control studies reported a survival benefit and no operative mortality for 110 patients undergoing a salvage retroperitoneal nodal resection. The median disease-free survival was

17–21 months, and the duration of overall survival ranged from 19 months to 18 years with a median of 34–44 months [280]. These series were collective over a time when the newer chemotherapy regimens were evolving (e.g., oxaliplatin, irinotecan, cetuximab, bevacizumab). There is no current data addressing the benefit of chemotherapy after resection of isolated retroperitoneal nodal disease. As in the case in patients with resected colorectal cancer with hepatic and pulmonary metastases, it is unclear if the addition of chemotherapy improves the observed survival statistics.

Metastatic Disease in the Elderly

Colorectal cancer remains one of the most commonly diagnosed cancers in the world with 60% of patients being over 70 years old and 43% are over 75 [281, 282]. The world's population is aging and it is estimated that the number of Americans over the age of 65 will double by the year 2030 and will account for 20% of the total population [283]. The average 65-year-old person can expect to live another 15 years and remain functionally independent for the majority of that time [284]. Thus, the number of older cancer patients is expected to increase. It is estimated that 50% of all cancer and 70% of all cancer mortality occurs in this age group [285]. Therefore, multidisciplinary teams will increasingly see older patients with colorectal cancer, and management of this distinct group deserves special mention.

When considering surgery, comorbidity, functional dependency, and older age are associated with early postoperative mortality in patients with gastrointestinal malignancies, with 30-day postoperative mortality rates underestimating postoperative mortality in older patients [286]. In regards to chemotherapy, the data available indicates that older patients derive the same benefit and have the same degree of toxicity as younger patients. The clinical trial data however may not be reflective of the average elderly patient seen in practice that is often suffering from more comorbidities and has greater functional impairment [287]. For these reasons, the International Society of Geriatric Oncology (SIOG) previously recommended that colorectal cancer patients >65 years of age requiring surgery should undergo a preoperative whole patient evaluation of the most common physiological side effects of aging, physical and mental ability, and social support. Further for those patients assessed as having physical or psychological comorbidities, it was recommended that a geriatrician was involved in the patient management [288].

Since those original recommendations, there have been multiple frailty indices proposed to detect vulnerability in elderly patients with cancer so that treatment can be adjusted accordingly. The process of these assessments, however, can be time consuming, and prescreening is often used to identify fit patients who are able to receive standard treatment versus those in whom a full comprehensive geriatric assessment should be done [289, 290]. The four most common indices utilized appear to be the abbreviated comprehensive geriatric assessment (aCGA), the Vulnerable Elders Survey-13 (VES-13), the Groningen Frailty Indicator (GFI), and the Geriatric 8 (G8). Unfortunately, at present, there is no universal screening tool that adequately identifies frailty in at-risk older patients, and sensitivity and specificity for these indices ranged from 67 to 87% and 59 to 73%, respectively, which questions the value they may offer to the clinician [290]. There has been a study that has shown that the aCGA and G8 were the best screens for older patients with cancer that qualified for elective abdominal surgery; the G8 had the highest sensitivity and negative predictive value and the aCGA was a good overall assessment tool [291]. The American College of Surgeons NSQIP Risk Calculator (http://riskcalculator.facs.org) also uses degree of independence and other comorbidity variables that can be used to assess surgical risk in the elderly. In particular, it also gives an assessment of the risk of discharge to a long-term care facility in addition to the risk of common complications. Colorectal surgeons should be aware of the availability of these assessments and can use them as tools to aid them in evaluating the elderly population.

Because of the ever-increasing complexity and diversity of treatment options for elderly patients with colorectal cancer, SIOG reassembled their task force in 2013 to revise treatment recommendations. As a result of that group's work, it was recommended that the following outcomes need to be considered in relation to contemplating surgery in the elderly population: immediate postoperative morbidity, 30-day postoperative morbidity and mortality, length of stay, discharge to nursing home, 1-year mortality, short-term and long-term functional outcomes, quality of life, and survival. With regard to contemplating chemotherapy management in these patients, it was recommended that the following outcomes need to be considered: toxicity, completion of therapy, quality of life, functional status, progression, survival, and composite end points. Furthermore, it is important to recognize that embracing the concept of individualized treatment in a multidisciplinary setting is key to further improvements in the management of elderly patients utilizing some form of comprehensive geriatric assessment, involving patients in decision-making by providing them with tailored information and the potential for morbidities in advance of treatment, as well as the need for encouraging investigators to design trials using low-toxicity treatments that maintain efficacy of full-dose treatments and patient-centered assessments to expand the evidence base in the treatment of older patients with colorectal cancer [292].

Summary

This chapter has summarized the approach to patients with stage IV colorectal cancer. Throughout a variety of studies, the one overarching principle has been the

emphasis on multidisciplinary evaluation. No one prescribed treatment protocol has proved more successful than others, and a combination of therapies across multiple specialties is now possible and an individualized approach to treatment is important. Available options include modern chemotherapy in the neoadjuvant or adjuvant setting, metastatic surgical resection with a variety of timing options, and nonsurgical ablative techniques. The overarching goal in the use of these treatment strategies is to improve survival and quality of life. There have been dramatic improvements in recent years, and although some patients cannot be cured, they can be effectively treated or palliated. As the approach to tumors can be highly individualized, consensus agreement with expert multidisciplinary evaluation remains of paramount importance in the care of these patients.

Appendiceal Neoplasms

Constantine P. Spanos and Andreas M. Kaiser

Abbreviations

AJCC	American Joint Commission on Cancer
DPAM	Disseminated peritoneal adenomucinosis
ENETS	European Neuroendocrine Tumor Society
HIPEC	Hyperthermic (or heated) intraperitoneal chemotherapy
LAMN	Low grade appendiceal mucinous neoplasms
PCI	Peritoneal carcinomatosis index
PMAC	Peritoneal mucinous adenocarcinomatosis
PMCA	Peritoneal mucinous carcinomatosis
PMP	Pseudomyxoma peritonei

Key Concepts

- Although appendectomy for appendicitis is the most common emergency operation performed by general surgeons, primary neoplasms of the vermiform appendix are rare, and each individual general surgeon will have limited personal experience in the management of such lesions.
- Most primary neoplasms of the appendix are not associated with specific signs or symptoms and are incidentally diagnosed after pathological analysis of the appendectomy specimen, or detected incidentally on imaging such as computed tomography (CT) done for other indications.
- Primary neoplasms of the appendix can generally be divided into epithelial, non-epithelial, and mixed lesions. Epithelial lesions include adenoma and adenocarcinoma. Non-epithelial tumors include neuroendocrine tumors (carcinoids), lymphoma, leiomyoma, leiomyosarcoma, and other even rarer rarities. Goblet cell carcinoids are mixed lesions with features of carcinoid as well as mucinous adenocarcinoma.
- Epithelial tumors, and specifically mucinous adenocarcinomas, are the most common primary appendiceal neoplasms.
- Pseudomyxoma peritonei is the result of a perforation and peritoneal dissemination of a mucin-producing epithelial neoplasm, most commonly originating from the appendix or the ovaries. In select patients, cytoreductive surgery with HIPEC should be considered.
- A mucocele is a morphologic cystic manifestation of an epithelial appendiceal neoplasm. Perforation leads to pseudomyxoma peritonei. Therefore, intact removal en-bloc is of utmost importance.
- Appendiceal carcinoids are rarely associated with carcinoid syndrome or multicentricity.
- The newest tumor staging guidelines distinguish appendiceal tumors from colon cancer, and separate between epithelial and non-epithelial lesions.
- The extent of surgical resection depends on the cell type, preoperative staging, the ability to achieve negative resection margins, and the probability of nodal disease.
- Surgery is the primary treatment for localized disease, whereas its role in metastatic disease needs to be individually analyzed and weighed against systemic chemotherapy.

Introduction

The appendix vermiformis is commonly regarded as the organ that will introduce a surgical trainee to the art of his or her chosen specialty. Inflammation of this organ, namely appendicitis, is the disease process which will be instrumental in "teaching" the fundamentals of history taking, physical examination and differential diagnosis of the acute abdomen to medical students and surgical residents. Appendectomy is the most frequent emergency operation

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_37

Table 37-1. Clinical scenarios depending on type and timing of diagnosis of appendiceal neoplasms

Scenario	Acute symptoms	Presumptive preoperative diagnosis	Surgery	Pre-/intraop evidence of perforation (P) or dissemination (D)	Timing of tumor recognition	Impact/action in decision-making
1. Acute	Y	Appendicitis	N	–	N	Rely on indirect signs/risk factors for identification of affected individuals
						Re-imaging?
2. Acute	Y	Appendicitis	Y	P–	(a) Intraoperative	Primary or secondary evaluation for more extensive/oncological surgery/treatment
				D–	(b) Only on final pathology	
					(c) Not recognized at all (missed opportunity)	
3. Acute	Y	Appendicitis	Y	P+	(a) Intraoperative	Appropriate treatment for perforation with primary or secondary evaluation for more extensive/oncological surgery/treatment
				D–	(b) Only on final pathology	
					(c) Not recognized at all (missed opportunity)	
4. Acute	Y	Appendicitis	Y	P+	Intraoperative	Primary appropriate treatment for perforation
				D+		Secondary assessment for more extensive surgery/treatment
5. Acute	Y	Appendicitis	Y	P–	Intraoperative: evidence of localized mucocele or tumor involving the appendix/cecum	Intraoperative determination of appropriate extent of resection
				D–		Possible frozen section
6. Elective	Y/N	Localized mucocele/ tumor involving appendix/cecum—no signs of PMP	Y	P–	Preoperative	Oncological resection
				D+		Preparedness for HIPEC
7. Elective	Y/N	Localized mucocele/ tumor of appendix/ cecum AND signs of PMP	TBD	P–	Preoperative	PCI
				D+		Systemic treatment and evaluation for CRS/HIPEC
8. Elective	Y/N	PMP, but no obvious cecal pathology	TBD	P–	Preoperative	Evaluation for other potential primary tumor locations
				D+		PCI
						Systemic treatment and evaluation for CRS/HIPEC
9. Elective	Y/N	PMP+distant metastases	N	P–	Pre-treatment	Systemic treatment
				D+		

performed by general surgeons with close to 300,000 performed in the United States annually [1, 2], of which a substantial proportion are performed laparoscopically. On comparably rare occasion, the pathology of the appendectomy specimen incidentally reveals an appendiceal neoplasm ("incidentaloma"), which sometimes is recognized even before or at least during surgery, but more often only after the patient has already been discharged from the hospital. Paradoxically and despite the fact that abdominal surgeons at all levels are very frequently involved in treating appendiceal pathology, appendiceal neoplasms are quite infrequent but may cause rather complex intellectual, management and technical challenges in subsequent surgical interventions (Table 37-1) [3].

Epidemiology

Primary neoplasms of the appendix have an incidence of 0.12 cases per 1,000,000 person years and are found in 0.9–1.4% of appendectomy specimens [3, 4]. They can be asymptomatic, be associated with appendicitis, or cause noninflammatory symptoms. Preoperative diagnosis based on symptoms, imaging, and laboratory results is extremely rare. Even intraoperatively, less than 50% appendiceal neoplasms are recognized as such. A retrospective cohort analysis of the Surveillance, Epidemiology, and End-Results database suggested that the incidence of appendiceal neoplasms has increased significantly in the past few decades from 0.63 to 0.97 per 100,000 population [5, 6]. It is unclear

TABLE 37-2. Reported incidence over time of appendiceal neoplasms in SEER database [5, 6]

Subtype	1973–2001 (*N*=2514)	2000–2009 (*N*=4765)
Mucinous adenocarcinoma (%)	38	38
Non-mucinous adenocarcinoma (%)	26	27
Carcinoid tumors (%)	17	28
Goblet cell carcinoids (%)	15	
Signet ring cell tumors (%)	4	7

TABLE 37-3. Tumor classifications and manifestations

	Localized[a]	Disseminated	Pattern of dissemination[b]
Epithelial	Adenoma (B)		L, H, P
	Adenocarcinoma (M)	Adenocarcinoma	L, H, P
	Mucocele (B)	PMP: Mucinosis peritonei	P
	Mucinous cystadenoma (IM, LAMN)	PMP: Disseminated peritoneal adenomucinosis (DPAM)	P
	Mucinous (cyst-)adenocarcinoma (M)	PMP: Peritoneal mucinous adenocarcinomatosis (PMAC)	P, L, H
		PMP: Peritoneal mucinous carcinomatosis (PMCA)	P, L, H
	Signet ring cell carcinoma (M)	Advanced/metastatic signet ring cell carcinoma	DI, P, L, H
Mixed	Goblet cell carcinoid (adenocarcinoid)	Metastatic goblet cell adenocarcinoid	P, L, H
Non-epithelial	Carcinoid	Metastatic carcinoid	L, H
	<1 cm (B)		
	1–2 cm (IM)		
	>2 cm (M)		
	Lymphoma (M)	Disseminated/multicentric lymphoma	Systemic
	Leiomyoma (B)		
	Leiomyosarcoma (M)	Metastatic leiomyosarcoma	H, L
	Kaposi sarcoma (M)	Disseminated Kaposi sarcoma	Systemic

LAMN Low grade mucinous neoplasia, *PMP* Pseudomyxoma peritonei
[a]*B* Benign, *IM* Intermediate malignant potential, *M* Malignant
[b]*P* Peritoneal, *L* Lymphatic, *H* Hematogenous, *DI* Diffuse infiltrative

though whether this is a true increase or a simple reflection of higher awareness and reclassification as a separate entity. The increase appears to have affected all histological subtypes in an equal fashion (Table 37-2) [5, 6]. Historically, carcinoid tumors were considered the most frequent neoplasms originating within the appendix, and in 1955 a systematic evaluation of 50,000 appendectomy specimens revealed only 41 epithelial neoplasms (0.082%) [7]. More recent publications, however, demonstrate that epithelial neoplasms are more frequent and represent 58% of malignant appendiceal tumors [5, 8]. At the same time, a surge was also noted for the frequency of distant metastatic disease [5]. In contrast, however, appendiceal carcinoids have an incidence of 0.15/100,000/year but the relative frequency compared to other primary sites of neuroendocrine tumors within the gastrointestinal tract has decreased to 16.7% [9, 10]. Epithelial appendiceal neoplasms—paralleling colorectal cancer—usually develop in the sixth or seventh decade of life, whereas non-epithelial pathology including neuroendocrine tumors occur at a younger age, namely the fourth to fifth decade [2, 5, 7, 8, 11]. At the time of diagnosis, a total of 74% of appendiceal cancer cases have already spread, and developed regional or distant metastases in 39% and 35%, respectively [5].

Anatomical Pathology and Staging

The literature unfortunately has for a long time shown little consistency and used a variety of nomenclatures, classification systems, and descriptive terms when referring to appendiceal neoplasms. The many synonyms for lesions of such rarity undoubtedly has led to confounding terminology. From an anatomical point of view, the appendix in essence has a smaller diameter but otherwise a similar layered wall structure as the rest of the large intestine; however there is a higher representation of immunological tissue components (GALT, gut associated lymphoid tissue). The appendix does not participate in processing of intestinal contents but produces 2–3 mL of mucin per day and may participate in immunological functions. The arterial blood supply originates from the appendicular artery which branches off the ileocolic artery; the venous drainage is via the superior mesenteric vein to the portal vein system; the lymphatic drainage follows the vascular structures and due to variability may parallel the ileocolic, right colic, and right branch of the middle colic artery.

Appendiceal neoplasms should be categorized according to the tissue of origin as well as the pattern of growth, expansion, and spreading (Table 37-3). As for the latter,

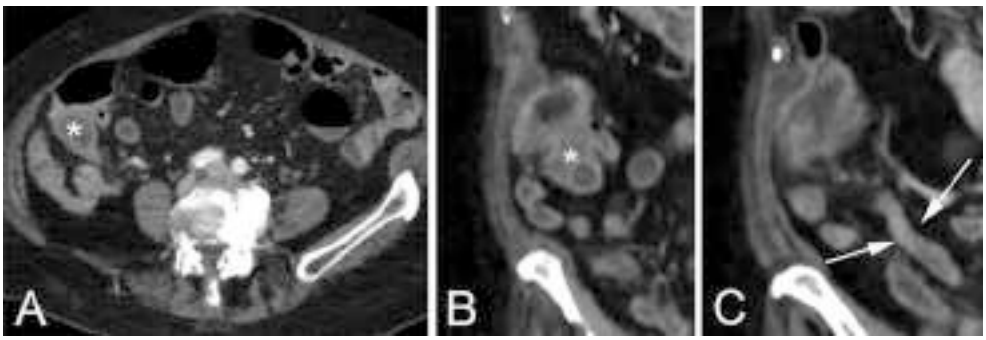

FIGURE 37-1. Appendiceal mucocele: the computed tomography shows the cystic enlargement at the base of the appendix (*asterisk*, panels (**a**) and (**b**)), as well as the moderately enlarged appendix (in-between *arrows*, panel (**c**)).

tumors may either metastasize via vascular, lymphatic, or transperitoneal route. A major distinction is made between epithelial and non-epithelial lesions, the latter of which includes among others neuroendocrine tumors such as carcinoid tumors.

Epithelial Neoplasms

Epithelial neoplasms are divided into mucinous and non-mucinous neoplasms [8]. Mucinous neoplasms of the appendix are classified according to the grade and aggressiveness of the tumor. Descriptively, these lesions characteristically can form mucoceles of the appendix, a morphologic term describing the dilation of the appendix with intraluminal accumulation of mucoid material (Figure 37-1). The obstruction can either be caused by the epithelial neoplasm itself, an independent tumor, or a benign process (retention cysts, mucosal hyperplasia). Rupture of a mucocele results in peritoneal spillage and spread of mucin and—depending on the malignant potential of the lesion—of cellular elements, which are the basis for mucinosis, pseudomyxoma peritonei, and carcinomatosis.

Low grade appendiceal mucinous neoplasms (LAMN) are well-differentiated neoplasms that morphologically resemble adenomas. LAMN has become the neutral term for a number of entities such as appendiceal villous or serrated adenoma, cystadenoma, borderline tumor of the appendix, and mucinous tumors of uncertain malignant potential. These lesions tend to grow slowly and grossly are characterized by a well-defined structure, cystic dilation, and mucinous content. The appendiceal wall is fibrotic and—as a sign of chronicity—may sometimes contain calcifications. Gross rupture (spontaneously or as a result of surgical manipulation) may be evident as mucin extruding on to the serosal surface or seeding of more distant peritoneal surfaces as evidenced by presence of mucin lakes. Histologically, the appendiceal mucosa is replaced by adenomatous proliferations of villous, papillary, serrated, or flat mucinous character. The columnar epithelial cells are mucin-rich and may have elongated (pencil-shaped), mildly hyperchromatic nuclei with nuclear pseudostratification, rare mitoses, and apoptotic nuclear debris. It is of note that the neoplastic epithelium on occasion may herniate through the muscularis propria and form "pseudodiverticula." One might speculate that these extensions represent a route by which such lesions perforate and disseminate to the peritoneal cavity [11].

Prognosis of LAMN depends on the presence or absence of epithelial cells outside the appendix. Tumors confined to the appendix generally have an excellent prognosis. However, LAMN may proliferate outside the appendix in a malignant fashion, producing pseudomyxoma peritonei and/or distant metastases. Pseudomyxoma peritonei (PMP) derived from perforation of a LAMN is characterized by abundant extracellular mucin, hyalinized fibrotic stroma, and harboring scant strips of low-grade mucinous epithelium [8]. The term is not strictly limited to appendiceal neoplasms but the condition can result from other tumor origins such as ovaries, gallbladder, and others. The prognosis of a ruptured LAMN is dependent on the amount and cellularity of mucin deposits, and recurrence rates increase when epithelial cells are present in the mucin. Most instances of PMP resulting from LAMN remain confined to the right lower quadrant. Even if the spread of PMP goes beyond the immediate vicinity, the lesion may pursue an indolent but progressive course. The superordinate term "PMP" has been categorized into disseminated peritoneal adenomucinosis (DPAM) and peritoneal mucinous (adeno-) carcinomatosis (PMAC or PMCA) [12]. The former reflects a low-grade pseudomyxoma arising from LAMNs, whereas the latter indicates peritoneal carcinomatosis. DPAM lesions contain scarce strips of low-grade mucinous epithelium with mild atypia and no significant mitotic activity; [12] these low-grade lesions usually cover but do not infiltrate the surface of the organs to which they adhere.

Appendiceal adenocarcinoma is also divided into mucinous and non-mucinous types. Mucinous adenocarcinoma of the appendix is characterized by a destructive growth pattern with tumor invasion of the appendiceal wall beyond the muscularis mucosae; infiltrating pools of mucin harbor cytologically malignant glandular epithelium arranged in strips, clusters,

and complex proliferations. Mucinous adenocarcinoma due to the increasing pressure of accumulating mucin is prone to rupture, spreading, and seeding into the peritoneal cavity, leading to formation of pseudomyxoma peritonei. Mucinous tumors spread along peritoneal surfaces, even in the absence of lymph node metastases. Peritoneal mucinous (adeno-)carcinomatosis (PMAC/PMCA) results from secondary peritoneal proliferation of appendiceal or intestinal mucinous adenocarcinoma nests that lead to invasion of parenchymal and visceral organs and the omentum, and potentially trigger secondary lymph node metastases at those sites.

Non-mucinous adenocarcinomas behave similarly to colonic adenocarcinomas, infiltrating the appendiceal wall and metastasizing to regional lymph nodes and the liver [11]. Non-mucinous adenocarcinomas show a spectrum of morphological features of the invasive component. In some cases the tumor is identical to colonic adenocarcinoma with malignant (pseudo-)glandular formations, increased stratification, and disorganization (compared to the regular columnar epithelium). In other cases, the malignant glands are tubular in shape, lined by cuboidal epithelium, associated with modest amount of extracellular mucin.

Signet-ring cell carcinoma is a rare but aggressive subentity of mucinous adenocarcinoma, characterized by dissolute growth and infiltration of mucin-containing cancer cells (signet rings); it almost never remains confined, may display an infiltrative growth below intact appearing mucosal surfaces as well as a rapid dissemination within the peritoneal cavity. Signet-ring cell carcinoma is typically associated with a poor prognosis.

Prognosis of appendiceal adenocarcinomas—similar to colon cancer—is primarily determined by the stage, but within stage IV also depends on the histological subtype and grading as well as the route of dissemination. Within each stage and histological subtype, poor differentiation is associated with unfavorable outcomes. Mucinous adenocarcinomas have a markedly worse outcome (reduced cancer-specific survival) than non-mucinous adenocarcinomas of the appendix (Table 37-4). This observation, which was based on published data analysis of the National Cancer Database (NCDB) [4], was recently implemented into the current staging guidelines by the American Joint Commission for Cancer (AJCC) [13]. Appendiceal carcinomas for the first time are classified separately from colonic adenocarcinoma, and distinction is made between mucinous and non-mucinous types; histologic grading for mucinous tumors is considered of particular importance for metastatic tumors (Table 37-5). Stage T4 is divided into T4a (penetration of visceral serosa) and T4b

Table 37-4. Cancer-specific survival for appendiceal adenocarcinoma stratified by stage and grade [4]

Subtype	Stages I–III (%)	Stage IV (%)
Mucinous adenocarcinoma ($N=1375$)		
Well differentiated	82	71
Moderately differentiated	64	51
Poorly differentiated	50	0
Non-mucinous adenocarcinoma ($N=860$)		
Well differentiated	69	48
Moderately differentiated	73	9
Poorly differentiated	55	5

Table 37-5. TNM staging by AJCC for appendiceal adenocarcinoma [13]

Stage	T	*N*	M
X	Primary tumor not determined, or any T	Regional lymph nodes not determined, or any *N*	Metastatic disease not determined, or any M
0	No evidence of primary tumor	No regional lymph node metastasis	No distant metastasis
Is	Carcinoma in situ: intraepithelial or invasion of lamina propria	–	–
1	Tumor invades submucosa	Metastasis in 1–3 regional lymph nodes	1a: Intraperitoneal metastasis beyond the right lower quadrant, including pseudomyxoma peritonei
			1b: Non-peritoneal metastases
2	Tumor invades muscularis propria	Metastasis in four or more regional lymph nodes	
3	Tumor invades through muscularis propria into subserosa or into mesoappendix		
4	4a: Tumor penetrates visceral peritoneum, including mucinous peritoneal tumor within the right lower quadrant		
	4b: Tumor directly invades other organs or structures		

Stage I: T1–2 N0 M0; stage II: T3–4 N0 M0; stage III: Tx N1–2 M0; stage IV: Tx Nx M1

(invasion of other organs). In mucinous tumors that penetrate the visceral peritoneum and cause mucin deposits confined to the right lower quadrant are still considered a T4a (that is a stage II if no lymph nodes are involved); when mucin has dispersed beyond the right lower quadrant, it is designated M1a (stage IV) [13]. M1 is divided into M1a and M1b to distinguish pseudomyxoma peritonei (M1a) from nonperitoneal metastasis (M1b) [13].

Neuroendocrine Appendiceal Lesions/ Carcinoid Tumors

The WHO classification utilizes the terms "neuroendocrine tumor" (NET), "neuroendocrine carcinoma" (NEC), and "mixed adeno-neuroendocrine carcinomas" (MANEC) [14]. Synonyms for NET include carcinoid tumors and well-differentiated endocrine tumors/carcinoma. Synonyms for NEC: poorly differentiated endocrine carcinoma and small cell/large cell endocrine carcinoma. Goblet cell carcinoids (now called carcinomas) are MANEC [14].

Carcinoids or carcinoid tumors represent NETs grade 1 and derive from a variety of dispersed neuroendocrine cells (formerly labeled as amine precursor uptake and decarboxylation cells, APUD cells). These cells and the resulting tumors are not only found in the appendix but also in the entire gastrointestinal tract and other organs and are therefore addressed more comprehensively in the next chapter. Nonetheless, appendiceal carcinoids are only extremely rarely associated with multicentricity, and there is no known association with multiple endocrine neoplasia (MEN syndrome).

Appendiceal carcinoids belong to the embryological and anatomical region of the midgut to include jejunum, ileum appendix, cecum, and right colon. More than foregut and hindgut carcinoids, these midgut carcinoid cells characteristically are hormone-active. Among other products (such as GH, GHRH, gastrin, calcitonin, substance P, insulin, and neurotensin), they produce serotonin from its precursor 5-hydroxytryptophan by means of the enzyme aromatic acid decarboxylase; serotonin is subsequently metabolized in the liver by monoamine oxidase to 5-hydroxyindoleacetic acid (5-HIAA), which is excreted in the urine.

On gross examination, carcinoid tumors of the appendix are yellow-tan firm nodules. 75% are located at the tip, 15% in the mid-appendix and 10% at the base of the organ. At the time of diagnosis, the majority (80%) is less than 1 cm, 14% measure between 1 and 2 cm, and 6% are greater than 2 cm in size [14]. Histologically, carcinoids are characterized by submucosal uniform cell conglomerates with a nested or insular pattern. The cytoplasm has a modestly eosinophilic, fine granularity, and the nuclei show the classic endocrine "salt-and-pepper" chromatin pattern. Tumors have positive reactions to silver stains (argentaffin/argyrophilic) and immunohistochemically to markers of neuroendocrine tissue, including neuron-specific enolase, synaptophysin, and chromogranin A [11]. Ki67 is used to determine the proliferative capacity of the tumor for grading according the current WHO classification [14, 15]. Under the electron microscope (which is not part of routine examinations), carcinoid tumors are typically found to contain numerous membrane-bound neurosecretory granules which store a variety of hormones and biogenic amines [16].

With increasing size of the lesion, the tumor may extend deeper into the wall and even reach the peritoneal surface or in up to 27% of cases infiltrate the mesoappendix. Hence, the AJCC staging for carcinoids is based on tumor size as it correlates with the incidence of metastases and represents the most important prognostic parameter, whereas depth of invasion, lymphatic, perineural, or serosal invasion lack prognostic power (Table 37-6). Lymph node metastases are

Table 37-6. TNM staging (by AJCC and ENETS) for neuroendocrine appendiceal tumors [15]

Stage	T (AJCC)	T (ENETS)	*N* (AJCC/ ENETS)	M (AJCC/ ENETS)
X	Primary tumor not determined, or any T	Primary tumor not determined, or any T	Lymph nodes not determined, or any *N*	Metastatic disease not determined, or any M
0	No evidence of primary tumor	No evidence of primary tumor	No lymph node metastasis	No distant metastasis
1	1a: Tumor ≤1 cm 1a: Tumor 1–2 cm	T1 Tumor ≤1 cm invading submucosa and muscularis propria	Lymph node metastasis	Distant metastasis
2	Tumor 2–4 cm or with extension to the cecum	Tumor ≤2 cm with invasion of submucosa or muscularis propria, and/or minimal invasion (up to 3 mm) of subserosa/ mesoappendix		
3	Tumor >4 cm or with extension to the ileum	Tumor >2 cm and/or extensive invasion (>3 mm) of subserosa/mesoappendix		
4	Tumor directly invades other adjacent organs or structures, e.g., abdominal wall and skeletal muscle[a]	Tumor invades peritoneum/other organs		

[a]Tumor adherent to other organs or structures grossly classified as cT4 but if microscopically negative adhesion as pT1–3 depending on depth of wall invasion

Stage I: T1 N0 M0; stage II: T2–3 N0 M0; stage III: T4 N0 M0 or Tx N1 M0; stage IV: Tx Nx M1

Table 37-7. Impact of appendiceal carcinoid size on lymph node metastasis and survival [11, 14, 18, 49]

Carcinoid size	LN metastases (%)	5–/10-Year survival rates (%)
<1 cm	<1.0–15.0	92–100
1–2 cm	3.0–47.0	81
>2 cm	20–86	31

rare for lesions of less than 10 mm diameter, but occur in 20–30% of patients with carcinoids greater than 2 cm in size (Table 37-7); distant metastases are comparably rare in appendiceal carcinoids. It should be noted that the staging system by the European Neuroendocrine Tumor Society (ENETS) differs from AJCC as it also takes into account depth of appendiceal wall and meso-appendiceal invasion with invasion greater than 3 mm representing more aggressive disease [17]. Five-year survival rates for patients with local, regional metastatic, and distant metastatic disease are 95%, 81%, and 31%, respectively [9, 15, 18].

Goblet Cell Carcinoids

This term may add confusion to the classification of appendiceal lesions. It is considered a hybrid between epithelial and NETs and is also referred to as mucinous adenoneuroendocrine carcinoma [19–21]. These tumors have a mean age of presentation in the fifth decade and behave more like adenocarcinoma than carcinoid. Clinically, goblet cell carcinoids in the middle third of the appendix may in fact cause appendicitis [22]. At surgical exploration, 10% or more of the tumors are found to have already widespread metastatic disease; two-thirds of goblet cell carcinoids are incidental findings on appendectomy and ileocecectomy specimens. Five-year survival rates are worse than for regular carcinoids and for stages I, II, III, and IV were 100%, 76%, 22%, and 14%, respectively, i.e., range from 50 to 80% for locoregional disease to less than 20% for patients with distant metastases [19, 20].

Rare Appendiceal Neoplasms

All other neoplasms are comparably rare and often represent a more systemic disease process. Among the rarities, primary lymphoma of the appendix is seen with some frequency; it affects patients of all ages but most frequently occurs in the second to fourth decade of life. In children and young adults, Burkitt's lymphoma is the most common subtype, whereas older patients are more likely to have diffused large B-cell lymphoma. Furthermore, the appendix has been reported as the site of relapse of several subtypes of lymphoma [11]. Any of these lesions may either present with acute appendicitis or through a palpable mass, intussusception, or lower gastrointestinal bleeding as rarer manifestations. Other even less common and therefore not further detailed lesions include Kaposi sarcoma, leiomyoma or leiomyosarcoma, or leukemic infiltrates.

Clinical Features

Appendiceal epithelial neoplasms are notorious for the absence of any specific signs or symptoms, especially at early stages. Complicating factor is that they escape detection by routine screening efforts such as colonoscopy [23]. If a tumor is concentric and causes obstruction of the lumen, clinical symptomatology of appendicitis may ensue. Red flags in patients with signs of "appendicitis" should include any age above 50, family history of colorectal cancer or inflammatory bowel disease, prolonged history, or anemia. At later stages, epithelial appendiceal neoplasms may present as a localized abdominal or pelvic mass, bowel obstruction, or as progressive, painless, abdominal distention when large volumes of mucin accumulate in the peritoneal cavity (pseudomyxoma peritonei) [2–5].

Even hormone-active tumors such as carcinoids remain silent and are only incidentally detected. Since they are frequently located at the tip of the appendix, they may not even trigger appendicitis. Carcinoid syndrome or "crisis" with flushing, wheezing, diarrhea, and eventually right-sided valvular heart disease results from the release of serotonin and other vasoactive substances. From appendiceal primary carcinoids, this is extremely rare (less than 5%) and requires presence of significant metastatic disease to allow these substances to escape the hepatic first-pass effect and be released into the systemic circulation.

Given the incredible variability of clinical circumstances under which an appendiceal neoplasm may be diagnosed, clinicians will have to develop concepts and algorithms to optimize and standardize their management (Table 37-1).

Diagnostic Procedures

Clinical examination is expectedly unreliable in detecting, confirming, or ruling out an appendiceal neoplasm. Tumor markers are limited and include nonspecific carcinoembryonic antigen (CEA) for epithelial lesions, or 5-HIAA metabolites in the urine for carcinoids. Neither marker is suited for screening or as a negative predictive test. Cross-sectional imaging (CT, MRI) is of greatest value in evaluating a suspected appendiceal neoplasm. Plain radiographs or contrast small bowel follow-throughs may suggest a mass effect when adjacent loops of bowel appear to be displaced, but are rarely definitive. Similarly, contrast enemas, even though rarely done, may provide a hint of an extrinsic impression on the cecum, terminal ileum, or sigmoid colon.

Ultrasonography in skilled hands may allow for identification of appendiceal abnormalities, including appendicitis, fecoliths, mucoceles (hypoechogenic structure), or on occasion a mass in the right lower quadrant. Cystic masses may have a heterogeneous appearance due to the combination of fine cellular framework with mucin-containing chambers with synchronously liquid, gelatinous, and viscous components. A lack of appendiceal wall thickening (>6 mm) suggests

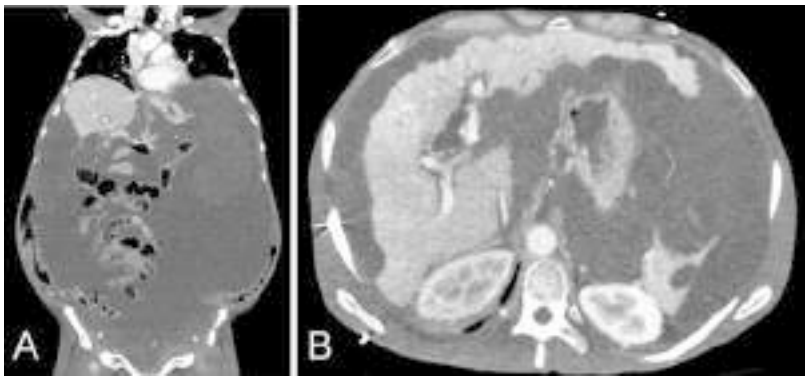

FIGURE 37-2. Pseudomyxoma peritonei: the computed tomography a coronal view (panel (**a**)) and axial view (panel (**b**)) of a patient with massive deposits of low attenuation mucin throughout the entire abdomen with scalloping of the liver contour and widening of the spaces between the compressed bowel loops.

absence of inflammation (appendicitis). A target sign either implies an enlarged and edematous appendix or an intussusception. To a limited degree, mucinous ascites can be detected and even quantified, but for comprehensive assessment of pseudomyxoma, ultrasound is not well suited.

CT or, less commonly used, MRI are the cross-sectional imaging modalities of choice as they provide reproducible, complete, and quantifiable evaluation of the whole abdomen [24, 25]. They are indicated for workup of right lower quadrant symptoms, or after the fact when diagnosed tumors (epithelial and non-epithelial) require lymph node and systemic staging, treatment planning, or evaluation of treatment response. Tumors of sufficient size can be demonstrated as a moderately enhancing soft tissue mass or a cystic dilatation of the appendix beyond 15 mm, which should raise suspicion if noted as an incidental finding [26]. Bowel displacement is an indirect sign of a pathological extraluminal process and is best visualized by adequate opacification of the terminal ileum and cecum by means of intraluminal contrast and differs from an abscess by the lack of inflammatory signs. Features of a mucocele include well-encapsulated and smooth lesions in the right lower quadrant with regular wall and low attenuation that depends on the amount of mucin in the tissue and the center of the lesion [27]. Presence of punctuate, curvilinear calcifications in a right lower quadrant cystic lesion are highly suggestive of a mucocele: they develop as a dystrophic response to a chronic inflammatory process. Myxoglobulosis is an anecdotal variant of an appendiceal mucocele with formation of multiple translucent or calcified mucin globules rather than a homogenous mucin lake.

Pseudomyxoma peritonei is characterized by low attenuation ascites and serosal implants which when not obvious are best seen as scalloping of the liver contour, at peritoneal reflections, or the pouch of Douglas (Figure 37-2). For treatment strategy and prognosis, it is important to quantify areas affected by PMP. The peritoneal carcinomatosis index (PCI) is a summary score with a maximum of 39 points from nine abdominal squares and 4 small bowel segments, whereby each area is scored between 0 and 3 when deposits are >5 cm [24]. Positron emission tomography (PET scan) may have a role for detection or monitoring of systemic metastatic disease but is notoriously ineffective in assessing pseudomyxoma peritonei.

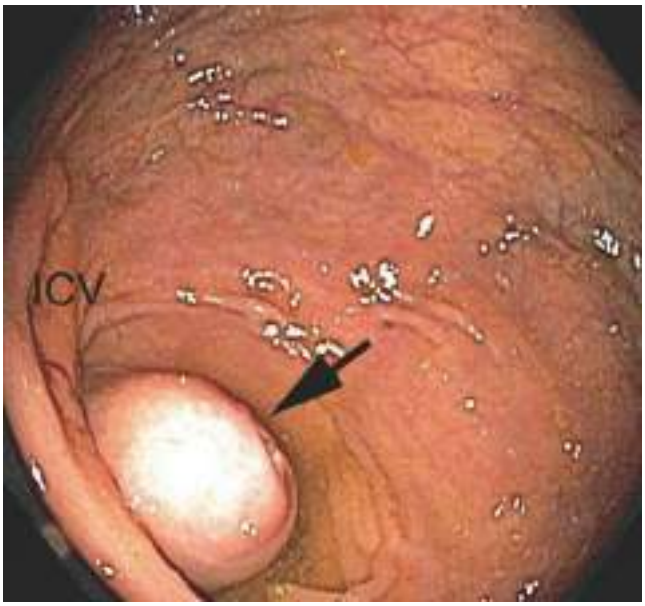

FIGURE 37-3. Colonoscopic appearance: even though appendiceal neoplasms frequently escape endoscopic detection, they occasionally lead to an extramucosal protrusion (*asterisk*) of the appendiceal orifice into the cecal lumen. ICV: ileocecal valve.

Since most carcinoids are surgical/pathological incidentalomas, most diagnostic investigations are performed after the initial operation. For the majority of incidentally diagnosed, well-differentiated appendiceal NERs of <10 mm, no postoperative diagnostic procedure is necessary [15]. After complete resection of 10–20 mm lesions, a single CT or MRI to rule out lymph node and distant metastases is recommended, but without level I evidence [15]. For lesions >20 mm, CT and or MRI of the abdomen is recommended; in addition a PET scan or a somatostatin receptor scan in combination with SPECT/CT (or Somatostatin Receptor PET with 3-phase CT scan) may be considered to detect or rule out distant tumor spread.

Appendiceal neoplasms typically evade detection by colonoscopy [23]. Occasionally, a protrusion of the appendiceal orifice or release of mucoid material may be recognized (Figure 37-3). However, colonic evaluation (colonoscopy, CT

colonography) is recommended prior to any elective intervention for a suspected or proven appendiceal neoplasm, because both epithelial and NETs may be multicentric and/or be associated with a synchronous lesion in up to 10–20% [28].

Medical Management

Management of localized appendiceal neoplasms is primarily surgical. Nonsurgical modalities come into play for locally advanced or metastatic lesions as well as for primarily systemic neoplasms such as leukemia or lymphoma. Pseudomyxoma of too significant extent (high PCI) may not benefit from cytoreductive surgery and HIPEC (see later). Adjuvant and palliative systemic chemotherapy are still largely based of 5-fluorouracil and typically combined with other conventional agents (oxaliplatin and others), or biological drugs such as bevacizumab [29]. Regimens and timings before, during and after surgery remain areas of research [30, 31]. Somatostatin is being used for metastatic and particularly symptomatic carcinoid tumors. Radiation treatment is not part of routine management of any appendiceal tumor and is reserved for special circumstances on an individualized basis.

Surgical Treatment of Appendiceal Lesions

Surgery is the primary treatment for localized disease with the goal to achieve a curative R0 resection; in metastatic disease, the role of surgery needs to be individually analyzed and weighed against systemic chemotherapy or best palliative care. Surgical decision-making should therefore take five questions into consideration as also alluded to in the previously listed clinical scenarios:

1. Has the primary tumor already been removed?
2. Was the clinical situation associated with possible tumor spillage?
3. For a given tumor, what entails an adequate margin?
4. What is the probability of nodal involvement?
5. In case of locally advanced or metastatic disease, is aggressive surgical intervention superior to conservative management?

Depending on the answers, there are four possible surgical responses (Table 37-8): (a) appendectomy only, (b) hemicolectomy or completion hemicolectomy, (c) cytoreductive surgery and peritonectomy with or without HIPEC, or (d) conservative management.

Appendectomy

Appendectomy alone should be reserved for premalignant lesions, carcinoma in situ (Tis), or carcinoids of less than 1 cm diameter provided that a sufficient margin can be obtained. Carcinoids of 1–2 cm represent a grey zone but may be associated with a higher than previously reported incidence of nodal disease [18], suggesting that appendectomy may not suffice. An appendiceal mucocele requires careful dissection to avoid perforation of the lesion. If the case is approached laparoscopically, placement of the whole appendix/cecum into a specimen bag prior to starting the dissection may be a strategy to avoid rupture and spillage or conversion to a laparotomy [32].

TABLE 37-8. Operations performed for appendiceal neoplasms

Appendectomy	Right hemicolectomy	Cytoreduction + HIPEC	Nonsurgical
Intact mucocele	Invasive adenocarcinoma	PMP with PCI ≤16 (–20):[a]	PMP with PCI > (16–)20?[a]
Adenocarcinoma tis		– Diffuse mucinous adenomucinosis peritonei	Adenocarcinoma with diffuse systemic metastases
		– Peritoneal mucinous (adeno-) carcinomatosis	Adenocarcinoma with peritoneal disease AND systemic metastases
		Perforated appendiceal neoplasm without visible PMP?	
Appendiceal carcinoid <1 cm, R0	Appendiceal carcinoid 1–2 cm, R0?		Carcinoid with diffuse systemic metastases beyond one organ
	Appendiceal carcinoid >2 cm		
	Any carcinoid with insufficient margin (R1, questionable R), multifocality, invasion of mesoappendix >3 mm		
	Any carcinoid with nodal involvement		
	Any carcinoid with systemic metastases to the liver only		
	Goblet cell carcinoid	PMP from goblet cell carcinoid	Widespread systemic metastases, or PMP from goblet cell carcinoid with systemic metastases

[a]*PMP* Pseudomyxoma peritonei, *PCI* Peritoneal carcinomatosis index

Right Hemicolectomy

For non-perforated appendiceal adenocarcinoma, carcinoids larger than 2 cm and any of the previously mentioned lesions with unfavorable features or whose margins are insufficient with an appendectomy alone, an oncological right hemicolectomy with a mesocolic lymph node dissection is indicated [15, 18]. Oncological resection for adenocarcinoma achieves better 5-year survival rates than appendectomy alone [33]. The incidence of lymph node metastases in appendiceal carcinoid tumors increases with size of the tumor (Table 37-7). There is controversy regarding the surgical management of patients in which perforation of a mucinous appendiceal neoplasm has occurred resulting in pseudomyxoma peritonei. Some argue that a right hemicolectomy is not necessary in this situation as the outcome is determined by the peritoneal disease rather than the lymph nodes [32, 34].

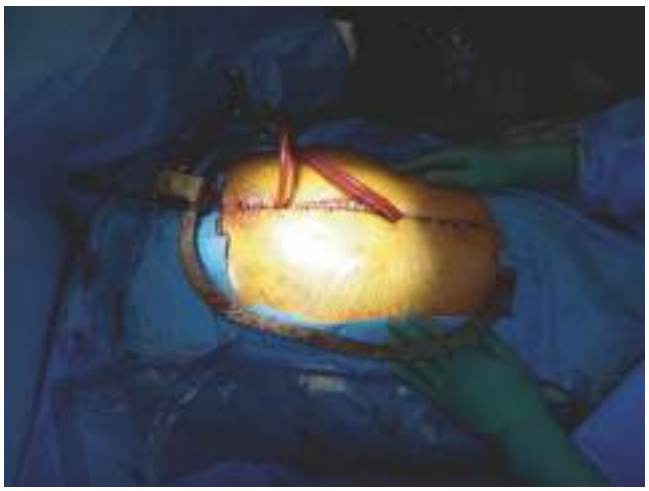

FIGURE 37-4. Hyperthermic intraperitoneal chemotherapy (HIPEC) (Courtesy of Eric K. Johnson, M.D.).

Cytoreductive Surgery and HIPEC

In cases of advanced peritoneal dissemination, cytoreductive surgery with HIPEC is performed in selected cases [15]. If pseudomyxoma peritonei is unexpectedly encountered during an operative exploration, the patient would be best served by careful retrieval and cytological analysis of any mucinous fluid present, and referral to a specialized center with expertise in cytoreductive surgery and HIPEC [35]. Minimization of surgical manipulation and mobilization of intra-abdominal viscera will facilitate the subsequent cytoreductive surgery performed later.

The mainstay of surgical treatment for disseminated peritoneal disease is the arduous operative task of cytoreductive surgery and heated intraperitoneal chemotherapy (HIPEC) (Figure 37-4). In retrospective series, this surgical modality has demonstrated favorable results in carefully selected patients [36], but at the same time was associated with a substantial morbidity and mortality; [37–41] in addition, most series note that incomplete cytoreduction was unable to achieve a relevant benefit as the recurrence rates were very high [37, 42, 43]. It seems rather obvious that the outcomes depend on the extent of the initial disease whereby a number of authors recommended to limit cytoreductive surgery and HIPEC to patients with a PCI of less than (16–)20.

In reviewing the evidence supporting the use of cytoreduction and HIPEC, it should be noted that the literature on the technique and outcomes continues to have significant limitations. On one hand, most series are retrospective and inconsistent in regards to inclusion criteria, extent of disease, concomitant treatment, protocols, and follow-up. Selection bias is inherent to their study designs. Furthermore, they are heavily dominated by Sugarbaker [44], who has advocated for the use of cytoreduction and HIPEC not only for appendiceal neoplasms, but also for peritoneal carcinomatosis arising from non-appendiceal cancers. Corroboration of his data by other groups is in process, but at the same time challenged by availability of more aggressive systemic chemotherapy regimens, the latter of which parenthetically has been found to increase the risk of complications after HIPEC [31]. Most importantly, however, there is a lack of prospective randomized data on direct comparison of HIPEC and cytoreductive surgery with systemic chemotherapy alone. The only prospective randomized trial to date that suggested improved outcomes with HIPEC compared to systemic treatment only was limited by a chemotherapy regimen (fluorouracil-leucovorin) that many feel was not representative of modern treatment standards [43]. A heated debate continues as to whether HIPEC should be considered the standard of care or still an experimental approach [45, 46].

In preparation for cytoreductive surgery and HIPEC, adequate staging and quantitative assessment using the PCI [24], colonic clearance, aggressive hydration, and bowel cleansing are essential. Considerations include provisions for stomas, timely prophylactic vaccination for splenectomy (against pneumococcus, meningococcus, and H. Influenza) and placement of a gastrostomy tube and feeding jejunostomy tube. Cytoreductive surgery aims at removing or reducing all visible tumor implants to less than 2 mm in size as only complete cytoreduction allows for adequate drug penetration into residual tumor deposits. It typically includes omentectomy and stripping of all parietal peritoneal surfaces, including the subdiaphragmatic spaces and the paracolic recesses (peritonectomy). However, it may also involve aggressive multiorgan resection including tumor-involved bowel (colon, small bowel) or other organs (gallbladder, spleen, uterus/ovaries, and others) or the posterior rectus sheath may be removed. For the HIPEC phase of the procedure, a number of open or closed techniques have been reported. We have typically used the closed technique to minimize heat dissipation, spillage of perfusate, and safety hazard to health personnel [47, 48]. The incision is temporarily closed to the size of a gel port through which large-bore afferent and efferent cannulas are placed to the peritoneal cavity. The heated chemothera-

peutic drugs are circulated throughout the abdominal cavity via pumps and heat exchangers (heart-lung machine). The most frequently used drug is mitomycin-c, which is administered for a duration of 60–120 min at a temperature of 41–43 °C. Other drugs have been used and are being tested without any increased benefit. Reconstructions and anastomoses are to be performed after the hyperthermic perfusion phase. Cytoreductive surgery and HIPEC are associated with formidable morbidity that may exceed 50% (Table 37-9). Apart from myelosuppression and nephrotoxicity with intensified diuresis, complications include sepsis, respiratory failure, ileus, anastomotic leak, abscess, enterocutaneous fistula, acute renal failure, thromboembolic events, and in the long run formation of hostile adhesions. The mortality rates in initial reports were approximately 10%, but could be reduced significantly in more recent series (Table 37-9). In the majority of reports, PCI score, PMCA tumor type and completeness of cytoreduction were significant prognostic factors. Perioperative or neo-adjuvant chemotherapy is currently a matter of debate and is not routinely used.

Conclusion

Appendiceal neoplasms are rare lesions. Most individual surgeons will encounter few, if any, during their career. Nevertheless, when a diagnosis of such a lesion is made, careful investigation of the histopathology and rational analysis of the various parameters are of paramount importance in order to finalize treatment and follow-up. There are numerous areas (e.g., incidentalomas, conservatively treated "appendicitis," perforated tumor without visible implants, and others) that await clarification of guidance which should be developed on preferably prospective data.

Carcinoids, GISTs, and Lymphomas of Colon and Rectum

David J. Maron

Key Concepts

- Treatment of colonic carcinoids is segmental resection including mesenteric lymph nodes.
- Somatostatin analogues control the symptoms of carcinoid syndrome and help limit progression of disease.
- Rectal carcinoids less than 1 cm may be treated by local excision, while tumors greater than 2 cm require radical resection.
- Imatinib blocks activation of the KIT oncoprotein in gastrointestinal stromal tumors.
- Patients with colonic lymphomas that produce symptoms are best treated with surgical resection prior to chemotherapy.

The majority of neoplasms that arise in the colon and rectum are adenomas and adenocarcinomas; however, other tumors may present as well. It is important for the clinician to understand the biology of these tumors so that proper therapy may be offered. Tumors may develop from epithelial, mesenchymal, neural, vascular, or lymphoid tissue. While there are a number of rare colorectal tumors, this chapter will discuss three more commonly occurring non-adenomatous neoplasms.

Carcinoid Tumors

Carcinoid tumors were originally described in 1888 in two patients with multiple small tumors of the ileum by Otto Lubarsch, a German pathologist. In 1907, Siegfried Oberndorfer first used the term "Karzinoid," which translates as "carcinoma-like," hinting that these tumors behave differently from adenocarcinoma [1]. It was believed that although these tumors could metastasize like carcinomas, their clinical course was typically fairly benign.

Electronic supplementary material: The online version of this chapter (doi:10.1007/978-3-319-25970-3_38) contains supplementary material, which is available to authorized users.

Histology

Carcinoids are slow growing tumors of the neuroectodermal origin and belong to the amine precursor uptake and decarboxylation (APUD) system. They originate from Kulchitsky or basogranular enterochromaffin cells located in the crypts of Lieberkuhn [2]. Microscopically, these tumors are composed of monotonous sheets of small round cells with uniform nuclei and cytoplasm. The cells contain very dense neurosecretory granules that contain various secretory peptides; these granules are similar to synaptic vesicles found in neurons. The cytoplasmic features are typically benign-appearing and mitotic figures are infrequent. Five histologic patterns of carcinoid tumors include insular, trabecular, glandular, undifferentiated, and mixed. Insular and trabecular patterns are typically associated with a more favorable prognosis. Distinguishing between benign and malignant carcinoids can be difficult; however, increased cellular atypia, high mitotic activity, or necrosis is often associated with more aggressive tumors.

Carcinoid tumors have specific staining patterns related to the amines and peptides they produce as well as cytoplasmic proteins they contain. Serotonin is capable of reducing silver salts to metallic silver, and therefore carcinoid tumors that produce serotonin and stain positive with silver stains are described as "argentaffin positive." Some tumors are capable silver uptake but not reduction, and these may be demonstrated by the addition of an external reducing agent; these tumors are referred to as "argyrophilic." Carcinoid tumors of the midgut are typically argentaffin positive, while those in the hindgut are often mixed (6–70% argyrophilic and 8–16% argentaffin positive) [3]. Silver staining has been abandoned in favor of immunohistochemical staining for cytoplasmic proteins, including chromogranin, synaptophysin, and neuron-specific enolase [4].

Carcinoid tumors have been shown to produce at least 30 bioactive compounds [5]. These compounds include amines such as serotonin and histamine, proteins (including various hormones and kinins), and prostaglandins. Serotonin is

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_38

derived from the amino acid tryptophan in a two-step process and is stored and transported in platelets. As tryptophan is an essential amino acid important in the production of proteins such as niacin (vitamin B_7) and nicotinamide (vitamin B_3), deficiencies of these vitamins may occur if large quantities of tryptophan are consumed in the production of serotonin by carcinoid tumors. Metabolism of serotonin occurs first in the liver (monoamine oxidase) and then in the kidney (aldehyde dehydrogenase) to produce 5-hydroxy-indole-acetic acid (5-HIAA), which is excreted in the urine.

Incidence and Distribution

Carcinoid tumors may originate in the foregut, midgut, or hindgut. Foregut tumors arise in the thymus, respiratory tract, stomach, duodenum, and pancreas. Midgut carcinoids originate in the jejunum, ileum, appendix, and proximal colon. Hindgut tumors arise in the distal colon and rectum. The distribution of carcinoids varies among reports. In a series of almost 3000 carcinoid tumors, Godwin [6] found that the most frequent site of origin was in the appendix (38%), followed by the ileum, rectum, and bronchus (23%, 13%, and 11.5%, respectively). Modlin and Sandor [7] combined Godwin's series with an additional 5000 carcinoid tumors and reported the most common site as the small bowel (28.7%) followed by the bronchus, appendix, and rectum (25.1%, 18.9%, and 12.6%, respectively). A recent report noted that since the implementation of screening colonoscopy in the United States, the incidence of rectal carcinoids has surpassed that of small bowel carcinoids [8]. Carcinoid tumors are associated with an increased risk of synchronous colorectal and small bowel tumors, as well as metachronous lung, prostate, and urinary tract neoplasms [9, 10]. The reason for this association is unknown; however, it has been theorized that the various peptides secreted by carcinoid tumors may have tumorigenic properties [9].

Clinical Presentation

Approximately half of all gastrointestinal carcinoids are diagnosed following appendectomy for suspected appendicitis. Carcinoids of the appendix are discussed in detail in Chap. 37. Colonic carcinoids most commonly occur in the seventh or eighth decade of life and are more common in women than in men [11]. They may present as a polyp or as a mass that is indistinguishable from a colon carcinoma, both grossly and on radiographic visualization. Many patients with colonic carcinoids are asymptomatic or have symptoms from another condition that prompt an investigation that leads to the diagnosis [12]. Those tumors that are symptomatic produce symptoms similar to colonic carcinomas (bleeding, abdominal pain, and change in bowel habits).

Carcinoids may arise throughout the colon; however, they are more commonly found in the cecum. Ballantyne and colleagues reported 48% of colonic carcinoids were found in the cecum, 16% in the ascending colon, 6% in the transverse colon, 11% in the descending colon, and 13% in the sigmoid colon [13]. Murray et al. reported similar results, with 73% of tumors found in the cecum, 7% in the ascending colon, and 20% in the sigmoid colon [14].

Symptoms of rectal carcinoids, when present, are typically rectal bleeding or change in bowel habits. Most rectal carcinoids, however, are asymptomatic and are found at the time of colorectal cancer screening. The incidence of rectal carcinoids in all patients undergoing sigmoidoscopy is estimated at 0.05% [15, 16]. These tumors typically appear as a solitary 1–1.5 cm mobile submucosal nodule with an intact overlying normal mucosa. Malignancy is frequently associated with carcinoids larger than 2 cm with invasion through the muscularis propria. These tumors often will appear ulcerated and present with rectal bleeding. Metastatic disease tends to occur less frequently in carcinoid tumors of the hindgut (rectum 18%) when compared with midgut carcinoids (small bowel 34%, colon 60%) and foregut tumors (stomach 23%, bronchopulmonary 21%) [6].

Carcinoid Syndrome

Systemic symptoms produced by carcinoid tumors are referred to as the carcinoid syndrome. Although classically described as the hallmark of carcinoid tumors, carcinoid syndrome occurs in only 10–18% of patients with carcinoids, and in only 50% of patients with advanced disease [3]. The symptoms include flushing of the skin, non-bloody diarrhea, and abdominal pain. The symptoms are often episodic and may be precipitated by stress or the ingestion of certain foods, caffeine, or alcohol. The flushing may involve the face or the entire body and may occur for a few minutes or last for several hours. Flushing may also be associated with excessive tearing, salivation, and bronchopulmonary spasm leading to wheezing. Flushing occurs in up to 85% of patients with the carcinoid syndrome, and it is believed that kallikrein secretion is responsible for these symptoms [17]. Abdominal symptoms such as cramping and watery diarrhea occur in 80% of patients with carcinoid syndrome, and are likely due to the secretion of serotonin. Intestinal obstruction may also develop secondary to mesenteric fibrosis, and fibrosis of the retroperitoneum may lead to ureteral obstruction. Treatment of symptoms of diarrhea includes loperamide, diphenoxylate/atropine, and other antidiarrheal medications. Antihistamines or H2 receptor antagonists may be helpful in reducing flushing symptoms.

Patients with carcinoid syndrome may also develop right-sided heart failure. Serotonin has an effect on myofibroblasts which results in fibroplasia, increased vascular tone, bronchoconstriction, and platelet aggregation. These effects may lead to pulmonary hypertension, tricuspid and pulmonary valve stenosis, and right ventricular hypertrophy and fibrosis [5]. Patients with higher levels of serotonin (higher urinary

5-HIAA levels) have been found to have increased valvular damage [3]. The left side of the heart is spared from the effects of carcinoid products as the lungs are capable of inactivating these substances. Surgical repair or replacement of the affected valves has been met with significant postoperative morbidity.

The liver is capable of metabolizing and inactivating most of the peptide hormones secreted by carcinoid tumors. It is for this reason that the carcinoid syndrome typically develops only after the tumor has developed metastases in the liver. Alternatively, primary carcinoid tumors located outside the portal venous system (bronchopulmonary) or gastrointestinal tumors that develop lymph node metastases or direct invasion into the retroperitoneum may also present with carcinoid syndrome [18].

Carcinoid syndrome occurs most frequently in patients with metastatic disease from a midgut carcinoid tumor. In fact, 90% of patients with carcinoid syndrome have midgut carcinoids, and 60% of patients with metastatic small bowel carcinoids will develop symptoms. This is likely due to the ability of midgut carcinoids to produce high levels of serotonin [19]. In contrast, foregut tumors typically lack the enzyme required to convert 5-hydroxytryptophan into serotonin, and hindgut carcinoids rarely produce serotonin. Therefore rectal carcinoids, even in the presence of metastatic disease in the liver, almost never result in the carcinoid syndrome.

Diagnostic Tests

The majority of carcinoid tumors of the colon and rectum are found during colonoscopy or are discovered during abdominal exploration for another condition. Full endoscopic evaluation of the colon and rectum should be performed to evaluate for synchronous malignancies. Endoscopic ultrasonography has been used in the evaluation of rectal carcinoids, and has been shown to have a 75% accuracy rate in determining the depth of invasion and presence of lymph node metastases [20]. This may be helpful in determining whether the carcinoid is amenable to endoscopic resection [21].

When endoscopic biopsy is not feasible, biochemical tests may help to make the diagnosis of carcinoid. Although carcinoid tumors may produce a variety of hormones, the most widely used tests are related to serotonin. The most useful biochemical test for diagnosing carcinoid in the symptomatic patient is the 24 h urine 5-HIAA assay. Normal excretion ranges from 2 to 8 mg/24 h, and a diagnosis of carcinoid syndrome in patients with excretion exceeding these levels has a sensitivity and specificity of 73% and 100%, respectively [22]. Certain medications including acetaminophen and salicylates, as well as serotonin-rich foods such as bananas, pineapples, nuts, and avocadoes may falsely elevate urinary 5-HIAA levels and should therefore be avoided during the test.

In addition to a CT scan of the chest, abdomen, and pelvis to evaluate for metastatic disease, somatostatin receptor scintigraphy (SRS) may be helpful in identifying occult metastases and to determine if the patient is likely to respond to treatment with octreotide. The majority of carcinoid tumors express receptors (SSTR 1–3) that have an affinity for somatostatin [23]. SRS therefore has a high sensitivity in detecting carcinoids; however, approximately 10% of tumors do not express the somatostatin receptor. Whole body positron emission tomography (PET) using ^{18}F-Dopa may also be useful in detecting carcinoid tumors. Hoegerle et al. compared the use of CT, SRS, and PET scans in the localization of primary and metastatic carcinoid tumors and found that PET imaging was more sensitive in localizing primary tumors and lymph node involvement, while CT was more sensitive in identifying distant disease [24]. Krausz et al. compared ^{18}F-Dopa PET/CT imaging with SRS and found that PET/CT demonstrated more true positive tumor foci and was better tolerated by patients [25]. The TNM staging of carcinoid tumors is similar to that of adenocarcinomas of the colon (Table 38-1).

Treatment

The treatment of carcinoid tumors is surgical resection. The type of surgery depends on a variety of factors, including whether the tumor is amenable to local or endoscopic resection and whether surgical debulking of tumor may help to reduce the symptoms of the carcinoid syndrome. The choice of the appropriate procedure is based on the location of the tumor, the likelihood of residual primary disease, and the presence of lymph node or metastatic disease. Guidelines for resection are summarized in Table 38-2.

Carcinoids of the small bowel are frequently multicentric and have a propensity for developing obstruction secondary to intussusception, mesenteric fibrosis, and kinking of the bowel (Figure 38-1a, b). Metastasis to regional lymph nodes approaches 50% [26], and tumors less than 1 cm in diameter are associated with a 20–30% incidence of lymph node involvement. Size of the tumor is a poor predictor of distant metastasis, as tumors less than 0.5 cm have been shown to metastasize to the liver. Surgical management should therefore include a formal small bowel resection with wide mesenteric excision of the associated lymph nodes. This should be performed even in the presence of metastatic disease to reduce the incidence of small bowel obstruction due to tumor or fibrosis of the mesentery. As one-third of carcinoids of the small bowel may be multicentric, it is important to examine the entire small intestine to evaluate for synchronous lesions [26].

Carcinoids arising in the colon are often asymptomatic until they develop into large tumors with lymph node metastases. Colonic resection similar to that performed for adenocarcinoma is therefore recommended, with the extent

TABLE 38-1. TNM staging of carcinoid tumors

Stage	Characteristics
Tumor	
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through muscularis propria into subserosa or nonperitonealized pericolic or perirectal tissues
T4	Tumor directly invades other organs or structures and/or perforates visceral peritoneum
Regional nodal metastases	
NX	Regional lymph nodes cannot be assessed
N0	No nodal metastasis
N1	Metastasis in 1–3 pericolic or perirectal nodes
N2	Metastasis in four to more pericolic or perirectal nodes
N3	Metastasis in any node along course of a named vascular trunk and/or metastasis to apical node
Distant metastasis	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

determined by the location of the disease [27]. Outcomes following colectomy for colonic carcinoids are varied. Welch and Donaldson [28] reported that 5-year survival was similar to that of survival in patients with carcinoma of the colon, while Berardi noted that the average survival following resection of colonic carcinoid was 26 months [29]. Location of the primary tumor may affect outcomes, as in one series cecal tumors were found to have an incidence of 71% metastases while tumors elsewhere in the colon had only a 33% incidence [30]. Spread and colleagues [31] noted that survival in patients with colonic carcinoids was significantly lower when compared with carcinoid tumors of the rectum or appendix, and was also significantly lower than survival in patients with adenocarcinoma. Al Natour and colleagues recently reviewed 929 patients with colonic carcinoids and found that those patients with intramucosal tumors less than 1 cm in diameter had only a 4% risk of lymph node metastasis [32]. They concluded that small tumors confined to the mucosa may be appropriately treated by endoscopic resection.

As carcinoid tumors of the rectum may be amenable to local excision, less invasive treatment may be an option in some patients. It is important to balance the benefits of a less morbid intervention with the risks of local recurrence and nodal involvement (and hence the risk of metastatic disease). Transanal or endoscopic excision is adequate for most tumors less than 1 cm in diameter. Formal transanal excision of the full thickness of the rectal wall allows for a precise assessment of the depth of penetration, and is more likely to result in negative margins of resection. However, this may not be necessary for many patients, as recurrence is rare even when there is an involved margin following endoscopic excision of tumors less than 1 cm in diameter. Invasion of the muscularis propria (T2) has been associated with lymph node metastases in up to 47% of patients [33]. In an analysis of 106 patients with rectal carcinoid, muscularis invasion was the only independent prognostic factor for predicting 5-year survival, and size of the tumor was significantly associated with muscular invasion [34].

In addition to muscularis propria invasion, rectal carcinoids whose size is greater than 2 cm in diameter are also at significant risk of lymph node metastases. Patients should therefore be considered for proctectomy with excision of the mesorectum to allow for assessment and clearance of the nodal basin. The treatment of rectal carcinoids measuring between 1 and 1.9 cm remains uncertain and must be individualized based on tumor features and the overall health of the patient. In a series of 62 patients, lymph node metastases were found in 69% of patients with tumors ranging 1.1–2 cm in diameter [35]. Shields and colleagues evaluated 202 patients with rectal carcinoids and found that tumor size greater than 1 cm and evidence of lymphovascular invasion were independent predictors of lymph node involvement [36]. Lymph node involvement was also associated with the development of distant metastasis and significant decrease in survival. Perineural invasion has also been demonstrated as a poor prognostic factor [37]. These findings have led some authors to conclude that rectal carcinoids larger than 1 cm should routinely be treated with radical resection in suitable patients [35, 36].

Carcinoid tumors are typically slow-growing and patients often exhibit favorable 5- and 10-year survival rates despite the presence of extensive metastatic disease. Surgical treatment of metastatic carcinoid in the liver may be of benefit in improving survival and may help to provide long-term palliation of hormone-related symptoms in patients who are unable to tolerate or do not respond to medical treatment with somatostatin analogues. Various techniques have been employed, including hepatic resection, radiofrequency ablation, cryosurgery, and chemoembolization. Wedge resection or lobectomy of hepatic metastases not only improves symptoms associated with the carcinoid syndrome but also has been shown to prolong survival [38]. As metastatic carcinoid tumors derive the majority of their blood supply from the hepatic artery (while hepatocytes receive blood supply primarily from the portal venous system), chemoembolization may play an important role in patients who are unable to tolerate hepatic resection. Patients with large tumors or those who are refractory to somatostatin frequently experience significant short-term improvement in their symptoms [39]. Liver transplantation has also been employed in patients with metastatic carcinoid, with outcome similar to those seen in patients who undergo transplantation for hepatocellular carcinoma [40].

The efficacy of systemic chemotherapy in the treatment of metastatic carcinoid is limited. Various agents have been used, including 5-FU, streptozotocin, cisplatin, doxorubicin, etoposide, and dacarbazine, either as monotherapy or in combination. The largest study reported is a comparative trial of combination therapy with 5-FU and doxorubicin versus 5-FU and streptozotocin [41]. This study demonstrated an improvement in median survival in the streptozotocin arm (24.3 months vs. 15.7 months); however, there were no differences between the two treatments with regard to response rate (16% vs. 15.9%) or progression-free survival (5.3 months vs. 4.5 months). More aggressive carcinoids may respond well to combination therapy with cisplatin and etoposide [42]. The use of continuous infusion 5-FU combined with octreotide has also shown some promise, with reports of a 24% partial response rate and disease stabilization in 69% in a small series of patients [43].

More than 80% of carcinoid tumors express surface receptors for somatostatin (especially receptor subtype 2), and therapeutic strategies have therefore focused on the development of agents that target these receptors. Activation of these receptors results in reduced hormone synthesis and secretion, thereby leading to complete or partial relief of symptoms associated with the carcinoid syndrome in up to 90% of patients [44]. Somatostatin analogues that have been used in the treatment of carcinoid include octreotide and lanreotide.

Octreotide may be given as a subcutaneous, intramuscular, or long-acting depot injection. Lanreotide has a longer half-life than octreotide; however, its use is not currently approved for use in the United States. In addition to the ability to control symptoms, somatostatin analogues may also help to limit the progression of disease. In a placebo-controlled double-blind, randomized trial of 85 patients, octreotide was associated with a significantly better median time to tumor progression (14.3 months vs. 6 months) and stable disease at 6 months of treatment (66.7% vs. 37.2%), although the trial did not comment on overall survival [45]. Interferon-alpha has also been used to treat metastatic carcinoid tumors with some success. Di Bartolomeo and colleagues reported symptomatic control in 80% of patients and reduction of 5-HIAA levels in 58% of patients treated with daily intramuscular injections of interferon-alpha [46]. When combined with octreotide in a randomized trial, interferon-alpha was found to significantly reduce the risk of progression when compared with octreotide alone, although again no survival benefit was found [47]. Significant side effects of fever, fatigue, and weight loss often limit the routine use of interferon therapy.

GISTs

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal neoplasm of the gastrointestinal tract and account for approximately 0.1–3% of all intestinal cancers. GISTs were first described by Mazur and Clark, who used electron microscopy to differentiate these tumors from other soft tissue sarcomas [48]. Most tumors arising from mesenchymal elements of the gastrointestinal tract were considered leiomyomas, leiomyosarcomas, and leiomyoblastomas; however, it was discovered that GISTs lack features associated with smooth muscle cells. Instead, it is believed that GISTs arise from the interstitial cells of Cajal or other pluripotential mesenchymal stem cells. The interstitial cells of Cajal coordinate autonomic movements of the gastrointestinal tract and are located within muscle layer of the intestinal wall.

Histology

Histologically, gastrointestinal stromal tumors typically have a spindle cell appearance and stain positive for the CD117 antigen, a marker for the KIT tyrosine kinase oncoprotein. In addition, 60–70% of GISTs will stain positive for CD34, a hematopoietic progenitor cell antigen [49]. These features help to differentiate GISTs from other sarcomas; leiomyomas stain negative for KIT and CD34 but positive for desmin, smooth muscle actin, and S100 [50].

Incidence and Distribution

GISTs typically occur in the sixth to seventh decade of life and affect men and women equally. Most tumors are sporadic; however, several hereditary syndromes are associated with GISTs. Carney's triad consists of (1) synchronous or metachronous GISTs, (2) extra-adrenal paraganglionomas, and (3) pulmonary chondromas [51]. This is usually seen in women before age 30 and is not associated with a KIT mutation. Patients with neurofibromatosis type I are also more commonly affected with GISTs. Tumors in these patients are more likely to occur at a younger age and often present with multiple small intestinal GISTs [52].

Gastrointestinal stromal tumors are most commonly found in the stomach (approximately two-thirds of cases), followed by the small intestine (about one-quarter of cases). Esophageal GISTs are rare, but tumors may also arise in extra-GI locations, principally in the mesentery, omentum, and retroperitoneum. Tumors located in the colon and rectum account for only 10–20% of GISTs, and of those, the majority arise in the rectum.

Clinical Presentation

GISTs are usually slow-growing lesions, and are often discovered incidentally during endoscopy or in the treatment of other conditions. The most common clinical symptoms are rectal bleeding and abdominal or rectal pain. Advanced lesions may present with a palpable mass, obstruction, or perforation (Figure 38-2). Kingham et al. found that symptoms were more common in patients with larger tumors; the median size of tumors was 8.9 cm in symptomatic patients, compared to 2.7 cm in asymptomatic patients [51]. Metastatic disease most frequently occurs in the liver and peritoneum; metastatic disease in the lymph nodes is uncommon [52].

Diagnostic Tests

Evaluation of a patient with a suspected GIST includes colonoscopy as well as endoscopic ultrasound, if feasible. Lesions are usually submucosal; however, biopsy may be aided with the use of endoscopic ultrasound-guided fine needle aspiration. Care must be taken as these tumors are frequently associated with neovascularization, and biopsy may result in significant hemorrhage [53]. Percutaneous biopsy with fine or core needle aspiration is an option for tumors that cannot be reached endoscopically; however, concern over tumor rupture and spread has been reported [51]. CT and MRI may aid staging and determining whether surgical resection is feasible. GISTs typically involve the muscularis propria, and radiographically have a characteristic appearance of a

FIGURE 38-2. GIST of the rectum presenting as a perianal mass.

well-circumscribed intramural mass. Larger lesions may have evidence of central necrosis. PET scanning is not helpful in diagnosis, however may be of benefit in evaluating the response to treatment [54].

Treatment

Surgical resection of GISTs offers the best chance for cure and is therefore the treatment of choice. It is recommended that resection include the tumor en bloc with any associated contiguous tissues with margins of at least 1 cm [55]. As GISTs rarely metastasize to the lymphatic system, lymphadenectomy is not necessary [56]. Although many gastrointestinal stromal tumors may have a pseudocapsule, enucleation of the tumor without resection of the pseudocapsule should be avoided, as this has been associated with increased risk of tumor recurrence.

Resection of rectal GISTs may be accomplished by radical resection (low anterior resection or abdominoperineal resection) or local excision (transanal excision or transanal endoscopic microsurgery), provided that the tumor and pseudocapsule can be removed with adequate margins (Video 38.1). Liu et al. evaluated 21 patients with rectal GISTs and found that most patients with tumors located within 5 cm of the anal verge were successfully treated with local excision; however, positive resection margin was associated with poorer disease-free survival [57]. Changchien et al. reported outcomes of 29 patients with rectal GISTs [58]. Higher local recurrence rates were seen in those patients who underwent wide local excision vs. those who underwent radical resection (77% vs. 31%), despite smaller mean tumor size in the local excision group (4.5% vs. 7.2%).

The development of imatinib has significantly impacted the treatment of gastrointestinal stromal tumors. As mentioned previously, the majority of GISTs have abnormal activation of the KIT oncoprotein which results in unregulated cellular proliferation. Imatinib is a selective tyrosine kinase inhibitor which blocks activation of the KIT oncoprotein. When used in adjuvant therapy, imatinib has been shown to significantly decrease the risk of recurrence. The American College of Surgeons Oncology Group (ACOSOG) conducted a prospective trial of 106 patients who had undergone complete gross tumor removal but were deemed to be high risk for recurrence [59]. Patients were given 400 mg of imatinib per day for 1 year and followed radiographically. The 5-year overall survival rate of those treated was 83%, significantly better than historical 5-year survival rates of 35%. Imatinib has also been used in patients where the tumor was felt to be too large to resect. In this situation, the use of imatinib has been shown to result in tumor shrinkage in more than 50% of patients [60, 61], thereby allowing surgical resection in selected patients.

Neoadjuvant imatinib therapy for rectal gastrointestinal stromal tumors has also been reported. Wang et al. reported three patients with GISTs in the distal rectum that would require abdominoperineal resection to achieve cure [62]. Following treatment with imatinib, all three patients had both significant shrinkage of the tumor and extension of the distance to the anal verge that allowed for sphincter-preserving procedures. Tielen et al. also found that patients treated with neoadjuvant imatinib had significant reduction in the size of their rectal GISTs; however, this did not lead to less extensive surgery when compared with patients who did not undergo neoadjuvant therapy [63].

The reported incidence of local recurrence and metastatic disease following complete surgical resection of GISTs varies, but approaches 50% in some series [56]. Yeh et al. reported outcomes of 40 patients who underwent resection of rectal GISTs and found that younger age (<50 years) and a high histologic grade of tumor were the two most significant prognostic factors for recurrence [64]. In the ACOSOG trial, the recurrence-free survival rate was found to be lower with increasing tumor size, high mitotic rate, and older age [59]. Patients with metastatic GISTs are typically treated with imatinib and evaluated radiographically. Approximately 45% of patients will demonstrate partial response and 30% will have stable disease; if response to therapy is seen, lifelong treatment can be used [65]. Overall survival is

significantly better in patients with metastatic GISTs when treated with imatinib. Blanke et al. reported a median survival of 58 months, in contrast to a median of 15 months in historical controls treated with cytotoxic chemotherapy [66]. In patients whose tumors develop resistance to imatinib, sunitinib has been used as a second line treatment with some success [51]. Patients with unresectable hepatic metastases may also be candidates for radiofrequency ablation or hepatic artery embolization.

Lymphomas

The gastrointestinal tract is the most common site of extranodal lymphoma. While the majority of these lymphomas arise in the stomach (74.6%), small bowel and colonic lymphoma are less common, accounting for 8.6% and 7%, respectively [67]. In fact, in a recent review of the Surveillance, Epidemiology, and End Results (SEER) database, primary colonic lymphoma accounted for only 0.4% of all colonic malignancies, however the incidence more than doubled between 1973 and 2004 [68].

Histology

Most lymphomas of the gastrointestinal tract are non-Hodgkin's lymphoma. Diffuse large B-cell lymphoma is the most common histologic type seen in the colon [69]. Other pathologic types in the colon include MALT-associated low-grade b-cell lymphoma, mantle cell lymphoma, and T cell lymphoma [70, 71]. Correct determination of the subtype is important for optimal treatment and prognosis. It is believed that lymphomas begin in the submucosal lymphoid tissue and spread either by direct extension or through lymphatic channels. Dawson et al. established criteria for differentiating between primary gastrointestinal lymphoma and secondary involvement of the intestinal tract by systemic lymphoma [72]. The diagnosis of primary lymphoma can be made: (1) in the absence of enlarged superficial lymph nodes, (2) absence of enlarged mediastinal lymph nodes, (3) normal total and differential and white cell count, (4) at laparotomy, only regional lymph nodes have metastatic disease, and (5) the liver and spleen are unaffected.

Incidence and Distribution

Most colonic lymphomas arise in the cecum or ascending colon, likely due to the increased lymphoid tissue in this segment of the colon. In fact, 70% of lymphomas occur proximal to the hepatic flexure [73]. Patients are typically between the ages of 50 and 70; sex predominance varies among different reports. Prolonged steroid use, inflammatory bowel disease, HIV, and EBV have been postulated as possible risk factors for the development of colonic lymphoma [74]. Both a modified Ann Arbor staging system and the TNM system have been used to stage gastrointestinal lymphomas.

Clinical Presentation and Diagnostic Tests

The most common presenting symptom of lymphomas of the colon is abdominal pain. Other symptoms mimic those of adenocarcinoma and include weight loss, rectal bleeding, change in bowel habits, anemia, weakness, and possibly fever. Tender abdominal masses may be present in up to 80% of patients at the time of presentation [75]. Growth of the lesions leads to obstruction in 20–25% of cases; however, perforation is uncommon (Figure 38-3). Colonoscopy with biopsy should be performed; however, in some cases superficial biopsies may not be sufficient to confirm the diagnosis. CT scan of the chest, abdomen, and pelvis should be obtained to extraintestinal disease.

Treatment

In patients with lymphoma that is confined to the bowel, treatment is surgical excision or systemic chemotherapy. Historically, given that a sizeable fraction of patients presented with symptomatic disease that required semi-urgent operation or underwent operation to establish a diagnosis, surgical resection was most often employed as therapy. In patients with localized disease where the diagnosis can be made preoperatively, the rationale for surgical treatment is to remove tumor that has the potential to obstruct, perforate, or

FIGURE 38-3. Lymphoma of the sigmoid colon invading the ileum (Courtesy of the ASCRS Image Library, Bruce Orkin, M.D.).

bleed, and potentially cure the patient if the tumor has not yet spread. Adjuvant chemotherapy, typically vincristine, cyclophosphamide, bleomycin, and doxorubicin, has been used to improve survival. Radiation therapy has also been advocated following resection of rectal lymphomas [76]. An alternative strategy is to treat with systemic chemotherapy and potentially avoid operation. One of the potential risks is perforation of the bowel if chemotherapy causes tumor necrosis. Given the low incidence of the disease, there are no randomized controlled trials to rely upon when making treatment decisions.

Aviles et al. treated 53 patients with B-cell lymphomas of the colon with surgery combined with chemotherapy and reported a 10-year survival of 83% [77]. Other authors, however, have reported far worse outcomes. Jinnai et al. reported results on a series of 130 patients who underwent surgical resection of colonic lymphomas [78]. Complete resection was possible in 55% of cases; however, 5-year survival was less than 40%. Prognosis was better in patients with tumors <5 cm in diameter and the absence of lymph node metastases. Lai et al. found that patients treated with surgery and chemotherapy had a 5-year survival of 62%, while 5-year survival in similar patients treated with surgery alone was only 14% [79]. Kim and colleagues compared response to treatment of 78 patients with B-cell lymphoma and 17 patients with T-cell lymphoma [80]. Those with T-cell lymphomas were younger, were more likely to present with perforation, and overall had a worse prognosis.

Part IV
Benign Colorectal Disease

39
Diverticular Disease

Jason Hall

Key Concepts

- The optimal diagnostic test to allow for optimal assessment of severity of diverticulitis is CT imaging.
- The majority of patients with acute diverticulitis will respond to antibiotic therapy.
- CT drainage of localized abscesses in diverticulitis will often avoid the need for emergency operations, even in patients who may not initially respond to medical therapy.
- Hartmann's resection can often be avoided in most patients requiring surgery for an acute attack. Resection with primary anastomosis, with or without proximal diversion (loop ileostomy), can be performed safely in the absence of physiologic instability.
- The indications for elective resection after an acute attack of diverticulitis are evolving but should be considered in patients who remain symptomatic or develop a definite complication (stricture, fistula, etc.)

Introduction

Colonic diverticula represent saccular outpouchings of the colonic wall. Most patients with diverticulosis are asymptomatic. Symptomatic diverticular disease represents a whole range of conditions ranging from mild abdominal pain and bloating to free perforation with peritonitis and sepsis. These presentations are stratified into complicated or uncomplicated diverticulitis. Patients with left-sided abdominal pain and sometimes fever and leukocytosis are considered to have uncomplicated diverticulitis. Complicated presentations are defined as episodes of free perforation, obstruction, stricture, fistula, or hemorrhage. Diverticular hemorrhage is associated with diverticulosis and not diverticulitis. Because of the wide range of clinical presentations and potential for significant morbidity/mortality, management of diverticular disease continues to represent a major challenge to clinicians. This chapter examines the current pathophysiology, evaluation, and treatment of left-sided colonic diverticulosis and diverticulitis. The management of diverticula of the foregut and diverticular bleeding is left to other sources for discussion.

Incidence

In the twentieth century, there has been a rising prevalence of diverticular disease in industrialized nations. Diverticulosis is rare in patients younger than age 30. The incidence of this colonic finding rises with age such that over 40% of patients develop diverticula by the age of 60 years. Over 60% of patients over 80 years have diverticular disease identified [1, 2].

In almost all cases (95%), diverticula involve the sigmoid and left colon. In some series, the number of diverticula increases proportionally with age. They are also found more proximally as age increases. This may explain why in the Western societies, right-sided diverticular disease is primarily identified in older patients with pan-diverticulosis [3, 4]. In Asian countries, however, diverticulosis occurs more commonly on the right side. Some authors estimate that in Asia, 70% of the diverticula isolated to the right side [5–7].

Ten to twenty-five percent of patients who develop diverticulosis will develop diverticulitis [8–12]. Administrative data sources suggest that the incidence of diverticulitis is increasing. According to the Agency for Healthcare Research and Quality, over 295,000 patient discharges for diverticulitis were reported at the United States hospital in 2006 [13]. One modern analysis of the National Inpatient Sample demonstrated that rates of admission and elective operations rose in the United States from 1998 to 2005. Rates of admission and surgical intervention rose 82% and 73%, respectively, in patients younger than 44 years [14]. Another study examining the same data source from 1991 to 2005 period noted an increase diverticulitis discharges from 5.1 cases per 1000 inpatients in 1991 to 7.6 cases per 1000 inpatients in 2005 ($p < 0.0001$). There also appeared to be conflicting data regarding the incidence of complicated diverticular disease.

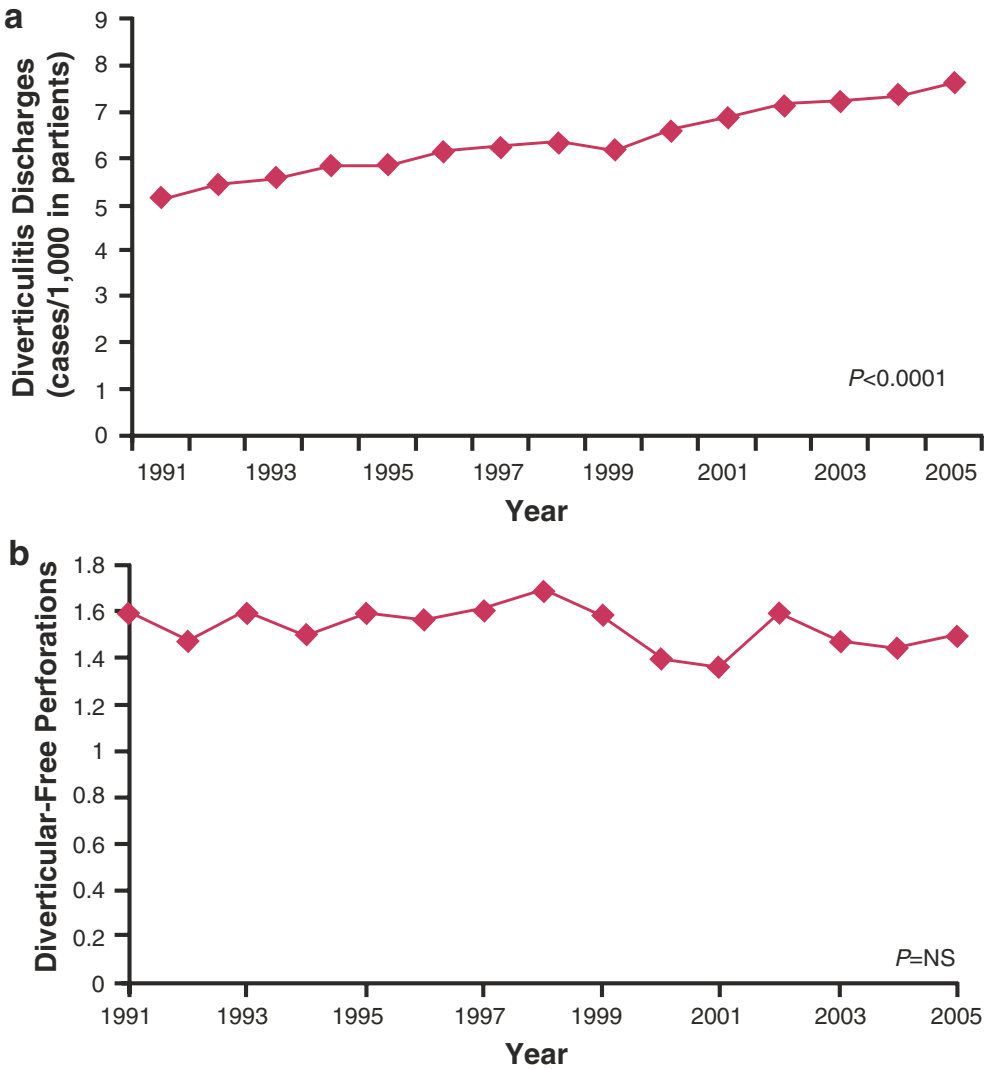

FIGURE 39-1. (**a**) Diverticulitis discharges (uncomplicated and complicated) in the Nationwide Inpatient Sample from 1991 to 2005. (**b**) Proportion of patient discharges for free diverticular perforation among all patients with diverticulitis in the Nationwide Inpatient Sample from 1991 to 2005. *With permission from Ricciardi* et al. *Dis Colon Rectum. 2009 Sep;52(9):1558–63 © Wolters Kluwer 2009* [15].

The proportion of diverticular abscess discharges increased from 5.9% in 1991 to 9.6% in 2005 ($p < 0.0001$). The proportion of free diverticular perforations, however, remained unchanged (1.5%) [15] (see Figure 39-1a, b). This increased incidence has been noted in other industrialized countries. A recent study from Norway revealed an increase in the incidence of diverticular diseases from 17.9 to 51.1 cases per 100,000 person/years over a 4-year time period [16]. More recent analysis of the National Inpatient Sample suggested that diverticulitis admissions peaked in 2008 (96/100,000). Rates of hospitalization for diverticular bleeding per 100,000 patients have declined from 32.5 to 27.1 (−5.4; 95% confidence interval (CI), −5.1 to −5.7) from 2000 to 2010 [17].

Pathophysiology, Etiology, and Epidemiology

Most colonic diverticula are pulsion or false diverticula. These types of diverticula contain only the mucosal and muscularis mucosal layers. Diverticula penetrate the colonic wall where vasa recta penetrate the circular muscle layer in order to provide blood supply for the mucous membrane (Figure 39-2) [18]. In a non-pathologic situation, diverticula are soft and compressible, allowing a free communication between the diverticulum and the colonic lumen.

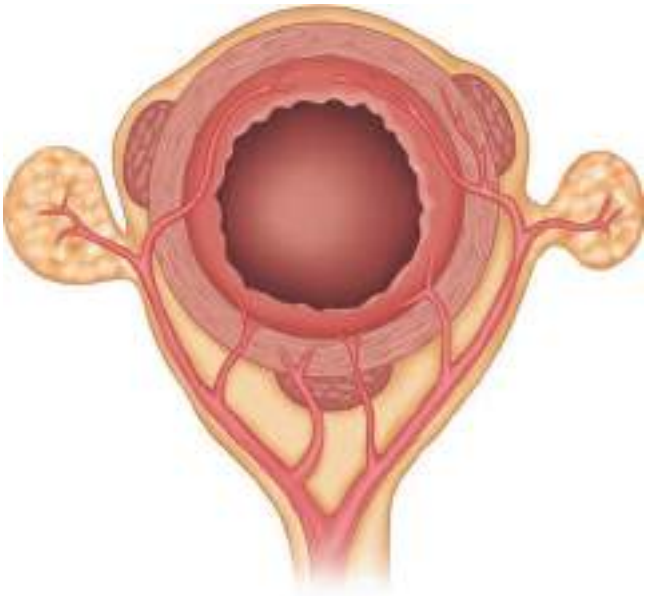

FIGURE 39-2. Vasa recta penetrate the colonic wall at taenia libera, omentalis, and mesocolica. This allows herniation of mucosa and submucosa at these sites.

The exact pathogenesis of progression from diverticulosis to diverticulitis is not clear. Classic pathophysiology mechanisms suggested that stasis or obstruction of the diverticulum orifice leads to bacterial overgrowth, increased intra-diverticular pressure, ischemia, and inflammation. This mechanism is one borrowed from the pathophysiology of appendicitis. Once the colonic mucosa is ischemic, ulceration can occur leading to a microperforation in most cases but sometimes formation of a peridiverticular abscess or free perforation with peritonitis [19].

Histology and Pathology

Many of the microscopic features of diverticulitis include thickening of the lamina propria, mucin depletion, and Paneth cell hyperplasia. Crypt abscesses and ulceration are also observed in some cases [20]. Many of the histologic features are similar to those associated with inflammatory bowel disease [21]. Hinchey developed pathologic criteria to classify the severity of diverticular disease. This classification has been used and is divided into Stages I–IV [22]. Stage I are patients with diverticulitis and a pericolic abscess. Stage II represents patients with distant abscesses such as a pelvic or retroperitoneal abscess. Stages III and IV are patients with purulent and feculent peritonitis, respectively (Table 39-1). A number of attempts have been made to extend the Hinchey criteria to a preoperative staging on CT scan [23] (Table 39-2). The utility of the system proposed by Hinchey and by others based on it is limited because purulent and feculent peritonitis can only usually be determined post hoc.

TABLE 39-1. Hinchey classification system

Stage I	Pericolic or mesenteric abscess
Stage II	Pelvic or retroperitoneal abscess
Stage III	Purulent peritonitis
Stage IV	Feculent peritonitis

TABLE 39-2. Modified Hinchey classification system

Stage 0	Mild clinical diverticulitis
Stage Ia	Confined pericolic inflammation phlegmon
Stage Ib	Confined pericolic abscess (within sigmoid mesocolon)
Stage II	Pelvic, distant intra-abdominal or intraperitoneal abscess
Stage III	Generalized purulent peritonitis
Stage IV	Fecal peritonitis

Modified from Warsavary et al. [24]

Role of Fiber

A number of authors have postulated that diverticular disease is related to fiber deficiency [25]. Painter and Burkitt studied colonic transit times and fiber contents in patients in Uganda and the United Kingdom. Patients with a higher fiber intake had more frequent bowel movements, faster colonic transit times, and larger stool volumes. Specifically, Painter and Burkitt postulated that a progressively more processed diet removed a large source of fiber from the Western diet. These data are confounded by a number of factors including differing life expectancies in industrialized and nonindustrialized countries [26]. It is interesting to not that as nonindustrialized societies have adopted a more Western diet; a number of authors have noted an increasing prevalence of diverticular disease [27].

A number of studies have examined dietary factors in large populations of patients with and without diverticular disease [28, 29]. Both studies demonstrated an inverse association between diverticular disease incidence and fiber intake. The relative risks associated with fruit and vegetable fiber intake were 0.62 [95% CI 0.45–0.86] and 0.55 [95% CI 0.37–0.84] [28]. Fiber found in fruits and vegetables conferred the most protective effect (compared with fiber from cereal), and a high intake of total fat and red meat increased the incidence of diverticular disease. Manousus et al. [29] compared individuals who ate a predominantly vegetarian diet to those who predominantly ate meat. The risk of developing diverticular disease was 50-fold greater in meat eaters. In a more recent cohort (47,228 male health professionals), popcorn, nut, and seed consumption was inversely correlated with diverticulosis or diverticular complications. This study refutes the adage that "nuts, corn, seeds, and popcorn" cause diverticulitis and should be avoided in patients who have had an attack of diverticulitis [30].

Alternative Pathophysiology Pathways and Taenia-Specific Elastosis

A number of non-dietary alternative theories regarding the evolution of diverticular disease have been proposed. Most of these theories center around the suggestion that the smooth muscle in the sigmoid colon behaves differently in other areas of the body. One particularly consistent finding in patients with diverticular disease is wall thickening often in the absence of inflammation [31]. Histologic studies have determined that colonic walls are thickened secondary to elastin deposition and not muscular hypertrophy or hyperplasia. In one study, the concentration of elastin in patients with diverticular disease was increased over 200% when compared with controls. The elastin is often laid down in a contracted form, leading to bunching of the taenia and apparent foreshortening of the bowel [32].

Despite the grossly increased muscle wall thickness, patients with diverticulosis appear to be more susceptible to mucosal herniation. In patients with diverticulitis, collagen fibrils demonstrate increased cross-linking with increased age; this process seems to increase most dramatically after 40 years of age, the age at which the incidence of diverticular disease also appears to increase. This same study demonstrated that patients with diverticulosis have an abnormally high amount of collagen cross-linkage in the colon wall. This difference persists even when patients were compared with age-matched controls. Increased cross-linkage of collagen fibers likely causes the tissues to become stiffer and less resistant to stretching. The loss of compliance of the colonic submucosa, the layer primarily responsible for tensile strength, may make the submucosa more susceptible to small tears when subjected to the higher intraluminal pressures triggered by segmentation. Any tear in this layer could potentially then lead to mucosal herniations and the formation of diverticulosis [33].

A possible genetic connective tissue defect has also been suggested because of reports of diverticular in young patients with Marfan's syndrome or Ehlers-Danlos syndrome [34–36]. It is likely that a number of processes including impaired motility, low fiber intake, inflammation, and elastin deposition contribute to the pathogenesis of diverticular disease.

Additional Risk Factors

Age

There has been considerable debate in the medical literature regarding the role of age in the pathogenesis of diverticulitis. Diverticular disease tends to affect patients during middle age as the incidence rises from 5% at age 40 to 80% by age 80 [37]. Traditionally, diverticulitis in younger patients has been described as more virulent, and young patients were thought to be more likely to have complicated disease and more likely to require resection [38, 39]. Young patients have been variably defined as under 50 years old in some series and under 40 or 45 years old in other series. Despite variability in what constitutes a "young patient," most modern series of younger patients with acute diverticulitis have noted a striking male predominance [40].

Sex

The prevalence of the disease among the sexes is difficult to ascertain. The prevalence has been estimated to be between 2:3 and 3:1 male-to-female ratio [12, 41]. More recent estimates suggest that patients with symptomatic diverticular disease under the age of 65 tend to be male. Some studies have demonstrated that male patients may present with more severe CT findings of diverticulitis than female patients [42]. Recent data suggests that men have a higher incidence of diverticular bleeding, while obstructions are more common among women [43].

Geographic Factors

Diverticulitis is much less common in Asian populations [25]. When diverticulitis does occur, it tends to involve the right-sided colon in up to 70% of cases [36]. It is unclear if this is an environmental, dietary, genetic, or geographic factor.

There is a relationship between increasing industrialization and incidence of this disease. A number of earlier studies have documented the low prevalence of the disease in African nations [44–46]. Other authors have noted increased rates of diverticulitis in Africans with increased penetration of the Western lifestyle patterns [47]. Reports from both Japan and Singapore have shown increases in prevalence approaching 20%. This is thought secondary to the increased acceptance of the Western diets [48, 49].

Physical Activity

Two studies have examined the effect of exercise on the development of diverticular disease [50, 51]. The risk of developing diverticular disease and levels of physical activity appear to be inversely related. This difference persisted even when the authors adjusted differences in dietary fiber intake. A potential drawback of the study is that the differences may have arisen from the fact that the ability to exercise might have been impaired or prohibited by symptoms of diverticular disease [50].

Smoking

The potential association between diverticular disease and smoking is contradictory. One large case-control study demonstrated that smokers had three times the risk of developing complications from diverticular disease than did nonsmokers [52]. Another large cohort study of 46,000 men in the United States failed to show a similar association [51].

Nonsteroidal Anti-inflammatory Agents

The use of nonsteroidal anti-inflammatory agents has been associated with the development of a number of gastrointestinal complications. Evidence suggests that chronic NSAID use is almost twice as common in patients with diverticular disease as healthy controls with no known colonic disease [53, 54]. While the health professionals follow-up study showed an increased incidence of uncomplicated diverticular disease in patients who used NSAIDs compared with their asymptomatic counterparts, additional studies have noted an increased risk of complicated diverticulitis with NSAID use [55]. One retrospective study showed a 23% higher risk of perforating diverticulitis in patients who took NSAIDs regularly compared with patients with diverticular disease who did not take NSAIDs [56]. An additional study of hospitalized patients demonstrated chronic NSAID use to be much higher in patients admitted with diverticular disease than the population as a whole. In addition these patients were four times more likely to develop perforated diverticulitis than patients with no history of NSAID use [57].

Caffeine Ingestion

Caffeine intake has been investigated as a possible contributing factor to the development of diverticular disease as it can affect colonic transit time [58]. No difference in caffeine consumption was identified in groups of patients with and without diverticular disease [51].

Obesity

A number of retrospective case series have noted a striking preponderance of obese patients with diverticulitis, particularly patients under the age of 40 [39, 59, 60]. In addition, two prospective cohort studies (the health professionals follow-up study and a Swedish study) have shown an association between body mass index (BMI) and diverticular disease [51, 61, 62]. The US health professionals study has shown an increased risk of diverticulitis and diverticular bleeding not only with increasing BMI but also waist circumference and waist-to-hip ratio [61]. A recent study from South Korea recently demonstrated an association between cross-sectional visceral fat area and complicated diverticulitis [63]. Obesity has been linked not only to inflammation but also to differences in the intestinal flora which may be potential mechanisms for the increased risk of diverticulitis [64–66]. Although this area of research is new, it may suggest that a large visceral fat mass may act as an immunologic or endocrine organ. This mechanism may affect incidence of diverticulitis.

Microbiome

Humans exist in a close relationship with a variety of microorganisms. Of particular interest are microorganisms which reside in the gastrointestinal tract. Microbes in the human gastrointestinal tract contain 10^{12}–10^{14} genes [67]. The aggregate, multi-organismic, genetic code of those varied microorganisms is referred to as the microbiome. There is little published clinical evidence suggesting a direct link between fecal microbiota and diverticular disease. A number of authors have extrapolated from other known relationships. For example, Daniels et al. explore findings of altered microbiota in the flora of patients with morbid obesity, colon cancer, irritable bowel syndrome, and inflammatory bowel disease. Based on these findings, they proposed that altered fecal microbiology may also have an effect on the pathogenesis of diverticular disease. While the finding of altered microbiota in various disease states is intriguing, there is still ample debate as to whether these changes are causative of disease or simply a phenotype of the disease process itself. [68].

Clinical Manifestations and Physical Findings

There are three main clinical presentations of diverticular disease (Table 39-3). The most common clinical presentation of diverticulitis is what is termed uncomplicated diverticulitis. This presentation is characterized by left-sided abdominal pain with or without an associated mass, fever, and leukocytosis. Patients generally resolve the acute episode after treatment with antibiotics. Typically most patients can be treated as outpatients.

Another manifestation is smoldering diverticulitis. This presentation only partially improves on antibiotics and medical therapy. Such patients have recurrent symptoms which can manifest with ongoing low-grade fever and left-sided abdominal pain. CT scans on such patients generally will demonstrate a persistent phlegmon, and these patients often require resection to treat ongoing symptoms. Some of these patients will present with associated obstruction, abscess, fistula, or perforation.

Table 39-3. Typical presentation patterns of diverticulitis

Acute diverticulitis
Typical, relapsing (chronic)
Subacute
Complicated diverticulitis
Obstruction
Mass/abscess
Fistula
Hemorrhage
Perforation
Chronic diverticulitis
Atypical
Atypical site (transverse, ascending)

Finally, a small group of patients may have atypical presentations. Most of these patients have chronic left lower-quadrant pain. They however lack objective evidence of diverticulitis such as leukocytosis, fever, or objective findings on CT scan. Many patients with atypical presentations of diverticulitis may have irritable bowel syndrome. Surgeons therefore must be facile with telling the difference between both conditions.

Symptoms

Patients with acute diverticulitis typically present with left-sided abdominal pain, fever, and leukocytosis. Associated with abdominal pain will be a physical finding of left lower quadrant pain and tenderness on examination. Patients with free perforation will typically present with diffuse peritonitis and signs of systemic toxicity. An abdominal mass may be palpable or mass appreciated on rectal or pelvic exam when there is a significant phlegmon involving the colon. Many patients will present with abdominal tenderness that is often associated with some degree of abdominal distension. Right-sided tenderness can be a presentation in patients that have a redundant sigmoid colon that extends to the right side of the abdomen. Free perforation is associated with diffuse abdominal pain, sometimes referred pain in the shoulder, and shortness of breath.

Many patients often describe changes in their bowel habits such as constipation, diarrhea, or an alternation in stool caliber. Rectal bleeding rarely occurs as a presentation of acute diverticulitis. If present, rectal bleeding is more suggestive of ischemic colitis or inflammatory bowel disease. In complicated presentations, an inflammatory phlegmon can be associated with a small or large bowel obstruction. Patients with an obstruction will present with abdominal distention and sometimes nausea and vomiting.

Patients with fistulas may have minimal abdominal complaints and may present initially to a urologist or gynecologist. Patients who develop complications of diverticular disease such as colovesical fistulas may present with pneumaturia, pyuria, or fecaluria, while patients with colovaginal fistulas may present with vaginal discharge, vaginal air, or stool per vagina.

A number of patients with “chronic” or atypical diverticular disease will present with pain as their predominant symptom in the absence of other physical findings. The pain is typically persistent and boring, remaining constant over long periods of time. It does not tend to be “crampy” in nature as in patients with irritable bowel syndrome but is difficult to distinguish from this entity [69].

Diagnostic Evaluation

Most laboratory tests are not terribly helpful in the evaluation of acute diverticulitis. Many patients with acute diverticulitis present with leukocytosis. Patients with a colovesical fistula may have an abnormal urinalysis and/or a culture with enteric organisms.

Although a number of different modalities have been used to evaluate patients with suspected diverticular disease, computed tomography has emerged as the study of choice. Flat and upright plain films of the abdomen are commonly obtained in the evaluation of the patient with acute abdominal pain to exclude obstruction or free intraperitoneal air. In patients with diverticular disease, the findings of plain films tend to be nonspecific [70]. Ultrasound has not gained wide acceptance in the United States. Contrast enemas are seldom currently used in the evaluation and management of diverticulitis. Water-soluble contrast studies are useful in which there is a potential need for urgent surgery and a stricture is suspected.

The most useful test for examination of patients with acute abdominal pain is the abdominal CT. CT findings associated with diverticulitis were first described over 30 years ago. These signs included the presence of diverticula, pericolic fat stranding, colonic wall thickening more than 4 mm, and abscess formation [71]. For evaluation of acute diverticulitis, CT has the ability to stage the severity of disease and adds the possibility of providing a roadmap for percutaneous drainage of an associated abscess. CT has the added advantage of detecting other intraperitoneal findings including hepatic abscesses, pylephlebitis, small bowel obstruction, colonic strictures/obstruction, and colovesical fistulas.

The first system for classifying the severity of diverticulitis on CT findings to guide clinical management was proposed by Ambrosetti. CT findings consistent with mild diverticulitis included localized wall thickening (>5 mm) and inflammation of the pericolic fat. Severe CT findings were the combination of localized wall thickening and inflammation of the pericolic fat with abscess, extraluminal air, or extraluminal contrast (Table 39-4). When the natural history of patients with diverticulitis was stratified by these CT criteria, the authors found that patients with severe CT findings underwent operative intervention more frequently than those patients with mild findings (33% vs. 15%). Patients under 50 years of age with severe findings on CT scan were also more likely to have recurrences or complications [72]. In prospectively collected dataset, patients with findings of severe diverticulitis on CT scan were more likely to have recurrent attacks of diverticulitis after an initial

TABLE 39-4. Ambrosetti CT criteria for diverticulitis severity

attack of acute diverticulitis treated with antibiotics when compared to patients with mild diverticulitis (39% vs. 14%) [73]. Poletti et al. explored CT and demographic predictors for nonoperative treatment failure in 312 patients with a first episode of left-sided diverticulitis and concluded that the presence of an abscess or extraluminal air >5 mm in diameter were significant predictors of treatment failure [74].

CT findings which are relevant to clinical management were reclassified into classification system based on the Hinchey classification system (Table 39-2). In grade 0 there is colonic wall thickening but not pericolonic fat stranding. Grade 1a consists of wall thickening and pericolonic fat stranding, while grade 1b includes a pericolonic or mesocolic abscess. Patients with grade 2 disease have distant intraabdominal or pelvic abscesses. Patients with grade 3 and grade 4 disease have purulent and fecal peritonitis, respectively. CT is somewhat limited in distinguishing between patients with grade 3 and grade 4 disease as purulent and fecal peritonitis often cannot be distinguished on imaging (Figs. 39-3, 39-4, and 39-5a–d) [75]. Kaiser et al. found that disease severity

FIGURE 39-3. Modified Hinchey Stage Ia Diverticulitis—*Arrow* points to pericolic inflammation and phlegmon.

FIGURE 39-4. Modified Hinchey Stage II Diverticulitis—*Arrow* points to pelvic abscess.

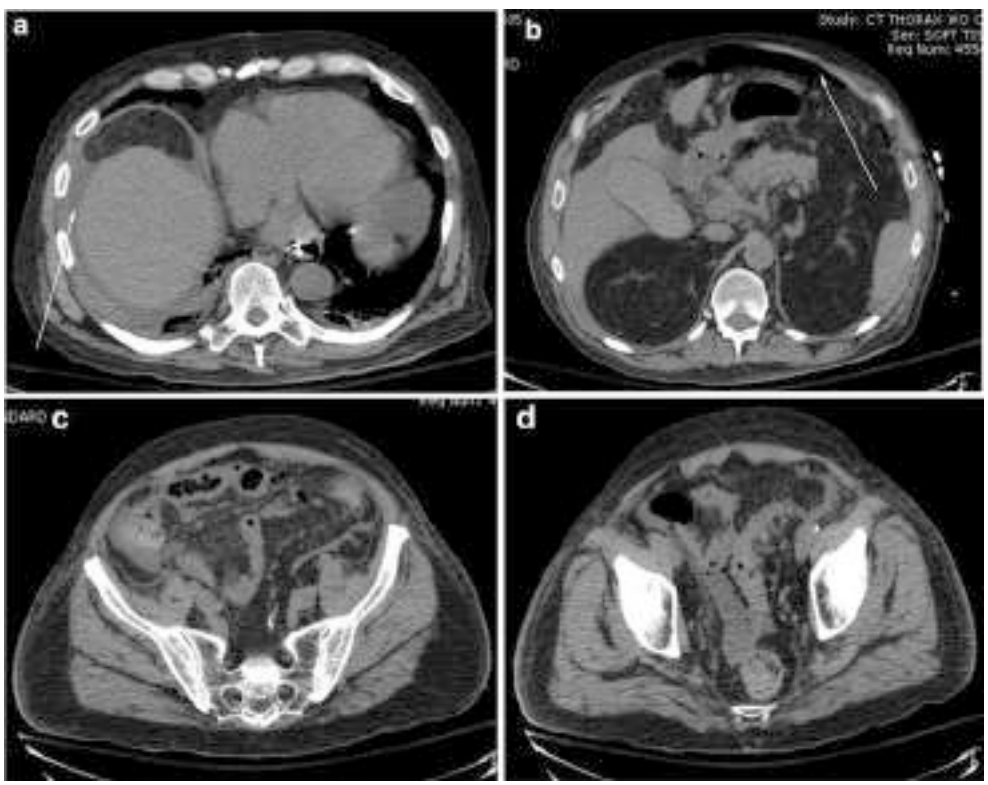

FIGURE 39-5. (**a**) Modified Hinchey Stage III Diverticulitis—*Arrow* points to free fluid. (**b**) Modified Hinchey Stage III Diverticulitis—*Arrow* points to free air. (**c**) Modified Hinchey Stage III Diverticulitis—Demonstrates intra-abdominal free fluid. (**d**) Modified Hinchey Stage III Diverticulitis—*Arrow* points to pelvic fluid.

using the modified CT Hinchey classification system correlated with postoperative morbidity and mortality. This group also found that the CT stage correlated with recurrence when patients were managed nonoperatively. The presence of a diverticulitis-associated abscess was one particular factor which was highly associated with high risk of failure of nonoperative management [76].

Endoscopic Evaluation

Endoscopic evaluation of the colon is recommended following an acute episode of diverticulitis. This approach is generally advocated to exclude the presence of a malignancy or an alternative diagnosis such as ischemic colitis or inflammatory bowel disease. In actual practice, finding a malignancy is rare. Bryan et al. evaluated 307 patients with flex sig (20%) or colonoscopy (80%) following an acute episode of diverticulitis. Interestingly, they found only 2 patients with colorectal carcinomas. A significant proportion of patients had advanced neoplastic lesions (3.4%), hyperplastic polyps (6.8%), and adenomas (8.8%) [77]. These findings were mirrored by a study by Lau et al., with 319 patients who underwent endoscopic surveillance. Overall, 26% of patients had polyps (9 polyps > 1 cm) and 2.8% were found to have colorectal cancers [78].

Endoscopic procedures (flexible sigmoidoscopy and colonoscopy) are generally not advocated during an acute episode of diverticulitis. A delay of 6 weeks following resolution of symptoms is recommended. This approach is encouraged in order to avoid potential conversion of a sealed microperforation into a free perforation [79]. This position has been questioned by other groups who have demonstrated that colonoscopy during an acute episode of diverticulitis can be safe. Even when optical examination of the colon is performed in the acute setting, a significant number of the procedures cannot be completed [79, 80].

Cystoscopy or cystography have been used to identify suspected colovesical fistulas. In CT scan era, however, the presence of air in the urinary bladder in the absence of instrumentation is considered diagnostic [81].

Differential Diagnosis

The differential diagnosis for suspected diverticular disease includes appendicitis, bowel obstruction, colorectal cancer, ischemic colitis, pyelonephritis, gynecologic disease, inflammatory bowel disease, and irritable bowel syndrome. Other diagnoses that should be entertained include endometriosis, tubo-ovarian abscess, pelvic inflammatory disease, ureteral calculi volvulus, stercoral ulcer, and ovarian torsion. Modern cross-sectional imaging is often helpful in diagnosing many of these clinical entities. The most important diagnosis to exclude on initial presentation is colorectal cancer. CT scanning confirms a diagnosis of diverticular disease, but often endoscopy is helpful to distinguish between diverticular disease and colorectal cancer and inflammatory bowel disease.

Treatment of Acute Diverticulitis

Treatment of Uncomplicated Diverticulitis

Antibiotics

Antibiotic therapy remains the most important component of the management of patients with acute uncomplicated diverticulitis. Despite the broad application of antibiotics in the operative and nonoperative therapy of diverticulitis, there have been few studies examining the optimal dosing and frequency of administration of these agents [82]. The microflora associated with diverticular microperforation include flora such as Gram-negative rods, Gram-positive rods, and anaerobic bacteria. The anaerobic bacteria are far more common and outnumber the aerobic 1000:1 [83]. There are a number of single and combination antibiotic regimens for the management of acute diverticulitis. All of the regimens have activity against the colonic flora; however, little is known about their efficacy [83]. Kellum et al. randomized 51 patients to a regimen of cefoxitin alone vs. gentamicin/clindamycin. Patients in need of an urgent operation were excluded. These authors concluded that the single-agent regimen exhibited similar efficacy to the two-agent regimen. They recommended the use of cefoxitin as this was cost-effective [84].

The American College of Gastroenterology guidelines for the treatment of diverticulitis include cefoxitin or ampicillin/sulbactam as single agents or a third-generation cephalosporin, aminoglycoside, or monobactam in combination with an anti-anaerobic agent [84]. The American Society of Colon and Rectal Surgeons published their practice parameters for the management of diverticulitis in 2006. They recommended that antibiotic therapy be selected to provide adequate coverage of the most common colonic organisms. The authors maintained that single and combination regimens were equally effective. Even with appropriate antibiotic therapy recurrences, approximately one-third of patients will have a recurrence [8].

The ASCRS guidelines were further revised in 2014 to suggest that antibiotics were “usually” used in the initial management of uncomplicated diverticulitis. These guidelines take account of new data which suggested that antibiotic therapy may be optional and uncomplicated diverticulitis [85]. de Korte et al. reported on a series of 272 patients who were studied in a case-control fashion. All patients in their study had mild diverticulitis and were admitted to one of two hospitals. In the first hospital, antibiotics were administered,

and in the second hospital, Foley IV fluids and bowel rest were prescribed. The authors found no difference in treatment failure [86]. The AVOD (Antibiotika Vid Okomplicerad Divertikulit—Swedish for 'antibiotics in uncomplicated diverticulitis') trial and a modest patient with uncomplicated diverticulitis into an antibiotic therapy and IV fluids vs. IV fluids the management of uncomplicated diverticulitis. This study treated 623 patients with CT confirmed uncomplicated diverticulitis. One group received intravenous fluids, and the other group received intravenous fluids and antibiotics. The authors found similar rates of recurrence, time to recovery, and complications in both groups [87]. A recent Cochrane Review of the subject examined three randomized trials. This study did not find a significant difference between antibiotic administration and no antibiotic administration in the management of uncomplicated diverticulitis [88].

Despite this new data, antibiotic therapy continues to be widely used in the management of all forms of diverticulitis. Patients with minimal symptoms and mild signs of peritoneal irritation can typically be treated as outpatients. Patients who present with fever, systemic symptoms, or inability to tolerate oral intake are usually hospitalized. Parenteral antibiotics are typically administered until the acute symptoms resolve. Once there is clinical improvement, the antibiotic route is changed to oral administration.

Diet

A diet that is rich in fiber may increase the bulkiness of stools, decrease colonic transit time, and therefore decreases intraluminal pressures [89]. The optimal amount of daily fiber is unknown; however, 20–30 g is a widely recommended figure. Recent evidence supports the notion that persons with diets high in fiber have decreased rates of diverticulosis and bear a lower risk of developing diverticulitis [28–30]. Based on this information, a number of dietary societies have suggested that there is little evidence to support a change of diet or elimination of specific foods following an episode of diverticulitis. The only requirement that is repeatedly emphasized across the medical literature is the need to maintain a high-fiber diet [90, 91].

Emerging Medical Therapies

Mesalamaine

As the microperforation pathophysiology of diverticular disease has come into question, there has been increased interest in the use of immunomodulatory agents in the management of diverticular disease. 5-ASA products and sulfasalazine alter DNA synthesis and cell cycle progression in lymphocytes. 5-ASA compounds are also thought to suppress leukotriene and prostaglandin synthesis, thus reducing proinflammatory states [84, 92]. Because a low-grade proinflammatory state is the proposed mechanism underlying chronic diverticular disease, a number of small trials have evaluated the effectiveness of mesalamine-like compounds. In all of these studies, the outcome of interest was symptom severity, and none reported any objective analysis of the actual inflammatory burden (i.e., imaging). In the original description of the use of mesalamine for the management of diverticulitis, Trespi et al. demonstrated that patients treated with antibiotics and mesalamine had decreased symptomatology [93].

Another study randomized patients with diverticulitis to a rifaximin-only arm vs. a rifaximin/mesalamine arm. Patients in the rifaximin/mesalamine arm demonstrated significantly improved bowel habits. They also had less recurrent episodes and demonstrated lower symptom severity [94]. In another study, mesalamine alone was compared to rifaximin alone. The authors compared several outcomes including general illness, nausea, abdominal pain/discomfort, emesis, dysuria, fever, abdominal tenderness, diarrhea, tenesmus, and bloating. Patients treated with mesalamine had significantly lower global scores than patients treated with rifaximin alone. Therefore this study concluded that mesalamine is an effective medication for preventing recurrence of diverticulitis and maintaining remission [95].

In a systematic review which included six randomized trials of 5-ASA products in the treatment of diverticulitis, patients treated with 5-ASA products had better outcomes than those not treated with 5-ASA. They also concluded, however, that larger trials which had objective confirmation of diagnosis by endoscopy are needed for confirmation of the initial data on this type of treatment [96]. Despite initial enthusiasm for the use of these products, they have not, at the time of this manuscript, found significant adoption in the United States.

Probiotics

Probiotics are marketed as preparations of naturally occurring colonic microflora which can have a beneficial effect on those that ingest them. Because patients with diverticular disease are thought to have altered colonic microflora due to constipation and stasis of fecal matter, it has been suggested that probiotics may have a role in the management of this disease [97].

Giaccari et al. examined the administration of rifaximin and *Lactobacillus* in patients with diverticular disease. They reported no complications and adequate symptom control. They concluded that the combination of rifaximin and *Lactobacillus* was an adequate regimen for prophylaxis against the complications of diverticular disease [98]. In a smaller study (15 patients), investigators compared administration of nonpathogenic *E. coli* with active coal tablets to coal tablets alone. These authors concluded that the length of remission was significantly longer when a probiotic was administered (14 months vs. 2.4 months) [99]. Although the initial results are promising, there is only a small amount of data supporting the use of probiotics.

Elective Surgical Management of Recurrent Uncomplicated Diverticulitis

For many decades, the indications for surgical management of diverticulitis were clear. Elective resection was suggested after two well-documented attacks of uncomplicated diverticulitis requiring hospitalization and/or after one episode of complicated diverticulitis. In patients under 40 years of age, elective resection was recommended after the first attack of complicated or uncomplicated diverticulitis. These guidelines were endorsed by a number of societies including the American Society of Colon and Rectal Surgeons, the Society for Surgery of the Alimentary Tract, the European Association for Endoscopic Surgery, and the American College of Gastroenterology [84, 100–102].

These recommendations have been challenged by new data. Salem et al. suggested that waiting until the fourth attack of uncomplicated diverticular disease would be associated with fewer intestinal stomas and fewer deaths [103]. Another study concluded that elective resection after the third attack would be more cost-effective. The guidelines for surgery were revised by the American Society of Colon and Rectal Surgeons in 2006 and suggested that the "number of attacks of uncomplicated diverticulitis is not necessarily an overriding factor in defining the appropriateness of surgery" [8]. These recommendations were echoed in the most current practice parameters. Recommendations should be individualized by the age and medical condition of the patient, by the severity and frequency of the attacks, and by the presence of ongoing symptoms [85].

Furthermore, most patients who present with complicated diverticulitis will have complicated disease on the first attack; resection after recovery from uncomplicated diverticulitis does not prevent the development of complicated diverticulitis [68, 104]. Interestingly, the risk of needing a colostomy following a successfully managed episode of diverticulitis is small (1/2000). Therefore, the practice of recommending elective surgery to avoid future stoma formation should be avoided [85].

Young Patients

Several authors have proposed that patients younger than 40–50 years of age present with a move virulent form of diverticulitis [104]. Historical recommendations have advocated sigmoid resection for young patients after one well-established attack of diverticulitis; however, this dictum has been called into question by recent evidence. Although younger men are proposed to have severe diverticulitis more often than older men, they require operative intervention less frequently [72]. In addition, other authors have pointed out that younger patients did not have different rates of conservative management, emergency operation, or mortality when compared to older patients [103]. Although there is some evidence that young patients present with a more virulent form of the disease, it is not clear that these patients will go on to have a recurrence. In a study by Guzzo et al., 1 patient out of 196 young patients (<50 years) had a free perforation after medical management of diverticulitis. The median follow up was 60 months. Recent analysis of a large administrative dataset suggested that young patients may indeed have a higher risk of recurrence (27%) but have low rates of emergency surgical intervention (7.5%) [105]. Given the current level of evidence, there is no clear mandate to treat young patients with diverticulitis differently than the other age groups [106].

Complicated Diverticular Disease

Complicated diverticulitis is defined as diverticulitis associated with perforation, fistula, abscess, stricture, or obstruction. Management of complicated diverticular disease is dependent on the particular presentation of the disease. Treatment of the complications of diverticulitis may range from treatment with bowel rest and parenteral antibiotics to emergent exploratory laparotomy. We will review the treatment options for each of the complications of diverticulitis separately.

Diverticular Abscess

Diverticular abscess occurs in approximately 10–25% of patients with acute diverticulitis. Abscesses include pericolic, hepatic, pelvic, and retroperitoneal abscesses. In women, a fistula from the colon to the adenexa may result in tubo-ovarian abscesses [107]. Traditionally, in patients with diverticulitis and an associated abscess, the goals of care were to treat the inflammatory process and later to operate on an elective basis when the risk of infectious complications is substantially lower. This approach was based on the observation that over 40% will develop recurrent sepsis [76]. However, reports of patients who have undergone percutaneous or operative drainage with no further septic sequelae have called this practice into question. Franklin and colleagues reported on 18 patients who underwent laparoscopic drainage of Hinchey II abscess, and at a follow-up of 4–34 months, 15 remained asymptomatic without the need to undergo resection [108].

Cross-sectional imaging of the abdomen is the most effective way of diagnosing and staging diverticular abscesses. The initial approach to patients with diverticular abscess includes bowel rest, antibiotics, and close observation. Abscesses less than 4 cm in size often resolve with intravenous antibiotics alone without the need for further procedures [8, 109–111]. For those patients with diverticular

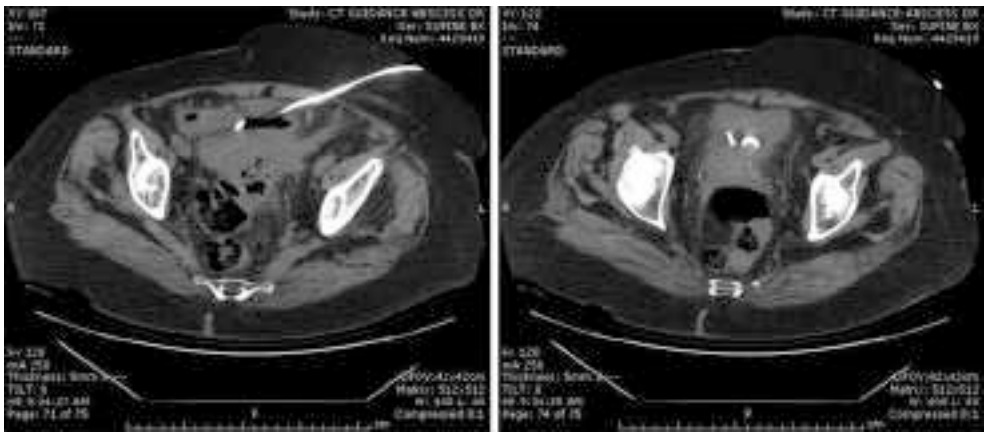

FIGURE 39-6. Pigtail catheter in a complex diverticular pelvic abscess.

abscess who do not improve on initial antibiotic therapy and continue to have signs of sepsis (fever, abdominal pain, and leukocytosis), percutaneous drainage is preferred.

A recent review suggested that 20–30% of diverticular abscesses were amenable to percutaneous drainage and the failure rate of percutaneous drainage was 20–30% [111]. The preferred approach for percutaneous drainage is usually by a transabdominal route (Figure 39-6) [112]. If the abscess is not accessible by this route, a transgluteal, transperineal, or transrectal routes may be employed. Transabdominal tends to be better tolerated in terms of patient comfort when compared to other access routes. In patients with simple unilocular abscesses, successful drainage is achieved in approximately 80%. Patients with more complex abscesses associated with loculations and fistula or whose drainage route transverses normal organs are associated with a higher failure rate [112]. The expertise and skill of the interventional radiologist is also associated with a higher success rate.

The decision for surgery following successful drainage of a diverticular abscess should be approached on a case-by-case basis. Diverticulitis associated with abscess denotes more severe diverticulitis, and a substantial number of patients require sigmoid resection. While 40–50% of patients admitted with diverticular abscesses respond to conservative treatment, sigmoid resection is recommended for selected patients particularly those with more complex or larger abscesses and those with recurrent or persistent symptoms such a colocutaneous fistula [113]. Ideally, elective surgery is performed after initial treatment with antibiotics and/or percutaneous drainage as indicated.

Perforated Diverticulitis

Approximately 1% of patients with diverticulitis develop free perforation which may include purulent or fecal peritonitis (Figure 39-1b). Free perforation almost exclusively develops on the first attack of diverticulitis and is generally not seen in patients who have had multiple attacks of diverticulitis. Similarly, there is general consensus that patients with perforated diverticulitis manifested by purulent peritonitis or feculent peritonitis require operative intervention. The mainstay of treatment for perforated diverticulitis over the last several decades has been the Hartmann procedure which resects the disease and eliminates the septic focus. A disadvantage of the procedure is the requirement for a second major surgical procedure to reverse the colostomy and the attendant morbidity and potential mortality of the procedure. Data from large administrative databases suggest that at least one-third of patients may never undergo reversal [114], and up to 70% of patients, over 77 years may not undergo reversal [115]. Women are less likely than men to undergo Hartmann reversal [114, 116].

There has been renewed interest in performing resection and primary anastomosis in selected patients with Hinchey III and Hinchey IV diverticulitis. A number of systematic reviews and meta-analyses have suggested that primary anastomosis is superior to Hartmann resection for patients with perforated diverticulitis; however there is considerable selection bias [103, 117]. In clinical practice, the decision to perform a primary anastomosis should be done on a case-by-case basis. A number of technical- and patient-related factors must be considered by the surgeon to determine if the patient is a good candidate for a primary anastomosis. Hemodynamic instability, diffuse peritonitis (either purulent or fecal), ischemia or significant edema of the bowel at an intended site of anastomosis and anemia, malnutrition, and immunocompromised state are general contraindications to a primary anastomosis [118]. Although discussed frequently in the literature, data from the Nationwide Inpatient Sample has not shown any evidence that primary anastomosis is being more commonly used as the preferred procedure for patients who undergo surgery for acute diverticulitis [14].

Recently, alternatives to resection and definitive treatment with laparoscopic lavage have been reported. Based on a small series of successful laparoscopic lavage for treatment of patients with perforated diverticulitis with purulent peritonitis, a prospective multi-institutional study of 100 patients has been reported [119]. Patients with perforated diverticulitis and generalized peritonitis underwent laparoscopic lavage

as definitive treatment. No effort was made to mobilize and resect the sigmoid colon. The median age was 62.5 years with a follow-up of 36 months. Eight patients were found to have fecal peritonitis and converted to an open procedure and underwent resection. The remaining 92 patients were successfully treated with laparoscopic lavage with a 4% morbidity and a 3% mortality. Two patients later required intervention for a pelvic abscess, and two patients presented with recurrent diverticulitis in the study period. These data challenge our conventional surgical teaching and suggest that selected patients with purulent peritonitis from diverticulitis may be successfully treated with laparoscopic lavage without resection of the affected segment of colon [119].

A subsequent review of eight studies of 213 patients with acute complicated diverticulitis managed by laparoscopic lavage has noted a 3% conversion rate. Ten percent of patients had complications, and during a mean follow-up of 38 months, 38% of patients underwent elective sigmoid resection with primary anastomosis [120]. Given these results, it appears that lavage can be appropriate in selected circumstances. However, in a substantial proportion of patients, it does not effectively eliminate the septic focus. Based on this the ASCRS clinical practice guidelines recommended against its use as alternative to colectomy until more information and longer follow-up is available [85].

Fistulas

Fistulas occur in 2% of patients with diverticular disease [121]. The localized inflammatory process develops into an abscess which then decompresses into adjacent viscera (Table 39-5). Patients who develop fistulas generally do not need emergent intervention as the abscess has decompressed; in fact many patients with fistulas may have few abdominal signs and symptoms. Colovesical fistulas are the mostly common (65%), followed by other types of fistulas including colovaginal, coloenteric, colouterine, and colocutaneous fistulas [122–125].

Colovesical Fistulas

Colovesical fistulas are more common in men than in women. Women affected with a colovesical fistula have usually undergone a prior hysterectomy. Patients often present with prominent urinary symptoms including polymicrobial urinary tract infections, pneumaturia, and fecaluria. CT scanning reveals air and/or contrast in the bladder in the absence of prior instrumentation (Figure 39-7a–c). If performed, cystoscopy shows inflammation generally at the dome of the bladder and, on occasion, vegetable material in the urine. Colovesical fistulas may also be associated with locally advanced bladder or primary colon cancer. Cystoscopy and colonoscopy may be an appropriate test to exclude a malignancy under the appropriate clinical circumstances.

The surgical principles for treatment of colovesical fistulas due to diverticular disease include resection of the affected segment (generally the sigmoid colon). The fistula is generally small and may be suture repaired. Ureteral stents are generally not needed. In some cases, the precise site of the fistula cannot be determined, and pinching it off is sufficient treatment; sutures are not absolutely necessary. A primary anastomosis can usually be performed safely. Omentum is used tointerpose between the anastomosis and the bladder. On occasion, nonoperative management is used for colovesical fistulas especially if the symptoms are minor and the patient has medical comorbidities conferring a significant operative risk. Suppressive antibiotics may be used to ameliorate symptoms in such cases [125].

Colovaginal Fistulas

Colovaginal fistulas occur almost exclusively in women who have undergone a prior hysterectomy (Figure 39-8). Signs and symptoms include vaginal discharge and passage of air per vagina. Often, women have seen a gynecologist initially for evaluation of vaginal discharge. A single-stage sigmoid resection can generally be performed, pinching off the site of the fistula and interposing omentum.

Colocutaneous Fistula

Colocutaneous fistulas rarely occur de novo and are generally seen in patients who have undergone prior colectomy or percutaneous drainage [125]. Risk factors for the development of colocutaneous fistula include unsuspected Crohn's disease and anastomosis to the distal sigmoid colon and not the proximal rectum.

Diverticular Stricture/Obstruction

Repeated attacks of diverticulitis may be associated with the development of a sigmoid stricture and progressive obstructive symptoms. Less commonly, complete large bowel

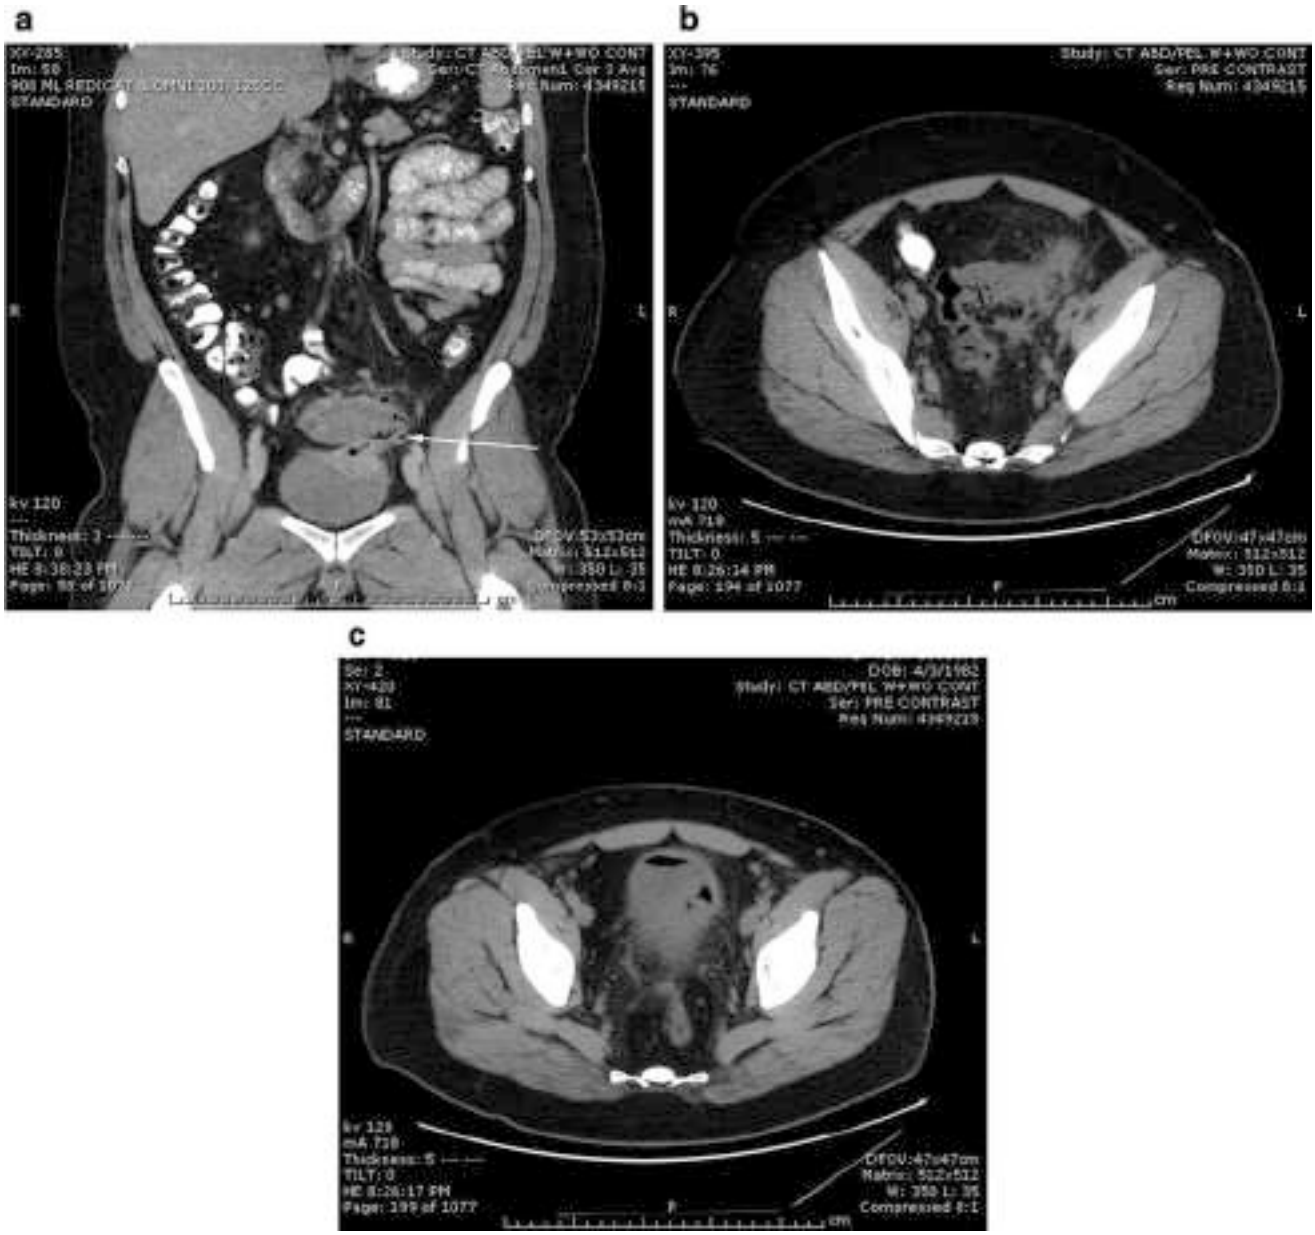

FIGURE 39-7. (**a**) *Arrow* points to colovesical fistula. (**b**) Inflamed sigmoid colon adjacent to fistula. (**c**) Air in non-catheterized bladder consistent with colovesical fistula.

obstruction associated with diverticular disease develops (Figure 39-9). The major differential diagnosis is with obstructing colon cancer. While large bowel obstruction is most commonly associated with obstructing colon cancer, approximately 10% of large bowel obstructions are attributable to diverticular disease [126]. Colonic stricturing typically develops after a number of recurrent attacks leading to fibrosis with the colonic wall. Small bowel can also become adherent to a focus of inflamed colonic tissue leading to associated small bowel obstruction.

The approach to management depends on whether the obstruction is complete or partial. Patients with a partial obstruction that resolves with bowel rest, intravenous hydration, and antibiotics may be able to undergo elective resection. In some patients, treating the acute inflammatory phlegmon allows for resolution of the obstruction. Endoscopic or radiologic evaluation can then be performed and elective resection planned. For patients with complete obstruction, there are a number of surgical options. In the past, persistence of obstruction after treatment with antibiotics typically required sigmoid resection, end colostomy, and Hartmann closure of the rectum because of the concern about the increased risk of anastomotic leakage in patients who had dilated and edematous bowel or who were not able to

undergo preoperative mechanical bowel preparation. While the Hartmann resection is still an excellent option in selected patients, other options include sigmoid resection with primary anastomosis and diverting proximal stoma (usually a loop ileostomy), on-table lavage and primary anastomosis, or colonic stenting placement followed by semi-elective sigmoid resection.

On-table lavage is a technique which allows for cleansing of the fecal laden, obstructed colon before potential anastomosis. The technique has been described by Murray et al. [127] and involves mobilization of the splenic flexure and at times the hepatic flexure. A Foley catheter attached to warm irrigation fluid is introduced through the appendix. If surgically absent, the catheter may be placed through a cecostomy or ileostomy. Corrugated anesthesia tubing is placed through the distal colon and secured with umbilical tape. The colon is lavaged until the returns are clear. The technique may be used in selected patients who are hemodynamically stable and in whom there is minimal contamination. While the need for mechanical bowel preparation has been called into question for elective colon resection, this claim has not been critically evaluated in patients with bowel obstruction [128]. Lee et al. described the use of on-table lavage and sigmoid resection with primary anastomosis in 33 patients with diverticular disease who underwent nonelective resection. There were no anastomotic leaks in this series, but there was a significant (18%) incidence of wound infection [129]. While this technique is interesting, often patients with large bowel obstruction have severely dilated colons that are not good candidates for anastomosis with or without bowel preparation.

A number of authors have demonstrated that treatment of acute colonic obstruction with self-expanding metal stents is a viable option particularly in patients with obstructing colon cancer [130, 131]. Colonic stenting for benign obstructions is associated with a high rate of stent migration as well as other delayed complications. In a series of 104 procedures from one center, eight patients had obstruction from a benign etiology [132]. After colonic stenting, many required reinterventions and only three patients achieved a benefit from stenting. From a technical standpoint, stenting a diverticular stricture which is potentially longer or more angulated may be more difficult than stenting a short segment stricture from colon cancer. Colonic stenting in benign disease remains a controversial procedure and should be embarked upon with caution [133–135].

FIGURE 39-8. Colovaginal fistula. *Arrow* demonstrates vaginal filling with contrast from pericolonic abscess.

Operative Therapy

Elective Management

Open sigmoid resection is generally performed through a midline incision. Preoperative mechanical bowel preparation is not necessary but is often performed [128]. Preoperative intravenous antibiotics are administered. The sigmoid colon is mobilized, and proximal and distal points are selected for resection. The proximal resection margin should be in soft pliable bowel, and it is not necessary to resect all proximal diverticula. The distal resection margin is the proximal rec-

FIGURE 39-9. Large sigmoid phlegmon causing a large bowel obstruction. *Arrow* shows a retrograde injection of contrast within the rectum which is unable to pass the obstruction.

tum as anastomosis to the distal sigmoid is associated with a higher risk of recurrent diverticulitis [136, 137]. It may be necessary to mobilize the splenic flexure to perform a tension-free anastomosis; alternatively, rectal mobilization will also afford additional length. One study suggested that an inframesenteric dissection with preservation of the inferior mesenteric artery decreased the incidence of anastomotic leak [138]. A hand-sewn or stapled anastomosis is performed. The anastomosis is most often performed with an EEA stapler.

In cases of fistulas to the bladder or the vagina, the fistula may be simply "pinched off," and a resection of bladder and/or vagina is not necessary. Once a fistula is pinched off, omentum can be used to interpose between the bladder and/or vagina and the colon.

Ureteral stents are generally not necessary but may be used in selected cases. Although they do not prevent ureteral injuries, they permit easy recognition and repair of such injuries [139]. A technique that may be helpful in mobilization includes "proximal to distal" resection in which the colon is divided proximal to the phlegmon with a linear stapler, and the colon is dissected proximal to distal, rather than performing a lateral to medical dissection [140]. This technique may facilitate easier identification of the ureter and avoid injury.

Although the rectum is not primarily involved with diverticulitis, inflammation of the proximal rectum may be encountered from the diverticular phlegmon or from an associated pelvic abscess or diverticular perforation. In such cases, based on sound surgical judgment and specific intraoperative factors, primary anastomosis potentially to the mid-rectum with proximal fecal diversion may be performed.

Minimally Invasive Surgery

The advent of laparoscopic surgery is ushered in a new era in the surgical management of diverticular disease. In the last decade, increasing numbers of resections for diverticular disease have been performed laparoscopically. Conventional laparoscopic techniques allow the surgeon to perform all the major portions of the case, including the anastomosis, through small 5 or 12 mm trocars (Figure 39-9).

A commonly practiced technique involves the use of a "hand-assisted" technique. In this type of approach, the surgeon's hand is placed into the abdomen though a small vertical lower midline or Pfannenstiel incision to assist in the mobilization of the colon. The dissection can be carried out in a medial to lateral or lateral to medial approach.

In the medial to lateral approach, a plane is made below the inferior mesenteric artery (IMA). The ureter, gonadal vessels, and other retroperitoneal structures are swept away. The IMA is then divided using a stapler or energy device. The sigmoid colon can then be mobilized up to the level of the splenic flexure by sweeping down the attachments of the left colonic mesocolon to Gerota's fascia and retroperitoneum. It may be necessary to mobilize the splenic flexure to perform a tension-free anastomosis, and there is evidence that suggests that the incidence of splenic injury is lower with a laparoscopic approach [141]. Proximal and distal resection margins can then be chosen. A hand-sewn or stapled anastomosis is performed. The anastomosis can be performed in an intracorporeal fashion. Alternatively, the anastomosis can be fashioned through the specimen extraction site. The use of the extraction site in cases of fistulas or abscesses often allows the laparoscopic completion of colectomies in patients with severe disease without conversion. Nonetheless, there are a wide range of published conversion rates as demonstrated in Table 39-6.

In the "conventional or straight" laparoscopic technique, the essential elements of the operation remain the same. The colon can be mobilized from a lateral to medial or medial to lateral approach. The specimen is typically extracted through a periumbilical vertical incision and the anastomosis performed in an intracorporeal fashion.

Prospective evaluation of hand-assisted laparoscopic techniques demonstrate that although operative times are similar to conventional laparoscopic surgery, conversions are less frequent (0% vs. 13%) [24].

Minimally invasive colectomy has a number of benefits. The Norfolk surgical group demonstrated that ileus and length of stay were less in patients who had their sigmoid colectomy completed laparoscopically [142]. Other authors have demonstrated decreased postoperative pain, wound infection rates, operative blood loss, and transfusions and a faster return to preoperative activity levels [143, 144]. The outcomes of 676 patients undergoing laparoscopic colectomy for diverticulitis were compared to those undergoing laparoscopic colectomy for non-diverticular disease. No differences were noted when comparing complications, mortality, length of stay, or oral feeding [145].

TABLE 39-6. Conversion rates in selected laparoscopic colectomy series

Urgent and Emergent Procedures

The Hartmann procedure resects the diseased segment of bowel, eliminates the septic focus, and allows for restoration of bowel continuity on an elective basis. The patient is approached through a midline laparotomy both to confirm the diagnosis and assess the degree of contamination and inflammation. Preoperative stoma site marking is helpful. The affected sigmoid colon is mobilized, and a proximal to distal approach is generally the easiest and safest. The bowel can be transected proximally and dissection carried down to the sacral promontory. A wide mesenteric dissection is unnecessary. The ureter should ideally be identified. All diseased and thickened bowel should be resected, and the resection margin should ideally be the proximal rectum. Alternatively, distal sigmoid, if not inflamed, can be left in place for later resection at the intended Hartmann reversal. The proximal rectum is transected with a stapler or oversewn depending on individual preference. The stoma is brought out on the left side; splenic flexure mobilization may be necessary to achieve adequate length particularly if there is significant foreshortening of the mesentery from the diverticular phlegmon. The colostomy is generally left in place for at least 3 months allowing the patient to sufficiently heal and hopefully facilitate identification of the Hartmann stump. Waiting longer can make identification of the Hartmann stump difficult secondary to fibrosis [161].

Selection of patients who may safely undergo resection and primary anastomosis in the acute setting requires considerable judgment and must take into consideration patient-related and disease-related factors. Primary anastomosis is not advisable for patients with hemodynamic instability, diffuse fecal or purulent peritonitis, immunocompromised patients, or those with severe anemia or malnutrition and those with ischemia or edema of the bowel at the proposed site of anastomosis [117]. Despite systematic reviews and a focus in the literature on performing primary anastomosis in the nonelective patient, a recent review of 267,000 patients admitted with acute diverticulitis and 335,000 patients (from 1998 to 2005) operated on electively for diverticulitis found no evidence that primary anastomosis was more commonly performed [14].

Minimally Invasive Colectomy for Complicated Disease

As laparoscopic colectomy has gained widespread use, this technique has been applied to patients with complicated diverticular disease. Martel et al. compared the outcomes of laparoscopic colectomy following treatment of complicated and uncomplicated disease in 183 patients. These authors demonstrated no difference in anastomotic leak rates and intraoperative complications. It should be noted however, that patients with complicated disease underwent conversion to open procedures more frequently (23% vs. 4%) [162]. While overall conversion rates differ among studies, higher rates of conversion in patients with complicated diverticulitis are noted in a number of series on this topic [142, 163, 164]. Some studies have noted that when complicated disease is restricted to fistula or abscess, then there is no increased risk of conversion when comparing patients with complicated and uncomplicated disease [165, 166]. A Chinese group has shown that laparoscopy is feasible in the management of complicated right-sided diverticulitis. Although patients in the laparoscopic group recovered bowel function more quickly (3.5 days vs. 5 days), the length of stay in both groups was similar [167].

Special Situations

Recurrent Diverticulitis

Recurrent diverticulitis following resection is uncommon. In the patient presenting with abdominal pain following resection for diverticulitis, a systematic evaluation should be performed to exclude other causes of pain. Etiologies such as inflammatory bowel disease, ischemic colitis, colorectal cancer, adhesive disease, gynecologic pathology, and irritable bowel syndrome should be considered. Patients with diverticular disease have significant overlap with irritable bowel syndrome. Additional pathology review of the resected segment of sigmoid colon may be helpful. Patients who present with "recurrent diverticulitis" may not have had diverticulitis (but only diverticulosis) on initial resection.

The development of recurrent diverticulitis should be distinguished from patients that develop persistent poorly characterized abdominal pain following resection. Munson et al. found that 27.2% of patients following resection for diverticular disease continued to have pain [168]. Parks and Connell noted persistence of mild symptoms in 24% of patients who underwent a three-stage resection for diverticulitis [169].

The most established risk factor for recurrent diverticulitis following resection is the level of anastomosis. Although diverticulitis may only involve a portion of the sigmoid colon, the entire sigmoid should be resected and anastomosis performed to the proximal rectum. The rectum is identified at the level at which the taenia fan out which is generally around the sacral promontory. The proximal resection margin is less well established, and the dictum has been to anastomose in "soft pliable bowel" [8]. It is unnecessary to remove all diverticula of the colon, but the anastomosis should be performed in an area that is free of diverticula. Two studies have looked at the level of anastomosis and the risk of recurrent diverticulitis. Benn et al. examined 501 patients undergoing sigmoid resection for diverticular disease. The incidence of recurrent diverticulitis was 6.7% with anastomosis to the proximal rectum compared with 12.5% in patients who underwent anastomosis to the distal sigmoid

colon. Thaler et al. also noted that the level of anastomosis was the only predictor of recurrence in regression analysis with patients with a colosigmoid anastomosis having a four times higher risk of recurrence compared to patients with a colorectal anastomosis [136].

Giant Colonic Diverticulum

The condition of giant colonic diverticulum is rare and was first reported by Bonvin and Bonte in 1946 [170]. Less than 150 cases have been reported in the literature [171]. These diverticula affect men and women equally and are most commonly found in the sigmoid colon. The average diameter is 13 cm, but diverticula as large as 40 cm have been reported. Two theories have been put forth for the development of giant diverticulum; one proposed theory is that the diverticulum becomes massive because of a ball-valve mechanism allowing air into but not out of the diverticulum [172]. Another theory suggests that air is trapped into the diverticulum because of gas-forming microorganisms without obstruction at the neck of the diverticulum.

Many patients with this entity are minimally symptomatic or present with mild episodes of pain. On abdominal palpation, a soft mobile mass may be appreciated. The differential diagnosis includes colonic duplication, pancreatic pseudocyst, Meckel's diverticulum or jejunal diverticulum, sigmoid volvulus, or emphysematous cholecystitis. More commonly, the abnormality is noted on abdominal CT scan. Treatment consists of sigmoid resection with anastomosis. Diverticulectomy, which was has been employed in earlier reports, is rarely performed today.

Diverticulitis: Other Sites

Right Colonic Diverticulitis

Right-sided diverticulitis is rare in the Western countries and more common in the Far East [173]. Cecal diverticula are of two types, both true and false. True diverticula contain all layers of the bowel wall and are usually congenital and tend to be solitary. Acquired diverticula of the cecum are false, containing mucosa and muscularis mucosa, tend to be multiple and tend to be associated with diverticula elsewhere in the colon. Patients with cecal diverticulitis present at a younger age than the average patient with sigmoid diverticulitis. The main differential diagnosis is that of acute appendicitis, and it may be difficult in the patient with right-sided abdominal pain, fever, and leukocytosis to distinguish cecal diverticulitis from acute appendicitis. Other differential diagnoses include chronic cholecystitis, mesenteric adenitis, ischemic colitis, pelvic inflammatory disease, pancreatitis, Meckel's diverticulitis, pyelonephritis, and sigmoid diverticulitis (with a redundant sigmoid loop). Laparoscopy is sometimes helpful to distinguish between cecal diverticulitis and appendicitis. A retrospective review of 49 patients at a single institution found the ratio of acute appendicitis to cecal diverticulitis to be 150:1 [174]. In the absence of peritoneal signs, patients may be treated with antibiotics. For those patients with repeated attacks or complications including perforation or abscess, resection is indicated. Fang and coworkers reviewed 85 patients treated for cecal diverticulitis [175]. Less than 40% were treated with antibiotics and bowel rest. Sixty-seven patients ultimately underwent laparotomy. In the 47 patients with a preoperative diagnosis of appendicitis, 24 underwent appendectomy, 9 underwent diverticulectomy, and 14 underwent right colectomy. In the 20 patients with a preoperative diagnosis of diverticulitis, all underwent right colectomy. Thorson and Ternent [176] have suggested a grading system to aid with the management of cecal diverticulitis (Table 39-7). These authors suggested that when diagnosis is uncertain then right colectomy is most likely the best option [176]. With refinements in technology and with the widespread use of CT scanning for evaluation of patients with abdominal pain, proceeding to laparotomy or laparoscopy without a relatively secure diagnosis is uncommon.

Table 39-7. Cecal diverticulitis classification system

Grade I	Easily recognizable projecting inflamed cecal diverticulum
Grade II	Inflamed cecal mass
Grade III	Localized abscess or fistula
Grade IV	Free perforation or ruptured abscess with diffuse peritonitis

Modified from Hinchey et al. [141]

Rectal Diverticulitis

Rectal diverticula are rare, are typically solitary, and are true diverticula including all layers of the bowel wall [37].

Transverse Colonic Diverticulitis

Diverticulitis involving the transverse colon is exceedingly rare with less than 50 cases reported and often confused with other conditions such as cholecystitis [177]. In a large series of 951 patients who all underwent CT scan on initial presentation of diverticulitis, Hall et al. found that the prevalence of transverse colon diverticulitis was 2.6% [42].

Immunocompromised Patients

Immunocompromised patients include patients on systemic steroids, patients with diabetes mellitus or renal failure, transplant patients who are immunosuppressed, patients with cirrhosis, patients with underlying malignancy, and

patients being treated with chemotherapy. Patients who are immunosuppressed are more likely to present with free perforation, presumably because of the inability to mount an inflammatory response and wall off the infection and are therefore more likely to require emergency surgery with resultant increased postoperative morbidity and mortality. In the combined series of patients who were immunocompromised who presented with diverticulitis, 40% had free perforation, 60% required emergency operation, and the overall postoperative morbidity and mortality were 65% and 40%, respectively [178–181]. Immunocompromised patients who present with acute diverticulitis and require emergent laparotomy should undergo resection, with colostomy, and should not undergo primary anastomosis because of the impaired immune system and impaired healing.

Conclusion

Colonic diverticular disease represents a wide spectrum of presentations and treatment options. While many of the current treatment methods have been used for the greater part of a century, their mode of application continues to evolve. As in all inflammatory conditions, the initial goal of therapy is to control infection. Once this is done, the surgeon is left with a variety of treatment algorithms and options which must be individualized for each patient.

Large Bowel Obstruction

Karim Alavi and Charles M. Friel

Key Concepts

- Initial management of large bowel obstruction should include early correction of fluid and electrolyte abnormalities and surgical or endoscopic decompression.
- The current indications of endoluminal colonic stents include palliation in cancer and in patients who are medically unfit.
- Following correction of fluid and electrolyte abnormalities in patients with acute colonic pseudo-obstruction, intravenous neostigmine should be attempted as the next step in management.
- Following successful endoscopic decompression of a sigmoid volvulus, given the high recurrence rates, the next step in management should be a segmental resection during the same hospitalization.
- CT scan is the imaging modality of choice for the diagnosis and subsequent management of large bowel obstruction.

Introduction

Large bowel obstruction (LBO) is a common surgical emergency encountered in a colon and rectal surgical practice [1]. It is caused by the blockage of fecal flow. While most causes are mechanical, nonmechanical causes (pseudo-obstruction) have also been described. LBO is a complex problem that will challenge even the most seasoned clinicians. The surgeon must not only manage the immediate emergency (i.e., the obstruction) but also consider the treatment of the underlying etiology and consider the long-term outcomes of any particular intervention. Therefore, no one strategy will be adequate for all patients. Surgeons must be familiar with all the causes of LBO and understand the myriad of treatment options so that therapeutic plans can be tailored to a variety of clinical presentations.

Etiology

Most LBOs are due to progressive narrowing of the bowel lumen caused by intrinsic lesions of the bowel wall (Table 40-1). The most common example of an intrinsic lesion is colorectal cancer, which accounts for nearly 50% of all LBOs. In fact, approximately 10% of all colorectal cancer will present with evidence of a LBO [1]. Diverticular disease also causes intrinsic compression of the lumen and is generally considered the second most common cause of LBO (≈10–20%). Other less common examples of intrinsic narrowing include Crohn's disease, ischemia, endometriosis, and radiation, all of which cause progressive thickening of the bowel wall and obliteration of the lumen and can often be difficult to distinguish from colorectal cancer.

Extrinsic lesions can also impinge the bowel lumen. Most commonly extrinsic compression is caused by non-colorectal malignancy, such as ovarian cancer. Other less common causes of extrinsic compression are hernias and adhesions, the most likely causes of small bowel obstructions but rare for LBO.

Because both intrinsic and extrinsic compressions are slowly progressive, the clinical presentation of LBO is often insidious. Even when patients seemingly present with an acute LBO, the astute physician can elicit a history of progressive constipation and narrowed stools for left-sided obstruction or crampy abdominal pain for right-sided disease. Depending on when patients seek care, the clinical presentation can be quite varied and management strategies will have to be adjusted accordingly. Mild obstruction, or bowel stenosis, may cause symptoms such as pain, cramps, and constipation. During colonoscopy, the endoscope may not pass through the stricture, and on barium enema the patient may have a classic "apple-core" lesion (Figure 40-1). Since these patients have no proximal bowel dilation and no stool and fluid accumulating upstream of the obstruction, they will not present with signs of systemic toxicity. Management of

these patients is generally simpler since there is no immediate danger and surgery can be planned on a semi-elective basis. Moderate obstruction will present with proximal bowel dilation and accumulation of feces and fluid upstream. Bacterial overgrowth is also common. These patients will be very distended on exam but may only have mild tenderness (Figure 40-2). Signs of systemic toxicity, including an elevated heart rate and increased leukocytosis, are usually absent. Nevertheless, depending on the degree of colonic dilation, these patients can be on the precipice of grave illness and need prompt management. Severe obstruction will present similarly except signs of systemic toxicity will be present. These patients need immediate resuscitation and often require emergent surgery.

The last major category of LBO is volvulus, a twisting of the redundant colon about the colonic mesentery (Figure 40-3). Colonic volvulus accounts for approximately 10–15% of all LBOs reported in the United States and other Western countries. Worldwide, however, colonic volvulus accounts for a significantly higher proportion of LBO [2–5]. It can occur anywhere in the colon, but sigmoid and cecal are by far the most common [2, 3]. In most series, the sigmoid colon accounts for the 50–75% of all colonic volvuli with the majority of the remaining being located in the cecum [2, 3]. In a review of the Mayo experience, Ballantyne noted that 56% of the patients had a sigmoid volvulus compared with 41% of patients who were referred from the local county [2], and this distribution seems typical of other studies. Cecal volvulus tends to be in younger patients and has a slight female predilection. In a review from Rabinovici of 561 cases over a 30-year period, the average age at presentation was 53 years and the ratio of female to men was 1.4:1 [6]. Similarly, Friedman reported that patients with cecal volvulus were 10 years younger than patients with sigmoid volvulus (61 years vs. 71 years of age) [3]. Lack of

FIGURE 40-2. Plain radiograph demonstrating a diffusely dilated colon.

FIGURE 40-3. Surgical findings of sigmoid volvulus.

FIGURE 40-4. Necrotic sigmoid colon in the setting of sigmoid volvulus and distended proximal colon.

fixation of the cecum and ascending colon to the retroperitoneum seems to be a predisposing factor, and oftentimes patients have had a previous surgical history, suggesting adhesions may also play a role [2, 3]. In contrast, sigmoid volvulus seems associated with chronic constipation and elongation of the colon, indicative of an acquired pathology. In the United States, patients are often elderly and frequently institutionalized [3, 4] with significant medical comorbidities, including psychiatric diseases. Worldwide, however, patients tend to be younger and live in rural environments [4, 5]. Unlike other causes of LBO, a volvulus often presents acutely with rapid onset of distension and pain. Since the mesentery is involved in this process, the risk of strangulation and ischemia is significantly higher when compared with the more common causes of LBO [3] (Figure 40-4). Therefore, rapid identification is critical to ensure prompt intervention to prevent bowel necrosis.

Pathophysiology

Competency of the ileocecal valve is critical in determining the urgency by which decompression is required. LBO, in the setting of a competent ileocecal valve and a distal obstruction or colonic volvulus, results in a closed-loop obstruction. The ileum continues to pour contents into the colon without reflux leading to an increase in intraluminal pressure colonic distension. These effects are often compounded by bacterial overgrowth. As intraluminal pressure rises, intramucosal and intramural hypoperfusion lead to venous occlusion, followed by arterial occlusion, thrombosis, and eventual necrosis. The evolution and extent of these changes depends on the degree and duration distension [7, 8]. The risk of progression to ischemia and subsequent necrosis is lessened to some degree by the presence of an incompetent ileocecal valve and reflux of colonic contents into the small bowel. Finally, in the setting of colonic volvulus, necrosis may manifest rapidly due to a sudden, tight compression of the mesenteric vessels caused by ongoing distension of the colon and twisting of the mesentery along the mesocolic axis.

The consequences of increased intraluminal pressure in various segments of the colon depend on the amount of tension to which the walls are subjected and vary based on the law of Laplace. For example, the cecum, which has the largest diameter, is exposed to the greatest tension [9]. According to Laplace's law (Pressure = Tension/Radius), the tensile force on the wall of the colon is equal to the intraluminal pressure multiplied by the diameter of the segment in question [7–10]. Given the large diameter of the cecum, the tensile forces on the wall are the greatest, thus posing the greatest risk for perforation. The cutoff for cecal diameter on plain abdominal film has long been cited to be 12 cm above which the risk of ischemia and perforation increase [11–14]. An arbitrary cutoff, however, should be used within the context of the overall patient condition. The characteristics and risk for ischemia are dependent on several factors, including (1) the degree of distension, (2) the duration of

distension, (3) the amount of tension on the colonic wall, and (4) the baseline characteristics of the system vasculature [8].

Presentation

Patients with LBO present with abdominal distension, crampy abdominal pain, and obstipation. As previously stated, the degree of stenosis often determines the acuity of the presentation. They may have associated emesis which is directly related to the competency of the ileocecal valve, location, and the duration of the obstruction. Patients with a competent ileocecal valve do not experience emesis and instead exhibit increasing distension and pain. These patients are at increased risk of necrosis and subsequent perforation [10]. An incompetent valve vents the colonic contents into the proximal bowel allowing for a more measured approach. Often, the acuity of the presentation helps clarify the underlying etiology. Obstruction may present acutely in the setting of volvulus but may be more chronic, with a history of preceding constipation, in the setting of cancer, diverticulitis, or inflammatory bowel disease (IBD).

On physical examination, patients present with a distended and tympanic abdomen. In the setting of ischemia, localized peritonitis along with signs of systemic sepsis may be present demanding urgent surgical exploration. In addition, there may be signs of intravascular volume depletion as the obstructed colonic segment becomes distended with fluid and gas due to bacterial overgrowth. A digital rectal examination should be performed in all patients to evaluate for a distal rectal or anal canal mass and to exclude other etiologies, such as fecal impaction or a foreign body.

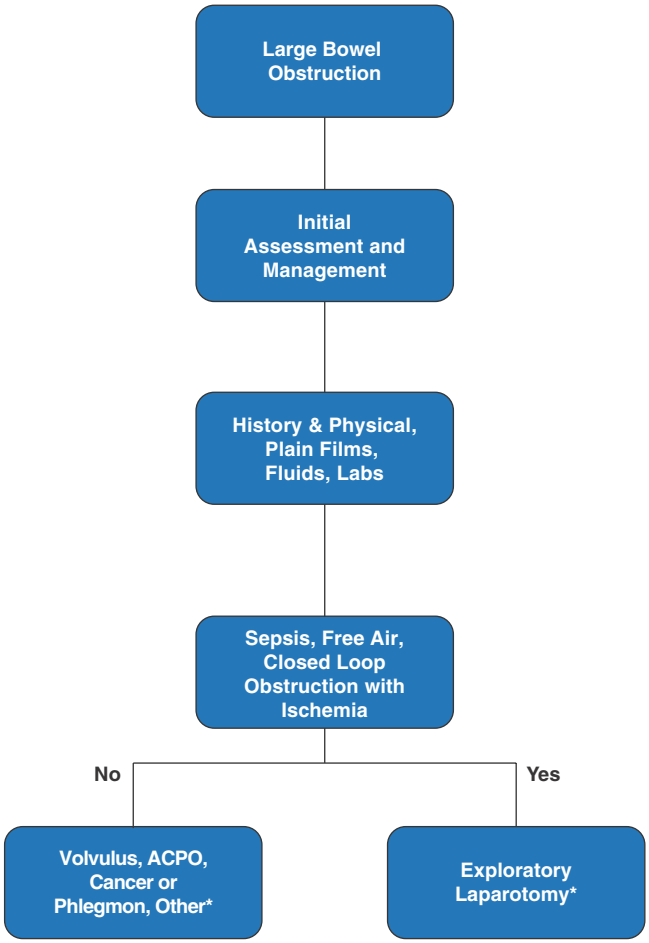

FIGURE 40-5. Proposed algorithm for initial presentation and management of LBO. ACPO = acute colonic pseudo-obstruction; *See Figures 40-9, 40-10, 40-18, and 40-21.

Initial Resuscitation (Fig. 40.5)

Initial assessment and management of patients with LBO, regardless of the diagnosis, should include a focused history and physical examination, complete blood work,including a complete blood count and serum chemistries, and flat and upright abdominal films. These initial tests can rapidly establish the diagnosis and exclude ischemia and/or associated perforation. Given the significant derangement in fluid and electrolytes, these patients are in need of aggressive fluid resuscitation and correction of electrolyte abnormalities. The adequacy of resuscitation should be closely monitored with insertion of a urinary catheter. In the setting of small bowel distension and associated emesis, decompression with a nasogastric tube may be helpful in averting an urgent exploration allowing time for ongoing resuscitation efforts. Stable patients, without signs of localized or systemic sepsis, can be studied further with radiologic imaging if necessary [14]. Diffuse peritonitis, however, mandates emergent surgical exploration.

Diagnostic Imaging

Abdominal Plain Film

Plain abdominal films are usually the first diagnostic imaging performed as they are quick and inexpensive and provide immediate feedback of underlying pathology. They also allow confirmation of abdominal catastrophe, such as free perforation or pneumatosis coli. Plain films help provide an estimation of colonic diameter, with a cecal diameter of 9–12 cm concerning for impending perforation. As discussed previously, an absolute cecal diameter associated with

impending perforation is debatable. Other variables, such as the duration of distension, appear to be as important as predictor [15]. In some cases, such as foreign body or volvulus, a plain film may be all that is necessary [1, 16, 17].

Plain films confirm the diagnosis of sigmoid volvulus by the classic presence of a "bent inner tube" or an "omega loop" pointing to the right upper quadrant (Figure 40-6). However, these findings are present in only 50–70% of cases [18–20]. Conversely, cecal volvulus presents with a "coffee-bean" deformity pointing to the left upper quadrant (Figure 40-7). Radiographs, however, demonstrate this condition in less than 20% of patients [19]. In a retrospective review of the presentation and management of colonic volvulus in Minnesota [21], plain films were insufficient in establishing the definitive diagnosis in 85% of cecal and 49% of sigmoid cases. In the setting of less common causes of volvulus, such as ileosigmoid knotting, or transverse or splenic flexure volvulus, abdominal plain films are even less reliable. Characteristic radiographic features of ileosigmoid knotting have been described and consist of double obstruction with a distended, obstructed sigmoid loop pulled toward the right and a proximal small bowel obstruction on the left [22, 23]. In practice, however, plain films are atypical and difficult to interpret leading to diagnostic delays [24]. In the absence of characteristic radiographic findings, the etiology of LBO can present a diagnostic challenge which can be compounded by the presence of coexisting megacolon or small bowel distension. If the patient's condition permits, additional studies may be necessary to establish the diagnosis.

FIGURE 40-7. Plain radiograph demonstrating "coffee-bean "sign of cecal volvulus with apex pointing to the left.

FIGURE 40-6. Plain radiograph demonstrating "bent inner tube" sign of sigmoid volvulus with apex pointing to the right.

Contrast Enema

When the etiology of LBO is in doubt, contrast enema (CE) may establish the diagnosis and localize the site of obstruction [25, 26]. Water-soluble contrast is preferred as the mortality of peritonitis secondary to barium is high if perforation is encountered. Furthermore, barium instilled proximal to a known stricture can exacerbate the LBO. In a study of 140 cases of LBO over a 4-year period examining the accuracy of contrast enema to plain abdominal film, CE had a sensitivity and specificity of 96% and 98%, respectively, in diagnosing LBO compared to a sensitivity and specificity of 84% and 72%, respectively, for plain films [27]. A CE classically shows a "bird's beak" deformity at the end of the column of contrast at the site of the torsion or obstruction. In the case of volvulus, the "bird's beak" deformity will classically be on the left side for sigmoid volvulus and on the right side for cecal volvulus. CE in colonic pseudo-obstruction will show free flow of contrast proximally and no obstruction or transition point. In some instances, such as fecal impaction, administration of the contrast may even be therapeutic [28]. Conversely, CE performed in LBO due to either an intrinsic or an extrinsic process may demonstrate a wisp of contrast

through the smooth narrowed channel. The presence of a channel and its anatomic properties, such as length, width, tortuosity, and smooth versus jagged, provides insight into the role of endoluminal stenting for relief of LBO. However, contrast enemas are not readily available, are associated with increased patient discomfort, and increase the risk of perforation. Finally, the sensitivity of CE is dependent on the experience of the radiologist and the patient body habitus [29].

Computed Tomography

Computed tomography (CT) is the imaging modality of choice [30, 31] providing valuable diagnostic information, such as the presence of proximal lesions, extrinsic disease, a closed-loop obstruction, or distant metastasis, helping guide management [32] (Figure 40-8). There are few studies comparing the CE and CT in the setting of LBO. Beattie et al. [31] studied the efficacy of CT scan in the diagnosis of LBO. They demonstrated a sensitivity, specificity, and positive predictive value of 91% for CT, which compares favorably to CE. Frager et al. [33] reported the results of CT, endoscopy, and CE in 75 patients with LBO. On subgroup analysis, CT compared favorably with a sensitivity of 96% compared to 80% for CE. Furthermore, CT correctly localized the point of obstruction in 94% of patients. Generally, CT is more readily, easier to obtain, and has supplanted CE as the diagnostic modality of choice for the diagnosis of LBO [32].

Management

Management of LBO is complex and can challenge even the most experienced surgeon. The rapidity with which decompression is achieved depends on the severity of the stenosis, acuity of the presentation, baseline clinical status of the patient, and the presence of overt sepsis. Frequently, efforts at decompression must occur despite unclear etiology providing a significant challenge for all providers. In actuality, the treatment algorithm for LBO is complex and is often guided by provider expertise, availability of resources, and resectability and location of the obstructing lesion.

Emergent Setting (Fig. 40.5)

Regardless of the etiology, patients presenting with LBO and signs of peritonitis, perforation, or closed-loop obstruction with evidence of ischemia or gangrene require emergent surgery following initial resuscitative efforts. If the patient's condition permits, the stoma site should be marked preoperatively. Appropriate broad-spectrum antibiotics should be administered with good aerobic and anaerobic coverage. As part of the informed consent, the indications, risks, and benefits of the different surgical options should be discussed. Patients should be placed in lithotomy position to allow ease of access to the rectum if necessary. Entry of the abdomen is best achieved through a midline incision as the distended colon usually precludes laparoscopic exploration. The proximal dilated colon can be decompressed by passage of a 12-gauge needle obliquely through the taenia coli of the transverse colon and attaching it to suction. This allows for immediate decompression and enhances handling. If the small bowel is dilated, the contents can be milked back into the stomach and removed through the nasogastric tube [34].

Unresectable Lesion (Fig. 40.9)

As previously mentioned, surgical options in the emergent setting are multifactorial. A proximal diversion without

FIGURE 40-8. Pelvic extracolonic lesion causing LBO due to extrinsic compression. *Arrow* points to compressed descending colon.

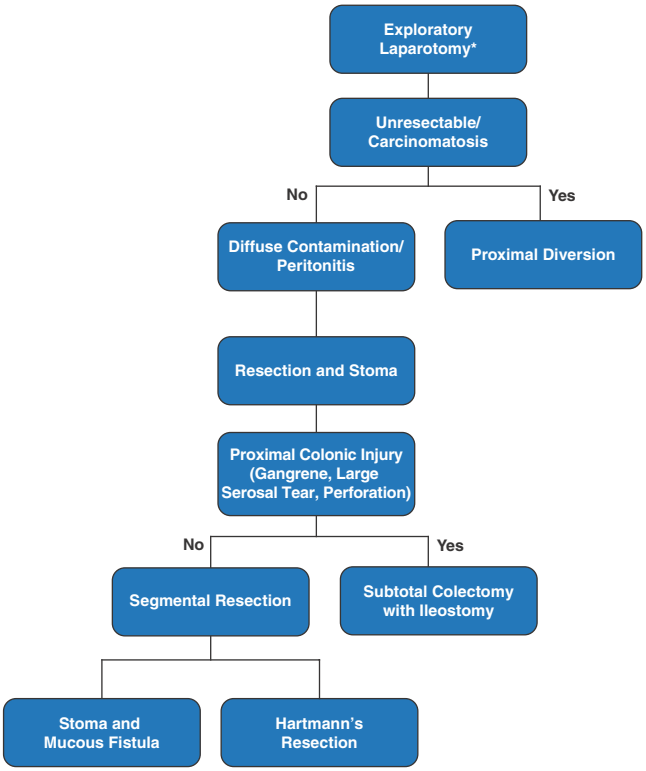

FIGURE 40-9. Proposed algorithm for patients presenting with LBO and associated closed-loop obstruction with ischemia, free air, or sepsis.

resection of the primary obstructing lesion is rarely required but may be necessary in the setting of diffuse carcinomatosis, hemodynamic instability, an unresectable inflammatory phlegmon, due to cancer, diverticulitis, or Crohn's disease, or inexperience of the surgical team. In this setting, a proximal diversion may be the only realistic option and does not always guarantee a permanent stoma. Gutman et al. [35] reported their experience on 71 patients with LBO secondary to cancer who underwent proximal loop colostomy without resection. Forty-nine patients (75.4%) eventually underwent resection of the tumor and closure of the colostomy within 3 months. The remainder of the cohort did not undergo further surgery due to either diffuse metastatic disease or severe comorbidities. Kronborg [36] performed a randomized trial of staged resection versus acute resection in 121 patients presenting with acute left-sided LBO secondary to cancer. They reported similar recurrence and survival rates between groups. While a staged procedure appears to have comparable outcomes to a single-stage surgery, the morbidity associated with repeat surgery is significant. A staged approach should be reserved for circumstances where the clinical condition of the patient, existing comorbidities, and intraoperative findings preclude resection of the obstructing process. Finally, a proximal diversion, such as with a loop colostomy, in the setting of an obstructing rectal cancer allows time for treatment with neoadjuvant chemoradiation, improving respectability of the primary lesion.

Resectable Lesion (Fig. 40.10)

During exploration and following resection of the obstructing lesion, the decision to restore intestinal continuity is dependent of the intraoperative findings and the general condition of the patient. If generalized peritonitis, hemodynamic instability, or gross fecal contamination is present, a primary anastomosis would be contraindicated. While laparoscopic approaches have been described, an open approach is more appropriate in the emergent setting. When feasible, the distal colon conduit should be exteriorized as a mucous fistula or buried in the subcutaneous tissue, in the inferior pole of the midline incision or at the stoma site. This allows for ease of access and early identification during reversal surgery. All attempts should be made to inspect the proximal colon for evidence of gross injury or synchronous pathology. In the presence of ischemia, perforation, coexisting lesion, or large serosal injury of the cecum, a subtotal colectomy may be indicated (Figure 40-11). Given the difficulty in identifying the underlying etiology in an emergent setting, every effort should be made to perform an en bloc resection following oncologic principles [34].

Non-emergent Setting (Fig. 40.10)

In the non-emergent setting, the management algorithm is based on the skill of the surgeon, the condition of the patient and proximal colon, the resources of the institution, and the etiology of LBO [1]. In a hemodynamically stable patient with no overt signs of sepsis, free air, or generalized peritonitis, the etiology of the obstruction, such as foreign body, pseudo-obstruction, or volvulus, can easily be identified on plain abdominal films. In the absence of these findings, more advanced imaging, such as a CT scan, is essential in defining the etiology and extent of LBO as well as other associated findings, such as diffuse carcinomatosis, metastasis, anatomy of the obstruction, and involvement of surrounding structures [30–32]. In the non-emergent setting, LBO secondary to right and transverse colon pathology proximal to the splenic flexure should be managed by primary resection and anastomosis when feasible. In fact, several authors have shown that primary anastomosis in the setting of right-sided LBO is safe with acceptably low anastomotic leak rates in the range of 2.5–5.2% [37, 38].

The management of LBO secondary to lesions distal to the splenic flexure is complex, challenging, and controversial. Specifically, the controversy has its roots in the uncertainty of the diagnosis, i.e., benign versus malignant, and the oncologic safety and efficacy of endoluminal decompression,

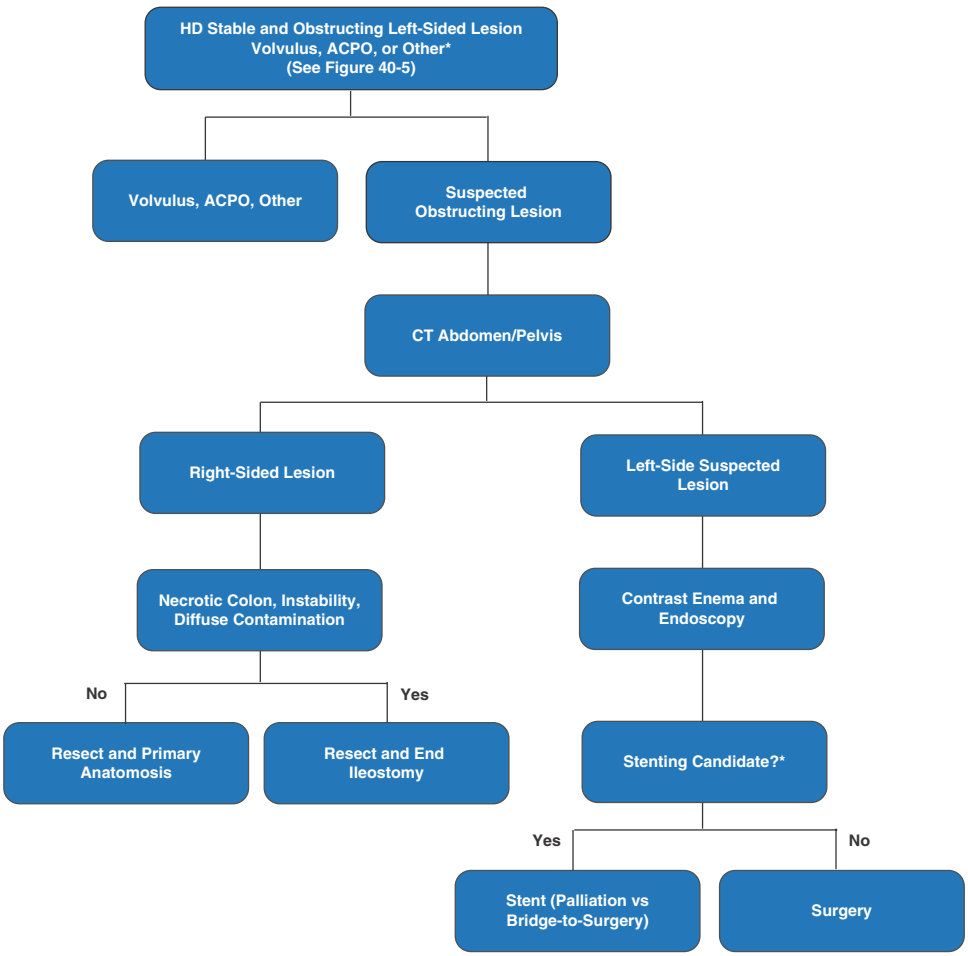

FIGURE 40-10. Proposed algorithm for LBO in a stable patient secondary to a left-sided lesion (diverticular or Crohn's phlegmon, cancer, or unclear etiology).

FIGURE 40-11. Distended and tense cecum with large serosal tear along the antimesenteric wall.

used as palliation or as a bridge to surgery. Furthermore, opinion on the timing and role of endoscopy, primary anastomosis with or without proximal fecal diversion versus staged resection with end stoma, on-table colonic lavage, and segmental resection versus subtotal colectomy remains divided and is often driven by the skill of the surgeon, intraoperative findings, and the clinical condition of the patient.

Endoscopy and CE

Endoscopy and CE are important tools in the initial management of LBO and should be considered *early* both as part of its diagnosis and management [1]. In the setting of LBO secondary to a luminal mass, endoscopy aids in the initial diagnosis. The risk of perforation and worsening obstruction can be obviated by the use of CO_2 insufflation. Studies on the use of CO_2 colonoscopy in ambulatory settings have demonstrated that CO_2 insufflation attenuates post-procedure abdominal bloating and pain compared to conventional air colonoscopy [39, 40]. Yasumasa et al. [41] studied parietal blood flow in rodent colon distended with air or CO_2. They reported that CO_2-distended colons resolved their distension sooner than conventional air-insufflated colons. Furthermore, they showed that prolonged colonic distension is associated with disturbances in parietal blood flow, resulting in

increased pain. In general, CO_2 colonoscopy is well suited and thus recommended in the setting of LBO as it is absorbed 250 times faster than air and is less likely to lead to proximal colonic distension and subsequent perforation. The order in which the tests should be performed is not established. If a colonic stent is contemplated, a CE is often obtained first to define the presence and anatomy of the channel and its suitability for stent deployment.

Self-Expanding Metallic Stents

Over the last several decades, enteral stenting has emerged as an alternative to surgery for many obstructions of the GI tract. Most of the early experience with stenting has been in the biliary tree and the esophagus. However, in 1991, Dohmoto described the use of a palliative colonic stent for a malignant obstruction [42]. Shortly thereafter, Tejero et al. reported his first experience with a self-expandable metal stent (SEMS) to relieve colonic obstruction prior to curative resection [43] and followed this with his report on a series of patients in 1997 [44]. In that series, Tejero et al. treated 38 patients presenting with colonic obstruction. There was 100% technical and 92% clinical success, and the era of the colonic stent was born. As GI interventionist has become more experienced, colonic stenting has emerged as an alternative to relieve a colonic obstruction, potentially obviating the need for emergency surgery and the associated morbidity of this approach [45].

Conceptually, SEMS are used either for palliation or as a "bridge to surgery." Patients who present with incurable disease and who have limited life expectancy may be able to avoid major surgery and the need for a colostomy with the successful placement of a colonic stent [46]. In contrast, patients with curable disease who present with a colonic obstruction may be stented to relieve the immediate indication for surgery. Patients can then be prepared for an elective procedure, allowing the opportunity to medically optimize patients with significant comorbidities, to complete a full colonoscopy, and to decompress a distended colon, all of which should produce a better overall outcome [47]. In addition, patients, who may have needed a large incision and a colostomy if emergency surgery was done, may now be candidates for a minimally invasive approach and a primary anastomosis [48].

Clearly, there are many potential benefits to colonic stenting for LBOs as outlined above. Complications of stents include technical failure, stent migration, re-obstruction, and perforation. Of these complications, perforation is the most concerning as it can lead to an immediate worsening of the clinical situation. In a systematic review of the literature, Watt et al. reported a wide range of perforations reported in the literature (0–83%) with a median of 4.5% [49]. Perforations can either be immediate, often from the guidewire, or delayed. While perforation is most likely at the site of the obstruction, overdistension of an already dilated colon can cause perforation in the more proximal colon [50]. Therefore, judicious use of air insufflation is important while inserting the stent. Perforation is also more likely with the use of balloon dilation, which causes a rapid expansion of the strictured area, and should be avoided. Instead, the strictured area should slowly dilate through the forces of the self-expanding stent [51, 52]. Delayed perforations are more common with stents that are placed for palliation as these stents are in for a prolonged period [53]. This is particularly true of stents across acute angles that can erode over time. More recently, several studies suggest a high rate of stent perforations in patients who are receiving bevacizumab for treatment of metastatic disease [53, 54]. Therefore, when bevacizumab is being considered as part of the treatment plan, stents should be used cautiously, and surgery to relieve the obstruction should be considered [52].

While full-thickness perforation can result in immediate septic decompensation and is usually clinically evident, several studies have noted silent perforations at the time of surgery as well. In the setting of potentially curable cancer, these perforations could negatively impact cancer control [55, 56] and remain a major concern with the use of colonic stents [52].

Technique

The majority of the literature on colonic stenting focuses on obstruction secondary to left-sided colon cancer. These lesions tend to be very focal and often quite short. Classically, they will resemble an "apple core" or a "napkin ring" on a barium enema. Conceptually, these tumors seem the most amenable to colonic stenting and probably have the highest rate of technical success. Pre-procedural imaging, such as a water-soluble CE or a CT scan with rectal contrast, can be helpful in delineating the anatomy and assessing the degree of obstruction. In the setting of complete obstruction, when no contrast passes, the probability of success diminishes and the potential for complications may increase [53]. When even a small amount of contrast passes through the lesion, the likelihood of passing a wire should also increase, which is the first important step in successful deployment of a stent (Figure 40-12).

SEMS have been placed using fluoroscopic guidance alone or with a combination of endoscopy and fluoroscopy [57]. It is prudent to administer some distal enemas to evacuate distal feces to facilitate placement [52]. Pre-procedural antibiotics are not routinely indicated. The colonoscope can then be passed to the lesion and the area inspected. Contrast can then be injected to outline the extent of the lesion and to estimate its length and contour. A guidewire is then passed through the strictured area and the location confirmed using fluoroscopy (Figure 40-13). Once the guidewire is in place, two colonic stent systems have been described.

FIGURE 40-12. Water-soluble contrast enema in a patient with LBO demonstrating narrow channel and apple-core lesion with proximal colon dilatation.

FIGURE 40-13. Fluoroscopy demonstrating .successful passage of guidewire across stricture.

The "through-the-scope" (TTS) system will allow the stent to be placed through the therapeutic channel of the colonoscope and then over the wire. Alternatively, if the stent will not fit through the channel, the stent can be placed entirely over the wire using the "over-the-wire" (OTW) technique. Ideally, the stent should be deployed with at least 2 cm of overlap above and below the stricture [52] (Figure 40-14).

FIGURE 40-14. Gross picture of stent across tumor with appropriate overlap above and below tumor.

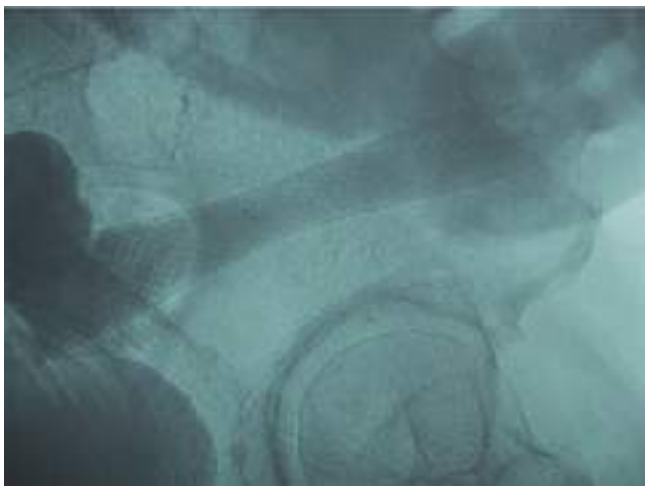

FIGURE 40-15. Radiograph demonstrating excellent positioning of the stent across stricture with the characteristic waisting at mid-stent.

To prevent re-obstruction, the diameter should be 24 mm at the mid-stent position [52]. Balloon dilation is associated with higher complications and should be avoided [52]. Upon completion, plain films can be obtained to confirm stent location, demonstrating appropriate waisting at mid-stent, and to ensure colonic decompression (Figure 40-15).

Once successfully deployed, the obstruction should resolve over the next few days allowing patient evaluation to be completed. Plain films can be obtained to confirm stent location and to ensure colonic decompression. For patients with resectable tumors, definitive surgery is best done within 7–14 day of stent placement [52].

Results

"Bridge to Surgery"

Most of the literature report technical success rates of approximately 90% for SEMS. In a pooled analysis of 1198 patients, which included 54 studies, Sebastian et al. reported an overall technical success rate of 93%. Interestingly, the clinical success for palliative stents was 91% but was only 71% for when used as a "bridge to surgery," since nearly 30% of these patients still required a stoma at the time of surgery [58]. Small et al. reported on the 10-year experience at the Mayo clinic, which included 168 patients when stents were placed for palliation and 65 as a bridge to surgery. In the preoperative group, the technical success was a very high 95%. Immediate clinical success was also quite high at 98%. However, 23% of the patients did experience a stent-related complication, including stent occlusion/migration (17%) and perforation (5%). Of the 65 preoperative patients, 4 (6%) required emergency surgery. A primary anastomosis was done in 39 (60%) of the patients, but 26 patients (40%) still required a stoma despite preoperative stenting to alleviate this need. Five risk factors were identified associated with stent complications, including male gender, complete colonic occlusion, mid-stent diameter less than 22 mm, balloon dilation prior to stent placement, and placement of the stent by an interventionalist not familiar with pancreaticobiliary procedures [53].

Unfortunately, most studies on colonic stents are single-institution retrospective reviews and are therefore subject to the usual biases associated with these reports. Most importantly, the exact "definition" of a LBO is often lacking. Are these patients completed obstructed, presenting with massive colonic distension and perhaps signs of toxicity? Or are many of the patients having mild symptoms from a tumor that a colonoscope could not traverse? Patients in the latter category are more likely to have technical success and fewer complications compared with patients in the former group, as shown in the Mayo clinic experience [53]. Direct comparisons between studies and, more importantly, comparisons with surgery, which is likely to have patients that are completely obstructed with signs of toxicity, can therefore be challenging.

The first randomized, prospective study comparing an endolaparoscopic approach (SEMS followed by a laparoscopic resection) vs. conventional open surgery for patients with left-sided colonic obstruction was reported in 2009 by Cheung and colleagues [48]. In this study, technical and clinical success was 83%. Importantly, no stent-related complications were reported, which is unusual. The primary endpoint was a successful one-stage operation. In this series, 67% of the patients in the endolaparoscopic arm had a successful one-stage procedure, compared with only 38% in the conventional arm. Furthermore, all the stomas in the endolaparoscopic group were reversed, whereas six patients in the conventional group had a permanent stoma. They concluded that preoperative stenting allowed for a minimally invasive approach and was more likely to leave patients' stoma free both in the short and long term. Key to the success was the lack of stent-related perforation or other complications.

More recently, there have been two multicentered, prospective, randomized trials looking at immediate emergency surgery compared with stenting followed by surgery for curable, obstructing colon cancer (one from France and one from the Netherlands) [55, 56]. The technical successes in these studies were both relatively low, at 53% and 70%, respectively. Furthermore, in both studies, the final stoma rates did not differ between the surgery and stenting arms. Of particular concern were the rates of perforation, reported at 19% in the Netherlands study. In both studies, there were a number of "silent" perforations that were not clinically identified but were discovered at the time of surgery and pathological evaluation. While the significance of these perforations is unclear, there is certainly concern about the long-term oncologic outcomes in these patients with potentially curable cancer [52]. Because of these issues, both of these studies were prematurely closed due to safety concerns with colonic stents. The major criticism of these studies is the low success rate of stent placement and the complications associated with these stents, which could be related to the experience of the operator or, more likely, to the patients having a complete LBO in these prospective series.

Finally, in a recent meta-analysis of three randomized trials, stents were less effective than surgery in relieving the bowel obstruction (53% vs. 99%) without improvement in overall morbidity, mortality, and permanent stoma rates (47% vs. 52%). While stents did offer some initial advantages, such as lower initial stoma placement, overall stents did not seem to offer the benefit that was once hoped. Appropriately, the authors did caution that these studies are underpowered and thus more studies are necessary to properly answer these questions [59]. Because of these concerns, current European guidelines published in 2014, which have been endorsed by the American Society of Gastrointestinal Endoscopy (ASGE), only recommend SEMS for patients with a nonmetastatic large malignant bowel obstruction who are poor surgical candidates and need medical optimization. According to ASGE, routine use of SEMS for this clinical scenario is no longer advocated [52].

Palliation

Colonic stenting may be appropriate for patients presenting with inoperable cancer, either from colorectal cancer or another malignancy, causing a LBO. This is particularly true of patients with short life expectancy due to the advanced disease [52]. Many of these patients can be successfully palliated without the need for a stoma or a major

abdominal procedure. Stents are more likely to re-obstruct over time compared with surgery but can often be treated with additional procedures, including a second stent [52, 53]. Choi et al. recently reported on 83 patients treated with colonic stents for palliative purposes. Initial technical and clinical success was reported to be 100 and 94%. However, short-term and long-term complications were noted in 11% and 31% of the patients, respectively. These complications included re-obstruction (22%), stent migration (11%), and perforation (6%). Not surprisingly, they demonstrated that stent complications accumulate over time and that at 6 months nearly 40% of the patients have had some complication related to the stent. Furthermore, as in previous studies, Choi and colleagues also concluded that complications were greater in patients with complete obstruction. Despite these problems, however, only 11 of the 83 patients ultimately required a colostomy for palliation [60]. Small et al. [53] reported similar results in the Mayo experience when stents were placed for palliation in 168 patients. In this series, initial clinical success was very high. At 6 months, however, 25% of the patients had additional obstructive problems requiring intervention. Ultimately, 35 patients (21%) did require surgery, but the majority of patients remained stoma-free until death. Success seems to be greater in patients with primary colorectal cancer, in comparison to extracolonic tumors causing extrinsic compression, where stents have been less effective [52, 61]. In conclusion, palliative stents provide an alternative for patients with advanced disease and a short life expectancy. For patients with longer life expectancy, palliative stents are likely to cause long-term complications. Under these circumstances, therefore, surgical palliation may be more appropriate.

Benign Disease and Right-Sided Lesions

While malignancy is the most likely cause of colonic obstruction, there are benign diseases, such as diverticular disease and Crohn's disease, which can also cause a LBO. The role of stenting under these circumstances remains unclear. These strictures tend to be long and tortuous, making for a challenging stenting procedure. While still possible, complications seem to be higher and results less promising [62, 63]. Long-term uses of stents under these conditions are often associated with perforations, fistula, and pain and should be avoided. Therefore, stenting for benign disease is currently not recommended [52].

Most of the literature on stenting is with left-sided lesions. While there are reports on stenting right-sided obstructions, the rationale for this approach is less clear. Since many obstructions proximal to the splenic flexure can be managed with a primary anastomosis, stents are not likely to improve the clinical picture and therefore are not routinely advocated. However, under situations when surgery is not an option, right-sided stents have been successfully deployed [64].

Resection

Emergent surgery and resection for a left-sided colonic obstruction was first introduced by Wangensteen [65]. As mentioned previously, in the setting of overwhelming sepsis, diffuse peritonitis, free perforation, or a closed-loop obstruction with ischemia, emergent exploration and resection, when feasible, are indicated and often necessary. A traditional three-stage operation is rarely performed but may be necessary in the setting of diffuse carcinomatosis, non-resectable inflammatory phlegmon or cancer with dense adherence to critical pelvic or retroperitoneal structures, or inexperience of the surgical team. Chereau et al. [66] presented their results on the surgical management of 83 patients presenting with LBO secondary to colorectal cancer. Sixty-one patients had an initial colostomy with an intention of performing a resection after recovery. Subsequent elective resection and primary anastomosis were performed in 45 (74%) patients with minimal morbidity and mortality. Despite these encouraging findings, a two-stage operation, with either resection of the obstructed segment and primary anastomosis with or without a proximal diversion or resection and Hartmann's procedure, is more commonly performed [1]. In the non-emergent setting, the choice of the operation is closely associated with the condition of the patient, viability of the bowel, site of the obstruction, and skill of the operating surgeon.

The advantages of Hartmann's procedure are clear and include avoidance of an anastomosis and shorter operative times. The procedure is completed by resection of the diseased segment, end colostomy, and closure of the distal segment which is left either buried in the subcutaneous tissue, intraperitoneal, or opened at the skin level as a mucous fistula. Management of the distal stump depends on large part on the length of the stump, health of the tissues, and thickness of the abdominal wall. Previous studies have shown that 35–55% of colostomies are not reversed, either due to patient wishes or existing comorbidities precluding reversal [67–69]. Technical difficulties can complicate reversal surgery and include identification of the rectal stump, dense adhesions, anastomosis to a short rectal stump, and the need for a proximal diversion. Thus, reversal of Hartmann's procedure is associated with substantial morbidity, including anastomotic leak rates ranging from 4 to 16%, and mortality [70–75]. Minimally invasive approaches, while feasible, can be technically challenging. A systematic review of thirty-five included studies comparing conventional to laparoscopic reversal of the Hartmann procedure showed that the laparoscopic approach has a shorter hospital stay (6.9 days vs. 10.7 days), longer operative times, and decreased morbidity when

compared to the conventional surgery. Regardless of the approach, the mean time interval between reversal and Hartmann's was 7.5 months [76]. Currently, however, high-level evidence demonstrating superiority of the laparoscopic approach to conventional surgery for Hartmann's reversal is lacking. Finally, Hartmann's procedure and its subsequent reversal surgery represent a substantial cost burden. Schilling et al. [77] studied 55 patients undergoing segmental resection for perforated sigmoid diverticulitis, 13 with Hartmann's procedure, and 42 with a segmental resection and primary anastomosis. As expected, the overall expenses and reimbursement for restoration of intestinal continuity were significantly higher for those patients undergoing Hartmann's procedure.

Primary anastomosis, when feasible, should be the procedure of choice for LBO due to left-sided LBO secondary to a cancer or benign process. Variables influencing the decision to perform a primary anastomosis are multifactorial and include the degree of proximal colon dilatation, clinical condition of the patient, and operative findings, such as diffuse fecal contamination, peritonitis, cecal perforation, and synchronous proximal lesions. Lee et al. [38] performed a retrospective review of 243 patients undergoing emergent resection and primary anastomosis for obstructing colorectal cancers. Both the operative mortality and anastomotic leak rates following primary resection and anastomosis were acceptable, 8.1% and 6.1%, respectively. Other studies have shown similar results [37, 78, 79]. In a survey of 500 US-based gastrointestinal surgeons, 53% of the respondents would perform a single-stage operation for LBO in "good-risk" patients [80]. Despite a relatively poor response rate, the findings of this survey and others are consistent and suggest that, if feasible, the majority of surgeons favor a single-stage resection for LBO [81, 82]. In summary, in carefully selected and hemodynamically stable patients, a single-stage operation is well tolerated and should be considered when technically feasible. Finally, the decision to perform a proximal diversion at the time of resection is up to the discretion of the surgeon and is multifactorial. Important considerations are the clinical condition of the patient, status of the bowel, and degree of contamination of the surrounding tissues. This decision is not without consequences, and the benefits must be balanced against the emotional and financial burden of a stoma and the associated morbidity of its reversal.

A subtotal colectomy with a primary anastomosis is a viable option in select patients presenting with a left-sided LBO. Accepted indications for subtotal colectomy include cecal perforation, synchronous proximal lesion, ischemia of the proximal colon, or serosal injury of the cecum. The SCOTIA study group [83] conducted a randomized trial comparing segmental resection with intraoperative lavage to subtotal colectomy in patients with a malignant left-sided LBO. They reported comparable morbidity and mortality, but at 4 months the number of bowel movements was significantly higher in the subtotal group. Furthermore, following an ileosigmoid or ileorectal anastomosis, there appears to be a clear impact on the postoperative quality of life compared to those undergoing a segmental resection [84]. In general, the decision to perform a subtotal colectomy depends on the overall condition of the patient, operative findings, continence status, and comorbidities.

On-Table Colonic Lavage

On-table colonic lavage is another alternative that may allow a single-staged primary surgery for patients presenting with colonic obstruction. While there have been many reports questioning the need for routine bowel preparations prior to colon surgery, it is important to note that these studies were all done for elective colon resections when the bowel is decompressed [85]. The obstructed colon, with the associated distension and fecal loading [86], represents a different clinical situation with an increased rate of complications if a primary anastomosis is performed. In situations, therefore, when patients are clinically stable, an on-table colonic lavage may successfully relieve the colonic distension and fecal loading, allowing for a primary anastomosis.

Technique

On-table colonic lavage is best accomplished once the obstructing lesion has been resected. At this point, the surgeon should assess the surgical environment and as long as the patient remains clinically stable may proceed with the lavage. Mobilizations of both flexures are done to facilitate the procedure. The left colon needs to be fully mobilized so that the colon can easily extend beyond the abdominal cavity. An appendectomy is performed and a large-bore catheter inserted into the cecum and secured with a purse string. Alternatively, if the cecum is distended and thin walled, the catheter can be inserted in the terminal ileum with a purse string. Sterile-corrugated tubing is then secured to the descending colon using an umbilical tape. The tubing is draped over the bed into a waste container (Figure 40-16). Saline can then be used to irrigate the colon until it is clear which usually requires approximately 3–6 L. Initially, flow can be slow due to the solid stool and the surgeon may need to milk some of these contents through the tubing. However, once the stool becomes more liquid, the cleansing process flows smoothly. Upon completion of this procedure, the colon is often significantly decompressed and an anastomosis can be performed. Prior to the anastomosis, the colon should be carefully inspected for any injuries that may have occurred due to the colonic distension or from the procedure itself. An end-to-end anastomosis can be done, but, if there is

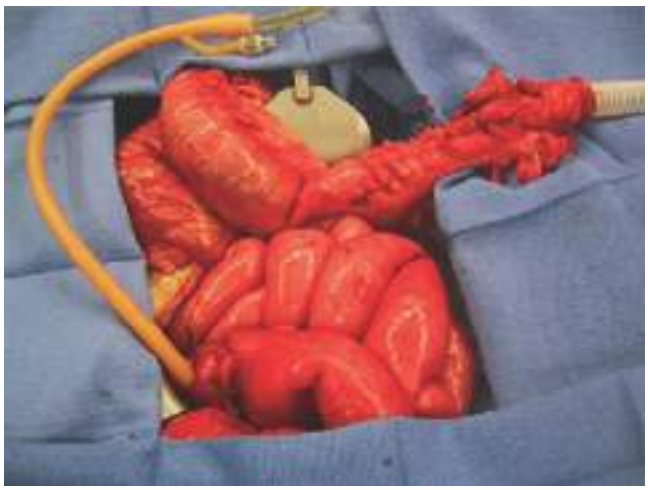

FIGURE 40-16. Technique for on-table lavage prior to creation of the anastomosis following a left colectomy for LBO. Sterile-corrugated tubing is secured to the descending colon using umbilical tape. Both the hepatic and splenic flexures have been mobilized to aid in the evacuation.

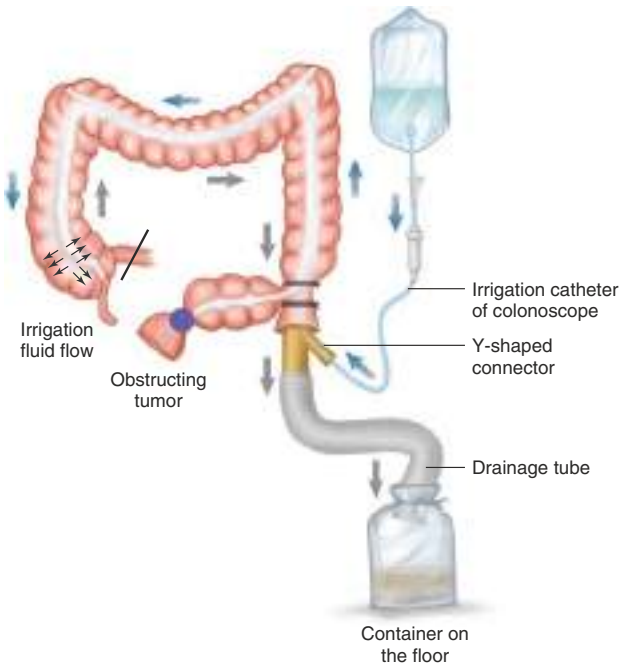

FIGURE 40-17. The new device for intraoperative colonic lavage, with an irrigation catheter or colonoscope entering the proximal colon through the Y-shaped connector up to the cecum. Flow of prewarmed saline solution irrigation (*clear arrow*). Flow back of feces (*black arrow*).

a significant caliber mismatch between the colon and the Hartmann pouch, an end-to-side procedure is preferred.

More recently, an alternative technique has been described using a Y-connector and a long colonic tube [87, 88]. The tube is placed through the descending colon just proximal to the obstructing lesion and passed into the cecum. The warmed saline can then be administered through the tubing, and fluid is evacuated out the other side of the Y-connector (Figure 40-17). By doing this, the surgeons can avoid an appendectomy and perhaps some infectious complications. Reportedly, this technique is faster and less likely to have associated contamination, although this has not been formally studied.

Results

Several studies have reported successful primary resections with acceptable rates of anastomotic leak. Murray et al. reported the early experience at Lahey Clinic. In this series, 21 patients had an on-table colonic lavage with no anastomotic leaks and only three wound infections [89]. Forloni et al. reviewed his experience with intraoperative colonic lavage in the setting of a left-sided bowel obstruction and also reported no leaks in 61 patients. He reviewed the literature at that time and reported leak rates that ranged from 0 to 13% in selected studies [90]. More recently, Jung and colleagues reported on 171 patients treated with intraoperative colonic lavage and a primary anastomosis over a 12-year period. The rate of anastomotic leakage was 5%, which was nearly exactly the rate for non-obstructed patients having the same procedure during that time period. Similarly, the wound infection rate of 3.5% was not different than the elective cases. These results are particularly good given that the patients in the obstructed arm were more ill and more likely to have an emergent operation [88] compared with the non-obstructed patients.

In 1995 a multicentered, prospective trial comparing subtotal colectomy with intraoperative colonic lavage with a segmental colectomy reported on 91 total patients. The anastomotic leak rate was 9% for the subtotal colectomy group compared with 5% for the colonic lavage group, but this was not statistically significant [83]. However, functional outcomes were significantly better for patients having a segmental resection, with regard to bowel frequency and the ultimate need for a permanent stoma. The authors concluded that intraoperative colonic lavage with a segmental resection was safe and the preferred technique when compared with subtotal colectomy [83]. In a similar nonrandomized retrospective review, Torralba et al. compared their experience with intraoperative lavage and subtotal colectomy. More complications were associated with the colonic lavage (41% vs. 14%), the majority of which were infectious in nature. Functional outcomes, however, appeared to be similar. He concluded that subtotal colectomy is preferred when part of the sigmoid colon can be preserved. However, in the setting of distal sigmoid or rectosigmoid obstruction or when patients have anal incontinence, intraoperative colonic lavage may be preferred [91].

While many surgeons believe the lavage is critical to the procedure, there are several reports of one-stage resections

of obstructing left-sided lesions with limited colonic decompression without colonic lavage [92–94]. In these series, the stricture is resected and the left colon decompressed of most of the solid stool. The rest of the colon, however, is not fully irrigated as described above. In these series, the leak rates ranged from 1.7 to 4.1%. These studies suggest the possibility that decompression and not cleansing are the major contributors to success. However, without randomized trials, it is very difficult to come to firm conclusions.

More recently, a randomized, prospective trial comparing colonic stents with intraoperative colonic lavage was reported [95]. The authors hypothesized that complications between the two groups would be similar, but, given the concerns of perforation with colonic stents, intraoperative colonic lavage would be the preferred technique. However, after just 28 patients, the trail was stopped due to the high rate of anastomotic leakage in the lavage cohort (30%) compared with the stent group (0%). In addition, the long-term cancer survival between these two small groups was similar.

In summary, intraoperative colonic lavage is an acceptable alternative to managing a LBO. The major disadvantages include the additional time to perform, which can be as much as 60 min, and the additional dissection it often requires [91]. Anastomotic leak rates seem acceptable but, given the results of the most recent randomized trial [95], may need further prospective studies. The major advantage is the ability to do an anastomosis while preserving colon and colonic function. Until we fully understand the potential disadvantages of colonic stents on oncologic outcomes, intraoperative colonic lavage remains a viable option for surgeons.

Special Circumstances

Volvulus

Sigmoid Volvulus

Presentation and Diagnosis

Patients with sigmoid volvulus present with abdominal pain, distension, and a paucity of bowel movements. Emesis is rare and usually represents a chronic process with associated small bowel distension. A history is often difficult to obtain as most patients presenting with sigmoid volvulus are infirm and residents of long-term care facilities. Physical exam findings include a distended and tympanitic abdomen. If peritonitis is present, then ischemia and/or gangrene of the colon must be assumed and further diagnostic testing is unnecessary. Emergent exploration and resection, with or without a stoma, are recommended. In the non-emergent setting, an abdominal radiograph is usually the first diagnostic test obtained. Plain radiographs are diagnostic for a sigmoid volvulus in 57–90% of patients [18, 21, 96, 97]. However, the classic "coffee-bean" or "bent inner tube" sign is present in <60% of cases [18, 98] (Figure 40-6). Given the ease with which it can be obtained and the wealth of additional information provided, CT scan may be supplanting plain film as the diagnostic study of choice in suspected volvulus. Furthermore, in the presence of coexisting proximal colon and/or small bowel distension creating a diagnostic dilemma, CT scan provides valuable diagnostic information. A primary finding on CT scan is the presence of a whirl sign in the mesentery. However, its presence is not pathognomonic for sigmoid volvulus. The sensitivity of the whirl sign in the setting of sigmoid volvulus is variable ranging from 57 to 100% [99, 100]. While its absence does not exclude the presence of a volvulus, the location of the whirl sign, right versus mid-left, may differentiate a sigmoid from a cecal volvulus [100]. If the diagnosis remains in doubt, a CE may confirm the presence of a sigmoid volvulus by a bird's beak deformity on the left side compared to a right upper quadrant location for a cecal volvulus [25–27].

Treatment

Immediate reduction and prevention of recurrences are the tenets of management of sigmoid volvulus. Endoscopic reduction and decompression is the initial treatment of choice in uncomplicated sigmoid volvulus [18]. While a rigid proctoscope is effective in reducing sigmoid volvulus and may be more readily available in emergent and rural settings, flexible endoscopy is preferred due to its overall safety and ability to inspect the mucosa of the involved segment for ischemia [101]. The characteristic finding on endoscopy includes a "pinwheel" configuration of the mucosa (Figure 40-18). Detorsion and decompression is successful in 60–80% of cases [24]. A long flexible tube, such as a small-caliber chest tube or nasogastric tube, may be left in place to allow for continued decompression and to prevent retorsion. However, evidence demonstrating safety and efficacy of this maneuver is lacking.

Elective resection, preferably during the same hospital setting, following successful reduction is strongly recommended as endoscopic decompression alone has recurrence rates ranging from 20 to 90% [18]. Turan et al. [101] reported on 81 patients that presented with sigmoid volvulus and underwent endoscopic detorsion. Twenty of the 39 patients nonoperatively decompressed did not agree to an elective resection. The majority were lost to follow-up but 3 out of the 20 patients presented with a recurrence requiring surgery. A retrospective study of a 7 hospital system in Metropolitan Minnesota reported on the presentation and management of colonic volvulus in 103 cases of volvulus in 92 patients [21]. Of the 21 patients with sigmoid volvulus treated nonoperatively, 47.6% were readmitted with a recurrence. Of those

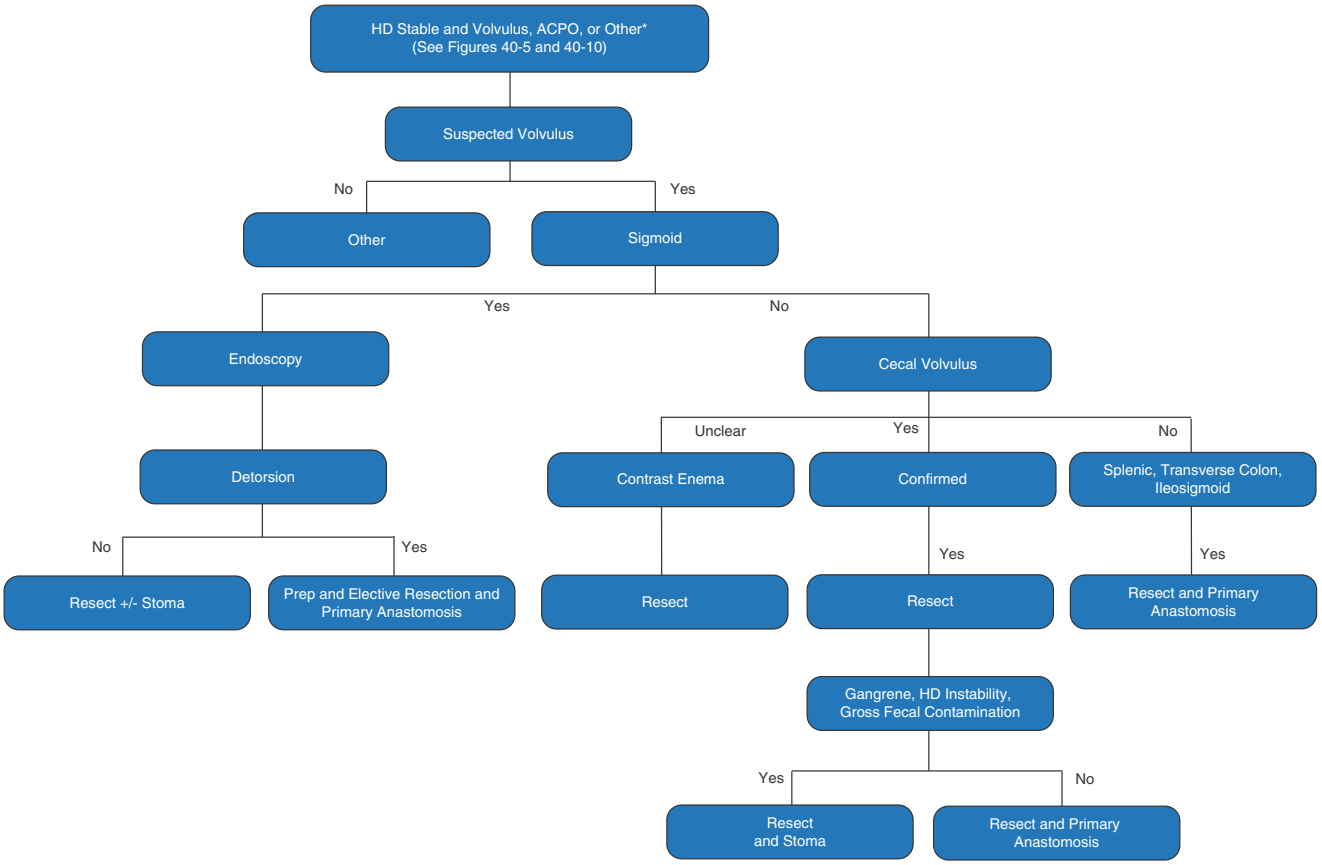

FIGURE 40-18. Proposed algorithm for LBO secondary to a volvulus in a stable patient.

admitted with a recurrence, 64% ended up undergoing surgery. Bruzzi et al. [102] reported on their experience of 65 patients treated for sigmoid volvulus over a 10-year period. Nonsurgical reduction was successful in 95% of patients. Recurrence after initial decompression was 67% at a median follow-up of 5 years. Hougaard et al. [103] reviewed their experience with 41 patients presenting with sigmoid volvulus. Fourteen patients were treated with decompression alone with a recurrence rate of 82% and a 1-year mortality of 50%. The high recurrence rate after detorsion alone coupled with the high 30-day mortality of emergent resection, 43% vs. 6% [24, 96, 97, 103], favor elective resection during the same hospitalization for most eligible patients. In preparation for elective resection, a colonoscopy should be performed to evaluate for proximal pathology.

The standard procedure includes a sigmoid resection and primary anastomosis accomplished using either open or minimally invasive techniques [104, 105]. Due to the redundancy of the colon and elongated and narrowed mesentery of the sigmoid colon, an open approach, utilizing a minilaparotomy incision, is usually all that is necessary [106, 107]. Recurrences are rare when sigmoidectomy is performed in an elective setting with a primary anastomosis [102, 108, 109]. Recurrence rates increase in the presence of coexisting megacolon and diffuse colonic dysmotility. Chung et al. [110] reported on 35 patients treated for sigmoid volvulus. Six patients had a recurrence following sigmoid colectomy with coexisting megacolon and megarectum. Morrissey and colleagues [111] reviewed their single-institution experience with recurrence rates following sigmoidectomy in 29 patients with sigmoid volvulus. Their review included all procedures, including Hartmann's and laparotomy with non-resection. They reported a recurrence rate of 36% for sigmoidectomy and primary anastomosis. The most consistent variable associated with recurrence was the degree of colonic involvement. Patients with disease limited to the sigmoid colon had a 6% recurrence rate compared to 82% for those associated with megacolon [18]. Enthusiasm for performing a subtotal colectomy in the setting of megacolon and presumed dysmotility must be tempered against the morbidity of a radical surgery in a frail and often institutionalized patient population.

A number of non-resectional techniques have been proposed for the treatment of sigmoid volvulus. A common

element among all these procedures is fixation of the colon to the abdominal wall for prevention of recurrence. These techniques include extraperitoneal sigmoidopexy [112], endoscopic sigmoidopexy with or without tube fixation [113], mesenteric fixation techniques [114, 115], parallel colopexy [116], tube sigmoidostomy [117], and percutaneous endoscopic colostomy [118–120]. The majority of reports in the literature are small single-institution case series with no randomized trials demonstrating direct head-to-head comparisons. Lack of strong supporting evidence for nonresectional techniques and improved perioperative management techniques favors resection and primary anastomosis as the procedure of choice.

If endoscopic decompression is unsuccessful or if there is concern for gangrene of the colon, emergent exploratory laparotomy and sigmoid resection are indicated. Exploration is typically through a midline incision with open reduction of the volvulized sigmoid. In the presence of gangrene, care must be taken to control the vascular pedicle prior to reduction in order to avoid severe hemodynamic instability. If resection is considered, the decision to perform a primary anastomosis is based on common surgical principles: hemodynamic stability, nutrition status, adequacy of blood supply, presence of tension, or degree and characteristics of contamination. If any of these factors are present, then Hartmann's procedure should be contemplated. In the emergent setting, timely assessment of the patient for proper location of the stoma is not feasible. This problem is compounded by a dilated colon mandating creation of a larger than usual trephine. Consequently, these patients are at increased risk of parastomal hernias [24].

Emergent surgery for sigmoid volvulus is associated with significant morbidity and mortality and should be avoided if possible. Kuzu et al. [121] reported on 106 patients that underwent emergent resection for sigmoid volvulus over an 8-year period. Fifty-seven cases had a primary anastomosis. The overall mortality rate was 6.6%, and this rate increased to 11% if the colon was ischemic or gangrenous. In a Veterans Affairs study [122] designed to review the outcomes of emergent treatment for sigmoid volvulus, the mortality rate was 24% for those undergoing emergent surgery versus 6% for elective resection following endoscopic decompression. Atamanalp et al. [109] reported on their single-center experience for the treatment of 686 patients with sigmoid volvulus over a 46-year period. Emergent surgery was performed in 447 patients with a morbidity and mortality rate of 35% and 16%, respectively, compared to 12.5% and 0%, respectively, for elective surgery. Despite a trend toward increased complication and mortality rates, the majority of studies support sigmoid resection and primary anastomosis, even in the emergent setting. Nevertheless, the surgeon must balance the risks of an anastomosis against the increased morbidity and decreased quality of life of a stoma as well as the risks of a second surgery.

Sigmoid volvulus is the most common cause of intestinal obstruction in pregnancy worldwide occurring at rates of 3.1–12.5% [123]. Despite its association with intestinal obstruction during pregnancy, its incidence is rare presenting a diagnostic and treatment challenge [18]. The diagnostic delay is often compounded by reluctance of physicians in obtaining radiographic imaging out of concern for harm to the developing fetus. The delay in diagnosis can increase the risk for gangrene and septic complications [124]. As with nonpregnant patient, flexible sigmoidoscopy is the diagnostic and treatment modality of choice. Endoscopic detorsion should be undertaken in the first trimester with elective resection delayed until the second trimester, when the risk to the fetus is diminished. During the third trimester, endoscopic detorsion should be followed by close observation allowing for completion of fetal maturity, followed by delivery, and then elective resection [24]. At any time during the initial presentation or during the observation period, if signs of gangrene and peritonitis are present, then exploratory laparotomy and Hartmann's procedure are indicated.

Cecal Volvulus

Presentation and Diagnosis

The clinical presentation of cecal volvulus is directly linked to the acuity of the presentation and the type of volvulus. Cecal volvulus involves the axial clockwise rotation of the colon around its mesentery. Findings such as abdominal distension, pain, nausea, vomiting, and obstipation can mimic signs and symptoms of small bowel obstruction. If the volvulus is allowed to progress to strangulation, then peritonitis and systemic sepsis will ensue. Diagnosis is first suspected by the classic appearance of a dilated colon in the shape of a "coffee bean" with the apex pointing to the left upper quadrant (Figure 40-7). This classic radiographic finding, however, is present in less than 20% of cases [19]. If the diagnosis is in question, a CE can provide clarity by demonstrating the characteristic column of contrast ending in a "bird beak," the sight of the torsion, in the right upper quadrant. If CE is unavailable or the diagnosis remains in question, a CT scan may be helpful in establishing the diagnosis. CT may reveal the coffee-bean or bird beak signs, as well as the presence and location of the whirl sign [100]. Due to its ready availability, CT is the first imaging test ordered, on initial presentation, often obviating the need for further imaging. Conversely, in cecal bascule there is no axial twist but an anterior-superior folding of the cecum over the proximal ascending colon, without rotation (Figure 40-19). The cecum is often located in the right upper quadrant on imaging [125]. There is no axial twist of the mesentery and thus these patients often present in subacute fashion. Patients present with intermittent nausea, vomiting, and abdominal pain with

FIGURE 40-19. Classic endoscopic "pinwheel" appearance of a sigmoid volvulus.

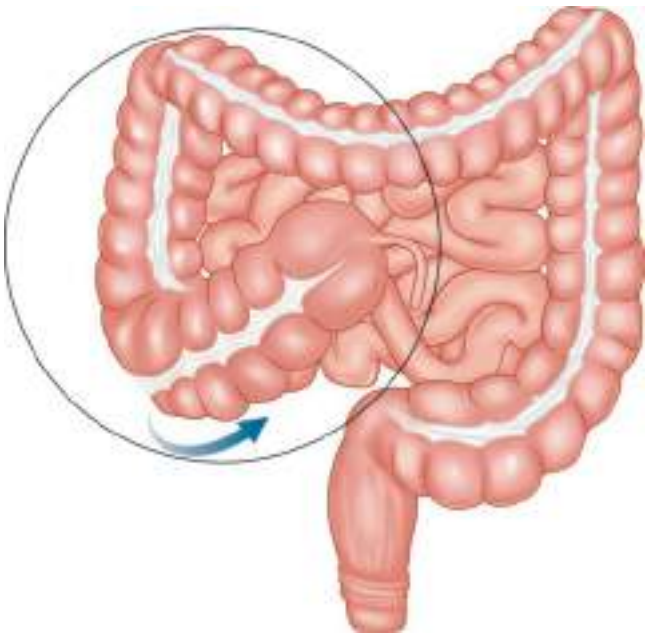

FIGURE 40-20. Illustration of cecal bascule demonstrating the anterior-superior folding of the mobile cecum over the proximal ascending colon.

symptoms improving with passage of flatus. Typically, the symptoms are vague and chronic in nature leading to diagnostic delays.

Treatment

Endoscopic attempts at decompression of a cecal volvulus are typically unsuccessful and should not be attempted [126]. Exploratory laparotomy is the treatment of choice with the findings at exploration helping dictate the course of the operation. In the setting of a gangrenous colon, attempts should not be made to untwist the colon prior to resection due to the risk of the release of toxins and ensuing septic shock [19, 127]. Vascular control should be obtained and the nonviable segment of colon resected. In reality, anatomy of the volvulized segment precludes resection without untwisting of the segment first. It is, therefore, critical that the surgical and anesthesia team work closely together during this critical moment of the operation. The extent of hemodynamic instability, contamination, malnutrition, and comorbidities will determine the safety of a primary anastomosis following resection.

Non-resection techniques have also been described. These include untwisting only, cecopexy, and insertion of a cecostomy tube. A cecopexy is performed by developing a flap of peritoneum and affixing it to the anterior border of the right colon. A cecostomy entails insertion of a tube into the cecum for venting of air as well as to allow for a point of fixation. Detorsion of the bowel alone is associated with recurrence rates as high as 70% and should be abandoned [128]. In a study comparing different techniques for management of cecal volvulus, the morbidity, mortality, and recurrence rates of cecopexy were 15%, 10%, and 13%, respectively. The same study reported that cecostomy morbidity, mortality, and recurrence rates were even worse at 52%, 22%, and 14%, respectively [6]. Given the improved perioperative and anesthetic techniques of the modern era and the low morbidity of segmental resection, these techniques should be abandoned except in rare instances where the patients' condition and operative findings preclude a resection.

Uncommon Types

Ileosigmoid Knotting

Ileosigmoid knotting is the wrapping of the ileum around the sigmoid colon leading to obstruction (Figure 40-20) [22]. Patients with ileosigmoid knotting present with nausea, vomiting, abdominal distension, and pain. Their clinical presentation is often more dire, with associated sepsis, dehydration, acidosis, hypotension, and tachycardia. Due to its rarity, there is often a diagnostic delay leading to potentially catastrophic consequences. Imaging may suggest the diagnosis by a distended sigmoid colon on the right and distended small bowel loops on the left [23, 129]. However, these findings are not consistently present, and 70% of patients will have gangrenous bowel at surgery [19]. In general, if ileosigmoid knotting is suspected, these patients should be resuscitated and emergently explored. Four variants of the

ileosigmoid knot have been previously described and include (1) type I (most common), the ileum (active component) revolves around the sigmoid colon; (2) type II, the sigmoid colon (active component) revolves around the ileum; (3) type III, the ileocecal portion revolves around the sigmoid colon; and (4) undetermined, difficult to decipher which is the active or the passive component. Types I and II can be further classified into subtypes A and B depending on whether the torsion is clockwise or counterclockwise, respectively [130]. The intraoperative options are largely dependent on the overall condition of the patient, the anatomy of the ileosigmoid knot, the state of the bowel segments involved, and the surgeon experience. It is not uncommon that several segmental resections are required with creation of one or several anastomosis.

Splenic and Transverse Colon Volvulus

Splenic and transverse colon volvulus has rarely been reported with incidence rates ranging from 2 to 3% [19]. Risk factors include an elongated and redundant colon, narrowing of the mesenteric attachments, malfixation of the mesenteries, and constipation [131]. Chilaiditi syndrome or transposition of a loop of transverse colon between the diaphragm and the liver with an associated elongated mesentery and a hypermobile colon has also been implicated as a potential cause [132, 133]. Patients with either a transverse or splenic flexure volvulus will present with symptoms of acute or chronic LBO. Due to the rarity of its presentation, diagnosis is often delayed risking necrosis of the involved segment and increased mortality [24]. Radiographic features previously attributed to splenic and transverse colon volvulus include (1) a markedly dilated, air-filled colon with an abrupt end at the splenic flexure; (2) two widely separated fluid-filled loops, one in the cecum and the second in the transverse colon; (3) an empty descending and sigmoid colon; and (4) a characteristic beak at the splenic flexure on CE [19, 134]. A transverse colon volvulus may also present with an "inverted coffee-bean" sign in the upper abdomen [135]. Absence of these radiographic features does not exclude the diagnosis; thus, a high index of suspicion is required to avoid diagnostic delays. The treatment of splenic and transverse colon volvulus typically involves surgical exploration and resection with or without a primary anastomosis. Similar to other types of volvulus, the decision to create a stoma depends on several factors, including the overall condition of the patient and the bowel, the degree of contamination, and the feasibility of the anastomosis.

Acute Colonic Pseudo-Obstruction

Acute colonic pseudo-obstruction (ACPO) can have a varying clinical presentation depending on the duration of onset and the overall condition of the patient. Common signs and symptoms include a paucity of bowel movements and gas, severe abdominal distension, and pain [12]. Unless an incompetent ileocecal valve is present, nausea and vomiting are typically absent in the acute setting. Signs of systemic toxicity are typically absent unless gangrene and/or perforation have occurred. While in rare cases, a plain radiograph may be diagnostic; more commonly, the distinction between functional and mechanical causes of LBO requires advanced imaging. A CE and CT scan are most commonly used to distinguish between these possibilities. As discussed previously, a water-soluble CE has high sensitivity and specificity in the diagnosis of a LBO [27]. However, due to its variable availability and risk of perforation in an already compromised setting, CE has been largely replaced by CT scan as the diagnostic modality of choice in ACPO [136]. Common CT findings of ACPO include proximal colonic dilatation and a transition at or near the splenic flexure [136]. Finally, CT also allows for evaluation of mechanical causes of LBO.

The majority of patients with ACPO can be managed conservatively with bowel rest, aggressive fluid and electrolyte replacement, and elimination of offending agents, if possible (Fig. 40.21). Variable success rates have been reported using hourly position changes, including prone, left, and right lateral decubitus. However, broad implementation and overall success of these measures in the standard clinical setting is limited. In general, supportive measures alone are successful in about 70% of patients with morbidity and mortality rates of 6% and 10%, respectively [137].

When supportive measures fail, more advanced treatment options become necessary. Historically, colonoscopic decompression was the treatment of choice, usually after 3–4 days of failed supportive therapy. However, multiple prospective studies have reported on the efficacy and validated the use of neostigmine as first-line treatment in ACPO [138–141]. Valle et al. [142] performed a meta-analysis of four randomized trials reporting on the use of neostigmine in ACPO. One hundred and twenty-seven patients were included. Neostigmine effectiveness to resolve ACPO with only one dose was 89.2% versus 14.65% ($P < 0.001$, NNT = 1 [95% CI 1–2]). They concluded that neostigmine is a safe and effective option for patients failing supportive measures. Neostigmine is a reversible acetylcholinesterase inhibitor thus increasing acetylcholine and promoting intestinal activity. Optimal dose and route of administration of neostigmine are debatable. The standard dose is a 2–2.5 mg bolus administered over a 3–5-min period. The onset of action is usually 20–30 min. A repeat dose may be necessary in refractory cases [15]. Several authors have also reported on the effectiveness of continuous infusion technique in ACPO [139, 143]. Oral administration is generally not recommended due to its erratic absorption in the gastrointestinal tract. The parasympathetic overactivity attributed to

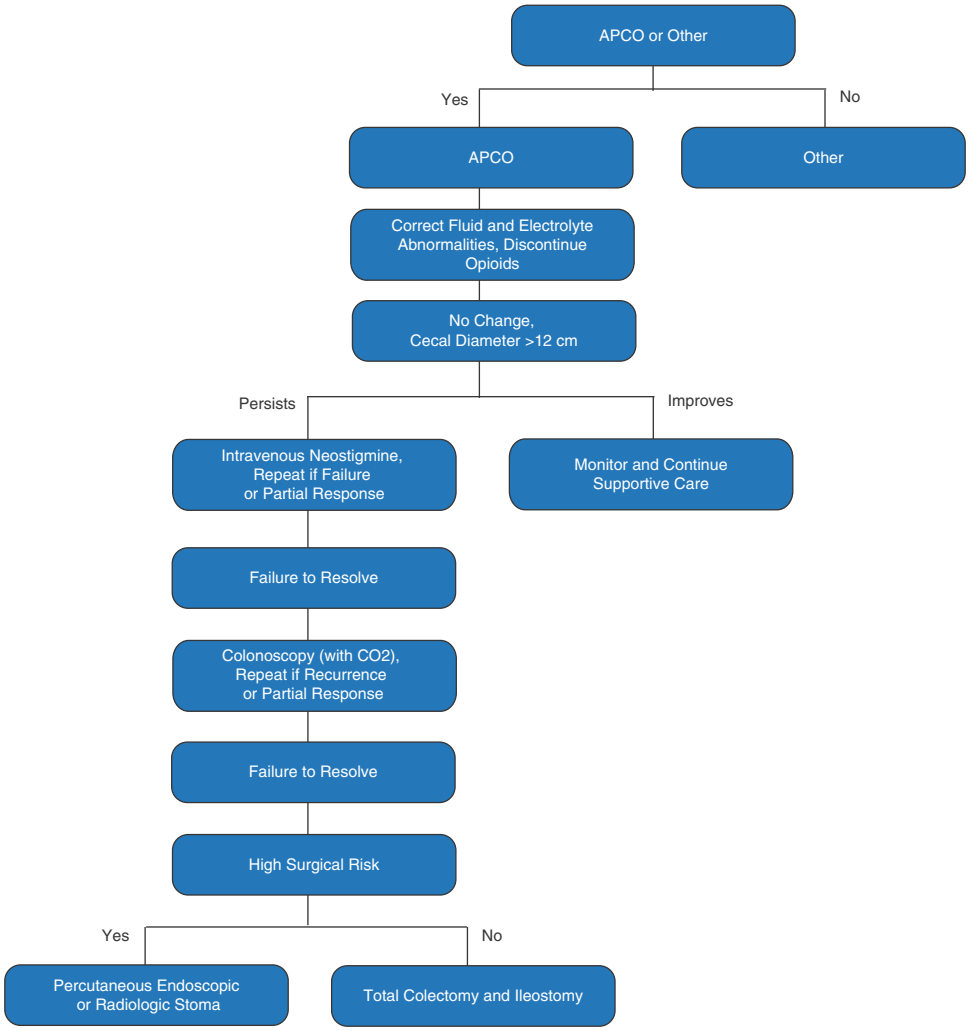

FIGURE 40-21. Proposed algorithm for LBO secondary to ACPO.

neostigmine can lead to predictable adverse events, including bradycardia, hypotension, asystole, seizures, restlessness, nausea, emesis, and abdominal cramps. Patients should be closely monitored in a telemetry unit for cardiac arrhythmia. Relative contraindications to its use include recent myocardial infarction, acidosis, asthma, chronic obstructive pulmonary edema, bradycardia, renal insufficiency, and therapy with β-blockers [12]. Recurrence rates after neostigmine administration vary from 17 to 38% [15]. Recurrences may be prevented by administration of polyethylene glycol (PEG) following decompression. Sgouros et al. [28] reported on 25 patients initially treated with neostigmine with resolution of ACPO in 88%. ACPO recurred in 33% of patients in the placebo group compared to 0% in the group receiving PEG. Recently, alternatives to neostigmine have been studied. These include pyridostigmine, a long-acting acetylcholinesterase inhibitor with less severe side effects than neostigmine, a μ-opioid receptor antagonist such as methylnaltrexone, and 5-hydroxytryptamine receptor 4 (5-HT4) agonists such as prucalopride [144–146]. While initial data appears promising for the use of these agents as alternatives to neostigmine, further studies are needed to establish efficacy and safety of these agents.

When all supportive and pharmacologic measures fail, endoscopic decompression is recommended. The efficacy of colonoscopic decompression has not been established in randomized clinical trials. The Standards of Practice Committee of the American Society for Gastrointestinal Endoscopy (ASGE) has issued guidelines for colonoscopy in ACPO [147]. In general, it is a safe procedure; however, there are important issues to consider when performing a colonoscopy in a patient with ACPO. Colonoscopy for ACPO should be

performed without administration of oral laxatives or bowel preparation and with minimal air insufflations. If available, carbon dioxide (CO_2) should be substituted for room air as it is absorbed faster with less residual distension and pain and minimal changes in pCO_2 [148, 149]. In patients undergoing colonoscopy for decompression of ACPO, sedation with benzodiazepines alone is preferred because narcotics further inhibit colonic motility. Cecal intubation is generally not necessary. Decompression at the level of the hepatic flexure is usually sufficient to achieve decompression. Some authors report on placement of a decompression tube over guidewire to allow for continued decompression [147]. Controlled trials demonstrating success of this technique are lacking; thus, its routine use cannot be advocated. Success rates of colonoscopic decompression alone vary ranging from 61 to 95% after an initial procedure and 73–88% after one or more procedures. Recurrences, however, continue to be problematic and have been reported to occur in up to 40% of patients [12, 150]. It is, therefore, not uncommon to require a second decompression after the initial successful colonoscopy. Complications, specifically perforations, while rare remain a major concern [15]. In general, the risks of colonoscopy and its high recurrence rates outweigh its benefits as a first-line treatment in the setting of ACPO. In summary, colonoscopy should be considered rescue therapy in those patients that have failed all supportive and pharmacologic measures.

Alternative endoscopic measures have also been described for the treatment of refractory ACPO. Percutaneous endoscopic colostomy (PEC) of the cecum, performed either with combined fluoroscopy and endoscopy or endoscopy alone, allows for venting of the colon and administration of antegrade enemas with PEG solution, if necessary. An introducer method using T-fasteners that secure the cecum to the abdominal wall has also been described. There are no reports establishing superiority of any single method. Reported complication rates are as high as 42% and include wound infection, bleeding, hematoma formation, perforation, granuloma, retraction, and buried bumper, making removal difficult [151]. The major advantages of PEC are avoidance of general anesthesia and the morbidity of a colectomy and an ileostomy. Conversely, the PEC is at risk of occlusion with thickened residual stool, dislodgement and diffuse peritonitis, leakage, and skin erosion. Further studies are required to define its efficacy, safety, and overall role in the management of ACPO. For now, it may be a useful option in patients with refractory ACPO who are otherwise poor surgical candidates.

Exploratory surgery with either a cecostomy or total abdominal colectomy is rarely necessary and should be reserved for patients with diffuse peritonitis or refractory ACPO. Cecostomy, via a minilaparotomy or laparoscopy, can provide effective decompression of the colon while minimizing the morbidity of a laparotomy and colectomy. While laparoscopic approaches have been described, they can be challenging in the setting of a diffusely dilated colon. Regardless of the approach, a cecostomy is often confronted with similar challenges facing PEC, including skin erosion, appliance fit and management, and catheter displacement [15]. More commonly, exploratory laparotomy is indicated with the extent of colon resection dictated by the degree of colon involvement. If feasible, enough colon remnants should be left behind to act as either a mucous fistula or a long Hartmann's pouch, left buried in the subcutaneous tissue or free intraperitoneal. Morbidity and mortality rates for surgery are significant ranging from 6 to 30%, respectively, reflecting significant underlying disease [152]. In summary, surgery should be reserved for patients who fail all conservative and endoscopic measures.

Other

Notwithstanding the etiology, the overall management of LBO is similar. Fluid and electrolyte replacement, bowel rest, radiographic imaging, and relief of the obstruction, either by surgery or endoluminal measures, remain the pillars of management of any patient presenting with a LBO. The following section discusses some of the more rare causes of LBO.

Endometriosis

Bowel obstruction is a rare outcome of ectopic endometrial glands. The rectum and sigmoid are the most common sites for implantation of ectopic endometrial implants in the gastrointestinal tract [153]. Once implanted, endometrial implants become intrinsic to the bowel wall leading to progressive luminal narrowing [154] (Figure 40-22). Typical symptoms include dyschezia, rectal bleeding, and constipation. Bowel obstruction occurs in less than 1% of patients with endometrial bowel implants [155]. On endoscopy, a submucosal mass may be seen with eccentric wall thickening and narrowed lumen (Figure 40-23). CT scan and water-soluble CE are invaluable in preoperative evaluation and allow for detailed characterization of the obstruction and surrounding organ involvement. Lesions causing LBO are typically large (>2 cm) and are unlikely to respond to medical therapy. Surgery is often necessary for definitive treatment and symptom relief. Excision of the implant only is rarely successful in the setting of large implants causing a LBO. These patients will require a segmental resection and a low or ultra-low colorectal anastomosis performed as a single- or two-stage surgery. Long-term follow-up data demonstrate improvements in dyschezia, no anastomotic recurrences, and thus no rectal bleeding [154, 156].

FIGURE 40-22. Water-soluble CE demonstrating smooth narrowing at rectosigmoid due to endometrioma. *Arrow* points to sight of obstruction at rectosigmoid junction.

FIGURE 40-23. Endoscopic appearance of submucosal causing luminal narrowing.

Fecal Impaction

Patients with LBO due to fecal impaction, especially the infirm and mentally impaired, present with nonspecific symptoms presenting a diagnostic challenge [157]. A history of chronic constipation along with new-onset abdominal pain, pelvic pressure, and diarrhea are not uncommon findings. The diagnosis is often confirmed by performing a digital rectal examination with the hallmark findings of copious hard or clay-like stool in the rectal vault. Plain abdominal radiographs or more advanced imaging, such as CT scan, may be required if the impaction is more proximal. The traditional treatment of fecal impaction involves digital manipulation, enema instillation, or disimpaction under anesthesia. For more proximal impaction, the hydrostatic effects of a water-soluble contrast enema may be diagnostic and therapeutic. Starting a bowel maintenance program, following successful disimpaction, is critical. Laparotomy is rarely necessary and required only in the presence of complications such as stercoral ulcer perforation.

Gallstone

Gallstone ileus, a rare complication of cholelithiasis, is an infrequent cause of mechanical bowel obstruction. The gallstone usually passes through a biliary-enteric fistula and lodges most commonly in the terminal ileum and ileocecal valve. LBO due to a migrating gallstone is even a rarer event, occurring in 4% of all patients presenting with gallstone ileus [158]. Typical signs and symptoms of LBO are present in addition to pneumobilia on imaging. CT scan remains the gold standard for diagnosis. Surgical exploration and stone extraction via colotomy are often necessary. A simultaneous cholecystectomy is not recommended as these patients are typically infirm with multiple comorbidities and are at risk of significant perioperative morbidity and mortality.

Intussusception

Intussusception is a rare cause of bowel obstruction in adults with the majority occurring in the small bowel or ileocecal valve. Colocolonic intussusceptions account for 17% of confirmed cases of intussusception [159]. The majority of colonic intussusceptions are due to malignant lesions, primarily adenocarcinoma and lymphoma (Figure 40-24). Benign causes, such as lipoma, adenomas, and Peutz-Jegher polyps, have also been described. Adult intussusception presents with acute, subacute, or chronic nonspecific symptoms leading to diagnostic delays. Due to the concern over malignancy, hydrostatic reduction is usually not recommended [160]. Given the concern of underlying malignant etiology, segmental resection is often required following oncologic principles.

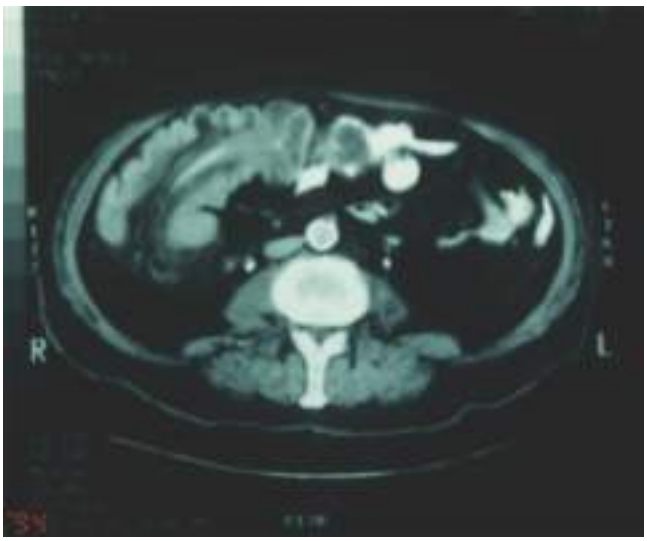

FIGURE 40-24. CT scan demonstrating colocolonic intussusceptions due to a lipoma.

Conclusions

LBO is a complicated clinical scenario that presents significant challenges to surgeons. Management will depend on many factors, including the location of the obstruction, the etiology of the obstruction, and the medical condition of the patient. There are multiple options available to treat these complicated patients, including surgery and, more recently, endoscopic procedures. Ideally, emergent situations can be converted to elective or semi-elective procedures with improved surgical morbidity and mortality. However, despite our best efforts, there will still be patients who require emergency surgery and the creation of a colostomy, which should never be considered a failure. Ultimately, the surgeon who is willing to explore different options depending on the clinical presentation is likely to achieve the best outcomes.

Lower Gastrointestinal Hemorrhage

Brian R. Kann and H. David Vargas

Key Concepts

- Common etiologies of lower gastrointestinal hemorrhage include diverticular disease, angioectasia, ischemic colitis, and neoplasm.
- The primary consideration in managing the patient with acute lower gastrointestinal hemorrhage is ensuring adequate volume resuscitation.
- Patients presenting with massive lower gastrointestinal bleeding should be evaluated for upper gastrointestinal and anorectal sources via gastric lavage and anoscopy/proctoscopy.
- Screening for active bleeding via CT angiography or ^{99m}Tc-RBC scan increases the likelihood of identifying active bleeding on mesenteric angiography.
- An active bleeding source seen on mesenteric angiography can often be managed with superselective transcatheter embolization.
- The patient with a self-limited major lower gastrointestinal hemorrhage that has stopped should undergo colonoscopy for further evaluation after a mechanical bowel prep.
- In certain circumstances, colonoscopy for the evaluation of active lower gastrointestinal bleeding may be considered; if active bleeding is encountered, therapeutic options include clipping, injection, and argon plasma coagulation.
- The unstable patient with uncontrolled, unlocalized lower gastrointestinal hemorrhage should undergo a total abdominal colectomy, in most cases with an ileostomy.
- The patient with ongoing or recurrent hemorrhage from a localized lower gastrointestinal source may be managed with a targeted, segmental resection.
- Clinical pathways and predictive models may help better guide the management of patients with acute lower gastrointestinal hemorrhage, limiting unnecessary admissions and optimizing the use of resources.

Introduction

Lower gastrointestinal bleeding (LGIB) refers to the passage of visible blood from the rectum and classically originates from a source distal to the ligament of Treitz. This distressing condition challenges both the clinician and patient, as LGIB may potentially arise from anywhere along a large anatomic distribution, may result from an array of pathologic conditions, can vary widely in severity, and frequently stops spontaneously prior to definitive diagnosis. In fact, no definitive source is found in approximately 10% of all cases of LGIB [1–3].

Descriptions reported by patients and witnesses can offer a spectrum of qualifiers in regard to the volume, color, associated symptoms, and hemodynamic consequences. The patient and family often experience significant stress and emotion by the sight of any significant quantity of blood passing from the rectum and likely experience an understandable sense of urgency to seek rapid medical evaluation and treatment. Thus, it is not uncommon for patients to present to emergency departments with less serious degrees of rectal bleeding. In fact, a report from an urban medical center reviewed over 1100 patients admitted for LGIB and found that over 20% of their hospitalized patients ultimately were identified to have a diagnosis of hemorrhoids [4]. The financial burden of LGIB per hospitalization ranges from $9700 to $11,800 [5, 6]. Clinicians bear the burden of determining which cases represent potentially life-threatening bleeding that mandates hospitalization and utilization of critical and costly resources.

The purpose of this chapter is to review the scope of the problem of LGIB, to identify underlying causes and their clinical presentation, and to help surgeons and other clinicians develop a rational approach to the diagnosis and treatment of patients experiencing LGIB.

Epidemiology

LGIB represents a broad clinical entity of varied severity and etiologies, and obtaining accurate epidemiologic data represents a formidable endeavor. Outpatient office visits provide one measure of the prevalence of LGIB, with over 1.7 million office visits in the United States for rectal bleeding occurring in 2009 [7]. Hospitalization data presumably reflects more serious LGIB, and in a review of a large hospital administrative database, admissions for all gastrointestinal bleeding [upper gastrointestinal bleeding (UGIB) and LGIB] were found to occur in approximately 97 cases per 100,000 persons, with 60.6 cases/100,000 persons due to UGIB and 35.7 cases/100,000 persons for LGIB [8]. This report assessed trends from 2001 to 2009 and revealed that the incidence of UGIB dramatically decreased (78.4–60.6 cases/100,000 persons), while cases for LGIB decreased as well but to a lesser extent (41.8–35.7 cases/100,000 persons). A study sponsored by the Agency for Healthcare Research and Quality queried the Nationwide Inpatient Sample Database and also noted a decreasing trend in the incidence of UGI bleeding (decreased by 14%), while during the time period of 1998–2006, the incidence of LGIB actually increased by 8% [9]. In this study, LGIB attributable to diverticulosis decreased by 7%, while anorectal hemorrhage increased by 41%. In Spain, a study involving ten academic hospitals between 1996 and 2005 found a similar decrease in UGIB (87/100,000–47/100,000), while LGIB increased from 20/100,000 to 33/100,000 [10]. Lastly, a recent prospective and population-based study from Iceland reported the highest incidence of LGIB at 87/100,000 persons, which equaled the incidence of UGIB [2].

While LGIB affects both the young and the old, the incidence of LGIB increases dramatically with age. Laine et al. reported that the incidence of LGIB for patients age <65 was 9.8/100,000, while individuals age >65 were found to have an incidence of 127.7/100,000 [8]. This phenomenon is likely explained by the simple fact that many of the conditions responsible for LGIB, such as diverticulosis coli and angioectasia, increase in incidence with age. Gender differences have not been consistently found in studies with regard to LGIB, and a recent survey of the Nationwide Inpatient Sample Database did not identify any difference in diverticular bleeding among men and women [11]. However, in this study, race was examined and found to be a significant factor with African Americans experiencing a higher prevalence of diverticular bleeding (34.4/100,000 persons) than Caucasians (20.3/100,000). Racial demographic data have not been consistently reported among most of the large database epidemiologic studies [7, 8, 12].

Etiologies of LGIB

Benign Anorectal Causes: Hemorrhoidal Bleeding and Fissures

Hemorrhoids and anal fissures commonly are associated with the appearance of bright red blood with bowel movements. The latter is commonly differentiated by the presence of pain during and after evacuation. Blood may be reported on the toilet paper with wiping, on the stool, or in the toilet bowel itself. In some cases, patients with bleeding internal hemorrhoids describe dripping of blood, or even streaming of blood, into the toilet bowl. Hemorrhoidal bleeding accounts for a substantial number of hospitalizations, representing 5–20% of all admissions for LGIB [1, 2, 4, 12]. Chronic bleeding from hemorrhoids over time also may result in iron deficiency anemia [13]. Hemorrhoids and anal fissures are generally not a likely cause of massive lower GI hemorrhage, although persistent bleeding hemorrhoids may require urgent operative intervention on occasion [4].

Diverticulosis Coli

Diverticulosis coli represents an acquired outpouching of the mucosa through the muscular layers of the colonic wall adjacent to penetrating vessels, the vasa recta. Diverticulosis increases with age; roughly 60% of individuals will develop diverticula by the age of 80, although it is estimated that perhaps only 15% will develop actual bleeding as a complication [14, 15].

Though the majority of patients with diverticulosis are not likely to experience clinically significant bleeding, diverticulosis is generally felt to represent the most common cause of LGIB not of anorectal etiology, accounting for 30–65% of cases [2, 4, 14–17]. In terms of severe hemorrhage, diverticular bleeding is certainly recognized as the most likely etiology [18, 19]. The theory behind diverticular bleeding describes the erosion of vasa recta through the mucosa at the neck or at the dome of the diverticulum [20]. Risk factors that predispose to diverticular bleeding include the use of nonsteroidal anti-inflammatory drugs (NSAIDs), hypertension, and anticoagulant use [1, 19, 21].

The diagnosis of a diverticular bleed is often considered presumptive, noting the presence of diverticulosis on colonoscopy without any other definitive bleeding site. Colonoscopy will provide definitive confirmation in the minority of cases (22%); criteria for diagnosis include colonoscopic identification of active bleeding or stigmata of bleeding such as an adherent clot or visible vessel [1]. Most diverticular bleeds present with painless hematochezia, which is often significant in volume. The natural history of

these episodes generally indicates spontaneous cessation in up to 80% of cases [1, 18]. The incidence of recurrent bleeding varies and has been noted to be as high as 40% in one series, though more recent series indicate rates on the order of 10–15% [22–24].

Angioectasia

Angioectasias [also known as angiodysplasia, arteriovenous malformations (AVMs), and vascular ectasias] are dilated, tortuous vascular abnormalities of the submucosa (Figure 41-1). The most widely accepted theory proposes that, with aging, low-grade obstruction of the submucosal veins traversing the colonic muscular layers results in incompetency of the precapillary sphincters, producing a small arteriovenous communication and subsequent dilation [25]. Colonic lesions more commonly occur in the cecum and right side of the colon, tend to be multiple, and are estimated to be the underlying etiology of bleeding in 3–15% of LGIB episodes [26–28].

The clinical presentation of LGIB due to angioectasia varies, and the color of blood has been reported to range from occult blood to melena to painless hematochezia [29]. Historically, angiodysplasia has been characterized by chronic or recurrent LGIB [30–32]. Factors that predispose to bleeding include increased age, comorbid conditions, multiple lesions, and the use of antiplatelet and anticoagulant therapy [33]. Recurrent bleeding is associated with multiple lesions, anticoagulation and antiplatelet therapy, the number of prior bleeding episodes, and rate of bleeding (events/year) [25].

In regards to recurrent bleeding, one must consider that angioectasias tend to be multiple and often involve proximal regions of the intestinal tract that require investigations in addition to colonoscopy. A recent report (which included diagnostic studies of the small bowel such as capsule endoscopy and double balloon enteroscopy) identified angioectasias most commonly in the jejunum (80%), followed by the duodenum (51%), stomach (22.8%), right colon (11.4%), and ileum (5.4%); nearly two-thirds of patients had lesions in multiple locations [2].

Ischemic Colitis

Ischemic injury of the colon occurs as a result of compromised blood flow and may be responsible for up to 16% of cases of LGIB, although most series indicate the incidence to be in the range of 10% [1, 3, 34, 35]. Bleeding typically occurs as a result of reperfusion of an ischemic segment of bowel, with sloughing of the mucosa and varying degrees of ulceration and necrosis (Figure 41-2). Bleeding generally is less severe when compared to diverticular bleeding or that related to angioectasias and, in some cases, may not be part of the clinical presentation at all. There is a spectrum of scenarios that may fall under the category of ischemic injury. Clinically, ischemic injury of the colon may be broadly considered as two distinct entities: (1) the traditional concept of "ischemic colitis" which affects primarily the left colon and is notable for transient and rapidly reversible ischemia and (2) other variants of "colonic ischemia" (CI) which may be due to arterial occlusion, thromboembolic disease, venous occlusion due to mesenteric venous thrombosis, or severe hypotension with a resultant low-flow state, also called non-occlusive mesenteric ischemia (NOMI). The mechanism of interrupted blood supply, the anatomic distribution at risk, and the prognosis vary between the two entities. The latter forms are more typically associated with severe, irreversible ischemic injury, greater risk of necrosis, increased risk of surgical resection, and mortality [36].

"Ischemic colitis" generally refers to a less severe ischemic intestinal injury that tends to be transient and revers-

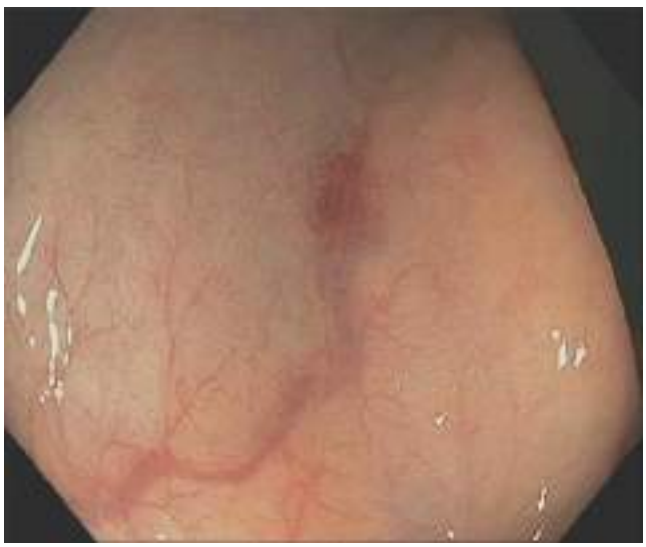

FIGURE 41-1. Angioectasia, seen on colonoscopy.

FIGURE 41-2. Ischemic colitis, seen on colonoscopy.

ible. Certain segments of the hindgut appear more vulnerable to this transient interruption of blood flow. These segments classically are referred to as the "watershed" regions: (1) the splenic flexure (Griffith's point), where vessels originating from midgut (superior mesenteric artery distribution) and hindgut (inferior mesenteric artery distribution) communicate via the marginal artery of Drummond, and (2) the rectosigmoid colon (Sudeck's point), where the marginal artery generally is not present and the arterial blood supply is provided by end sigmoidal vessels with less collateral redundancy [37].

Patients with ischemic colitis often present with cramping, abdominal pain, and associated tenderness localized to the left side of the abdomen; they may also experience associated nausea, vomiting, and an urgency to defecate. Typically, patients describe diarrheal stools that become bloody within 24 h of onset and can be either bright red or maroon-colored. Generally, bleeding from ischemic colitis is less severe and blood transfusion is necessary in fewer than 5% of patients. Symptoms generally resolve quickly (within 2–3 days) due to rapid restoration of blood flow, and acute complications requiring surgical intervention occur rarely.

Conversely, patients experiencing acute mesenteric vascular occlusion due to thromboembolism or mesenteric venous thrombosis, or those suffering from profound hypotension requiring vasopressor therapy (NOMI), are at greater risk for severe and irreversible ischemia, bowel necrosis, and need for urgent surgical intervention. Patterns of ischemia tend to be either pancolonic or isolated right colonic ischemia (IRCI) and are more likely to be associated with small bowel ischemia and infarction. Outcomes following surgical resection are remarkable for high mortality rates, ranging from 37 to 47% [38, 39].

Neoplasms of the Large Intestine

As with diverticulosis and vascular ectasias, the incidence of colorectal cancer increases with age [40]. Bleeding from neoplastic lesions of the large intestine generally presents according to anatomic location, with cecal and right-sided lesions more likely to cause occult blood loss, whereas left-sided and rectal lesions tend to present with visible blood per rectum. Acute massive hematochezia due to ulceration of the tumor is rare in the setting of colorectal cancer, and colorectal cancer represents less than 10% of all cases of LGIB requiring hospitalization [2, 4].

Additional Causes of LGIB

The definition of LGIB describes a large anatomic region with multiple additional conditions that may potentially give rise to bleeding, and these are briefly discussed in this section.

Post-polypectomy hemorrhage occurs after less than 1% of colonoscopic polypectomies [41]. However, given the vast numbers of colonoscopies and polypectomies performed annually (1.7 million colon cancer screening colonoscopies in the United States), this may account for up to 8% of all episodes of LGIB [42].

Inflammatory bowel disease (IBD) commonly presents with LGIB. However, severe, massive hemorrhage as the primary symptom prompting hospitalization occurs infrequently and accounts for less than 6% of all patients with a diagnosis of either Crohn's disease or ulcerative colitis [43–45]. Crohn's disease involving the colon and rectum is more likely to be a cause of LGIB as compared with isolated small bowel disease. While IBD more commonly affects the young patient, one must keep in mind the bimodal age distribution of IBD, which should be considered as a potential etiology of LGIB in the older patient as well.

Nonsteroidal anti-inflammatory drugs (NSAIDs) increase the risk of LGIB, especially in patients with diverticular disease. Remarkably, the prevalence of NSAID use among patients experiencing LGIB remains high, reported to be 86% in one series [46]. The association of NSAID use and LGIB may be the result of a specific effect of the medication on the mucosa or alternatively may exacerbate an underlying condition such as diverticulosis. In regard to the former, NSAIDs can cause a type of colitis that can be confused with IBD, characterized by ulcerations and weblike strictures, afflicting primarily the terminal ileum and right colon. Clinically, this can present with massive LGIB and even perforation [47].

Infectious hemorrhagic colitides due to bacterial infection must be considered in the individual experiencing LGIB. Inflammatory diarrhea is characterized by bloody and mucopurulent stool that is often associated with fever, tenesmus, and severe abdominal pain [48]. Common pathogenic bacteria causing inflammatory diarrhea include *Campylobacter*, *Salmonella*, *Shigella*, enteroinvasive and enterohemorrhagic *Escherichia coli*, and *Yersinia* species [49]. In North America, the most common clinically significant strain is *E. coli* O157:H7 [50]. These bacteria naturally occur in the intestines of healthy cattle. Transmission to humans occurs by eating undercooked ground beef or by drinking unpasteurized milk or juice. Consuming food or water contaminated with cow manure or raw ground beef can also lead to infection. The disease can be transmitted from person to person, notably from a child's diapers to their caregivers; additionally, low levels of chlorine in wading/swimming pools can predispose to infection [51, 52]. The infection causes mucosal injury with resulting bloody diarrhea, which is generally self-limited, requiring only supportive care. The most severe consequence of infection is hemolytic-uremic syndrome, characterized by thrombocytopenic thrombotic purpura and renal failure.

HIV-positive patients may experience LGIB from a variety of potential causes. Viral infections may be due to herpes simplex virus, cytomegalovirus, and HIV-related idiopathic proctocolitis. Additionally, one must also consider Kaposi's sarcoma. Sexually transmitted pathogens causing bloody diarrhea include *Chlamydial* species, with *C. trachomatis* infection being the most prevalent among homosexual males. *Neisseria gonorrhoeae* also can produce hemorrhagic proctitis, presenting with bloody mucoid diarrhea [49].

Radiation injury to the large intestine can be either acute (<3 months) or chronic. The incidence of chronic proctitis after pelvic irradiation is approximately 5–20% [53]. Chronic injury results in endarteritis obliterans that leads to neovascularization and telangiectasias, most commonly in the rectum. The incidence of radiation proctitis appears more likely if acute toxicity was observed during the course of treatment [54, 55]. The most common symptom of chronic radiation-induced proctitis remains rectal bleeding, while other associated symptoms include fecal urgency, incontinence, rectal pain, and mucoid discharge. More severe consequences include stricture and necrosis, resulting in potential fistulization to the urethra [56]. Endoscopy represents the diagnostic test of choice for evaluating radiation-induced proctocolitis and should be performed to exclude the possibility of an associated neoplasm of the large intestine, which can be seen in up to 12% of cases [57]. Typical endoscopic findings include telangiectasias, edema, ulceration, necrosis, and stenosis. Biopsy should be performed judiciously due to the known risk of non-healing ulcers and development of fistulae to the urethra and/or bladder [58].

Ulceration of the rectum has been described as a source of LGIB that can be severe and unrelenting, often requiring urgent colonoscopy and intervention. These ulcerations can result from stercoral injury or de novo in acutely ill patients.

Dieulafoy's lesions, most commonly found in the stomach, may be located elsewhere in the gastrointestinal tract 30% of the time, including the colon, the rectum, and the small intestine. These lesions represent a rare cause of GI bleeding (1–2%), though it has been suggested that this may underrepresent the true incidence due to a lack of recognition of the entity [59], as they have been identified via endoscopy and colonoscopy with increasing incidence in recent decades. Characteristic endoscopic findings describe a solitary vessel, histologically normal but large in diameter, protruding through the mucosa without surrounding ulceration [60]. Bleeding can be violent and voluminous and lead to life-threatening hemorrhage. The cause of Dieulafoy's lesions remains uncertain, and the range of clinical presentation includes reports occurring in acutely ill hospitalized patients as well as in newborn infants [59]. Approximately 5% of Dieulafoy's lesions are estimated to occur in the colon and rectum, with the right colon being the most common location [60].

Ectopic varices represent another rare but sinister cause of LGIB. Ectopic (non-esophageal) varices may occur in up to 70% of patients with portal hypertension and cirrhosis. Colorectal varices are well described but fortunately not a common cause of hemorrhage. Rectal varices result from portosystemic shunting and decompression of the inferior mesenteric vein and superior rectal veins via the middle and inferior rectal veins. Rectal varices do not prolapse, tend to be blue-gray in color, and may extend from the rectum superiorly to the squamous epithelium of the anus distally, in distinction to internal hemorrhoids, which may prolapse, tend to be purple in color, and generally do not extend proximally into the rectum [61]. The vessels tend to be serpentine in morphology, submucosal, and extend from the squamous epithelium cranially [62]. Bleeding from varices results from wall tension that is proportional to transmural pressure and the radius of the vessel. Similar to esophageal varices, the major determining factors are vessel size and portal venous pressure [63]. Fortunately, bleeding from rectal varices is rare, occurring in 0.5–3.6% of all cases [64–67]. However, when bleeding occurs, hemorrhage can be massive and life-threatening, requiring urgent intervention. Optimization of medical management remains paramount, including consideration of decompression procedures such as transjugular intrahepatic portosystemic shunt (TIPSS) [68]. Endoscopic techniques, such as injection sclerotherapy, as well as interventional radiology techniques, such as embolization, have been reported to be effective. While band ligation has been described as a treatment modality for esophageal varices, rectal varices less commonly are amenable to ligation technique, with variceal size (>9 mm) being an important predictor of poorer outcome [69].

Obscure bleeding from a small intestinal source has been estimated to account for 5% of LGIB episodes. Previously an anatomic territory that proved difficult to image endoscopically, the small bowel can now be directly visualized using techniques such as device-assisted enteroscopy (balloon and double balloon enteroscopes) and video capsule endoscopy. Such technologies prove far more sensitive than contrast studies or computed tomography and can identify many of the varied diagnoses causing bleeding, such as angioectasias, ulcerations, small bowel tumors, and IBD. In younger patients with LGIB, one must always consider Meckel's diverticulum, especially when bleeding is acute and massive [70]. Radionuclide imaging identifying ectopic gastric mucosa assists in confirming this diagnosis.

Table 41-1 summarizes the distribution of causes of LGIB, as reported in a number of large epidemiologic studies.

TABLE 41-1. Lower gastrointestinal bleeding—distribution of etiologies

Author (Year)	Diverticulosis (%)	Hemorrhoids (%)	Neoplasm (%)	Angioectasia (%)	Ischemic colitis (%)	IBD (%)	Colitides (%)	Ulcers (%)	Post-polypectomy (%)	Small bowel (%)	Radiation (%)	Other (%)	Unknown (%)

Models Predicting Severity of LGIB

Patients presenting with LGIB represent a considerable challenge to healthcare teams and hospital systems, given the heterogeneous nature of causes, spectrum of severity, and often elusive nature with spontaneous cessation of bleeding prior to definitive diagnosis. While occasionally dramatic in presentation, the vast majority of patients with LGIB do not require surgical intervention and experience exceedingly low mortality. Ideally, healthcare teams could better serve patients by employing a model to predict which episodes require hospitalization and help direct rational use of diagnostic testing and intervention. Validated models predicting severity and guiding management for UGIB exist and are widely employed [71]. However, models for predicting LGIB behavior have been much more difficult to develop and validate, given the heterogeneity of the clinical syndrome and the complexity of its clinical presentation.

Velayos et al. prospectively evaluated parameters identified within the first hour of presentation with LGIB to an emergency department and attempted to identify risk factors for adverse outcomes. A total of 448 patients were prospectively followed, and multivariate regression analysis identified three independent risk factors for severe LGIB: initial hematocrit less than 35%, presence of abnormal vital signs 1 h after initial medical evaluation, and gross blood on initial rectal examination. Severe LGIB occurred in 79% of patients with three risk factors, 57% of patients with two risk factors, 17% of patients with one risk factor, and zero patients with no risk factors [72].

Strate et al. also sought also to identify risk factors for severity of LGIB and predict which patients would most benefit from aggressive care and intervention. Multivariable logistic regression analysis of a cohort of 252 patients identified seven independent risk factors for severe LGIB: initial heart rate greater than 100/min, initial systolic blood pressure less than 115 mmHg, syncope, non-tender abdomen, bleeding per rectum during the first 4 h of evaluation, aspirin use, and Charlson Comorbidity Index score of more than 2. Severe LGIB was seen in 84% of patients with more than three risk factors, 43% of patients with one to three risk factors, and 9% of patients with no risk factors [3].

As a follow-up, Strate et al. then prospectively validated their predictive model in a cohort of 275 patients, noting that the number of positive risk factors, calculated within 4 h of presentation, significantly correlated with major clinical outcomes, including surgery, death, blood transfusions, and length of hospital stay. They concluded that the triage of high-risk patients (three or more risk factors) to urgent interventions could be used to improve utilization of resources and quality of care [34]. It should be noted that this model made the assumption that hemorrhage due to ischemic colitis and IBD is generally mild to moderate, so LGIB due to these etiologies was not included in the study group.

Patel et al. prospectively applied an algorithm to the evaluation of patients presenting with uncomplicated rectal bleeding. If the patient's hemoglobin was >13 g/dl, SBP> 115 mmHg, and the patient was not anticoagulated, the patient was discharged with plans for an outpatient flexible sigmoidoscopy within 6 weeks. This algorithm was applied to a series of 57 patients, and potential inpatient admissions were avoided in 35%. Only one discharged patient was readmitted with severe colitis, and avoidable admissions were reduced from 50 to 1.8% [73].

Although predictive models such as these have been developed and validated, it is unclear as to what extent their implementation will impact clinical practice and improve patient outcomes. Certainly, the application of practical and predictive clinical models for the evaluation and management of LGIB will become more relevant to physicians in the future, given the economic and administrative pressures on healthcare systems to demonstrate appropriate resource utilization and cost reduction efforts.

Presentation, Evaluation, and Management

Due to the diversity in underlying etiologies, the presentation of LGIB can range from occult bleeding to life-threatening hemorrhage. Of paramount importance is rapid assessment of the patient's hemodynamic stability. Patients presenting with massive gastrointestinal bleeding and signs of hemodynamic instability, chest pain, shortness of breath, or orthostatic hypotension should immediately have two large-bore intravenous lines placed and undergo rapid volume resuscitation with crystalloid while awaiting labs and availability of cross-matched blood; in extreme circumstances, one may consider transfusion with non cross-matched type O negative blood. Continuous monitoring of vital signs is essential, and a Foley catheter should be placed to monitor urine output.

Placement of a nasogastric tube and gastric lavage is essential. Aspiration of frank blood, clot, or coffee grounds should prompt further investigation for UGIB via upper endoscopy. A bilious aspirate all but excludes an upper gastrointestinal source, while a clear aspirate is indeterminate, as there could be source of bleeding distal to a contacted pylorus.

A thorough history and physical examination should be performed, including an intake of the patient's medications, paying particular attention to NSAIDs, anticoagulants, and antiplatelet agents that may exacerbate bleeding, as well as beta-blockers that may mask the physiologic response to hypovolemia. Pertinent points in the history should include onset and duration of bleeding, volume and frequency of bleeding, color of blood (bright red, maroon, or tarry), and presence or absence of clots. A history of abdominal pain and weight loss may suggest IBD, ischemia, or malignancy, though colorectal cancer rarely presents with massive

hematochezia. The presence of significant pain represents a branch point in the evaluation of the patient with LGIB and should prompt earlier cross-sectional imaging if the patient is hemodynamically stable. Other salient questioning should focus on comorbidities such as cardiovascular, pulmonary, or hepatic disease, the presence or absence of chest pain, shortness of breath, lightheadedness, anorectal pain, and the date and findings of the patient's most recent colonoscopy and/or upper endoscopy. Particular attention should be paid to those who have undergone prior intestinal surgery due to the possibility of an anastomotic ulcer and those who have been previously treated with abdominopelvic radiation, implicating radiation proctitis/colitis/enteritis.

Physical examination should begin with assessment for signs/symptoms of hypovolemic shock. Once the patient's volume status has been assessed and appropriate resuscitation has been initiated, a more focused physical exam should ensue. Abdominal examination should focus on the presence of pain, palpable masses, distention, scars from prior surgeries, and hepatosplenomegaly. Stigmata of chronic liver disease, such as jaundice, caput medusa, or palmar erythema, may suggest variceal bleeding. Visual inspection of the perineum should be performed to evaluate for thrombosed or prolapsing hemorrhoids, anal fissure, or anal masses. Digital rectal examination should be done to assess for the presence of a rectal mass, and anoscopy and/or rigid proctosigmoidoscopy should be performed to evaluate for a distal source of bleeding, such as internal hemorrhoids, proctitis, ulcers, or varices.

Laboratory studies should include a basic chemistry panel, complete blood count, coagulation parameters, and type and cross. Coagulopathies should be corrected via transfusion of blood products and/or factors as appropriate. Patients with cardiovascular disease or those with chest pain or shortness of breath should undergo an electrocardiogram, and if abnormal, cardiac enzymes should be assessed.

Initial volume resuscitation of the hypovolemic patient should include bolus infusion of isotonic crystalloid, such as normal saline or lactated Ringer's solution, aiming to restore normotension. Continued hypotension despite aggressive crystalloid infusion should prompt transfusion of packed red blood cells. Further transfusion should be guided by the patient's hemodynamic response and change in hemoglobin. A hemoglobin transfusion threshold of 9–10 g/dL has traditionally been employed, especially in patients with significant cardiovascular disease. While data regarding a more restrictive pattern of transfusion specifically in patients with LGIB is lacking, a number of studies in patients with UGIB have demonstrated improved outcomes using a more restrictive threshold, as low as 7 g/dL, in low-risk patients [74–76]. For patients requiring transfusion of multiple units of PRBC, concurrent administration of platelets and fresh frozen plasma may prevent dilutional coagulopathy.

Colonoscopy

When patients present with a self-limited LGIB, colonoscopy is the diagnostic modality of choice, identifying either a definitive or presumed source of bleeding in 74–100% of cases [77–83]. The major advantage of colonoscopy is the potential for concurrent diagnosis and therapeutic intervention, even in the absence of active bleeding. Because most bleeding stops spontaneously, colonoscopy is typically performed semi-electively, usually following a mechanical bowel preparation. However, the optimal means of bowel preparation and timing of colonoscopy is often a topic of debate. While the use of a mechanical bowel purge allows for more complete visualization of the colonic mucosa, it also necessitates a delay in performing the procedure. If bleeding has stopped by the time colonoscopy is performed, it is often difficult to know which, if any, of identified abnormalities was responsible, especially when multiple sources, such as diverticula or AVMs, are identified.

A pooled analysis of studies looking at colonoscopy after mechanical bowel preparation for the evaluation of LGIB found a diagnostic yield of 91% [25]. Early colonoscopy has been found to correlate with a shorter length of admission, primarily due to increased yield. Strate and Syngal reported that time to colonoscopy was an independent predictor of length of hospital stay in patients presenting with hematochezia. The absence of visible blood or active bleeding at the time of colonoscopy was also related to a shorted length of stay [84]. A number of other studies have suggested that urgent colonoscopy within 12–24 h of presentation can improve the diagnostic yield [79, 80, 85, 86].

In contrast to "early" colonoscopy is the concept of "urgent" colonoscopy, usually performed within a few hours of the patient's arrival. Jensen et al. studied the role of urgent colonoscopy (within 6–12 h of hospitalization) in patients with hematochezia and known diverticulosis after a 3–4 h mechanical colon purge in two sequential prospective trials. In the first trial, 23% of patients were found to have definitive signs of diverticular bleeding during colonoscopy and were managed medically, not endoscopically. Nearly half of these patients experienced rebleeding, and two-thirds of those that rebled required emergency hemicolectomy. In the second trial, 21% of patients had signs of diverticular hemorrhage at the time of colonoscopy, half of which were found to have active visible bleeding. All patients with signs of diverticular hemorrhage were treated endoscopically, and none had recurrent bleeding or required surgery [79].

Others have reported conflicting data regarding improved outcomes with urgent colonoscopy. Green et al. randomized patients with lower GI bleeding to urgent colonoscopy after a raid purge or a standard care algorithm based on angiographic intervention and expectant colonoscopy. They reported no differences in main outcome measures, including mortality, hospital stay, ICU stay, transfusion requirements, early and late rebleeding, and need for surgery [80]. Laine et al. performed

a prospective randomized trial comparing urgent colonoscopy (within 12 h of presentation) to elective colonoscopy (36–60 h after presentation). Though the trial closed prematurely due to inadequate enrollment and statistical power, the urgent group showed no decrease in diagnostic or therapeutic interventions, number of transfusions, length of stay, or hospital charges [87]. A number of other studies have also reported data indicating that urgent colonoscopy for acute LGIB may not be advantageous [78, 88].

In an effort to minimize the delay needed for mechanical bowel preparation, some have proposed the use of enemas to clear the left colon, though oral bowel preparation has been shown to clearly increase the diagnostic rate for colonoscopy compared with enemas alone [89]. In some instances, rapid enemas can be used prior to immediate colonoscopy after the onset of massive hematochezia to simply help distinguish a right-sided from a left-sided source; if blood is only seen in the left colon, further diagnostics should focus there [90]. Often, an acute bleed will clear the colon distal to the bleed of any solid stool, though there may be significant clot to clear during the procedure. Repaka et al. published a prospective feasibility study looking at urgent colonoscopy without oral bowel preparation aided by water jet pumps and mechanical suction devices (hydroflush colonoscopy). In a series of 13 procedures, a presumed or definitive source of bleeding was seen in all patients, a defined source was identified in 5/13 (38.5%), and endoscopic hemostasis was achieved in four of these. Complete colonoscopy to the cecum was performed in 9/13 (69.2%), and no patients required a repeat colonoscopy due to inadequate preparation [91].

In addition to the increased diagnostic yield, another advantage of early or urgent colonoscopy is the potential for therapeutic intervention if a source is identified. Colonoscopic interventions for cessation of active bleeding include clipping, band ligation, injection of epinephrine or saline, monopolar or bipolar electrocautery, laser coagulation, or argon plasma coagulation (APC). Bleeding diverticula can be treated by submucosal injection of epinephrine (diluted 1:20,000 in saline) in 1-mL aliquots into four quadrants around the base of the diverticulum. This can be done either with or without application of a heater probe applied at a low power setting for 1–2 s, though this does increase the risk of perforation. Early rebleeding rates for injection range from 0 to 35%, with minimal procedure-related complication [79, 80, 92].

Endoscopic clips can also be applied, either alone or as an adjunct to injection. A number of case series and retrospective studies have described successful endoscopic clipping for the management of LGIB of diverticular origin with rebleeding rates ranging from 0 to 21% [93]. Endoscopic clipping of the base of the diverticulum has been reported to have comparable success rates and complication profiles when compared with epinephrine injection [94–96]. Clipping of diverticula located in the right colon, as opposed to the left colon, has been reported to be a predictor of refractory hemorrhage [97].

Alternatively, endoscopic band ligation has been described in the management of diverticular hemorrhage with excellent success rates and low rebleeding rates [98, 99]. Setoyama et al. compared patients treated with endoclips and those treated with EBL and found initial success rates of 100% in both groups; however, rebleeding was seen in only 6% of patients treated with EBL, compared with 33% of those treated with clips [100].

AVMs can be treated either with electrocautery, APC, or laser coagulation. Multiple sessions may be required, and long-term rebleeding rates range from 10 to 39% [32, 101]. A combination of APC and endoscopic clipping has also been reported [102]. The risk of complications, including perforation, ranges from 2 to 7%. One must keep in mind that AVMs in particular are more often located in the thinner-walled right colon, increasing the risk of perforation with any intervention.

A novel means of obtaining endoscopic hemostasis for diffuse bleeding diatheses in the colon, such as radiation- or NSAID-induced colitis, has been described by Kratt et al. who reported the use of Hemospray (Cook Medical, Bloomington, IN), a mineral-based granular powder that absorbs water and induces the clotting cascade. They reported introducing it via a colonoscope throughout the cecum and ascending colon in an elderly patient with NSAID-induced colonopathy, successfully ceasing hemorrhage and avoiding the need for an urgent colectomy [103].

Radionucleotide Scintigraphy

Nuclear scintigraphy has long been utilized as a means of detecting active GI bleeding. Two techniques can be employed for the detection of active GI bleeding—^{99m}Tc-sulfur colloid and ^{99m}Tc-labeled RBCs, the latter of which has been shown to be superior for the detection of GI bleeding [104, 105]. ^{99m}Tc-RBC scanning requires labeling a small sample of the patient's blood with technetium and then injecting it back into the patient's bloodstream, followed by scintigraphic scanning. Active hemorrhage is indicated by extravasation and pooling of the radionucleotide tracer (Figure 41-3).

The procedure is not invasive, carries little risk, and does not require mechanical bowel preparation. Other benefits include its high sensitivity and the slow washout of the tracer, which allows repeat scanning over periods of up to 24 h in instances of intermittent bleeding. This is important to take into consideration, given that rebleeding can be seen in up to 27% of patients after an initial negative ^{99m}Tc-RBC scan [106]. The main drawbacks are that this technique requires some prep time to extract and tag the RBCs (approximately 30 min), and there is no possibility for therapeutic intervention.

Detection of bleeding as slow as 0.04–0.05 cm^3/min has been reported with ^{99m}Tc-RBC scans [107, 108]. The sensitivity

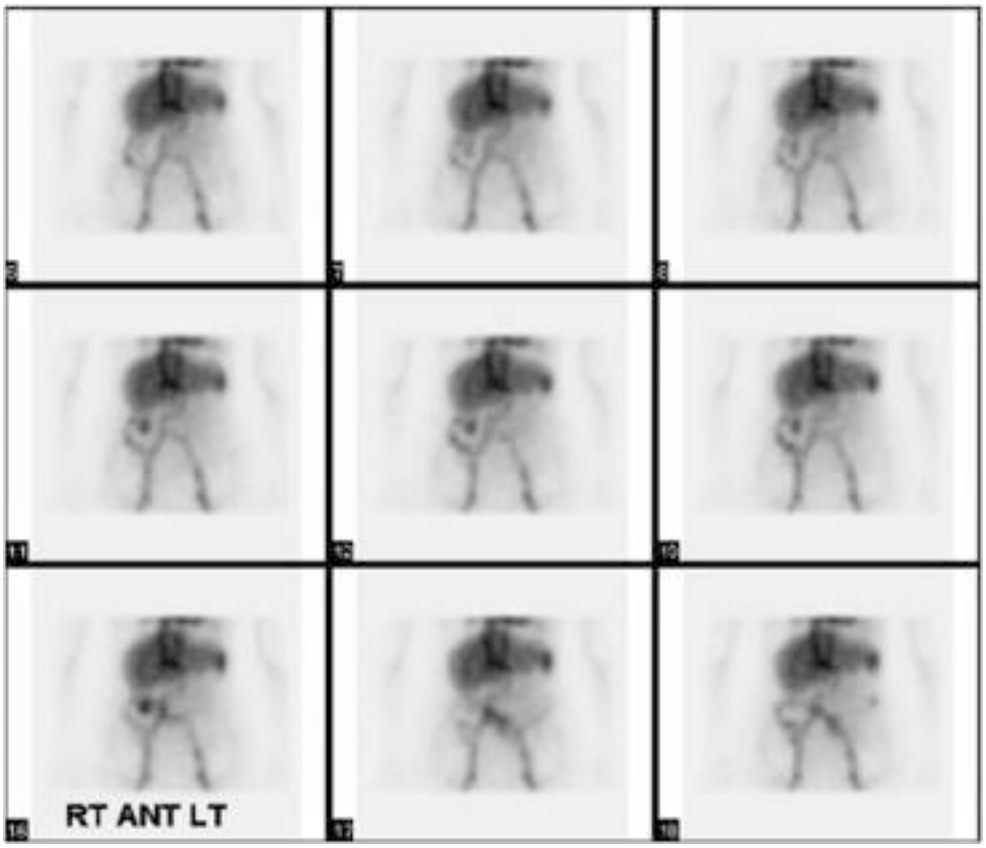

FIGURE 41-3. ^{99m}Tc-RBC scan showing active extravasation in the right lower quadrant. RBC = red blood cell.

is linked to the volume of extravasated RBC at the site of bleeding. While detection of low rates of bleeding is possible, hyperperistalsis may distribute the labeled RBCs over a substantial length of bowel, reducing the sensitivity. Feingold et al. found that patients who were hemodynamically unstable at presentation were more likely to have a positive ^{99m}Tc-RBC scan than those who were hemodynamically stable (62% vs. 21%) [109]. Reported accuracy in detection of the anatomic site of bleeding varies widely (41–94%) [110, 111], mainly because of rapid movement of tracer within the lumen of the bowel due to peristalsis and gravity, as well as difficulty discriminating colon from overlying small bowel. Because of the variability in accurate localization of the anatomic site of bleeding, most algorithms that include ^{99m}Tc-RBC scanning in the evaluation of patients with LGIB use it as a screening study prior to proceeding with mesenteric angiogram rather than as a localizing study. In a retrospective review of 271 angiograms published by Gunderman et al., the use of screening ^{99m}Tc-RBC scans prior to mesenteric angiography improved the diagnostic yield from 22 to 53% [112].

Because of the lack of reliability in determining the actual anatomic site of bleeding, segmental resection based on ^{99m}Tc-RBC scan localization alone is generally not advocated. However, a number of studies have attempted to refute this dogmatic approach. Suzman et al. retrospectively evaluated patients with LGIB who underwent a preoperative ^{99m}Tc-RBC scan and ultimately required surgery; 97.3% had correct localization based on surgical pathology, and only one of 50 patients over the 5-year period of the study required subtotal colectomy because of nonlocalized bleeding [113]. In a similar study, Gutierrez et al. reported an 88% accuracy of ^{99m}Tc-RBC scans in determining the site of bleeding [114]. Despite these reports, the decision to perform a segmental resection based on ^{99m}Tc-RBC scan localization alone should be made only after careful consideration.

Computed Tomography Angiography

Recent advances in computed tomography have led to the development and validation of CT angiography (CTA) techniques. Sixty-four-row CTA allows thinner collimation, faster scanning times, greater anatomic coverage, and better multiplanar reformatted images, greatly expanding its diagnostic role for the evaluation of LGIB [115]. With its widespread availability, CTA has largely supplanted ^{99m}Tc-RBC scanning as the initial means of evaluating most patients presenting with acute LGIB who do not have a contraindication such as renal insufficiency or allergy to contrast dye. Besides the detection of active bleeding, CTA has the added

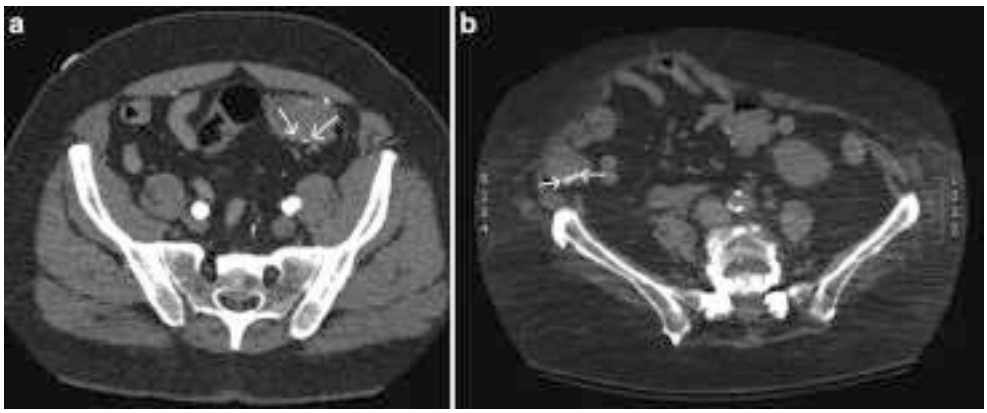

FIGURE 41-4. (**a**) CT angiogram showing active extravasation in the sigmoid colon. (**b**) CT angiogram showing active extravasation in the cecum.

advantages of being able to localize the site of bleeding and identify any coexisting pathology. A positive CTA (Figure 41-4) should prompt further therapeutic efforts, such as angiographic embolization, or if the patient is showing signs of massive hemorrhage, targeted surgical resection of the culprit segment of intestine.

The rate of bleeding able to be detected by CTA has been reported to be as low as 0.3 mL/min [116]. The sensitivity of CTA for localization of a LGIB source is 91–92% when active bleeding is present, though it drops to as low as 45–47% when bleeding is intermittent [117]. In a prospective trial, Ren et al. found that CTA had an accuracy of 90.5% in the detection of active GI bleeding, and treatment planning was correctly established on the basis of CTA findings with an accuracy of 98.4%. Another prospective study comparing the diagnostic performance of CTA with angiography, colonoscopy, and surgical findings reported a sensitivity of 100%, specificity of 96%, positive predictive value (PPV) of 95%, negative predictive value (NPV) of 100%, and accuracy of 93% [118].

A prospective trial published by Obana et al. found that the detection rate of colonic diverticular bleeding by CTA alone was only 15.4%, but jumped to 46.2% when combined with colonoscopy [119]. Nagata and colleagues evaluated rates of detection of a LGIB source comparing early colonoscopy following urgent CTA with early colonoscopy alone and found that the detection rate was higher with colonoscopy following CTA than with colonoscopy alone for vascular lesions (35.7% vs. 20.6%, $p=0.01$), leading to more endoscopic therapies (34.9% vs. 13.4%, $p<0.01$) [120].

A major advantage of CTA in the evaluation of the patient with LGIB is its ready availability and ease with which the study can be performed and rapidly interpreted, leading to earlier and more targeted therapeutic intervention. It is a noninvasive study that does not require mechanical bowel preparation and carries very little risk. The main disadvantage is the small risk of contrast nephropathy, which may limit its use in patients with renal insufficiency.

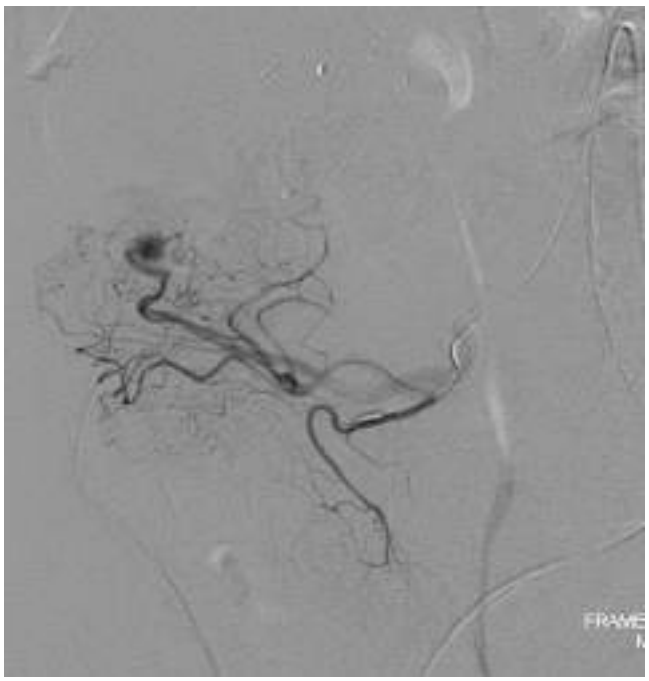

FIGURE 41-5. Mesenteric angiogram showing active extravasation from a branch of the ileocolic artery.

Angiography

Diagnostic Angiography

Diagnostic mesenteric angiography was first reported in the evaluation of hematochezia in 1963 [121]. Despite being an invasive procedure with a number of potential complications, its major advantage is the ability to perform a therapeutic intervention if active bleeding is identified (Figure 41-5). Angiography requires a more rapid rate of bleeding (0.5–1.5 cm^3/min) than nuclear scintigraphy to detect active extravasation. Identification of active bleeding following a positive "screening" ^{99m}Tc-RBC scan or CTA may be hampered by the intermittent nature of most LGIBs and the time

delay between the positive scan and the performance of angiography.

Ng et al. studied the timing of extravasation in a ^{99m}Tc-RBC scan and its role in predicting a positive mesenteric angiogram. They found that an immediate blush had a 75% PPV for active extravasation found on angiography, whereas a delayed (>2 min) blush had an NPV of 93%, suggesting that patients with a delayed blush may not require diagnostic angiography and may instead be observed and evaluated with colonoscopy after a bowel prep [122].

The diagnostic yield of mesenteric angiography depends on patient selection, the timing of the procedure, and the skill of the angiographer [123, 124]. A review by of the literature by Vernava et al. [77] reported diagnostic yields ranging from 40 to 86%. Abbas et al. found that angiography successfully localized bleeding sites in 51% of LGIB episodes; positive localization correlated with hemodynamic instability on arrival, a drop in hemoglobin level ≥50% from previous admission, and a transfusion requirement of ≥5 U of PRBC within 24 h [125].

Tan et al. reviewed patients with LGIB who had a positive CTA followed by mesenteric angiography and found that factors associated with a positive mesenteric angiography included nondiverticular etiology and hemoglobin <10 g/dL; when mesenteric angiography was performed within <150 min of the CTA, it was 2.89 times more likely to identify an active bleeding source [126]. A similar study by Koh et al. also found that mesenteric angiography after a positive CTA was 8.56 times more likely to be positive when performed within 90 min of the CTA [127]. Rasuli et al. reported that older age, ICU admission, and having received 4 U of PRBC over 12 h or 5 U over 24 h were indicators of a positive mesenteric angiogram [128].

For patients with recurrent intermittent LGIB that continue to escape localization despite multiple diagnostic studies, one technique that is often discussed but rarely utilized is provocative angiography, which incorporates the use of heparin, thrombolytics, vasodilators, or some combination of these to induce a bleed that has ceased. Before considering provocative angiography, one must balance the risk of uncontrolled hemorrhage or intracranial hemorrhage against the potential diagnostic and therapeutic benefit. Small series have been reported with low complication rates and diagnostic yields ranging from 29 to 38% [129–131].

The risks associated with diagnostic mesenteric angiography include bleeding, access complications such as vascular injury and pseudoaneurysm, thromboembolic events, and contrast-induced nephropathy. Contraindications include contrast dye allergy and renal insufficiency that might limit the ability to administer intravenous contrast.

Therapeutic Angiography

If a blush or area of obvious extravasation is seen during diagnostic angiography, therapeutic intervention should be attempted. In the 1970s, the technique of vasopressin infusion via a selectively placed mesenteric arterial catheter to induce vasospasm was introduced, and fairly recently, this was the preferred means of intervention. Transcatheter infusion generally begins at 0.2 U/min and may be increased to 0.4 U/min if bleeding persists. Cessation of active bleeding is seen in up to 90% of patients, though the rate of rebleeding upon discontinuation of the infusion approaches 50% [132]. Because of the antidiuretic effect of vasopressin, there is a tendency toward fluid retention and congestive heart failure, so its use in patients with significant cardiac disease becomes somewhat limited, especially considering the significant volume resuscitation many patients with LGIB require.

Vasopressin infusion was previously favored over intravascular embolization due to the high rates of intestinal ischemia and perforation (in as many as 20% of cases) reported with the use of larger catheters, which only allowed for embolization of larger vessels. However, the availability of "microcatheters" now allows for transcatheter superselective embolization of much smaller target vessels with a negligible risk of intestinal ischemia. Success rates with cessation of active arterial bleeding range from 50 to 100% with rebleeding rates of 22–24% [133–136]. Complications such as transmural ischemia and stricture formation, which were more common in the past following embolization of larger segmental vessels, now occur rarely with the use of superselective embolization angiography and are usually asymptomatic. Due to its efficacy and low risk of complications, superselective embolization is now considered by most to be the first-line angiographic therapy for LGIB. Materials used for embolization include microcoils, polyvinyl alcohol particles, and gelfoam.

Tan et al. published a retrospective review of 265 patients undergoing mesenteric angiography for LGIB, of which 32 (12%) underwent superselective embolization. Immediate cessation of bleeding was seen in 31 (97%), though only 20 (63%) were subsequently discharged with no further interventions. Seven patients rebled, and a total of nine required surgery; postembolization ischemia was seen in only one patient (3%). Rebleeding was more likely to occur if the bleeding source was the small bowel or if the presenting hematocrit was <20.0% or platelet count was <140; surgical resection was more likely if the underlying etiology of bleeding was diverticular disease or if the presenting hematocrit was <20.0% [134].

Compared with nuclear scintigraphy as a "screening" test for LGIB, pre-angiography localization of hemorrhage site by CTA has been shown to be more precise and consistent with angiographic findings. Pre-angiography CTA followed by therapeutic angiography typically results in administration of similar cumulative volumes of intravenous contrast when compared to angiography preceded by ^{99m}Tc-RBC, presumably due to pre-angiographic localization of the anatomic site of bleeding. The use of CTA prior to mesenteric angiography has been shown to have no effect on the incidence of contrast-induced nephropathy, given the similar volumes of contrast administration [137].

Localization of Small Bowel Bleeding

When a patient shows signs of ongoing GI bleeding in the face of negative evaluations of both the upper and lower GI tracts, one should consider evaluation for a small bowel source of bleeding. Options include video capsule endoscopy (VCE), double balloon enteroscopy (DBE), radionucleotide Meckel's scan, and, as a last resort, intraoperative push enteroscopy.

VCE and DBE have both been shown to have diagnostic yields in range of 55–65% in patients with hematochezia [117]. One disadvantage of VCE is failure to pass the capsule in instances in which structuring or obstructive disease is present, necessitating further intervention for retrieval. A dissolvable test capsule can be ingested prior to performing the study in an attempt to avoid this. Another disadvantage is that of missed lesions. As VCE generally records 2 frames/s, there have been reports of missed lesions subsequently seen on DBE [138]. Leung et al. randomized patients presenting with GI bleeding and nondiagnostic upper/lower endoscopy to undergo further evaluation via either VCE or angiography and found a higher diagnostic yield with VCE (53.3% vs. 20.0%, $p=0.016$) with no differences in long-term outcomes, including further transfusion, rebleeding, and mortality [139]. Newer devices are able to capture as many as 35 frames/s, which should greatly enhance the diagnostic accuracy. VCE takes significant time to perform and is most commonly utilized to evaluate for an occult source of chronic bleeding, not in the presence of massive LGIB.

DBE is a technically challenging and time-consuming procedure that should only be attempted by a skilled endoscopist who has training and significant experience with the technique. Despite these limitations, DBE compared to VCE has the added benefit of both localization and potential therapeutic intervention if bleeding source is identified. If a site of bleeding is identified but endoscopic intervention is not possible, the endoscopist can mark the site of bleeding with endoclips or tattooing for later identification at the time of possible radiologic or surgical intervention. Similar to VCE, the role of DBE in the setting of acute, massive LGIB is somewhat limited. However, Mönkemüller et al. have reported a series of 17 emergency DBEs for overt obscure GIB in which they successfully identified a source of bleeding in 59% [140].

A Meckel's scan relies on uptake of ^{99m}Tc-pertechnetate in ectopic gastric mucosa within a Meckel's diverticulum that has the potential for GI hemorrhage (but not active GI hemorrhage, for which ^{99m}Tc-RBC scanning would be more appropriate). The procedure is noninvasive, has minimal morbidity, and has both specificity and PPV approaching 100%, though its sensitivity is much lower at 62% [141–143]. Concurrent administration of H-2 blockers has been shown to increase the diagnostic yield.

Surgery

Despite the frequency with which patients present for evaluation of LGIB, the number of patients who require emergency surgery without a preoperatively localized site of bleeding is less than 5% [4]. However, in hemodynamically unstable patients with ongoing LGIB unresponsive to initial resuscitative efforts, emergent surgical intervention is indicated. Also, patients in whom a source of bleeding has been localized but therapeutic efforts are either unsuccessful or not feasible should be considered surgical candidates, as should those with massive transfusion requirements. Six units of PRBC in a 24-h period has traditionally been considered the threshold trigger prompting surgical intervention, though this varies depending on institution and the clinical state of the patient. Bender et al. reported a 45% mortality rate for patients undergoing emergency surgery for LGIB when a total of ten or more units of PRBCs were transfused preoperatively, compared with 7% when less than ten units were transfused [144].

When ongoing LGIB hemorrhage is present and a source cannot be localized despite multiple diagnostic studies or if the patient is too unstable for additional diagnostic studies, the patient should undergo exploratory laparotomy. The small bowel should be thoroughly examined to exclude a Meckel's diverticulum or a palpable mass that could be a source of bleeding. Transillumination of the small bowel may reveal small tumors or angiodysplasia. If the patient is stable, an intraoperative colonoscopy can be performed with luminal lavage and irrigation of sequential segments with proximal compression of the colon. Intraoperative push enteroscopy can also be considered if a colonic source is not identified and there is bright red blood and/or clots in the terminal ileum, though this can be technically challenging and time-consuming.

If a clear source cannot be identified and there is no obvious source in the stomach or small bowel (and an anorectal source has been excluded), the bleeding source is presumed to be colonic. In this scenario, and in the face of ongoing hemodynamic instability or ongoing frank hemorrhage, a total abdominal colectomy should be performed with either an end ileostomy or, in select circumstances, an ileoproctostomy. Generally speaking, most would advocate avoiding an anastomosis, given the indication for emergent laparotomy. If the patient is unstable or on vasopressors, has required multiple transfusions, or is markedly hypoalbuminemic, an end ileostomy is usually the safer option, as it eliminates the risk of anastomotic leak. Furthermore, ongoing bleeding from a source proximal to the colon can be identified quickly and more easily identified endoscopically via an ileoscopy. An ileoproctostomy, while an acceptable choice in properly selected patients, carries with it the risk of anastomotic leak, which can have devastating consequences, especially given that most patients who require emergency surgery for LGIB have numerous preexisting comorbidities; many of these patients may require ongoing use of vasopressors in the immediate post-op period, further compromising the anastomosis. Plummer et al. found a mortality rate of 17% in patients undergoing emergency surgery for unlocalized

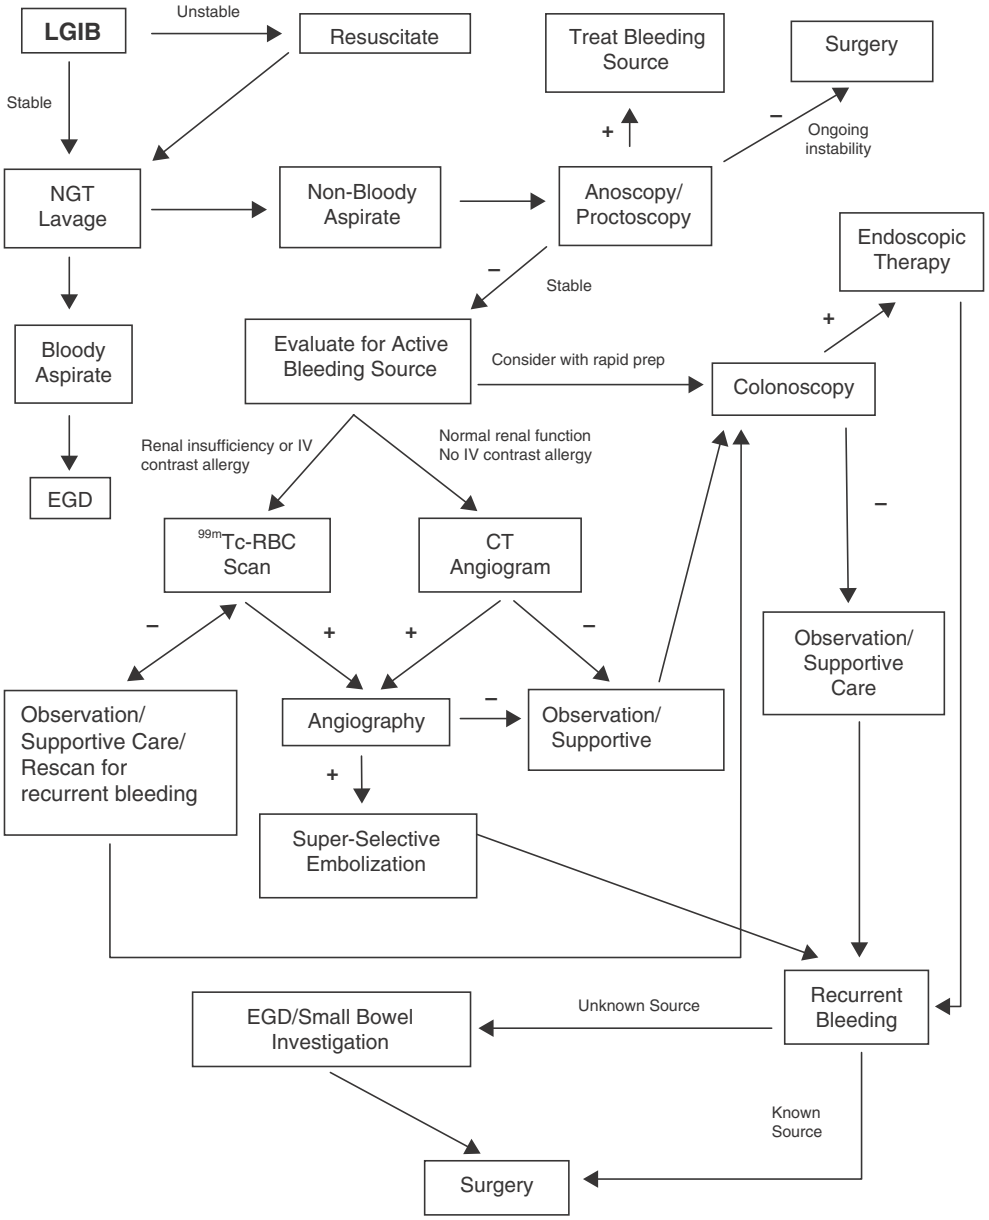

FIGURE 41-6. Algorithm for the evaluation and management of the patient with LGIB (lower gastrointestinal bleeding).

LGIB, with the main contributor being sepsis from an anastomotic leak [145]. Rebleeding rates after total abdominal colectomy generally are less than 5%, and modern advances in postoperative ICU care have reduced postoperative mortality to 2–6% [146–151].

When the bleeding site has been localized but endoscopic or angiographic attempts to control it have failed, a targeted segmental resection is indicated, either with primary anastomosis or a stoma dictated by the patient's clinical condition at the time of surgery. In this scenario, rebleeding rates and mortality are 4–10% and 0–40%, respectively [77, 147–149]. Compared with subtotal colectomy and ileorectal anastomosis, segmental colectomy provides measurable improvements in postoperative morbidity, BM frequency, social restrictions, and overall quality of life [152].

A "blind" segmental resection without preoperative localization should not be performed. The previously held tenet that the majority of GI bleeds are left-sided is no longer felt to be accurate. Blind segmental resections have been shown to have mortality rates ranging from 30 to 57% with rebleeding rates of 33–75% [148, 151, 153, 154].

Summary

LGIB is a commonly encountered condition, with a number of possible etiologies and several options for evaluation. Key points in the management include restoring hemodynamic stability, identifying and localizing ongoing bleeding, and cessation of hemorrhage, either by radiographic or

surgical means. There are a number of options in the evaluation of patients with LGIB, which should be individualized to the experience of the evaluating physician and available resources.

New technologies such as CTA and earlier use of colonoscopy now allow for more rapid and accurate detection of active bleeding; the number of nondiagnostic invasive angiograms has diminished, and pre-angiographic localization of an active bleeding site via CTA helps to facilitate treatment via therapeutic angiography. Advances in interventional techniques and use of microcatheters have improved the efficacy of therapeutic angiography and reduced the risk of postembolic ischemia. Fewer patients are undergoing emergency surgery for nonlocalized bleeding, even fewer are requiring subtotal colectomy for nonlocalized LGIB, and those who do require surgery fare much better than in the past due to improvement in postoperative ICU care.

However, despite the advances and new technologies, LGIB can still present significant diagnostic and therapeutic challenges to the treating physician. Employing a well-defined strategy in the evaluation and management of the patient can help to minimize unnecessary hospital admissions and make the best use of healthcare resources. An algorithm summarizing the evaluation and management of the patient presenting with LGIB is presented in Figure 41-6.

42 Endometriosis

Michael J. Snyder

Key Concepts

- Endometriosis is a common cause of young women having major surgery.
- Endometriosis causes infertility, pelvic pain, and dyschezia.
- Laparoscopy has revolutionized the diagnosis of endometriosis.
- Symptomatic endometriosis usually requires surgery.
- Excision of deep pelvic endometriosis is often a combined procedure with gynecologists and urologists.

Introduction

Endometriosis is a disease characterized by the presence of endometrial glands and stroma outside the uterine cavity. It is one of the most common conditions requiring surgery for women during their reproductive years. Endometriosis, while not fatal, may be associated with disabling pain and intractable infertility. The degree of symptoms varies widely and does not always correspond to the extent of pathology encountered at surgery. Small lesions may cause severe pain and infertility, while larger lesions may be asymptomatic and be found only incidentally during surgery for other diagnoses. Diagnosis is typically made or confirmed at laparoscopy or during laparotomy. Colon and rectal surgeons often become involved in the management of patients with intestinal endometriosis. This involvement may occur as a result of a combined procedure with a gynecologist or in management of an endometrioma masquerading as a neoplastic or inflammatory lesion. Treatment for endometriosis is usually multimodal and may require surgery in those patients with infertility, pelvic pain, obstruction, or a poor response to hormonal suppression. While advances in diagnostic tests and therapy have been made, endometriosis remains a frustrating and incompletely understood disease for both the patient and her physicians.

Epidemiology

The true prevalence of endometriosis is unknown. There is no noninvasive screening test for endometriosis, and its diagnosis depends on the visual or pathologic identification of implants during laparoscopy or laparotomy. Various authors have estimated that up to 15% of all women of reproductive age and one-third of infertile women have endometriosis [1, 2]. A study by Houston et al. is the only population-based study of endometriosis [3]. After reviewing the medical records for Caucasian women in Rochester, Minnesota, during the 1970s, they estimated that 6.2% of premenopausal women have endometriosis. The potential economic and societal cost of endometriosis was illustrated by the US Health Interview Survey. It found that 50% of women with endometriosis were unable to work at some time during the prior 12 months, losing an average of 17.8 days [4].

While endometriosis is primarily a disease of the reproductive years, the widespread use of exogenous estrogens and increasing obesity in our society have made it more prevalent in postmenopausal women. Conversely, there is a decrease in the incidence of the disease when women use oral contraceptives or experience multiple pregnancies [5]. These observations, coupled with the fact that the incidence of endometriosis increases over time after a woman's last childbirth, suggest that uninterrupted menstrual cycles predispose susceptible individuals to the development of endometrial implants [6]. An inverse relation with smoking and exercise is most likely due to diminished estrogen levels. There is no racial predilection for endometriosis other than in Japanese women who have double the incidence of the disease than do Caucasian women [7].

Etiology

The precise etiology that completely explains the cause and pathogenesis of endometriosis is unknown. The two most popular theories as to its etiology are coelomic metaplasia and the implantation of viable endometrial cells from retrograde menstruation through the fallopian tubes. Coelomic metaplasia, postulated by Meyers, suggests that under the correct hormonal milieu, the coelomic epithelium will undergo metaplastic changes and transform into endometrial tissue [8]. He bases his theory on studies demonstrating that the peritoneum and uterine endometrium both originate from embryonic coelomic epithelium. While this theory offers a good explanation for endometriosis in men and non-menstruating women, it does not adequately address the anatomical distribution and clinical pattern of endometriosis. The vast majority of endometriosis occurs in the pelvis, but the peritoneum at risk with this theory is evenly distributed throughout the abdominal cavity. In addition, metaplasia should worsen with age, and endometriosis clearly does not.

Retrograde menstruation, first proposed by Sampson in 1921, remains the most plausible explanation for the distribution of endometrial implants [9]. This theory postulates that endometriosis arises from retrograde menstruation through the fallopian tubes and into the peritoneal cavity. Viable endometrial tissue has been demonstrated in menstrual effluent, and endometriosis has been induced both in primates, with artificially produced retrograde menstruation [10], and in women volunteers who permitted injection of menstrual tissue into their peritoneum [11]. This theory, however, is probably only part of the answer.

While retrograde menstruation is very common, occurring in virtually all women, endometriosis affects only a small minority. Clearly other factors must be involved to permit the implantation and growth of endometrial tissue. Several studies indicate a possible genetic aspect to endometriosis. Simpson et al. demonstrated that the disease appears to occur more commonly within families. He found a 7% relative risk for blood relatives of affected individuals as opposed to a 1% relative risk for non-blood controls [12]. Additionally, the clinical manifestations of the disease were more severe among the related group. It appears that the inheritance pattern is polygenic or a combination of genetic and environmental factors. This conclusion is consistent with the clinical associations with delayed childbearing and uninterrupted cyclic menstruation.

Dmowski et al. have theorized that the genetic factor may involve the immune system [13]. They demonstrated depressed cellular immunity in monkeys with spontaneous endometriosis. Other investigators have confirmed alterations in both cellular and humoral immunity in humans [14, 15]. The most striking change observed in cellular immunity is the high concentration of activated macrophages and decreased functional capacity of natural killer cells. The most significant abnormality in humoral immunity is the presence of autoantibodies against different cellular components. These changes have been observed in both the peritoneal cavity and the systemic circulation, suggesting that endometriosis may be a systemic disease. It is still unclear whether these changes represent manifestations of the disease or a subsequent reaction to it. This research, however, suggests that mild subclinical immunosuppression may subsequently lead to endometriosis many years later.

Table 42-1. Sites and incidence of endometriosis

Common	Less common
Ovaries 60–75%	Appendix 2%
Uterosacral ligaments 30–65%	Ureter 1–2%
Cul-de-sac 20–30%	Terminal ileum 1%
Uterus 4–20%	Bladder < 1%
Rectosigmoid colon 3–10%	Abdominal scars < 1%

Rare, the diaphragm, inguinal canal, liver, spleen, kidney

Clinical Manifestations

The most common sites where endometriosis occurs are summarized in Table 42-1. The most frequent of these are in the pelvis. Potential sites of implantation in the abdomen include the appendix, small bowel, and diaphragm. Rarely, implantation may occur in the inguinal canal (in patients with hernias), surgical incisions, the vulva, vagina, cervix, or systemically in the lungs, bronchi, or kidneys.

As the majority of women have disease confined to the pelvis, the most common presenting complaints relate to menstrual irregularities, pelvic pain, and infertility. Many women with endometriosis may be completely asymptomatic, and the natural history of the disease in these patients has never been well defined. In studies with placebo arms, a few interesting observations have been made. A trial involving infertile women with otherwise asymptomatic endometriosis revealed that laparoscopic scoring of the severity of the disease increased over the length of the study in almost 50% of the placebo group [16]. Another study compared pain scores in women receiving placebo versus gonadotropin-releasing hormone (GnRH) analogs [17]. The cumulative dysmenorrhea rate and severity of pain were significantly lower in the treatment group suggesting a progressive course of the disease. Other studies on infertile women revealed that mild endometriosis can spontaneously resolve and that medical therapy may only suppress the disease until hormonal stimulation resumes [18].

Pelvic Pain and Dysmenorrhea

Pain is the most common symptom of endometriosis, affecting up to 80% of patients subsequently diagnosed with the disease. Endometriosis has been discovered in 30–50% of women undergoing laparoscopy for pelvic pain [19].

Pelvic pain associated with endometriosis presents as dysmenorrhea, dyspareunia, or chronic noncyclic pelvic pain. There are women, however, with extensive endometriosis and little or no pain. Total lesion volume does appear to correlate directly to the degree of pain [20]. Symptoms are related to the depth of penetration of the lesion, the type of lesion, and its location. Implants involving the uterosacral ligaments and rectovaginal septum are most often implicated. The pain is typically most intense just prior to menstruation and lasts for the duration of menstruation. The pain is often associated with back pain, dyschezia, and levator muscle spasm and is more severe with advanced stages of endometriosis.

Dysmenorrhea occurs in most women with endometriosis. The association is not well understood, and some have hypothesized that high uterine pressures cause dysmenorrhea with retrograde menstruation a consequence of these elevated pressures [21]. Other investigators, however, have failed to show an increase in the prevalence of dysmenorrhea with early stage endometriosis [22].

Dyspareunia, deep pelvic pain with vaginal penetration, is usually a symptom of advanced endometriosis. Dyspareunia is most pronounced just prior to menstruation and is associated with specific coital positions. The presence of dyspareunia is often indicative of the degree of fixation of the pelvic organs, especially in the cul-de-sac of Douglas and the rectovaginal septum.

Chronic noncyclic pelvic pain is pain present for longer than 6 months and may be intermittent or continuous. The pain is often associated with both perineural inflammation and uterosacral ligament involvement with endometriosis [23]. Gastrointestinal and urinary complaints may accompany the pain.

Pain in the shoulder during or just preceding menstruation may be due to endometrial implants involving the diaphragm. The diaphragm should always be viewed during laparoscopy, so these diaphragmatic deposits can possibly be treated with laser vaporization. Differentiation from adhesions associated with pelvic inflammatory disease (Fitz-Hugh-Curtis syndrome) is usually not difficult unless the two pathologies coexist.

The pathophysiology of pain arising from endometriosis is not completely clear. Pain may occur from the cyclic growth and subsequent increase in pressure within the capsule surrounding the implant. Alternatively, extravasation of menstrual debris into the surrounding tissue may occur with subsequent edema and release of inflammatory mediators. As the implant matures with surrounding unyielding scar tissue, the stretching of this scar by the products of the endometrial glands may produce pain. This scenario is probably particularly true for deeper implants. A study by Cornille discovered that all women with implants deeper than 1 cm experienced severe pelvic pain [23].

Adhesions, very common in endometriosis, may be associated with pain. Adherence of the colon and small bowel along with retroflexion of the uterus from extensive posterior adhesions may occur. Such retroflexion and fixation of the rectosigmoid can result in pressure on the sacrum with consequent back and rectal pain.

Since the 1960s, multiple investigators have attempted to define the role of prostaglandins in the pathogenesis of pelvic pain [24, 25]. Macrophages are responsible for the removal of foreign material such as the endometrial implants. They are present around the endometrial implants and are potent producers of inflammatory mediators such as the prostaglandins. Both prostacyclin (PGI-2) and prostaglandin E-2 are able to sensitize pain receptors to chemical mediators. Leukotriene B-4, another macrophage product, is a potent chemotactic agent and leukocyte activator. These factors are thought to explain some of the pelvic pain, but not all the studies agree [25]. The relative transient nature of prostaglandin action and the inherent difficulty in measuring pain complicate attempts to quantify the impact of chemical mediators.

Infertility

The relationship between endometriosis and infertility is also unclear. Some studies have demonstrated a high percentage of infertile patients with endometriosis [26]. Certainly, those reports comparing rates of endometriosis for women undergoing elective laparoscopic sterilization versus laparoscopy for infertility have demonstrated a fourfold or greater increase in the infertile group. In women with known endometriosis, the infertility rate is 30–50%. Whether endometriosis causes infertility or is the product of uninterrupted menstruation is still hotly debated.

There is little disagreement that moderate to severe disease with mechanical distortion of the fallopian tubes, ovaries, and peritoneum can potentiate infertility. Pelvic endometriosis and the resulting inflammatory response can produce dense, fibrotic adhesions that may significantly interfere with both the oocyte release from the ovary and the ability of the fallopian tube to pick up and transmit the oocyte to the uterus. Blockage of the tube may produce a hydrosalpinx, and in one recent study, endometriosis was the etiology in 14% of patients undergoing tubal reconstruction for occlusion [27]. In moderate or severe endometriosis, the pregnancy rates following surgery are 50% and 40%, respectively, compared to only 7% when expectant management is practiced [28, 29]. Surgical treatment of these patients is clearly beneficial.

Treatment of infertile patients with mild endometriosis is more problematic. A study by Inoue on 2000 infertile women with mild endometriosis did not reveal any improvement in fertility with either medical or surgical therapy when compared to expectant management [30]. Other studies have demonstrated a lower pregnancy per cycle rate in patients with endometriosis compared to those free of the disease [31].

Intestinal Symptoms

Although some women with intestinal endometriosis may be asymptomatic, some degree of intestinal complaints is found in those women with moderate to severe disease.

Bowel involvement occurs in 12–37% of cases of endometriosis. Depending on the site of involvement, the symptoms of endometriosis may vary somewhat. In patients with intestinal endometriosis, the rectosigmoid is involved in over 70%, followed by the small bowel and appendix. Rectosigmoid disease often results in alterations in bowel habits such as constipation, diarrhea, a decreased caliber of the stool, tenesmus, or, rarely, rectal bleeding. Such symptoms appear more often around the time of menses and are most likely due to the inflammatory nidus of the endometrial implant. Anal physiology performed between menses does not reveal any evidence of motility or neural disorders except an increase in the resting pressure of the internal anal sphincter [32]. Colonic endometriosis can present with obstruction and may be difficult to differentiate from other causes of large bowel obstruction, such as Crohn's disease or neoplasm. This difficulty is of particular concern in the postmenopausal woman on hormone replacement therapy.

Intestinal perforation may occur with endometriosis. Colonic perforation has been reported during pregnancy from endometriosis [33]. Perforation also occurs with transmural appendiceal endometriosis. For those patients with asymptomatic intestinal endometriosis, the natural history appears to be benign. Prystowsky and Stryker, who followed 44 patients with known intestinal endometriosis for a period of 1–12 years, found that only one patient developed clinically significant gastrointestinal symptoms [34]. Consequently, intestinal resection in these asymptomatic patients is probably unwarranted.

Confusion between small bowel endometriosis and Crohn's disease is common, as both can produce similar laparoscopic, endoscopic, and even histologic findings (Figure 42-1). Small bowel implants involving the terminal ileum are often noted incidentally at the time of laparoscopy and may often be asymptomatic. When symptoms occur, they are usually nonspecific such as recurrent abdominal pain and bloating. Occasionally, acute or chronic small bowel obstruction develops from extensive fibrotic adhesions which are due to endometriosis.

FIGURE 42-1. Gross pathologic specimen of endometriosis involving the small intestine. The specimen cut open with the typical appearance of an endometrioma after hormonal therapy inducing diminished vascularity.

The next most frequent site of intestinal endometriosis is the appendix. Endometrial implants are not infrequently found when the appendix is removed incidentally. The clinical significance of appendiceal endometriosis is less than that involving the small bowel and colon. Although endometrial implants may produce acute appendicitis with right lower quadrant abdominal pain, nausea, fever, and leukocytosis, historically most abdominal explorations for presumed acute appendicitis with a subsequent diagnosis of endometriosis have been due to ruptured endometrial cystic implants involving the ovary. Endometriosis of the appendix may also produce a chronic obstruction of the intestinal lumen with formation of a mucocele or peri-appendiceal inflammatory mass that is difficult to distinguish from a neoplasm. Finally, endometrial implants of the appendix and cecum may serve as lead points for an intussusception.

Malignant Transformation

Malignant transformation of endometriosis was previously considered an uncommon complication of the disease. Almost 80% of the tumors are ovarian, and two-thirds are endometrial carcinomas. An increase in the incidence of ovarian cancer in women with endometriosis has been reported in multiple studies [35, 36]. The histiotypes involved are endometrioid and clear cell tumors. Endometriosis and ovarian cancer are both seen in hyperestrogenic states, and patients with ovarian neoplasms arising from endometriosis are younger than the typical ovarian cancer patient with most tumors occurring in the fourth decade of life [37]. Symptoms of pelvic pain and an enlarging pelvic mass are the most common symptoms. In women with known endometriosis, a cyst larger than 10 cm, cyst rupture, or a change in the nature of the chronic pelvic pain are potential signs of malignancy. Interestingly, while oral contraceptive use decreases the risk of ovarian cancer in general, the effect is exaggerated in those tumors associated with endometriosis [38]. As endometrioid and clear cell ovarian cancers carry a poor prognosis, the long-term use of oral contraceptives is recommended by some to decrease the risk of malignant degeneration [38].

The rectosigmoid colon is the most common site for extragonadal tumors arising from endometriosis. Prolonged unopposed estrogen exposure is a significant risk factor, and rectal bleeding is the most common symptom. Recurrent symptoms of pelvic endometriosis following hysterectomy and bilateral salpingo-oophorectomy can be possible signs of malignant degeneration. Endometrial carcinoma is the most common tumor type. Histologically, the tumor must be shown to arise from the colon rather than invading it from another source. The diagnosis also requires that endometriosis or premalignant changes in endometrial glands be found contiguous with the invasive neoplasm [39].

Treatment of both ovarian and extragonadal tumors is based on the particular stage of the tumor. The prognosis is generally good with tumors confined to the ovary or an extragonadal site having 5-year survivals greater than 60%. Even if a locally extensive tumor is encountered, there may be a benefit from aggressive local resection.

Diagnosis

Physical Examination

Patients with mild cases of endometriosis may have a normal physical examination, and the diagnosis may not even be suspected unless the patient undergoes laparoscopy. For patients with pelvic pain, careful bimanual and rectal examination may reveal nodularity or induration especially in the uterosacral ligaments or cul-de-sac of Douglas. Fixed tender retroversion of the uterus in a patient without previous pelvic surgery may raise suspicion for endometriosis. Palpation of the ovaries may reveal an ovarian mass. As these ovarian masses are generally soft and cystic, those less than 5 cm in diameter may be difficult to palpate. Cyclical pain or bleeding from any location, especially coinciding with menses, should be adequately investigated for endometriosis. The inguinal canal, previous incisions, umbilicus, and lungs can all be potentially involved with endometrial implants.

Laboratory Evaluation

CA-125, an antigen expressed on tissues derived from human coelomic epithelium, is elevated in women with moderate to severe endometriosis. However, the sensitivity and specificity of this test are poor as the antigen may be mildly elevated in other diseases and within the normal range in women with mild endometriosis. The concentration of CA-125 does correlate with the severity of the disease and is probably most useful in gauging response to medical therapy. It may also be of value in following women postresection who had elevated levels preoperatively and are again exhibiting symptoms of endometriosis. No other serum markers are commercially available, but assays of antiendometrial antibodies and endometrial secretory protein PP14 are currently being evaluated for clinical relevance [40].

Endoscopy

As the lesions begin on the outside of the intestine, endoscopic evaluation of the large bowel is often normal except in severe disease or infiltrating nodular endometrial implants. Occasionally, serosal involvement with adhesions can lead to obstruction. Endoscopically, the mucosa is generally intact, occasionally associated with significant luminal narrowing. Infiltration of the submucosa, while uncommon, may produce

FIGURE 42-2. Polypoid endometrial implant of the colon causing mucosal abnormalities.

nodularity and distortion of the overlying mucosa (Figure 42-2). These findings may be difficult to visually differentiate from Crohn's disease, ischemia, or malignancy. Pressure against these areas of distorted bowel may produce pain that suggests the diagnosis of endometriosis. In addition, biopsies of the mucosa, taken in areas of endometriosis, can resemble solitary rectal ulcer or prolapse syndromes. Rarely is the diagnosis of endometriosis definitively confirmed by endoscopy or from endoscopic biopsies. Colonoscopy is, however, useful in excluding colon cancer from the differential diagnosis, especially in older patients presenting with a rectosigmoid mass while on hormone replacement.

Rigid proctoscopy is very helpful in predicting the depth of rectosigmoid involvement in patients with severe endometriosis of the cul-de-sac of Douglas. After two enemas are given to remove any fecal debris, the rigid proctoscope is deployed above the rectosigmoid and slowly withdrawn with care to maintain adequate insufflation. The mucosa is often fixed over an area of submucosal or deep muscular involvement with tethering or puckering and loss of the normal mucosal mobility. In our experience, these mucosal findings have correlated with significant intestinal wall invasion by the endometrial implant and often a need for intestinal resection.

Imaging Techniques

Imaging techniques used to facilitate the diagnosis of endometriosis include ultrasonography, barium enema, computerized tomography (CT), magnetic resonance imaging (MRI), and immunoscintigraphy. Many of these tests are obtained for the evaluation of chronic pelvic pain and/or bleeding from the reproductive tract or colon. They are primarily utilized to rule out more common conditions, but there are some findings that may strongly suggest the diagnosis of endometriosis before visual or pathologic confirmation by laparoscopy or laparotomy.

Transvaginal ultrasound has been used for several years to evaluate ovarian endometriomas. It is a sensitive test and in experienced hands provides specificity greater than 90% for ovarian endometriosis. Ultrasound of the pelvis, however, is not very sensitive in detecting focal non-ovarian endometrial implants. Endometriosis has been termed "the great mimicker" because the appearance on ultrasound is highly variable with some lesions being nearly sonolucent and others quite echogenic.

Endorectal ultrasound is a potentially valuable tool to determine rectal wall invasion by endometrial implants in the cul-de-sac. Chapron and colleagues studied the reliability of endorectal ultrasound in assessing the depth of bowel invasion with rectovaginal endometriosis [41]. In seventeen patients with proven deep pelvic endometriosis, the ultrasound revealed infiltration of the bowel wall and suggested the need for intestinal resection. The ultrasound findings were subsequently confirmed at laparoscopy and evaluation of the pathologic specimen in sixteen patients. Twenty-one other patients with endometriosis of the cul-de-sac of Douglas whose ultrasounds did not show infiltration of the rectal wall did not require intestinal resection and were able to have complete removal of the endometriosis with laparoscopic techniques without complications. The accuracy of ultrasound was confirmed by Doniec and colleagues who determined both the sensitivity and specificity of preoperative staging of rectal wall involvement by endometriosis to be 97% [42]. The only real concern in evaluating patients having cul-de-sac endometriosis by endorectal ultrasound is the significant discomfort experienced by the patient when rectal distention from the balloon probe compresses the endometrial implant.

Barium enema examination is another imaging technique often obtained by gynecologists for the intestinal complaints associated with deep pelvic endometriosis. The lateral and prone cross table views of the rectum offer excellent evaluation of the cul-de-sac of Douglas as long as care is taken in ensuring that the balloon is kept in the distal rectum (Figure 42-3). Studies in patients without bowel wall involvement are either normal or reveal smooth extrinsic compression with normal mucosa. Deep invasion of the bowel wall by endometriosis produces a variety of appearances on barium enema. Irregularities of the rectal wall such as tethering or even polypoid lesions may be difficult to distinguish from inflammatory bowel disease or neoplasm. Strictures of the rectosigmoid may also be identified on barium enema.

Computerized tomography is the imaging technique probably used most frequently for the evaluation of abdominal and pelvic pain. Unfortunately, there is no standard CT appearance for a mass cause by endometriosis to clearly differentiate it from pelvic masses due to other causes. Cystic lesions are more commonly seen on the ovaries, while deeper pelvic disease usually consists of either solid lesions or mixed cystic/solid lesions. CT evaluation of the pelvic sidewall for endometrial implants is better than ultrasound, but there is still significant overlap between infectious and malignant pathology. CT scanning is probably most useful for patients with pelvic pain and a negative ultrasound to assess the musculoskeletal boundaries of the pelvis and the rectosigmoid colon.

FIGURE 42-3. Barium enema demonstrating a rectosigmoid stricture from endometriosis.

When pelvic endometriosis is strongly suspected, magnetic resonance imaging (MRI) is more useful than CT scanning because of the benefit of imaging in multiple planes and the lack of ionizing radiation. MRI may be the best noninvasive modality for imaging suspected endometriosis. Colorectal involvement on MRI is strongly suggested when there is disappearance of the fat plane between the rectum and the vagina, loss of the hypointense signal of the anterior bowel wall on T2-weighted images, and a contrast-enhanced mass on T1-weighted images involving the bowel wall [43]. Sagittal images are particularly valuable in imaging the cul-de-sac of Douglas. MRI is superior to CT scanning for extraperitoneal lesions and the evaluation of pelvic masses [44]. Identification of endometrial implants is dependent on the hemorrhage that occurs in these lesions. The time between imaging and the most recent hemorrhage may determine in which weighted images the masses are most intensely seen. The sensitivity and specificity of MRI for detecting and adequately evaluating colorectal endometriosis are approximately 78% and 98%, respectively [44].

FIGURE 42-4. Laparoscopic view of an endometrial implant on the small intestine.

Immunoscintigraphy with radioactive iodine-labeled CA-125 monoclonal antibodies has been studied to clarify the extent of pelvic endometriosis, particularly in the face of severe pelvic adhesive disease [45]. In such a study of 28 women, 22 had a positive test with 16 confirmed to have endometriosis. Two of five women had a negative test despite having histologically confirmed endometriosis. As such, immunoscintigraphy is not currently recommended for screening and remains primarily a research tool.

Laparoscopy

The diagnosis of endometriosis usually requires direct visual and/or tactile assessment of the abdomen and pelvis. Laparoscopy is currently the initial approach to many patients suspected of having endometriosis and has revolutionized both its diagnosis and treatment (Figure 42-4). In experienced hands, laparoscopic evaluation is 97% sensitive and 77% specific diagnosing endometriosis [46]. Obtaining a biopsy to confirm the visual diagnosis is strongly recommended for at least one lesion and is especially critical for deep disease and endometriomas greater than 3 cm in diameter to exclude malignancy [47]. Most patients with severe pelvic pain and many patients with refractory infertility undergo laparoscopy. The timing of laparoscopy in relation to the menstrual cycle is unimportant except in patients being evaluated for infertility. In these patients, the procedure is performed in the luteal phase to provide additional valuable information concerning ovarian function.

The technique of diagnostic laparoscopy has become widespread in both the surgical and gynecologic literature. A camera, often attached to a video monitoring system with photographic and recording capabilities, is introduced at the level of the umbilicus or upper abdomen, while a second instrument is placed in a suprapubic location to allow manipulation of the pelvic and abdominal viscera. A thorough examination of the entire abdomen and especially the pelvis is critical to enable complete assessment of the disease. Both ovaries should be mobilized to evaluate the pelvic peritoneum, and the uterus should be manipulated to allow complete visualization of the cul-de-sac of Douglas, uterosacral ligaments, sigmoid colon, and ureters. It is important to view the base of the appendix as well as the distal small bowel.

Obtaining a complete assessment of the abdominal and pelvic viscera can be technically demanding. The accuracy of laparoscopy is completely dependent on the surgeon's visual evaluation of the abdomen and pelvis. The findings of endometriosis can be very subtle, and several studies have demonstrated that visually normal peritoneum may have microscopic evidence of endometriosis [48]. The extent of endometriosis should be carefully documented and staged. The current staging system has been formulated primarily for infertility and was revised by the American Society for Reproductive Medicine in 1998 (Figure 42-5) [49]. This revision is certainly an improvement over previous staging systems that were more concerned with adhesions than with implants. Virtually all patients with intestinal lesions requiring resection are stage 4 especially if they have cul-de-sac involvement.

The current classification system, however, is often not useful for the gastrointestinal surgeon. The more critical information for the surgeon is the identification and location of intestinal lesions. There is no uniform type of endometrial lesion. The classic implant is nodular with a variable degree of fibrosis and pigmentation. The color may be black, white, brown, blue, or even red. The appearance of the lesion may be vesicular, papular, or hemorrhagic (Figure 42.5). Glandular tissue is found in the great majority of these lesions. Lesions may change color or consistency over time, with red lesions noted early in the course of the disease and blue/black ones typical of older implants. Healed implants appear as fibrotic nodules. There are also a wide variety of atypical lesions occasionally associated with positive biopsies. The inability to definitively identify endometriosis through purely visual means necessitates pathologic confirmation of the disease before a definitive diagnosis can be made, especially in mild disease.

Implants in the cul-de-sac of Douglas, which occur in nearly 20% of women with endometriosis, were initially described by Cullen in 1920. Ninety percent of these represent an important variant that is especially relevant for the intestinal surgeon. Histologically, these lesions are characterized by desmoplastic tissue composed of fibrous and smooth muscle cells with strands of endometrial glands and stroma. The major component of the lesion is the fibromuscular tissue and not the endometrial tissue typical of other locations. These implants are both proliferative and infiltrating, and more than 25% extend at least five millimeters in

depth [50]. The depth of invasion may be difficult to assess laparoscopically, and the full extent of the implant may not be appreciated until laparotomy. The progressive fibrosis leads to narrowing of the intestinal lumen and occasionally to bowel obstruction.

These rectovaginal implants also behave differently during the menstrual cycle. There is poor to absent secretory changes during the luteal phase. Vasodilatation and not necrosis and bleeding occur at menstruation. Resistance to medical therapy is common with several studies demonstrating no significant decrease in mitotic activity in rectovaginal endometriosis after GnRH agonist treatment [51]. This resistance is felt to be due to estrogen receptor inactivity, inadequate drug access, or genetic programming that is only secondarily affected by estrogen.

Treatment

Treatment options for women with endometriosis are currently based upon the severity and type of symptoms. Currently, prevention of endometriosis is not yet possible, and therefore treatment is primarily begun to ameliorate symptoms. Some women with endometriosis are completely asymptomatic, and the implants are found incidentally at the time of surgery for other reasons. A study by Martin in 1989 revealed that 25% of women undergoing elective tubal ligation had asymptomatic endometrial implants [52]. This finding strongly suggests that not all women with endometriosis require treatment. Other authors have analyzed the prevalence of endometriosis in these asymptomatic women with regard to the time from their last pregnancy. They discovered that the odds of having endometrial implants increased significantly at 10 years following the last pregnancy [6, 53]. Consequently, as the natural history appears unclear, long-term follow-up of these patient cohorts may demonstrate late development of symptoms and the need for more aggressive medical or surgical management.

Before the introduction of diagnostic laparoscopy in the 1960s, exploratory laparotomy was the only modality available for the diagnosis and treatment of endometriosis. Laparoscopy revolutionized the diagnostic evaluation of these women and allowed patients with limited disease to undergo medical therapy. With improvements in laparoscopic techniques and equipment in the past decade, notably the development of laparoscopic laser techniques, many if not most early endometrial lesions can now be ablated or excised at the time of diagnosis. Even complex excisional surgery involving the bowel and ureter can be performed safely via a laparoscopic approach in many patients especially with mild and moderate disease. As advanced laparoscopic techniques have become more widespread, the indications and use of medical therapy are also evolving.

Medical Management

Medical therapy is designed to treat the symptoms of endometriosis, notably pelvic pain. As pelvic pain may have causes other than the endometriosis seen during laparoscopy, a trial of ovarian suppression is often used to help determine the contribution of the pain from the endometrial implants. In those patients with infertility, with or without pelvic pain, the primary goal is an intrauterine pregnancy. After other causes of infertility have been excluded, ovarian suppression may allow for laparoscopic removal of smaller endometrial lesions with optimal preservation of ovarian tissue.

Despite the many advances in the surgical treatment of endometriosis, there are still some significant advantages to medical therapy. Surgery can remove only lesions that are both visible and accessible. Microscopic disease or disease on vital structures is often left behind. Subsequent recurrence is not surprising. Additionally, there are complications associated with ablative surgery in the pelvis, especially if the woman requires multiple attempts at control of her disease. For infertile women, the adhesions that can form following any pelvic surgery may further impair the ability to conceive. In addition, laser destruction of ovarian implants may destroy germinal tissue and conceivably limit the reproductive potential from the involved ovary. In limited disease, medical therapy is comparable with surgery in terms of relief of symptoms, recurrence of disease, and subsequent pregnancy rates. Finally, medical therapy does not require specialized training or equipment and is much less costly than surgery.

Medical therapy alone also has significant potential disadvantages. All the hormonal therapies subsequently discussed have side effects and often require prolonged treatment. For example, medical therapies manipulate the hormonal environment to suppress the cyclic secretion of ovarian estrogen and progesterone, and this suppression induces atrophy of the ectopic endometrium so that over several months the implants regress. Advanced lesions, especially those with a nodular, proliferative histology, will often only partially regress. No current hormonal regimen can completely eradicate these lesions, and upon cessation of therapy, the lesions may again become symptomatic.

Oral Contraceptives

The first effective medical therapy for endometriosis was introduced by Kistner. He proposed the administration of high-dose, continuous estrogen/progestogens in 1958. These agents result in the induction of pseudopregnancy with hyperhormonal amenorrhea. Pituitary and ovarian function is thereby suppressed, and in the later stages of the treatment regimen, endometrial implants resorb and resolve. The usual treatment regimen consists of daily administration of a tablet for 6–9 months. When Vercellini and colleagues compared

oral contraceptives with GnRH agonists, they found that deep dyspareunia and pelvic pain were reduced in both groups with fewer side effects experienced by the oral contraceptive women. Pain relief appeared similar in the two groups at 1 year [54]. Side effects rarely cause cessation of treatment, but exacerbation of endometriotic symptoms may occur early in the course of treatment.

Another drug regimen used for the treatment of endometriosis involves administration of synthetic progestogens alone. This may induce a pseudopregnancy by acting in concert with endogenous estrogens. Ovarian suppression is often inconsistent. Both oral and depot preparations are available. In patients who do not desire pregnancy and in whom surgery is contraindicated, depot progestogens have been effective in ameliorating pelvic pain with equivalent efficacy to danazol [55]. Side effects include breakthrough vaginal bleeding, weight gain, and fluid retention.

Danazol

Danazol was first used extensively for endometriosis in the mid-1970s and, until the introduction of GnRH agonists (GnRH-a), was the most widely used drug for suppression of the ectopic endometrium. Danazol lowers peripheral estrogen and progesterone levels by a direct effect on ovarian steroidogenesis and pituitary production of FSH and LH. Danazol also binds directly to endometrial cellular receptors leading to atrophy and suppression of proliferation. In addition, danazol is a potent immunomodulator with beneficial effects on both humoral and cellular immunity [56].

The side effects of danazol necessitate discontinuation in less than 5% of patients for short courses [57] but are poorly tolerated for long-term suppression. Predictable manifestations of menopause are most common. Danazol also raises free testosterone levels and produces a hyperandrogenic state, especially at lower doses. Hirsutism, acne weight gain, and deepening voice changes may occur. In addition, since danazol alters lipid metabolism and liver function, it should not be used in women with elevated liver enzymes, liver disease, or complications of atherosclerosis.

Gonadotropin-Releasing Hormone Agonists

The introduction of GnRH-a as a new treatment modality for endometriosis has improved results primarily by a reduction in side effects. GnRH-a is a synthetic molecule derived from the ten-peptide-long GnRH. Continuous administration of GnRH-a completely suppresses pituitary release of FSH and LH. Administered either by injection or intranasally beginning in the mid-luteal phase of the menstrual cycle, the current recommended length of therapy is 6 months. Pain relief is complete in over 50% of women and significantly decreased in over 90%. Laparoscopic evaluation after 6 months of treatment indicates resolution or a significant decrease in size of the lesions in the majority of patients. Studies comparing danazol and GnRH-a indicate similar clinical efficacy [58].

Side effects of GnRH-a are predictably due to the sometimes profound hypoestrogenic state many of these women experience. Cessation of therapy for side effects is uncommon. The degree of bone mineral density loss that can occur with the typical 6-month treatment regimen is 5–6%. This limits the use of GnRH-a to 6 months. The bone mineral loss usually recovers 6–12 months after discontinuation and can be significantly prevented by the daily administration of tibolone [59]. Obviously, GnRH-a is not recommended for women with preexisting osteoporosis. Interestingly, a potentially serious complication can result when GnRH-a is inadvertently administered at the wrong point in the menstrual cycle, and a brief period of hypersecretion of FSH and LH occurs. Rarely, this upsurge in gonadotropin activity may precipitate an acute exacerbation in endometriotic symptoms, occasionally necessitating emergency surgical intervention [54].

A frequent use of GnRH-a is as a neo-adjuvant or adjuvant therapy for surgery. Benefits to include a reduction in postoperative adhesion formation and recurrence in the pelvis from lesions not visualized or removed at the time of surgery have been theorized [55]. Studies evaluating postoperative GnRH-a administration have failed to establish efficacy although ongoing investigation may still show a benefit [60]. Using the GnRH-a for a preoperative course clearly shrinks many of the nodules of endometriosis especially on the pelvic sidewalls, ovaries, and small intestine. It is important to document the location of these lesions as they may significantly change morphology. After a 3-month course of GnRH-a, the lesions have often lost much of their mass and may appear white. They can be difficult to see and may extend much deeper than appear initially. Unfortunately, the deep infiltrating lesions of the cul-de-sac and rectovaginal septum do not shrink as much, although the patient often has relief of her severe pelvic pain during the course of treatment. Most importantly, the dissection of the pelvic sidewalls is technically less challenging, facilitating removal of the peritoneal implants and better pelvic hemostasis and allowing careful preservation of the gonadal vessels in patients desiring children.

Future Drugs

Aromatase is an enzyme that catalyzes the conversion of androgens to estrogens. It is the rate-limiting step in the production of estrogen and endometriotic implants that express high levels of aromatase. There are currently two kinds of inhibitors, steroidal and nonsteroidal. Both classes of inhibitors reduce circulating estrogen to less than 10% of pretreatment levels in postmenopausal women or premenopausal women with nonfunctioning ovaries [61]. Consequently, as they do not block estrogen production completely, they are primarily indicated for postmenopausal women or in

conjunction with other agents to reduce the toxicity of the therapy. In a randomized trial, patients with severe endometriosis received either a combination of GnRH-a and an aromatase inhibitor or a GnRh-a alone. The combination therapy was effective in alleviating pelvic pain without concomitant bone mineral density changes and may become an alternative to extirpative surgery in some patients [61].

Another avenue of investigation has been with immunomodulators and anti-inflammatory drugs. As mentioned earlier, defects in the immune system may play a role in the development of endometriosis. Peritoneal macrophages are increased in both number and activity. Whether the elevated cytokines and other inflammatory agents are causing the disease or are the result of the lesions, the cascade of agents amplifies the response and appears to assist the progression of the disease [62]. Cyclooxygenase inhibitors have been studied in a prospective randomized trial compared to a placebo. Pelvic pain and dyspareunia were reduced in patients with stage 4 endometriosis [62]. While tumor necrosis factor (TNF) is elevated in the peritoneal fluid of patients with endometriosis, none of the TNF inhibitors have shown any efficacy although studies are ongoing [62].

Surgical Management

Surgical treatment of endometriosis has evolved significantly over time. Before the advent of laparoscopy and suppressive medical therapy, most operations were performed for advanced disease and consisted of radical removal of the uterus and ovaries. While the most effective treatment of pelvic pain still consists of surgical castration along with resection of the endometrial implants, many of these young patients strongly desire to maintain their options for pregnancy. Currently, surgery is considered conservative only when reproductive potential is preserved. Therefore, the major goal of surgical therapy for endometriosis is to completely excise or ablate the endometrial implants. Secondary goals include preservation of ovarian function and minimizing postoperative adhesion formation. Currently, we approach these patients in concert with gynecologists experienced with treating ovarian endometriosis to completely remove all gross disease, restore normal anatomy, and optimize fertility.

General Principles

Endometriosis is an invasive disease that can extend deeply into the retroperitoneum and is often surrounded by a rim of fibrosis that may make it difficult to completely assess the true extent of the implant. Removal of the lesions requires sharp excision or vaporization with electrocautery and/or the CO_2 laser. Both techniques have the potential for iatrogenic injury to the intestinal or urinary tracts. Recognizing when a lesion is completely ablated is highly dependent on surgical technique and the expertise of the surgeon. Utilizing techniques that minimize injury to the surrounding tissue, such as a cutting current to outline lesions to be removed by electrocautery and high-power density settings with the CO_2 laser, is desirable. Laparoscopic hydrodissection is also very useful in identifying normal surrounding tissue.

Meticulous hemostasis and frequent irrigation are critical to maintaining good visualization of the operative field in both open and laparoscopic surgery. Tissue planes are often distorted, especially in the cul-de-sac of Douglas, and intraoperative instrumentation of the vagina or proctoscopic evaluation of the rectum may help avoid iatrogenic injury to these structures. Finally, minimizing tissue trauma with gentle handling will decrease adhesions and maximize potential fertility.

All patients undergoing surgery for advanced endometriosis, either by an open or laparoscopic approach, should have a full mechanical and antibiotic bowel preparation. Prophylactic antibiotics and other appropriate practices for patients undergoing major abdominal or pelvic surgery are standard. Patients are positioned in the low lithotomy position with access to both the vagina and rectum for instrumentation. Ureteral stents are liberally used and are especially useful in women with severe obliterative disease in the cul-de-sac and in reoperative pelvic surgical procedures.

Provided that complete removal of the endometriosis is performed, no specific technique or approach has been proven to be superior. With endometriosis, the surgeon's experience and skill are paramount. In experienced hands, laparoscopic removal of extensive endometriosis can be accomplished. However, removal of deep lesions in the rectovaginal septum necessitating bowel resection still often requires open laparotomy to safely and completely excise the endometrial implant with restoration of intestinal continuity.

The management and techniques concerning the surgical treatment of ovarian and ureteral endometriosis are extensively discussed in the appropriate gynecologic and urologic literature. This discussion on surgical therapy will concentrate on management of intestinal lesions (Figure 42-6).

Rectovaginal Endometriosis

Endometriosis of the cul-de-sac of Douglas that extends into the rectovaginal septum is the most common site of intestinal involvement and may require intestinal resection. These lesions are often deep fibrotic nodules that extend from the posterior vagina and anterior rectum to the uterosacral ligaments (Figure 42-7a–d). Small superficial lesions involving the intraperitoneal rectum may be vaporized with the CO_2 laser or electrocautery. When using either technique, it is critical to initially outline the lesion to be removed to ensure complete extirpation as distortion of the planes, and tissue can otherwise make it difficult to assess the completeness of excision. Cutting current as opposed to coagulating current is preferred. The former technique minimizes carbonization

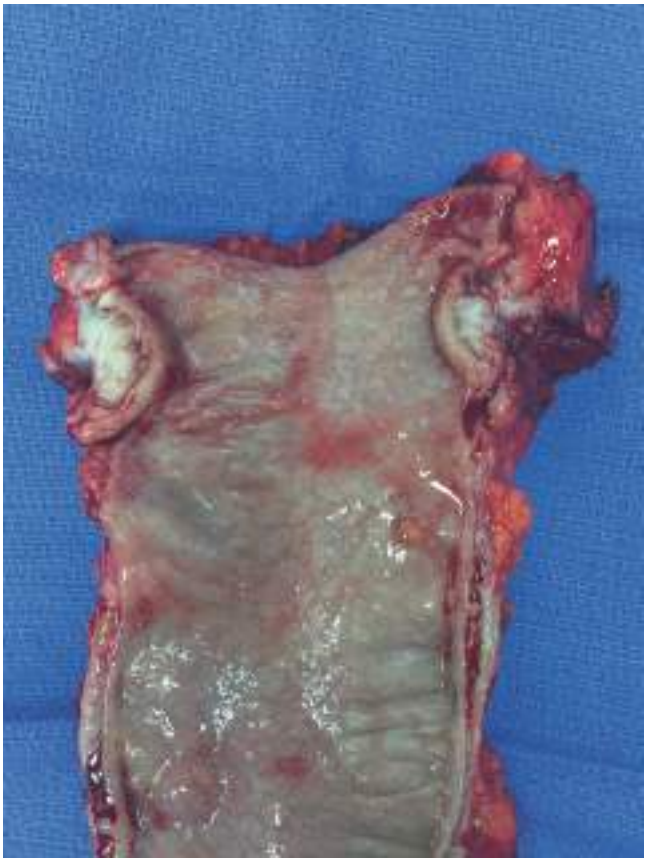

FIGURE 42-6. Opened specimen demonstrating the endometrial implant into the bowel wall.

that can make it challenging to recognize when an adequate depth has been achieved by the appearance of normal tissue. After the lesion is removed, the bowel wall is carefully assessed. Since most of these superficial lesions can be removed without entering the mucosa, the defects can be closed with interrupted transversely placed Lembert stitches.

The technique of removing superficial lesions is modified somewhat when it is performed laparoscopically. It is termed "shaving" and consists of meticulous removal of the lesion without entering the rectal mucosa. The endometriotic nodule is carefully dissected from the bowel wall, and any exposed mucosa is carefully sutured close. A series by Donnez and Squifflet of 500 patients undergoing "shaving" reported a 1.4% rate of rectal perforation and a recurrence rate of 7%. They felt that this superficial resection resulted in better postoperative intestinal function as opposed to segmental resection [63].

Surgical treatment of the deeper lesions is more controversial. Removal of the rectosigmoid with reanastomosis is technically demanding and should be performed by skilled intestinal surgeons to minimize complications in these young patients. As experience has grown, there has been a shift to more aggressive therapy, usually in conjunction with gynecologists who remove endometrial deposits on the ovaries and fallopian tubes. Medical treatment has not proven adequate for these infiltrating lesions, so it is no surprise that castration alone has also proven ineffective [64]. Many of these women suffer from chronic pain or partial colonic obstructive symptoms following bilateral salpingo-oophorectomy when the endometrial implant is not resected. As a result, excision of the implant either with a disk of rectal wall (Figure 42-8) or a formal anterior resection is recommended for women with symptoms related to the endometriosis. Both procedures can occasionally be performed laparoscopically if the endometriosis is completely removed. Unfortunately, laparoscopy often misses lesions that are not visually apparent and discernible only by palpation. It should be noted, however, that for severe disease, laparoscopic ablation, when possible, had similar crude pregnancy rates in comparison to laparotomy, and both techniques were clearly superior to medical management alone [65].

Indeed, the most appropriate surgical therapy for infertility complicating severe endometriosis is unknown. There are no randomized controlled trials demonstrating an improvement in fertility after segmental bowel resection. However, an observational study by Stepniewska and colleagues comparing a group of patients undergoing segmental bowel resection, with a group of patients having resection of endometriosis without a bowel resection, revealed an improved pregnancy rate when patients underwent resection [66]. Proponents of bowel resection also note the decrease in recurrence with bowel resection for severe endometriosis compared to more conservative options. Recurrent endometriosis has a significant negative impact in the pregnancy rate for women undergoing repeat surgery for endometriosis [67]. Achieving pregnancy was reduced almost 50% with recurrent endometriosis, and in vitro fertilization may be considered instead of another surgery for recurrent disease.

The infiltrating nodular endometrial implants involving the rectovaginal portion of the cul-de-sac often invade both the vagina and rectum (Figure 42-7a–d). Since removal of the implant will require resection of a portion of the rectal wall, dissection of the lesion from the vagina allows for en bloc removal of the lesion with the rectal wall. There is often no discernible plane between these lesions and the walls of the rectum or vagina. Care must be taken to avoid penetration of the vaginal wall with possible injury to the cervix, especially in women desiring eventual pregnancy. Often it is advantageous to mobilize the rectum in the posterior and lateral tissue planes to adequately define the lesion before attempting the anterior dissection. Blunt dissection of the rectovaginal plane below the area of involvement may help clarify the distorted anatomy and avoid inadvertent entry into the bowel lumen. After careful dissection of the lesion from the vagina, the normal rectovaginal plane is reached, and the fixed, hard mass may suddenly become mobile and amenable to resection.

Disk excision of the anterior rectal wall, by either laparoscopic or open technique, is performed for single lesions

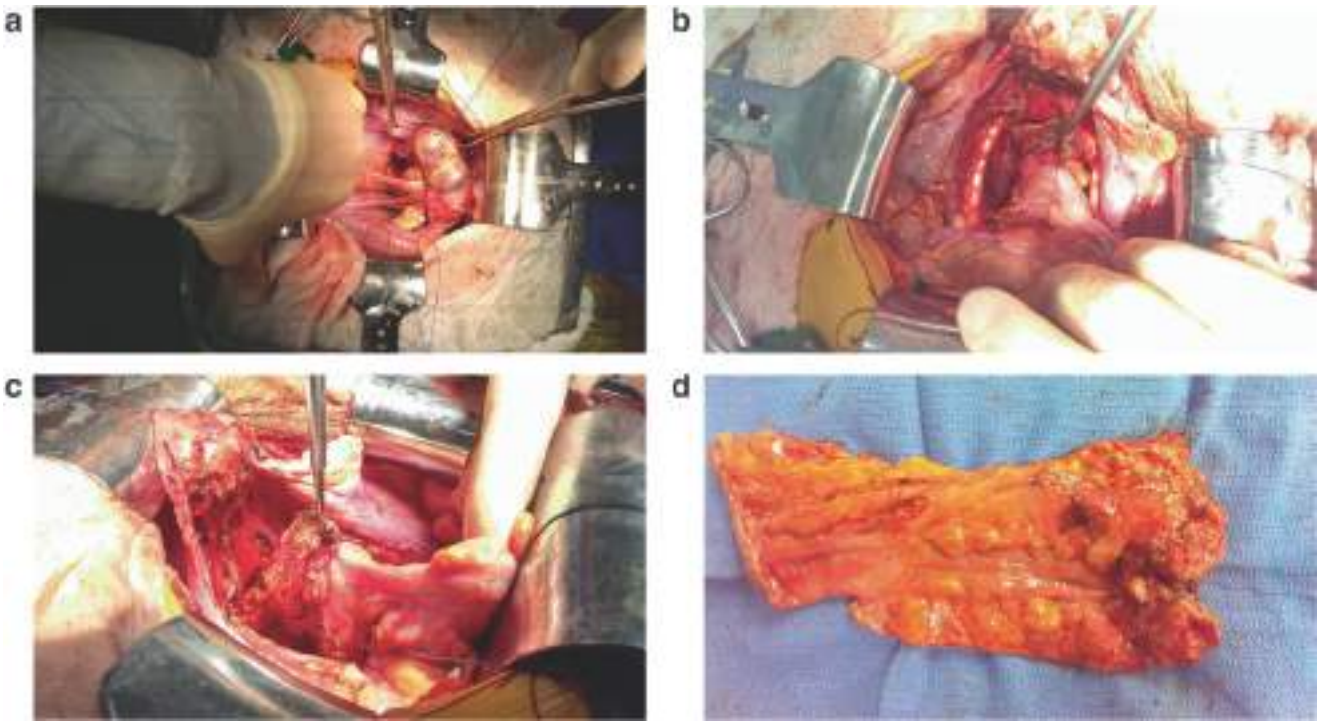

FIGURE 42-7. (**a**) Demonstrates the view of the endometrial implants obliterating the pouch of Douglas and an associated large endometrioma on the left ovary at the start of the procedure; (**b**) the large nodule of endometriosis has been dissected from the ureters and posterior vagina (note the lighted ureteral catheters that facilitate the dissection); (**c**) demonstrates visualization of the normal fat within the rectovaginal plane after fully dissecting cul-de-sac of Douglas and mobilizing the lesion rostrally out of the pelvis to allow resection; (**d**) demonstrates sectioning of the specimen to show the typical appearance of an endometrioma after hormonal therapy which induces diminished vascularity of the lesion.

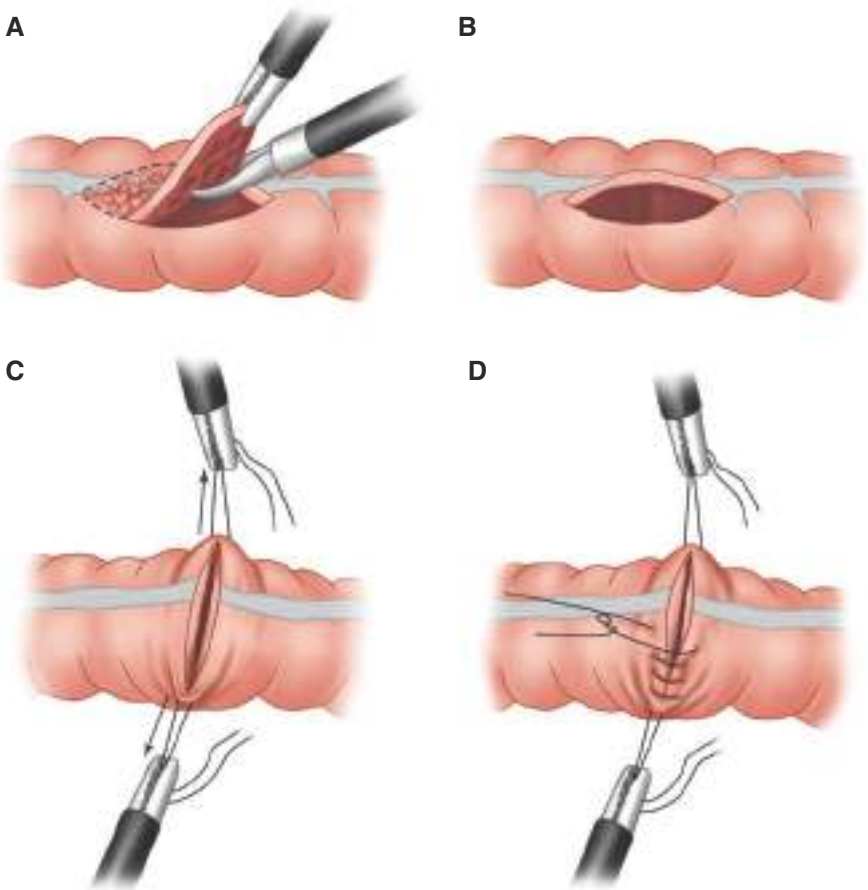
FIGURE 42-8. (**a**)–(**d**) Disk excision of an endometrial implant.



usually less than 3 cm in diameter. Contraindications to disk excision performed laparoscopically include sigmoid involvement; bowel stenosis, more than 50% circumference involvement; and multicentric disease [68]. After marking the lesions circumferentially with electrocautery, stay sutures are placed on either side of the endometrial implant. Full-thickness bowel wall excision is then performed with the cutting current electrocautery. Interrupted transverse absorbable sutures are subsequently placed to close the resulting defect. When performing the disk excision laparoscopically, the technique can be very similar to open surgery or may be done using a transanal stapler. An initial "shaving" may be performed to debulk the lesion. After placing a guide suture at the level of the lesion, a circular stapler is deployed, and the bowel lesion is sandwiched in the groove anteriorly between the stapler and the anvil by pulling gently on the guide suture. A full-thickness, partial circumference of the bowel wall is excised with the firing of the stapler [69]. The major complication of this laparoscopic technique is bleeding with significant bleeding requiring blood transfusion in about 10% of patients in two series [70, 71].

Segmental resection of the rectosigmoid is performed for larger lesions or when neoplasia is a concern. Margins are to grossly normal colon, and unless there are multiple lesions, a large colonic resection is not required. High ligation of the sigmoid vessels is also unnecessary, and the anastomosis may be either hand-sewn or stapled. When resection is performed laparoscopically, the involved segment may be removed by extending one of the port sites. Nezhat and Pennington have described a technique of prolapsing the lesion outside the anus for resection [72]. Redwine has described a transvaginal approach for specimen removal [73]. Open or laparoscopic excision of these deeply infiltrating rectovaginal lesions is very technically demanding. The lack of discernible tissue planes, the intimate association of the rectum and vagina, and the frequent occurrence of distal infiltration of endometriosis down to the mid- to lower rectum make laparoscopic resection possible only by surgeons very experienced in complex intestinal laparoscopy. A series by Senagore had eighteen patients with stage 4 endometriosis treated by laparoscopic intestinal resection. While they concluded that laparoscopic resection was technically possible, complications included a ureteral injury and an anastomotic leak requiring an ileostomy for diversion [74]. Even in the hands of experienced laparoscopists, rectovaginal fistula requiring ileostomy has been reported to occur following these resections [75]. Proctoscopic insufflation to assess for leak is practiced routinely by the authors with all rectal anastomoses, whether performed open or laparoscopically.

Small Bowel and Appendiceal Endometriosis

While endometriosis involving the small bowel or appendix is much less common than rectosigmoid disease, careful inspection of these organs is critical in patients with advanced endometriosis to ensure complete removal of all gross disease and to minimize recurrence. Superficial small bowel implants may be treated with sharp excision, electrocautery, or the laser, as described above. Deeper implants may require small bowel resection and, if within 5 cm of the ileocecal valve, may need an ileocecectomy. Appendiceal endometriosis is treated with appendectomy. Occasionally, a surgeon will encounter a patient with an endometrial implant while operating for another condition. While the lesion may exhibit a classic visual appearance consistent with endometriosis, a biopsy to confirm the diagnosis and exclude malignancy is important. Several studies have suggested that few patients with small asymptomatic endometrial implants of the appendix will become symptomatic, but no study has yet defined the natural history of these lesions. As a result, for those patients with asymptomatic endometriosis, observation is probably sufficient, but hormone replacement therapy should be avoided.

Results After Surgical Therapy

Recurrence of endometriosis after surgical excision is difficult to assess because of a wide variability in the operative approach to endometriosis by various authors and the obvious need for postoperative laparoscopy to document asymptomatic recurrence. While there are no long-term prospective studies to date, the larger studies suggest a histologically confirmed rate of recurrent endometriosis of approximately 19% [76]. Gauging the response to surgery by the resolution of preoperative pelvic pain or infertility is easier to measure. The largest series of intestinal resections for advanced intestinal endometriosis by Bailey et al. found that 86% of patients had complete or near complete relief of their preoperative pelvic pain. In addition, a 50% crude pregnancy rate was achieved which was comparable with rates found when treating much lower stages of disease [77]. These results in over 130 cases with a median follow-up of 5 years were achieved with minimal morbidity, no anastomotic leaks, and no documented instance of recurrent colorectal endometriosis. Laparoscopic series of intestinal resections performed for extensive endometriosis have reported similar pregnancy rates albeit with smaller number of cases, higher complication rates, and shorter long-term follow-up.

Combined Medical and Surgical Therapy

Both medical and surgical therapies for endometriosis have potential reasons why each treatment alone may not be successful in eradicating the disease and minimizing recurrence. Medical therapy affects endometrial implants variably, and there is a high instance of recurrence following cessation of therapy. Surgery may not remove microscopic disease, and postsurgical adhesions may contribute to postoperative

pelvic pain and infertility. For these reasons, combination therapy either pre- or postoperatively has been used for several years, although with a paucity of prospective randomized data to conclusively prove long-term improvement in recurrence and symptoms.

The rationale for preoperative medical therapy conducted over a period of 3–6 months is principally to decrease the inflammation and possibly the size of the endometrial implants. Presumably, this therapy will allow easier excision with diminished adhesion formation. Medical therapy may also reduce the vascularity of endometrial implants. A prospective study by Buttram in 1985 revealed an improvement in pregnancy rates with 6 months of danazol given preoperatively with all stages of endometriosis [78]. The optimal length of therapy and long-term (and not just delayed) recurrence rates must still be elucidated. Postoperative treatment with danazol and oral contraceptive pills has not been shown to have durability, and the initial excitement over improved recurrence rates at 12 months has not been duplicated after longer follow-ups. Our current use of combined therapy is a 3–6-month course of a GnRH-a prior to definitive surgery.

Conclusion

The diagnosis and management of intestinal endometriosis have evolved tremendously over the last 20 years with the widespread availability of laparoscopy and a clear understanding of the necessity to remove all endometrial implants in symptomatic patients. With the advent of stapling devices that facilitate low pelvic anastomoses, the intestinal surgeon should be able to resect the endometrial implants and restore bowel continuity in virtually all patients with minimal morbidity and preserved fertility, when desired. Further improvements in outcomes will probably not occur until a better understanding of the precise etiology and growth of the endometrial implant is discovered.

Trauma of the Colon, Rectum, and Anus

W. Brian Perry

Key Concepts

- Primary repair is the treatment of choice for all nondestructive colonic injuries.
- Resection and anastomosis is the treatment of choice for most destructive colonic injuries.
- Diversion should be considered in patients undergoing damage-control laparotomy or who have significant pre-injury comorbidities or significant hemodynamic derangement.
- Primary repair is appropriate for accessible rectal injuries.
- Diversion alone without direct repair is sufficient to treat isolated extraperitoneal rectal injuries.
- Presacral drainage and distal washout are no longer recommended for rectal injuries.
- Anal injuries are often amenable to delayed reconstruction.

Introduction

The management of the injured colon has evolved considerably over the past century and a half. Accumulated wartime experience demonstrates that mortality fell from >90% during the American Civil War to <10% in Iraq and Afghanistan (Figure 43-1). Many factors have led to this improvement, including better transport time (Figure 43-2), resuscitation, transfusion, antibiotics, and improved surgical techniques. Civilian experience paralleled this and further refined current treatment algorithms. Multiple well-done studies confirm the safety of primary repair for most injuries although care must still be used in damage-control situations. Extraperitoneal rectal trauma is typically managed by proximal diversion; the utility of routine distal washout and presacral drainage has recently been shown to be of no benefit. Anal trauma lends itself to delayed reconstruction in many cases.

Colonic Trauma

Epidemiology

Most colonic injuries are due to penetrating abdominal trauma. Gunshot wounds are the most common cause (Figure 43-3), followed by stabbing and impalement. The colon is the second most commonly injured organ in penetrating abdominal trauma, behind only the small bowel [1].

Blunt colonic injuries are rare, accounting for <10% of lesions found at laparotomy for blunt trauma, primarily from motor vehicle crashes. Lap belt use, especially without concomitant shoulder harness, increases the risk of visceral injury (Figure 43-4). Most blunt injuries are minor—small hematomas or serosal tears; more serious injuries typically involve devascularization due to avulsion from the adjacent mesentery (Figure 43-5). "Blowout" injuries due to a blast overpressure wave are occasionally seen in victims of explosions, sometimes without external signs of abdominal trauma [2].

The American Association for the Surgery of Trauma has published a grading scale for colonic injuries (Table 43-1) [3].

Diagnosis

Prompt abdominal exploration accurately finds the majority of colonic injuries in penetrating anterior abdominal trauma. It is important to remember that the diaphragm may rise as high as the nipple line or the bottom of the scapula at full exhalation. Wounds to the flank or back can cause colonic trauma in the absence of initial peritoneal irritation or hemodynamic instability; computed tomography (CT) with triple contrast is useful for delineating such injuries, with 90% sensitivity and 96% specificity [4].

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_43

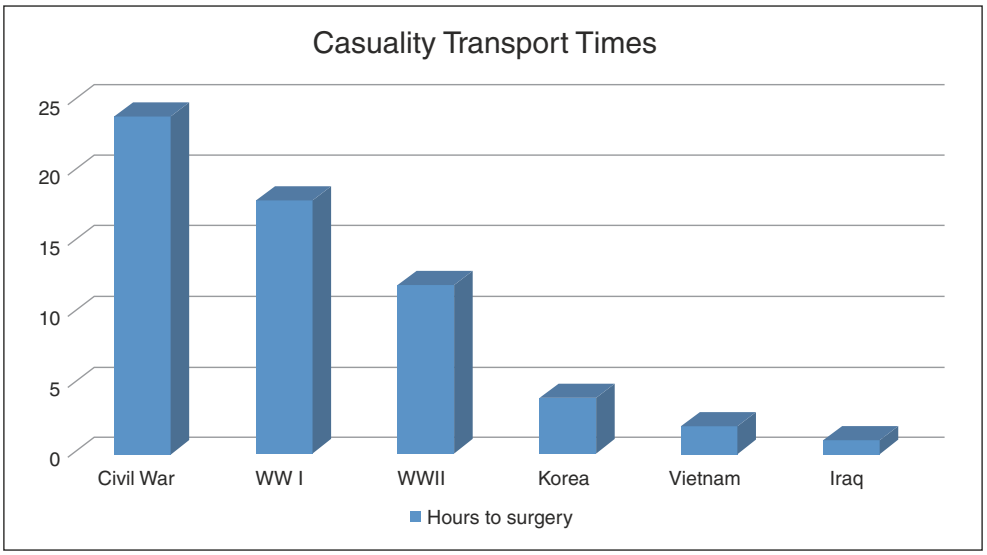

FIGURE 43-1. Time from injury to surgical management in American wars.

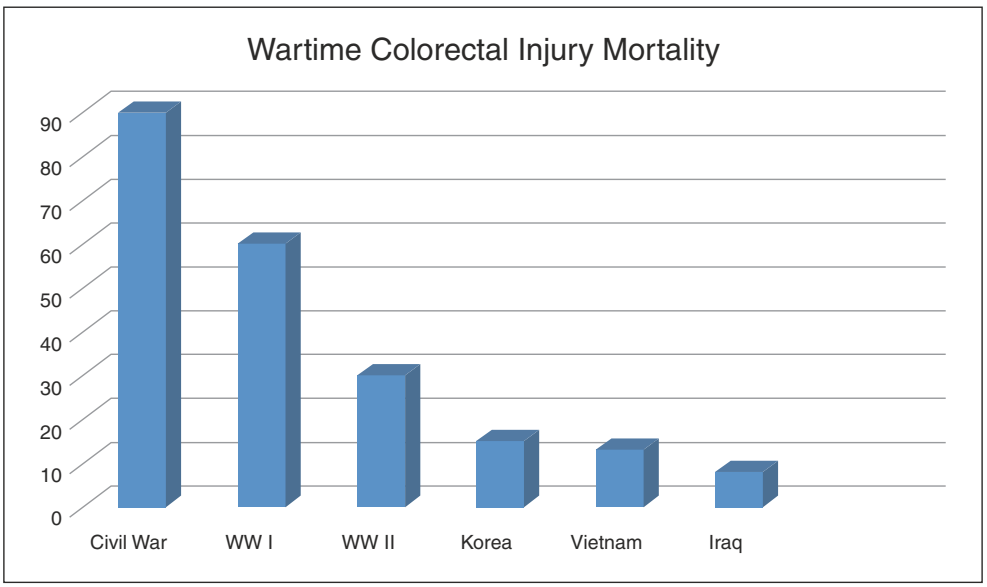

FIGURE 43-2. Mortality rate of penetrating colorectal trauma in American wars.

FIGURE 43-3. Destructive gunshot wound to the colon.

Accurate diagnosis of colonic injury is more difficult for a bluntly injured patient, whose examination is often compromised by concomitant brain or spinal cord trauma. Triple-contrast CT is the examination of choice in such instances. Organ-specific diagnosis is not always possible (or necessary). The presence of free intraperitoneal air mandates exploration for perforated hollow viscus. Free intraperitoneal fluid in the absence of solid organ injury should significantly raise the index of suspicion for bowel injury (Figure 43-6).

Diagnostic peritoneal lavage is rarely used in the contemporary evaluation of patients with suspected colonic injury. It may be useful in the austere environment where CT is unavailable or in the patient who cannot be safely transported due to profound instability or who is in the operating

TABLE 43-1. American Association for the Surgery of Trauma Colonic Injury Scale

Grade	Injury description
I	(a) Contusion or hematoma without devascularization
	(b) Partial-thickness laceration
II	Laceration ≤50% of circumference
III	Laceration >50% of circumference
IV	Transection of the colon
V	Transection of the colon with segmental tissue loss

theater for a prolonged period for other injuries. The presence of gross blood or fecal matter on aspiration or >500 white cells/>100,000 red cells on lavage analysis is highly suggestive of significant intra-abdominal injury and should prompt exploration [5].

Laparoscopy has little role in evaluating the most penetrating anterior abdominal trauma, but may be useful in stable patients with back, flank, or pelvic wounds.

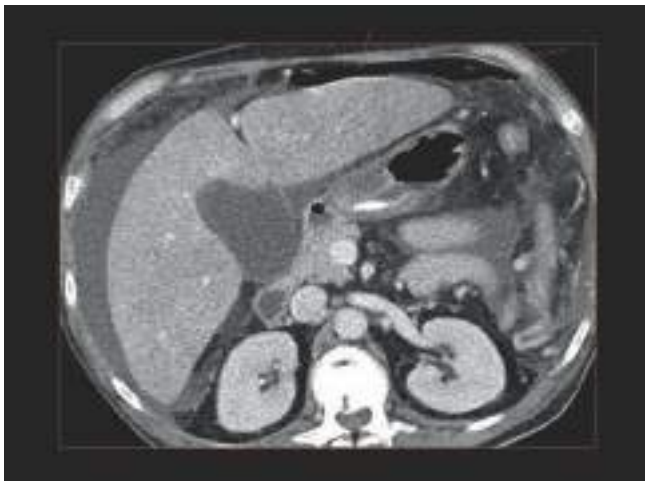

FIGURE 43-6. Computed tomography scan of a blunt trauma patient showing free air and free fluid in the absence of solid organ injury. Exploration revealed a cecal injury.

History of Military Colonic Injury Management

The accumulated experience of military surgeons has been critical to the evolution of current civilian colonic injury management [6].

With only a few exceptions, laparotomy was considered futile in the management of penetrating abdominal injury until the early stages of World War I. Wallace, in defiance of accepted doctrine, insisted that hemorrhage was killing soldiers and advocated for prompt laparotomy [7]. This approach was accepted by June 1915 and was augmented by more expeditious evacuation of the wounded (Figure 43-7); mortality decreased from 87 to 40% by Armistice Day [8].

Ogilvie reported his experience in the North African Campaign in World War II, recommending colostomy, although his data did not clearly support it. Mortality ranged from 44% for simple suture repair to 100% for resection and anastomosis [9]. Multiple authors have failed to find the "colostomy or court-martial" edict, but the US Army Surgeon General Circular clearly mandated colostomy for penetrating injuries [10]. Regardless of the true impact of this specifically, mortality declined further to around 30%.

Mortality continued to improve through the Korean War, but primary repair remained rare. During the Vietnam War, there were multiple series showing the feasibility of resection and anastomosis for right-sided injuries; left colon and rectal injuries were still treated with colostomy. Mortality fell to just over 13% [6]. Recent experiences in Iraq and Afghanistan with primary repair or resection and anastomosis showed some success in selected cases. However, intra-abdominal repair failure was >15% in one review, typically in patients with other injuries; such failure complicated subsequent continuity restoration in 75% of patients. This experience reinforces the concern for primary repair in patients who experience significant hemodynamic derangement pre- or intraoperatively. Despite the challenges of devastating injuries, mortality fell again to 8% [11, 12].

Current Operative Management

Civilian experience has paralleled the military experience. While surgeons returning from World War II adopted mandatory colostomy, this was questioned as early as the 1950s. Woodhall and Ochsner's case series showed success in highly selected cases of primary repair, with a mortality rate of 9% [13]. Stone and Fabian's landmark 1979 study randomized patients with penetrating colonic trauma to primary repair vs. mandatory colostomy, with significant exclusion criteria for devastating injuries, treatment delay, or extensive blood loss. With the selected cohort, repair proved to be superior to colostomy [14]. Subsequent studies have expanded on this seminal work.

Accumulated high-quality data have conclusively shown the safety and efficacy of primary repair in patients with grade II injuries, even in the presence of risk factors such as hypotension, multiple transfusions, and gross spillage. Studies by Chappuis [15], Sasaki [16], and Gonzalez [17] together randomized more than 300 patients to primary repair or colostomy, finding fewer complications in the repair group (Table 43-2).

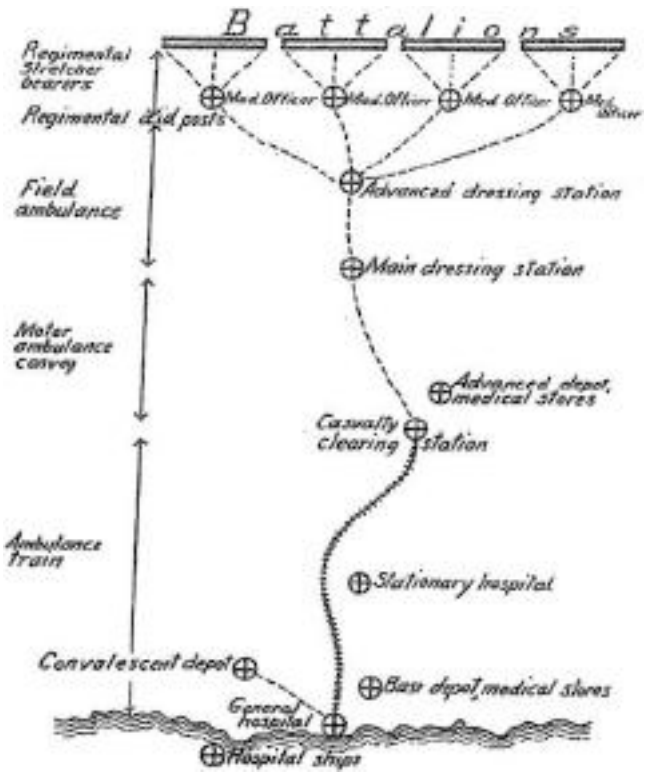

FIGURE 43-7. British Army system of casualty evacuation in World War I [7].

Grade III, IV, and V injuries require resection. Initially, primary anastomosis was reported to be successful in small retrospective series, with a leak rate of <3%. However, subsequent nonrandomized prospective single-institution reports called into question the universal applicability of this approach. Cornwell found two fatal anastomotic leaks in 25 patients [18]. Stewart et al. reported an overall leak rate of 14% but on subgroup analysis of patients needing >6 units of blood found the leak rate increased to 33% [19]. Murray found similar abdominal sepsis rates whether anastomosis or diversion was used, but also found higher leak rates in the more severely injured [20]. It is interesting that based upon this data, there is little advocacy for colonic repair/resection with protective diversion by loop ileostomy in select cases to minimize the impact of stoma reversal surgery.

To address these concerns, the American Association for the Surgery of Trauma (AAST) conducted a multicenter randomized prospective trial of diversion vs. resection and anastomosis for destructive colonic injuries. Colon-related mortality was 1.3%, all in the diversion group. Anastomotic leak rate was 6.6% with no deaths. Severe fecal contamination, transfusion of more than three units of blood, and inappropriate antibiotic selection were identified as risk factors for abdominal complications, up to 60% if all three were present. Shock on admission, delay of surgery, penetrating abdominal trauma index >25, and method of colon management (diversion vs. anastomosis) were not independent predictors of complications. The authors concluded that resection and anastomosis are the treatment of choice in all destructive colonic injuries regardless of severity of injury [21].

Sharpe et al. reported that adherence to a simplified management algorithm for penetrating colonic injuries reduces morbidity and mortality. In short, nondestructive injuries underwent primary repair without regard to underlying illness or patient condition. Destructive injuries had resection and anastomosis unless they had >6 unit transfusion requirement or significant pre-injury comorbidities. Protocol compliance was 90%; three-fourths of all the patients with destructive injuries avoided diversion. When compared to similar colonic injuries before the protocol was introduced,

TABLE 43-2. Randomized prospective trials of primary repair vs. diversion without exclusion criteria

	Primary repair		Colonic diversion	
Study	Number of patients	Rate of abdominal septic complications (%)	Number of patients	Rate of abdominal septic complications (%)
Chappuis [15]	28	14.3	28	17.9
Sasaki [16]	43	2.3	28	28.6
Gonzalez [17]	89	18	87	21
Total	160	13.1	143	21.7

those patients thus managed had fewer abscesses (18% vs. 27%) and colon-related mortality (1% vs. 5%). Suture line failure rates remained low (5% vs. 7%). They concluded that, with reasonable exclusions, destructive colonic injuries can be safely managed with resection and anastomosis [22].

Over the past two decades, the damage-control laparotomy (DCL) approach to devastating abdominal trauma significantly reduced morbidity and mortality. Abbreviated laparotomy and intensive ongoing resuscitation aim to avoid the lethal triad of coagulopathy, acidosis, and hypothermia [23]. The management of colonic injuries in these situations is evolving. Early in the DCL era, colostomy was considered mandatory. This eliminated the morbidity of intra-abdominal leak, but created other issues, especially during the reconstructive phase of patient care, as the presence of a stoma can make abdominal wall reconstruction problematic. Several authors reported their initial positive experience with selected repair or resection and delayed anastomosis after DCL, citing the potential ability to inspect the suture or staple line at subsequent operations [24–26]. Other series voice more caution in this patient population, especially when resection and anastomosis are required [27] or there is a persistent need for vasopressors to maintain stability (Table 43-3) [28]. Interestingly, the leak rate in studies where the authors touted the safety of delayed anastomosis was nearly identical to those who urged caution.

Sharpe and colleagues again analyzed their results using the previously described management algorithm in patients undergoing delayed anastomosis following DCL. Protocol adherence was only 55%. Adherence to the algorithm resulted in significantly lower rates of suture line failure (4% vs. 32%) and colon-related morbidity (22% vs. 58%). They were unable to identify other risk factors that would predict suture line failure [29]. Clearly additional multicenter trials are needed in this critically injured patient population.

Ciesla and Burch have developed an algorithm for the management of colonic injuries, utilizing the metabolic status of the patient, the location of the injury, the need for segmental resection, and the condition of the bowel wall at the time of repair. Taking into consideration the data presented, such an approach should lead to safe initial restoration of colonic continuity in 70–90% of injured patients (Figure 43-8) [30].

Technical Considerations

During the initial exploration for penetrating trauma, control of gross spillage with quick suturing or stapling should occur rapidly, as soon as exsanguinating hemorrhage is stopped. This needs not be definitive resection or repair. The colon needs to be fully mobilized above and below suspected injuries, with particular care paid to the flexures and rectosigmoid junction. In penetrating trauma, paracolic hematomas must be fully explored; this is less important for blunt injuries unless there are other signs of perforation such as soiling or retroperitoneal emphysema. In nearly all cases of penetrating colonic injury, the skin is left open, with planned delayed primary closure or secondary closure with a vacuum-assisted closure device.

Primary repair can be safely accomplished in a number of methods. There is little difference between single- and double-layered suture techniques [31]. Isolated injuries to the more capacious right colon may be amenable to elevation and application of a linear stapler (Figure 43-9). Perforations that are within a few centimeters of each other are best treated by removing the intervening bridge of tissue and performing a single repair (Figure 43-10).

Similarly, there is little difference between stapled and sutured anastomoses [32]. Adherence to the standard principles of no tension, good tissue approximation, and adequate blood supply is critical (Figure 43-11). There is typically no need for colonic lavage, even when a left-sided anastomosis is constructed. Ileocolostomy is associated with fewer leaks

TABLE 43-3. Delayed colonic anastomosis following damage-control laparotomy

Study	Number of patients with DCL and colonic injury (early deaths prior to re-exploration excluded)	Number of patients receiving primary repair or delayed anastomosis without proximal diversion (%)	Number of colonic leaks (%)	Notes
Miller [24]	19	11 (58%)	0 (0%)	
Georgoff [25]	61	28 (46%)	4 (14%)	Two additional leaks in patients with proximal diversion
Kashuk [26]	29	21 (72%)	6 (28%)	Four leaks confirmed, two suspected
Weinberg [27]	56	49 (88%)	6 (12%)	
Fischer [28]	68	41 (60%)	7 (17%)	Leak rate 50% in patients with persistent vasopressor requirements
Sharpe [29]	149	74 (50%)	9 (12%)	Leak rate 32% when established protocol not followed

DCL damage-control laparotomy

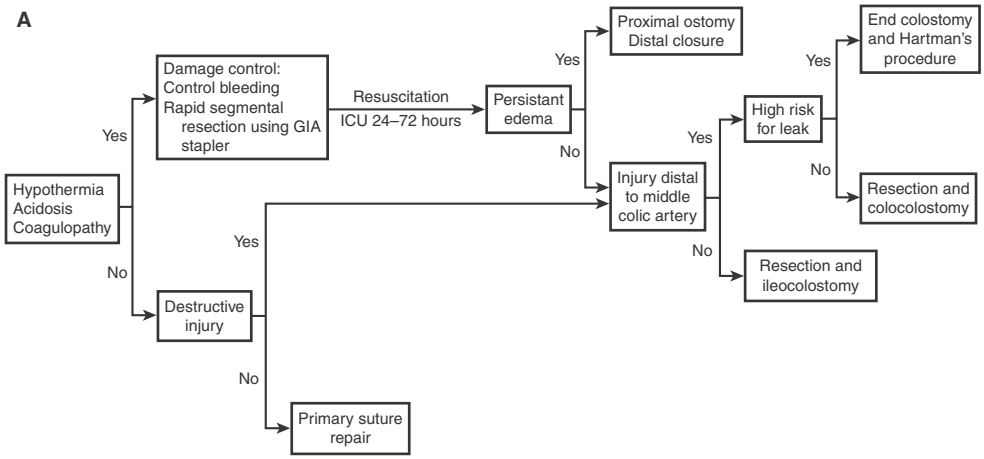

FIGURE 43-8. Algorithm for colonic injury management [30].

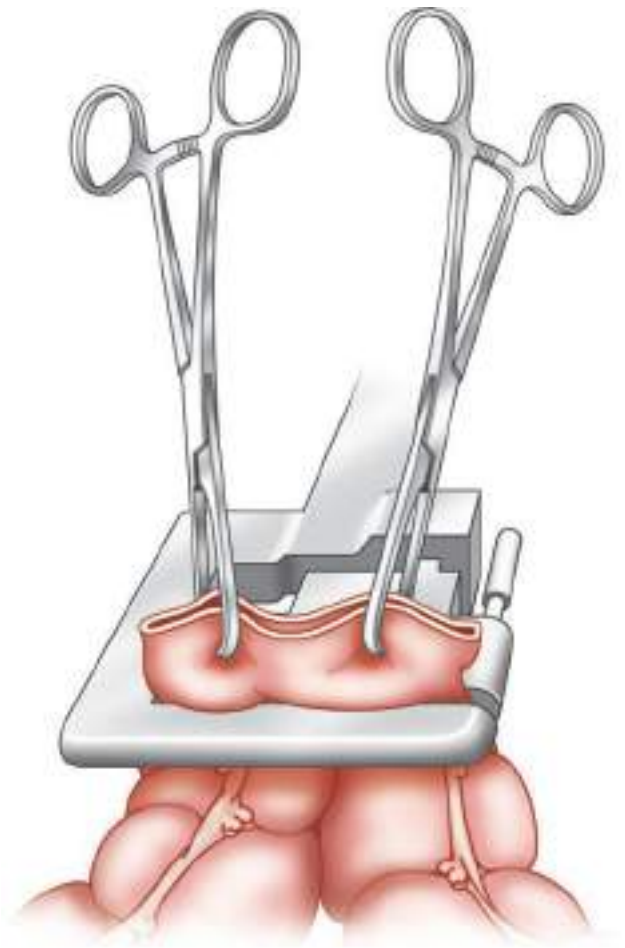

FIGURE 43-9. Grade II colonic injuries can be elevated and closed with a linear stapler, with care taken not to cause luminal narrowing.

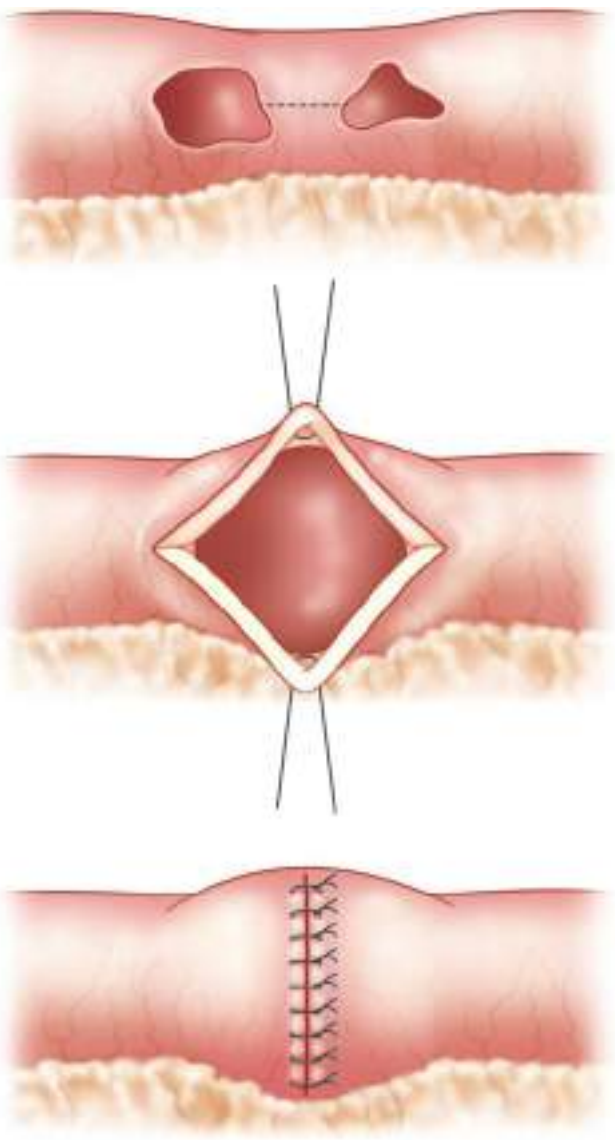

FIGURE 43-10. The intervening bridge of tissue between two close perforations can be removed and the resulting single defect can be closed transversely.

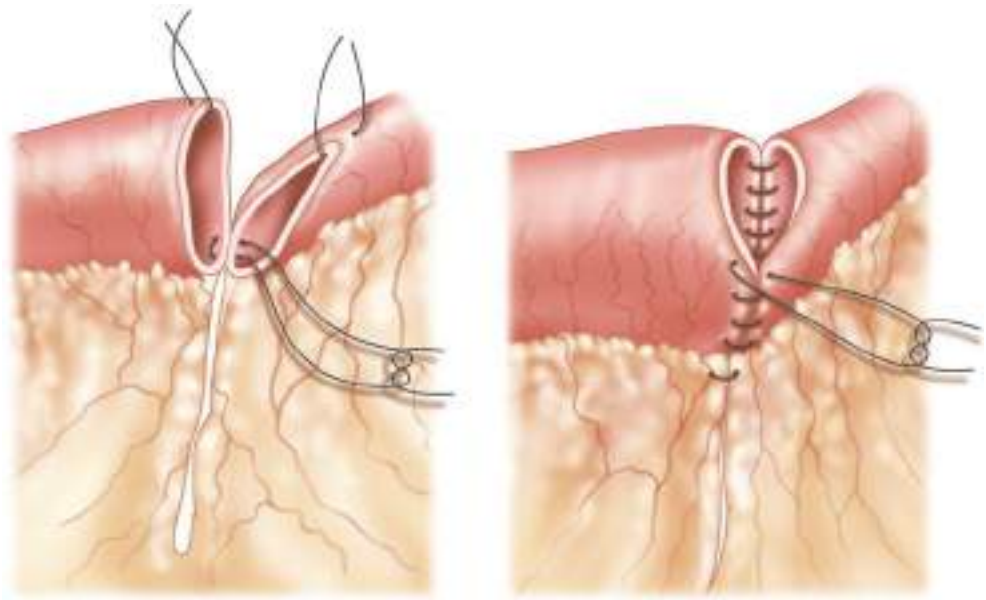

FIGURE 43-11. Single-layer hand-sewn colocolostomy.

FIGURE 43-12. Temporary abdominal closure can be accomplished with towels, a chest tube, and adhesive drapes if vacuum-assisted wound closure materials are not available.

than colocolostomy, making right hemicolectomy the procedure of choice for ascending colon and cecal injuries; there is little another difference between right- and left-sided colonic injuries.

Primary anastomosis with proximal fecal diversion with a loop colostomy or ileostomy has proven efficacious in elective resections for rectal cancer or in urgent resections for diverticulitis. The data are less clear in the setting of trauma. If chosen, loop ileostomy is easier to construct and take down. Loop transverse colostomies should be avoided when possible as they tend to be difficult to adequately pouch and tend to prolapse.

Should DCL be necessary, the colon can be left in discontinuity at the initial exploration; creation of a colostomy is not necessary. The abdomen is temporarily closed over nonstick plastic drapes, and a suction method of collecting fluid is fashioned (Figure 43-12). Once restoration of normothermia and correction of acidosis and coagulopathy are accomplished, the patient is returned to the operating room for further treatment based on the factors discussed above. When possible, the fascial edges should not be allowed to retract causing loss of domain (Figure 43-13). Temporary bridging mesh, either prosthetic or biologic, can be serially tightened at subsequent surgeries, facilitating eventual primary fascial closure (Figure 43-14).

FIGURE 43-13. Loss of domain with subsequent skin grafting becomes necessary if the fascial edges are allowed to retract.

FIGURE 43-14. Serial tightening of temporary bridging mesh allows for fascial closure after damage-control laparotomy.

Rectal and Anal Trauma

Epidemiology

The majority of rectal injuries are from penetrating pelvic trauma, more than 80% from gunshot wounds in most series. Accidental or intentional impalement, iatrogenic injuries, and rectal foreign bodies account for the rest. The rectum may be perforated in blunt force trauma, typically by the intrusion of sharp bony edges from severe pelvic fractures (Figure 43-15); direct blunt rectal injury in the absence of pelvic fracture is very rare [33, 34]. The anus may be injured in a similar manner. This chapter does not cover obstetrical anal injury.

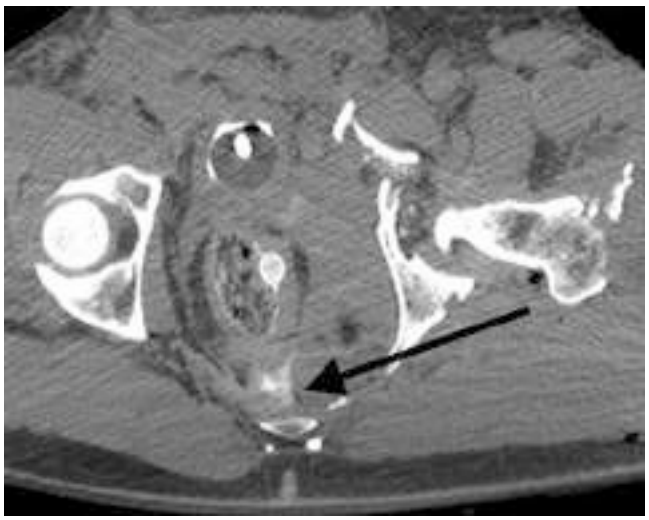

FIGURE 43-15. Computed tomography showing rectal injury with contrast extravasation from a severe pelvic fracture.

TABLE 43-4. American Association for the Surgery of Trauma Rectal Injury Scale

Grade	Injury description
I	(a) Contusion or hematoma without devascularization
	(b) Partial-thickness laceration
II	Laceration ≤50% of circumference
III	Laceration >50% of circumference
IV	Full-thickness laceration with extension into the perineum
V	Devascularized segment

The American Association for the Surgery of Trauma has published a grading scale for rectal injuries (Table 43-4) [3].

Diagnosis

The presence of gross blood on digital rectal examination is highly suggestive of rectal injury and mandates further evaluation. Sigmoidoscopy, either rigid or flexible, should be quickly performed, with an expected diagnostic accuracy of 80–95% [35]. Genitourinary injuries accompany up to one-third of rectal injuries; CT scan with bladder and rectal contrast is indicated for preoperative planning in stable patients [36]. Certain injury patterns, particularly transpelvic or buttock gunshot wounds, need thorough investigation even in the absence of rectal blood. Most anal injuries are obvious on external inspection, although occult sphincter disruption may occasionally occur.

History of Military Anorectal Injury Management

Mortality from penetrating battlefield rectal trauma was greater than 90% in World War I and still exceeded 60% early in World War II. With the edict mandating colostomy and the introduction of presacral drainage, mortality fell to <30% by the end of the war. The addition of distal rectal washout and improvements in casualty evacuation, resuscitation, and antibiotics were credited with mortality rates falling to <15% in Korea and Vietnam [6]. This leads to the classic "three Ds" of rectal injury management—diversion, drainage, and distal washout [37]. Recent reports from Iraq and Afghanistan showed overall mortality to be less than 8%. Soldiers with rectal injuries were more likely to have head, neck, or extremity injuries as compared to those with colonic injuries, largely due to the efficacy of modern body armor, which covers most of the abdomen and thorax [12].

Anal injuries in earlier conflicts were usually reported in series with rectal injuries, stressing prompt diagnosis, adequate debridement, and mandatory colostomy [38]. McCune noted in 11 of 41 patients that some function could be regained with a series of guided gluteal and sphincter exercises [39]. One of the signature injuries in the Iraq and Afghanistan conflicts is complex pelviperineal trauma caused by ground-level improvised explosive devices [40]. Glasgow analyzed 46 combatants with anal canal or sphincter injuries, the largest such series to date. Nearly 80% underwent fecal diversion; acute sphincter reconstruction was attempted in about 25%, but this did not influence eventual restoration of intestinal continuity. Of the patients available for long-term follow-up, 30% had a permanent colostomy, which was strongly predicted by the presence of concurrent intra-abdominal injury, hypogastric artery ligation, or pelvic fracture [41].

Current Management and Technical Considerations

While not specifically addressed in separate studies, there is consensus that intraperitoneal rectal injuries can be treated as colonic injuries.

Each of the "three Ds" has been challenged in the modern civilian management of rectal trauma. Several studies have shown that small perforations can be safely closed without proximal diversion, either transanally if low enough or from an abdominal approach if minimal rectal mobilization is required. Inaccessible injuries are still best managed by proximal diversion; extensive rectal mobilization is not recommended. If perforations cannot be safely closed, proximal diversion is still required [34, 42]. A recent study from South Africa demonstrated that laparoscopy is useful for evaluating stable patients without peritoneal signs who are suspected of having an isolated extraperitoneal rectal injury. If there is no evidence of intraperitoneal injury, then a loop sigmoid colostomy may be easily constructed [43]. Resection with stapling of the rectum distally and end colostomy is required for destructive injuries. Abdominoperineal resection is occasionally necessary in devastating open pelvic fracture [44]. These patients typically need damage-control surgery with pelvic packing; ligation or angioembolization of the hypogastric arteries may be necessary (Figure 43-16a, b).

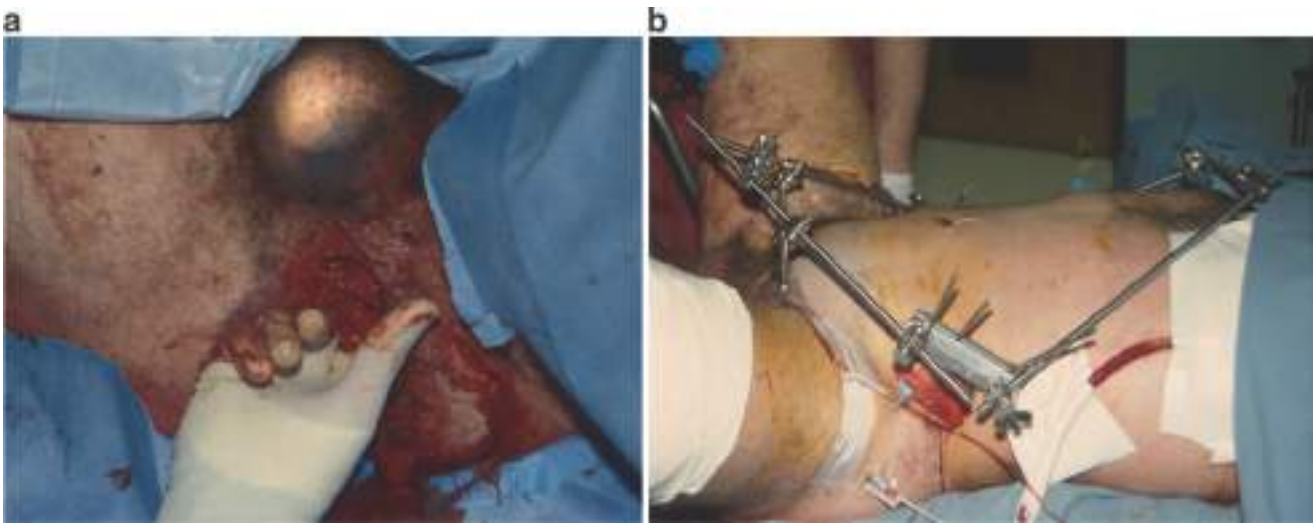

FIGURE 43-16. Severe open pelvic fracture with rectal injury. (**a**) Open perineal wound with exsanguinating hemorrhage which required expedient packing and angioembolization. (**b**) Note positioning of external pelvic fixation to allow laparotomy. Attention to colostomy siting is important to decrease the risk of pin tract infections.

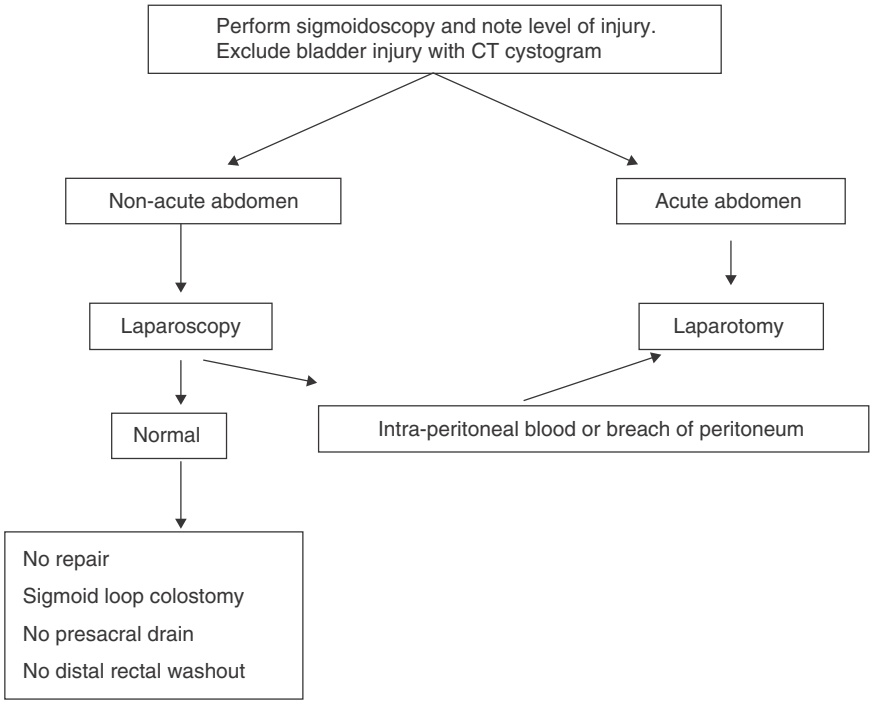

FIGURE 43-17. Algorithm for rectal injury management [43].

Routine presacral drainage has been examined in several studies, including one randomized prospective trial. The extensive disruption of normal tissue planes required showed no benefit. Presacral drainage is no longer recommended [34, 43, 45]. Closed suction drains placed in the pelvis after mobilization and repair of mid-rectal injuries at laparotomy may still be useful, as clean tissue planes are not violated.

Similarly, distal washout of the rectum has not been shown to have any benefit in the routine management of penetrating civilian rectal trauma. Liquefaction of the stool column with subsequent spread into the pelvic spaces has been touted as a potential negative result of vigorous rectal irrigation in traumatic injuries [34].

Nichol and Navsaria have developed an algorithm for the management of penetrating civilian rectal injuries, taking into account recent accumulated experience (Figure 43-17). At laparotomy, small visualized wounds can be primarily repaired, while destructive injuries will require resection and end colostomy.

Anal injuries can be repaired primarily in relatively clean wounds in stable patients; routine proximal fecal diversion is not required. For destructive perineal wounds, appropriate debridement and proximal diversion are paramount. A vacuum-assisted wound closure device can be used on the perineum for short periods while serial debridement is ongoing. Marking of the ends of the sphincters with nonabsorbable suture can aid later reconstruction. It is imperative to investigate the genitourinary tract, as many patients will have combined injuries (Figure 43-18a–e).

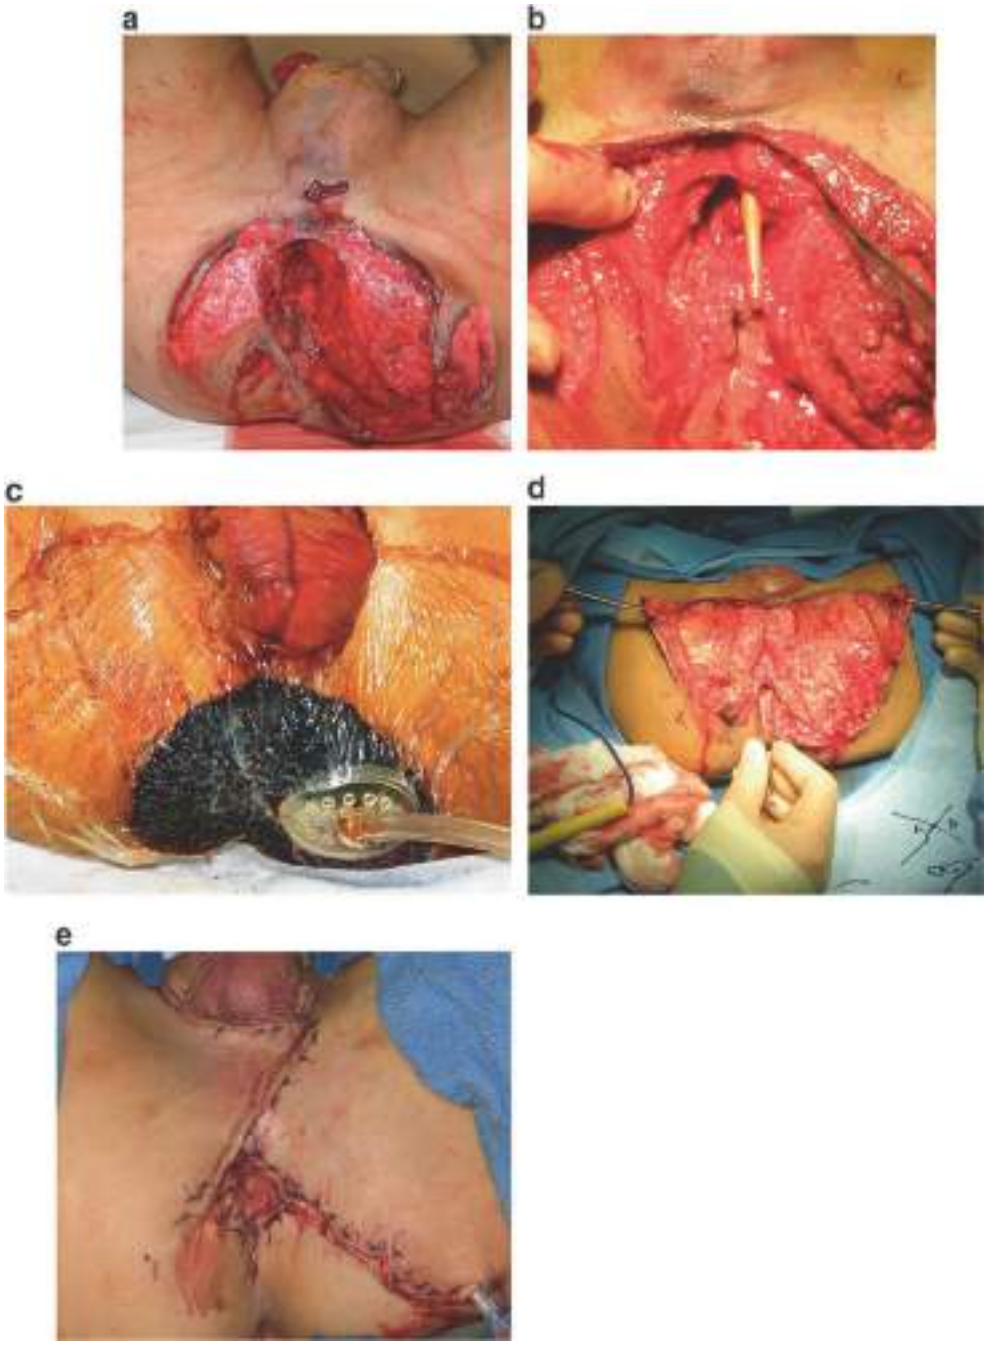

FIGURE 43-18. Destructive perineal and anal injury. (**a**) Mortar fragment entered the right hemiscrotum and exited the perineum, causing a massive injury. (**b**) Urethral transection was repaired through the perineum. (**c**) Serial debridements and vacuum-assisted wound closure changes created a healthy wound bed. (**d**) Flaps were constructed to facilitate closure. (**e**) After sphincteroplasty, the final wound closure. Colostomy was closed 6 weeks later and patient had excellent continence.

Inflammatory Bowel Disease: Pathobiology

Tara M. Connelly and Walter A. Koltun

Key Concepts

- The current theory on the etiology of inflammatory bowel disease is an exposure to an environmental factor of host or foreign origin in the individual with a genetic predisposition to dysregulated immunity.
- Over 150 genes and several hundred polymorphisms have been associated with the disease through genome-wide association studies (GWAS). Some are associated with CD, others with UC, and some with both diseases suggesting distinct but overlapping pathobiologies.
- The NOD2 gene, which is involved in bacterial recognition and response, was the first gene to be associated with the disease and is the most commonly associated gene.
- Defects in both innate and adaptive immunity have been demonstrated in murine models and human tissue from patients with the disease.
- Innate immunological processes involved in disease pathobiology include epithelial barrier function including tight junction integrity, autophagy, and pathogen recognition.
- Adaptive immunological processes involved in disease pathobiology include T cell activation, differentiation, and function.
- All major innate and adaptive immunological processes involved in both UC and CD have at least one associated gene known to be correlated with IBD through GWAS.

Introduction

Ulcerative colitis (UC) and Crohn's disease (CD) are the two broad subcategories of idiopathic, inflammatory bowel disease (IBD) first officially described in 1859 and 1932, respectively [1, 2]. They are relapsing, inflammatory conditions of the gastrointestinal tract with distinct yet overlapping clinical and pathological features due to the shared and yet disparate pathobiologies of each (Table 44-1). Their common characteristics are so pronounced particularly in Crohn's colitis and UC that prior to the hallmark paper formally differentiating the diseases written by Charles Wells in 1952, the two diagnoses were frequently but incorrectly thought to be a single illness [1].

Although the precise etiology of these two inflammatory bowel diseases is unknown, the current research model suggests that an environmental trigger causes disease in a host predisposed due to intrinsically impaired immunity [3–5]. Environmental factors suggested to play a role in either the cause or course of IBD include external agents (e.g., cigarette smoking, nonsteroidal anti-inflammatory drugs) or agents that are present within the host itself, namely, the commensal and pathogenic organisms comprising the intestinal microbiome. Some environmental factors such as prior appendectomy play a greater or lesser role in disease pathogenesis while others, such as smoking, have an opposite effect in the two diseases. Recently, using genetic techniques developed over the course of the Human Genome Project, significant genetic (allele) associations have been identified in both CD and UC. Although the majority of such IBD alleles are associated with both CD and UC, others are exclusive to one or the other disease. The combination of these host genetic factors with some environmental stimulus ultimately leads to an imbalance in the host immune system causing unregulated inflammation and compromise in the gut's mucosal integrity (Figure 44-1). The numerous and widely variable combinations of these host and environmental factors likely result in the many different features (or phenotypes) among individuals with either UC or CD.

Besides host immunologic predisposition, environmental factors, and the native microbiome, other theories of pathogenesis include exposure to noxious agents including pathogenic bacteria or viruses. Such theories both suggest a "triggering event" that precipitates IBD but also might "downregulate" the nascent immature immune system, as is suggested by the hygiene hypothesis (see below). Finally, IBD, besides being a dysregulated inflammatory condition,

may also reflect defects in epithelial cell health and compromised reconstitution or healing after injury, caused by again either an intrinsic genetic defect or environmental factors.

The Host Environment in UC and CD

IBD is more prevalent in more industrialized countries, among higher socioeconomic populations, in urban areas, and in geographic regions further from the equator [6–13]. Risk is increased in specific ethnic groups, such as the Ashkenazi Jewish population, the ethnic group with the highest disease incidence regardless of geographic location [8, 14]. These epidemiological phenomena suggest a genetic basis for disease but also a potential role for infectious causes, through an exposure to indigenous microbes or pathogens.

Possible Infectious Causes of IBD

Early observations of families with multiple affected members led to theories of an infectious etiology for IBD, specifically *Mycobacterium avium* subspecies *paratuberculosis* (MAP).

MAP causes Johne's disease, a CD-like illness in livestock. Despite intense early interest, no role for MAP in IBD has been proven to date, and these "familial" cases were likely due to a shared genetic predisposition [15]. However, at least three viruses (including the common Epstein-Barr virus and *Cytomegalovirus*), 6 yeasts, and over 20 bacteria have been associated with IBD through medical record reviews and serum antibody testing (Table 44-2) [16]. Although the majority of these organisms have been correlated with increased risk of disease development, some such as *F. prausnitzii* and *B. fragilis* may actually be protective [17–19].

The most robust evidence for pathogens in the etiology of IBD is the raised titers of antibacterial and antifungal antibodies including anti-CBir, anti-OmpC, anti-*Saccharomyces cerevisiae* antibodies (ASCA), and perinuclear antineutrophil cytoplasmic antibodies (pANCA) that are well documented in IBD patients (see Chap. 45 on IBD diagnosis) [20, 21]. It is not known if infection by these organisms is causative of disease (unlikely) or if their presence is due to an increased susceptibility secondary to impaired immunity or facilitated invasion of these pathogens through the ulcerated mucosa inherent to both UC and CD. This is a common problem in clinical studies of IBD patients, namely, what is causative vs. what is epiphenomenon, or simply related to the consequences of intestinal inflammation.

Smoking

Of all environmental factors studied, tobacco smoking has the most replicated association with IBD. There is increased risk of disease development and a more aggressive disease course with higher rates of both surgery and clinical recurrence documented in Crohn's patients who are current or former smokers. These associations appear to be "dose dependent" with the strongest association found in current smokers followed by former smokers [22–25]. In contrast, smoking appears to have a protective effect in UC patients. Smokers with UC have lower medication requirements and require surgery less frequently than UC patients who have never smoked [26]. The mechanism for these associations has not yet been elucidated. Studies on nicotine and nicotine replacement in the form of patches and chewing gum and the disease course of CD and UC have been inconclusive [27–29].

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAID) use has been commonly found to be associated with an increased risk of IBD development [30, 31]. The inhibition of COX-2 is the most studied mechanism in both human UC and CD tissue samples as well as animal models of colitis [32]. An alteration of gut microbiota, including an increase in the number of *Enterococcus* species, has been seen in IBD patients treated with NSAIDs. However, how such translates into disease is not known [33]. Studies on the role of NSAIDs in relapse/flares have produced conflicting results with the exception of aspirin which has not been shown to adversely affect disease activity [34–36]. Despite this lack of clarity, avoidance of NSAIDs is currently recommended in most IBD patients.

The Microbiome

Early exposure to a variety of pathogens is required for the development of a healthy immune system. A lack of varied pathogenic exposure, particularly in infancy and early childhood, may lead to an exaggerated immune response when the individual is exposed to these pathogens later in life [11]. This theory forms the basis of the "hygiene hypothesis" [37]. In IBD, this hypothesis is supported by the geographical clustering of patients in more "westernized" countries and in urban areas where more sanitary conditions, and thus less pathogenic exposure, can be found. This observation has led to trials administering Helminthes that are not commonly found in high-risk areas. Such early trials utilizing larvae from the porcine whipworm *Trichuris suis* suggested promising results in the amelioration of both CD and UC symptoms, but further, larger randomized control trials are needed [38, 39].

The inability to induce colitis in murine models with predisposing genetic mutations when raised in germ-free environments is further evidence of the concept of a role for the microbiome in disease. Such animals, when transferred to a

TABLE 44-2. Pathogens most commonly associated with IBD

Viruses	Bacteria	Fungi
Epstein-Barr [16, 205]	*Bacteroides* [206]	Basidiomycota [207]
Cytomegalovirus [16]	Firmicutes [206]	*Candida albicans* [208, 209]

	Ruminococcus [211]	*Saccharomyces* [209]
	Clostridium histolyticum [212]	
	Klebsiella [212]	
	Bifidobacterium [213]	

non-sterile environment and populate their intestinal tract with bacteria, then rapidly develop colitis [39]. Critics of the hygiene hypothesis note that as individuals migrate from a high childhood pathogenic exposure area (i.e., a "low-risk IBD" area) to a more westernized geographic location (i.e., a "high-risk IBD" area), their risk of developing IBD increases to nearly that of the new population suggesting early exposure is less critical than thought [40–42].

The observations of reduced intestinal microbiota diversity in IBD patients vs. non-IBD controls and the improvement of symptoms after stomal diversion of the fecal stream [17] have led to studies focused on further elucidating the role of gut bacterial imbalance or "dysbiosis" in IBD [43–49]. Thus, the promotion of gut microbe diversity by probiotic consumption has been investigated but thus far has been disappointing in CD. However, a role for the treatment and/or prevention of pouchitis in UC patients with ileal pouch-anal anastomosis (IPAA) has been seen, especially in decreasing pouchitis recurrence [50]. Similarly, fecal transplantation after initial treatment with antibiotics is suggested to promote microbial diversity. Results, again, have been conflicting and limited by small numbers, but possible benefits appear to be short-lived. Meta-analysis of 18 of these fecal transplant studies including 79 UC and 39 CD patients demonstrated a clinical remission of approximately 20 % for UC but as high as 60 % for CD, suggesting a possible though not definitive role in IBD pathogenesis and/or treatment [51].

Gut microbiomes vary by geographic location, and thus results from microbiome studies may not be relevant to all IBD populations. In a recent comparison of the gut microbiomes of Western European vs. Indian IBD populations, the majority of microbes detected differed. However, the presence of common overlapping microbes (e.g., *Faecalibacteria* and *Papillibacter*) was also demonstrated [52]. In addition to geographic location, earlier microbiome research may have been affected by the frequent antibiotic and steroid use seen in IBD patients. Controlling for treatment, Morgan et al. studied the gastrointestinal microbiome of 121 CD, 75 UC, and 27 healthy patients using fecal and biopsy samples. The majority of microbes showed a concordance in all IBD patients vs. controls. However, high Enterobacteriaceae counts were specific to CD, and Leuconostocaceae were decreased in UC. Interestingly, disease activity did not affect microbiome composition; however, age, smoking status, and IBD treatment did. Disease location was shown to affect the microbiome in CD patients with reduced Ruminococcaceae and *Faecalibacterium* seen in patients with ileal involvement [33].

An effort to more carefully characterize this microbiome as a "second genome" within the individual patient and to study the interaction between host genetics and microbial susceptibility has begun [53]. Controlling for antibiotic and immunosuppressant use, Knights et al. studied the microbiome and a panel of over 10,000 immunity-related genetic polymorphisms in over 450 IBD patients and found significant associations between 48 genetic variants and the increased presence of specific bacteria (e.g., NOD2 mutations and Enterobacteriaceae) [53]. This field is in its infancy with research rapidly expanding, which will probably be facilitated by the "big data" analytic techniques being used in genome analysis.

Appendectomy

Similar to smoking, an appendectomy paradox has been suggested in IBD. An increased likelihood of being diagnosed with CD is found in the first year following appendectomy by meta-analysis. However, this rate falls to that of the general population within 5 years [54]. Appendicitis may in fact be a misdiagnosed first manifestation of CD, contributing to this statistical association [55]. Separate meta-analysis has demonstrated a potential protective role of appendectomy in UC [56]. Mesenteric adenitis has also been suggested to have a protective effect in UC [57] but has not been studied in CD. The lymphoid appendix is involved in the adaptive immune response. Thus, it has been suggested that removal of the appendix impairs immunity and confers additional risk of developing IBD. Others suggest that the appendix sequesters antigens and so its removal with attendant antigens may prevent IBD.

The Role for Genetics in IBD

Early observations suggesting an infectious agent in the pathobiology of familial cases of IBD more likely reflected a genetic predisposition to both UC and CD that has now been well established. Genetic predisposition to both CD and UC was confirmed in early twin and familial studies using carefully maintained Scandinavian national registries and has since been replicated in multiple worldwide cohorts. In fact, the presence of a family member with IBD is the number one risk factor for developing the disease [58]. Up to 40 % of IBD patients have at least one affected family member [58]. Affected family members from "IBD families" are generally concordant for age of onset, location, and disease behavior [59–62]. As many as 75 % of families with multiple affected members manifest only a single type of colitis (either CD or UC). In the remaining 25 %, different family members can be affected by both CD and UC [40, 63]. Although genetic associations are well documented in both diseases, genetics plays a stronger role in CD than UC. This is particularly evident in twin studies. Monozygotic twin concordance rates for CD range from 20 to 50 % but only 14–19 % for UC. In UC, a familial concordance for extraintestinal manifestations has been demonstrated [64].

Early research was tedious and focused on genetic investigation of sibling pairs, searching for high rates of shared alleles in affected vs. non-affected individuals [65], candidate gene studies investigating the few known IBD-associated

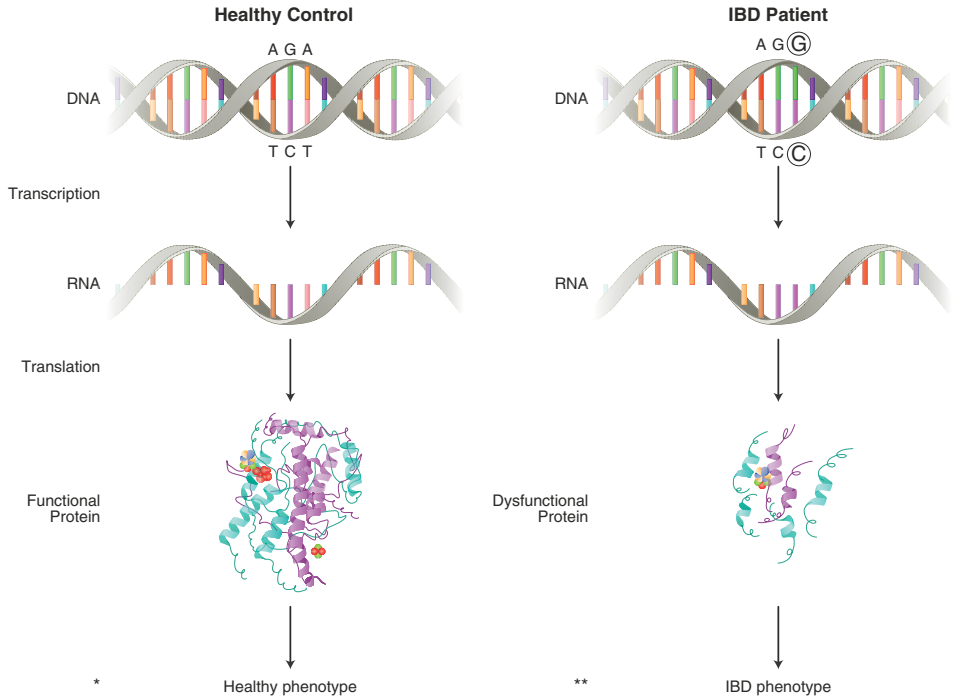

FIGURE 44.2. The possible downstream consequences of a single nucleotide polymorphism (SNP).

genes at the time and linkage studies where portions of the human genome or portions of specific chromosomes were shown to "travel" through generations with the disease process [66, 67]. The Human Genome Project (completed in 2003) [68] and the HapMap Project (completed in 2005) [69] have provided publically available databases of the most common genetic variants. These databases were used to interpret results obtained from genome-wide association studies (GWAS) where the genetic results from a large number of non-diseased control individuals were compared to those with IBD searching for significant genetic differences between the two groups (Figure 44-2) [70–72]. Typically 500,000–1 million single nucleotide polymorphisms (SNPs) were studied in thousands of diseased vs. healthy controls. SNPs, differentially expressed and identified using complex statistical analysis, were then "mapped" to relevant genes (usually through proximity) thereby identifying potential mechanistic pathways of disease pathogenesis.

Since the sequencing of the first human genome, genotyping coverage has increased while the cost has decreased. This trend is predicted to continue such that a complete human DNA sequence will soon be completed for less than $100 per patient [73, 74].

To date over 300 SNPs implicating over 150 genetic loci/genes have been associated with IBD (Figure 44-3) [70, 75, 76]. No single gene appears to be causative of either CD or UC, and thus inheritance is not the simple, Mendelian pattern seen in some diseases. Interestingly, several gene associations are shared between IBD and other immune-related diseases such as rheumatoid arthritis, multiple sclerosis, and even leprosy [76] suggesting overlapping pathobiology. The majority of the genes associated with IBD that have been discovered to date have roles in immune function, including innate and acquired immunity, and are discussed in more detail in the section below, Genetic Correlates Suggesting Mechanisms of Disease in IBD. A second group of genes appear to be involved in the health of the intestinal epithelium such as cation transporters and tight junction proteins suggesting IBD can also be the consequence of imperfect epithelial integrity or difficulty with reconstitution after injury [4, 70, 76].

Innate Immunity in Crohn's Disease

The innate immune system, present from birth, is the first line of host defense against enteric pathogens prior to the activation of adaptive or acquired immunity. Key functions of innate immunity have been demonstrated to play a significant role in CD: (1) epithelial barrier function and pathogen recognition and (2) autophagy (Figure 44.4a–c).

Epithelial Barrier Function

The epithelial barrier forms the interface between the luminal contents of the gut and the organ itself (Figure 44.4a). In the small bowel, four main cell types are found: enteroendocrine

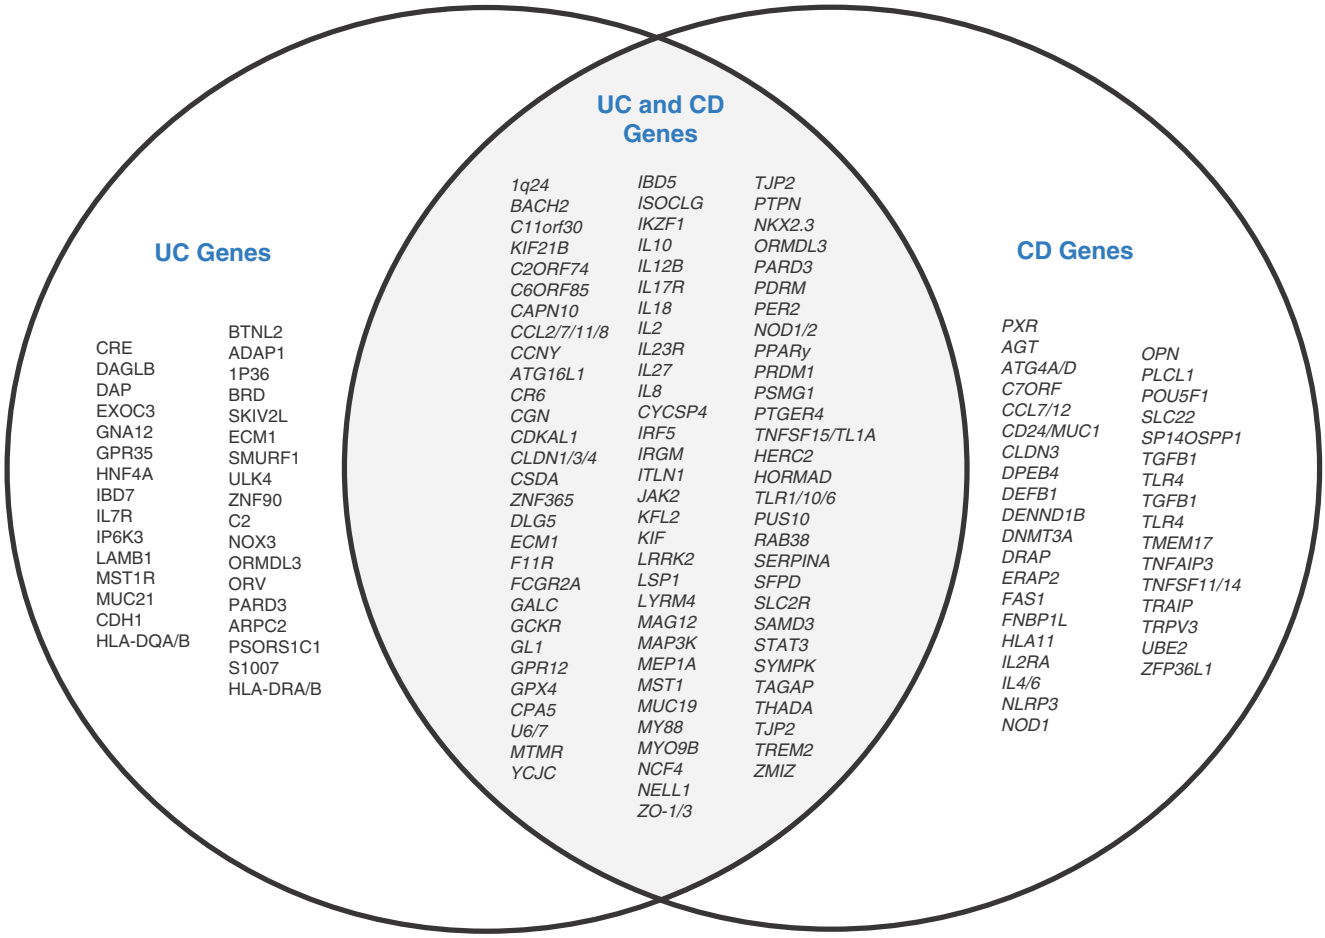

FIGURE 44-3. Genes associated with IBD. Genes associated with IBD found through genome wide association studies (GWAS) identifying single nucleotide polymorphisms (SNP) in proximity to the named genes.

cells, goblet cells, Paneth cells, and enterocytes. Goblet and Paneth cell dysfunction has been implicated in the pathobiology of CD. After differentiation, Paneth cells migrate to the base of the intestinal crypts while enteroendocrine cells, goblet cells, and enterocytes migrate to the villi. Goblet cells are interdispersed among the epithelial cells and store and secrete mucus into the intestinal lumen, thus forming a physical barrier over the intestinal mucosa to protect it from irritants and pathogens. Mucus also contains immunoglobulins such as IgA which aid in the regulation of inflammation and epithelial repair as well as binding and immobilizing enteric organisms. Paneth cells increase in number distally in the small intestine with the maximum concentration found in the ileum [77]. These cells are the main source of antimicrobial peptides in the small intestine and form a chemical epithelial barrier for pathogens [78]. Various antimicrobial peptides exist including lysozyme a phospholipase A2 and αdefensin, a hydrophobic peptide that forms pores in bacterial membranes resulting in lysis and death [79]. Decreased production of these peptides has been documented in CD involving the small intestine [80].

Epithelial cells contain cation transporters that move charged ions in and out of the cell to maintain homeostasis. How disease is caused by the altered movement of such cations between the intestinal lumen and tissue in IBD is unclear, but mutations in cation transporter genes have been associated with both CD and UC.

Junctions between adjacent epithelial cells control permeability across the intestinal mucosa and thus are necessary to avoid the passage of microbes from the intestinal lumen into the systemic circulation through these paracellular routes. The most commonly studied component of these junctions in IBD is the tight junction which is comprised of transmembrane proteins that interact with the intracellular actin cytoskeleton via plaque proteins which are under the control of several molecules. Tight junction abnormalities in IBD patients facilitate the uptake of antigens leading to inflammation and the release of cytokines such as interleukins, TNFα, and IFNɣ which in turn further propagate tight junction permeability (Figure 44-4b) [81]. Interestingly, abnormal tight junction function has been demonstrated in CD patients before the onset of disease and in unaffected family members

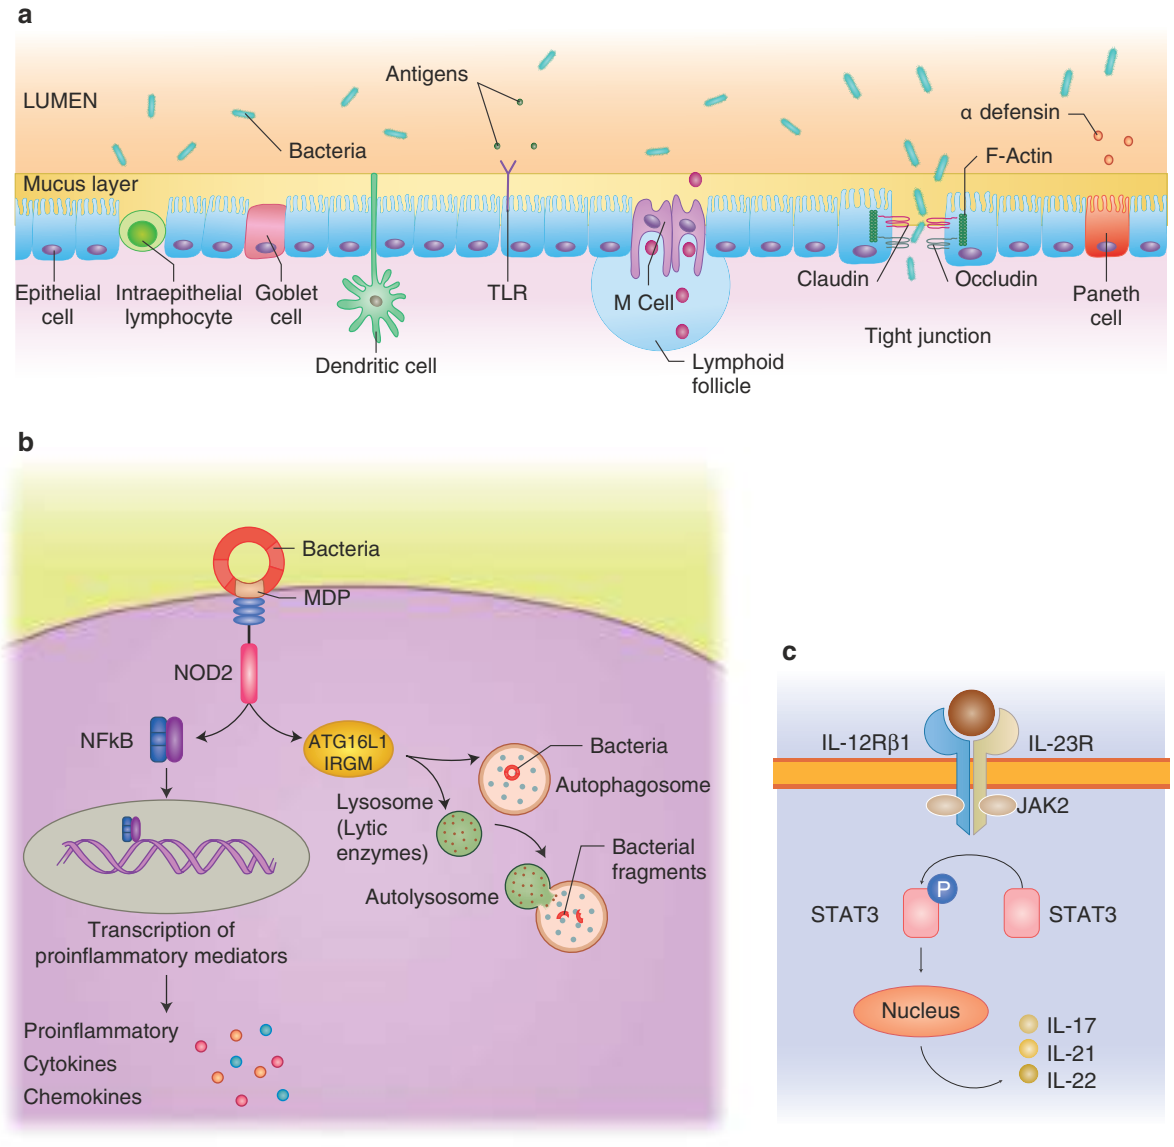

FIGURE 44-4. (**a**) The Epithelial Barrier. The epithelial barrier comprises the interface between the luminal contents of the gut and the organ itself. In the small bowel, 4 main cells types are found: enteroendocrine cells, mucous producing goblet cells, anti-microbial α defensin secreting Paneth cells and enterocytes. Additional cells of mucosal defense, include M cells shown channeling particles into the underlying lymphoid follicle and a dendritic cell reaching a dendrite between epithelial cells to make contact with lumenal antigens are depicted. The tight junction joining neighboring epithelial cells is comprised of transmembrane proteins that interact with the intracellular actin cytoskeleton is also depicted. In IBD, tight junction abnormalities allow the entry of antigens leading to inflammation and the release of cytokines such as interleukins, TNFa, INFy, which in turn further worsen tight junction permeability. (**b**) Autophagy and NOD2. The recognition and digestion of self and non self particles through autophagy is key to immunity. The figure shows the fusion of a lysosome with a bacteria-containing auto phagosome. This is in part dependent on functioning ATG16L1 and IR6M pathways. The NOD2/CARD15 pathway is also depicted, showing the recognition of MDP on the bacterial wall ultimately leading to NFkB activation that then results in changes in nuclear transcription of relevant inflammatory genes. (c) JAK/STAT PATHWAY STATs remain latent in the cell cytoplasm until, in response to signals from growth factors and cytokines through all sorts of receptors, become activated by receptor -associated tyrosoine kinases from the Janus kinase (JAK) family. STATs then dimerize, translocate into the cell nucleus and activate the transcription of inflammatory modulators.

suggesting a preexisting susceptibility to pathogen invasion due to baseline-altered permeability in CD patients [82].

Autophagy

In addition to providing an intact barrier, the healthy innate immune system also allows for the congenital ability to recognize certain antigens as foreign with subsequent "autophagy" or autodigestion and the recycling of either invading organisms or destroyed native cellular components [27]. Molecular signatures from a luminal pathogen (pathogen-associated molecular patterns or PAMPs) or from cellular debris resulting from cell stress or injury (damage-associated molecular pattern or DAMPs) are bound by pattern-recognizing receptors (PRRs) located on effector cells. This interaction activates a series of inflammation-inducing pathways including the adapter protein myeloid differentiation factor 88 (MyD88)-dependent pathway [83]. Downstream IgA production and release, epithelial cell proliferation and/or initiation of proinflammatory cascades results. Such PRR recognition of PAMPs and DAMPs is key to distinguishing "self" from "non-self."

Toll-like receptors (TLRs), the most commonly studied PRRs in IBD, are located within endosomes and on epithelial cell surfaces where they transverse the cell membrane. Although over a dozen TLRs are known, TLR2 and TLR4 have been demonstrated to play the most prominent roles in IBD [84]. TLR2 detects bacterial proteins while TLR4 detects an outer membrane component of gram-negative bacteria known as lipopolysaccharide (LPS) and functions primarily through the MyD88 pathway. However, TLR4 can also more directly activate inflammatory mediators such as tumor necrosis factor alpha (TNFα) and interferons (IFNs) through a MyD88-independent pathway.

Through the efficient degradation and recycling of cellular components, the process of autophagy is an energy-conserving mechanism for nutrient supply to the cell (Figure 44-4b). Autophagy is also involved in the adaptive immune system through the differentiation of T and B cells and the suppression of inflammation through mechanisms that have not yet been elucidated [85, 86]. During autophagy, the material for degradation is engulfed by the autophagosome. The autophagosome then fuses with a lysosome for degradation followed by presentation of the resultant peptide particles to HLA class II molecules for further processing. The main site of autophagy is the small intestinal Paneth cell; thus autophagy plays a stronger role in the pathobiology of CD than UC [78]. Mutations within several genes involved in this pathway are among the most highly replicated IBD-associated genes (NOD2/CARD15, ATG16L1, IRGM), providing evidence for the key role of dysregulated autophagy in the pathobiology of both diseases. These genes are discussed in further detail below in the Genetic Correlates section.

Macrophages

Macrophages are immunoregulatory cells involved in the pathobiology of IBD through two main mechanisms, proinflammatory cytokine secretion and phagocytosis. High levels of proinflammatory cytokines including IL-18 and IL-1 are produced and secreted by macrophages [86]. Secretion of these cytokines activates natural killer (NK) cells which then secrete interferon gamma (INFy) leading to dendritic cell (DC) activation. Once activated, DCs secrete TNFα, resulting in the recruitment of more inflammatory cells to the area [79]. IFNγ and IL-8 production leads to the maturation of macrophages and the formation of multinucleated giant cells [19] which are the key components of the granulomas characteristic of CD. Further release of proinflammatory cytokines potentiating T cell activation and further inflammation occurs when the granulomas themselves then present antigens to the T cells perpetuating the cycle of inflammation [79].

Macrophage and neutrophils are also recruited to the site of antigen presentation for phagocytosis. When levels of chemokines, cytokines (including IL-1 and TNFα), and leukotrienes are elevated, leukocytes traveling within blood vessels are signaled to cross the endothelial surface to reach the site of inflammation. Integrins, which are receptors on the surface of neutrophils, bind to factors such as mucosal addressin cell adhesion molecule-1 (MAdCAM-1) on the endothelium facilitating this margination and homing process [79, 87]. These integrins are the targets of some of the newest pharmacological treatments for IBD (See Chap. 46 on IBD treatment) [87].

APCs: The Bridge Between the Innate and Adaptive Immune Systems

Antigen-presenting cells (APCs) recognize both host enteric and foreign peptides. In the gut, APCs either travel to the location where a pathogen has breached the epithelial barrier or, alternatively, extend long armlike dendrites to reach through the tight junction between two epithelial cells to bind to intraluminal antigens. Dendrites also interact with M (or microfold) cells, specialized small intestinal cells that transport antigen directly from the lumen to APCs and T cells in a basolaterally located pocket via endocytosis [86] (Figure 44-4a). After antigen binding, APCs return to lymphoid tissue for presentation to T cells in a process guided by homing molecules. Such homing molecules include $\alpha_4\beta_{7,}$ present on effector T cells, and its ligand mucosal addressin cell adhesion molecule-1 (MAdCAM-1) which is expressed by small intestinal endothelial cells and colonic lamina propria cells [88]. A smaller role has also been demonstrated for the vascular adhesion molecule ELAM-1 (endothelial leukocyte adhesion

molecule-1) in both UC and CD [89]. In CD, the CCL25 chemokine and its receptor CCR9 have been demonstrated to contribute to small intestinal homing [87, 88].

Dendritic cells (DCs) are the APCs most implicated in the pathobiology of IBD (Figure 44-4c). One theory on the inappropriate response to self or foreign antigens and/or lack of tolerance to normal flora in IBD is that a "leaky" epithelial barrier may allow increased DC-antigen contact and an overstimulation of the systemic immune system [85]. Several DCs subsets have been found, some of which are involved in tolerance and others which are proinflammatory. IL-2 secreting DCs have been implicated in both UC and CD pathobiology [90]. IL-12 is a key cytokine involved in T cell function and is a driver of differentiation of naïve T cells to the IL-2 secreting Th1 subset thought to play a major role in CD [78, 91] (Figure 44-5).

Adaptive Immunity in Crohn's Disease

Together, the T and B lymphocyte response to the presence of antigen comprises the adaptive immune response. T and B lymphocyte activation results in the elimination of pathogens through direct killing, cytokine-mediated pathways, and antibody-mediated killing. T cell-mediated adaptive immune responses are better characterized in the pathobiology of IBD than the B cell response. T cells are predominantly located in the lamina propria and are divided into two main categories: CD4/memory T cells (which play a more predominant role in IBD) and CD8/cytotoxic T cells (whose main role is the production of IFNɣ). The secretion of the key immunological defense molecule, IgA, is the main function for B cells in IBD elucidated to date [87, 92].

Once bound with antigens on the surface of their major histocompatibility complexes (MHCs), APCs travel through the lymphatic vessels to the gut-associated lymphoid tissue (GALT), including the mesenteric lymph nodes and the intestinal lymphoid islands known as Peyers' patches. The antigen is then presented to the naïve T cell, and in the presence of costimulatory molecules, T cell activation followed by T cell subset differentiation occurs. Differentiation into one of four major subsets is guided by the influence of cytokines in the cellular milieu (Figure 44-5). A bias toward Th1 (T helper one) cell differentiation with associated TNF and IFNγ production is the main pathway of differentiation in CD [76, 93]. Abnormal Tregs (T regulatory cells) are well documented in CD. This relatively newly discovered T cell subset has an anti-inflammatory role through the promotion of tolerance to dietary antigens and gut microbiota and the suppression of immune responses through involvement in the production of the anti-inflammatory cytokine, IL-10 [94]. IL-17 secreting Th17 cells have been associated with both CD and UC but have a slightly stronger association with CD [76, 93, 95].

Cytokine Signaling

Several cytokines play a role in the pathways involved in IBD. Some maintain these pathways while others induce or disrupt them. Several of these cytokines are mentioned in the above sections. Key cytokines with genetic correlates associated with IBD are highlighted below in the Genetic Correlates of IBD section.

Innate Immunity in Ulcerative Colitis

The epithelial barrier plays a greater role in the pathobiology of UC as opposed to CD since the inflammation of UC is limited to the mucosa of the colon and rectum [96]. UC is characterized by a loss of epithelial integrity and damage to the goblet cells, enteroendocrine cells, and enterocytes. Unlike small intestinal CD, where these cells migrate to the villi, in UC, affected cells are found on the surface of the colon (as no villi are present in the colon). Paneth cells are only found in the small intestine; thus they do not play a role in the pathobiology of UC.

The role of the tight junction has been the focus of much research in UC [97]. Impaired tight junction permeability has been associated with an increase in proinflammatory cytokines even in quiescent IBD [98]. Autophagy is also involved in the pathobiology of UC but is more studied in CD [86, 99]. As granulomas are not found in UC, the role of macrophages in UC is likely limited to the production of proinflammatory cytokines [86] and the activation of NK and dendritic cells. Integrin mediators on the surface of neutrophils including MAdCAM-1 are also implicated in UC [79, 87, 100], and targeting of these molecules has also been shown to be effective in the treatment of UC (See Chap. 46 on IBD treatment) [87].

Studies on the role of DCs in IBD have more commonly focused on CD than UC. The luminal projection of DC dendrites may be affected by variations in tight junction permeability in UC, however [101]. Recent in vitro studies on DCs by Ueno et al. have suggested that exposure to cigarette smoke may affect DC function and be a key driver of T cell differentiation toward Th1 cells in CD and Tregs in UC [102], a potential explanation for the smoking paradox in UC vs. CD described above.

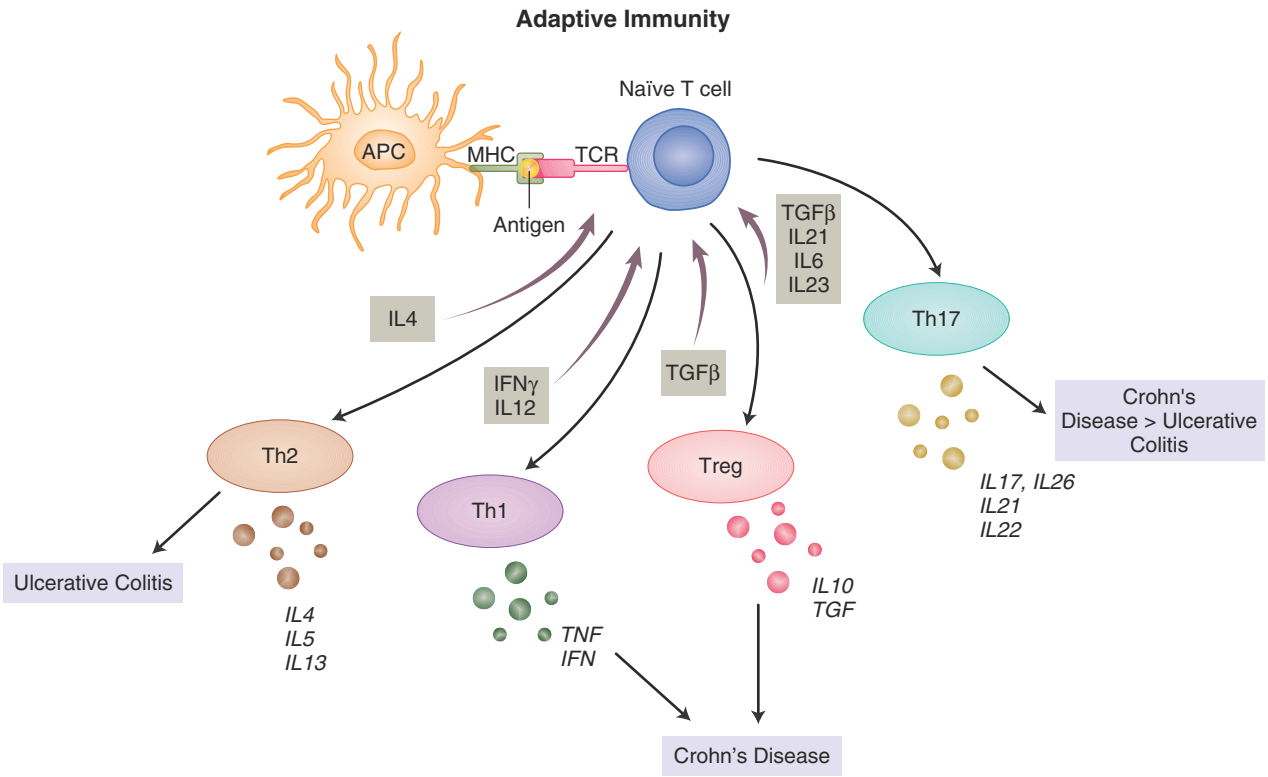

FIGURE 44.5. Adaptive immunity in Crohn's disease.

Adaptive Immunity in Ulcerative Colitis

T cell activation and differentiation is described in detail above. During differentiation, a Th2 cell bias leading to increased production of IL-4, IL-5, and IL-13 has been associated with UC (Figure 44-5). Th17 cells and their IL-17 secretion have also been associated with UC but to a lesser extent than CD [76, 93, 95].

Genetic Correlates Suggesting Mechanisms of Disease in IBD

Innate Immunity

Epithelial Barrier

The MUC family of glycoproteins is the main component of intestinal mucus. MUC2 is the most abundant glycoprotein and as such has been the main MUC gene of interest in IBD. Murine MUC2 knockout models develop an IBD-like colitis with features of both CD and UC [103]. Similarly, decreased expression of three members of the MUC family of genes, MUC2, 3, and 4, has been demonstrated in colonic tissue from UC patients when compared with control tissue while MUC19 polymorphisms have been associated with CD in humans [27, 104].

Anti-inflammatory prostaglandins are involved in epithelial mucosal repair. Prostaglandin E receptor 4 (PTGER4) SNPs have been associated with the development of CD [27]. A similar association has not been found in UC.

Polymorphisms in several cellular transport genes have been associated with IBD by GWAS; however, their roles in the pathobiology of IBD are not clear. This is true of the cation transport molecules OCTN1 (organic cation/carnitine transporters, also known as the solute carrier family 22, member 4/ SLC22A4) and OCTN 2 (also known as SLC22A5) located on chromosome 5. Mutations within both genes have been associated with UC and CD. These associations have been highly replicated through multiple GWAS studies [105]. Polymorphisms have also been associated with colonic involvement and anal disease in CD [105]. The mechanism for this association has not been elucidated, however.

Claudin and occludin are transmembrane bridging proteins found within tight junctions. Both are linked to the actin cytoskeleton via interactions with scaffolding proteins including the Zo (zona occludens) family [106, 107]. Claudin protein expression levels have been demonstrated to correspond to severity of inflammation in Crohn's colitis [108]. An absence of Zo-1 has been seen in experimental murine colitis models [109, 110]. When the ratio of claudin to occludin expression was studied, a significant increase in the ratio was demonstrated in diseased UC colon compared to

non-diseased UC colon and normal colon. In CD, the ratio did not vary with disease status, suggesting a greater role for these proteins in UC [96].

A number of IBD-associated genes including signal transducer and activator of transcription molecules (STATs), the intelectin-1 (ITLN1) and Drosophila discs large 5 (DLG5), domain class 5, also known as the octamer-binding transcription factor 4 (OCT4) and laminin beta 1 subunit (LAMB1), can be grouped together under the umbrella term "miscellaneous epithelial integrity genes." STATs remain latent in the cell cytoplasm until, in response to signals from growth factors, cytokines (including IL-2, IL-3, IL-5, and IL-7), thrombopoietin, and erythropoietin, they become activated by receptor-associated tyrosine kinases from the Janus kinase (JAK) family. STATs then dimerize, translocate into the cell nucleus, and activate transcription and the expression of various proteins (Figure 44-4c) [111–113]. STAT3 has been implicated in IBD but has a paradoxical effect in the innate and adaptive immune systems. When activated in innate immune cells (e.g., intestinal epithelial cells, neutrophils, and macrophages), mucosal barrier function is enhanced [114]. Conversely, when activated in T cells, an exacerbation of colitis is seen [115].

ITLN1 gene's protein product is expressed in the brush border of enterocytes and plays an important role in membrane stabilization and protection of the glycolipid barrier from pathogens [115]. SNP variants have been associated with IBD by GWAS, however. No studies on the functional consequences of these polymorphisms in IBD have been performed to date. Similarly, polymorphisms within the DLG5 gene, a guanylate kinase family member located at the cell-cell junction, have been associated with both CD and UC by GWAS [116] and replicated in smaller studies [117]. Functional studies have been limited to UC and have shown an increased expression of the protein in UC tissue vs. healthy control tissue [118].

Two genes POU5F1 and LAMB1 are exclusively associated with UC, again suggesting a greater role in epithelial barrier function in UC vs. CD. Similar to many IBD-associated genes, the POU5F1/OCT4 gene has been previously associated with other immune-mediated diseases such as toxic epidermal necrolysis [119] and psoriasis [120]. POU5F1's protein product is involved in stem cell pluripotency in the embryo and renewal in the adult. The gene has been associated with colonic adenomas and colorectal cancer (CRC) [121–123], perhaps by inhibiting dividing progenitor cells from differentiating [124]. Yasuda et al. demonstrated decreased expression in UC tissue with CRC vs. UC tissue with inflammation only [123]. Interestingly, this gene has also been associated with patient satisfaction after IPAA in a quality of life study inclusive of over 140 patients. Two SNPs within this gene were associated with poor emotional well-being, which may be the result of a more severe disease phenotype. An SNP within another immune-mediating gene, TNFSF14, was also associated with overall poorer quality of life, worse bowel symptoms, and poorer emotional well-being [125].

Laminin is a key component of the basement membrane and acts as an anchor for the single-layered intestinal epithelium and thus has a role in pathogen defense and cell adhesion [126]. LAMB1 codes for a subunit of laminin. Its expression has been demonstrated to be downregulated in colonic tissue samples from UC patients vs. controls [126]. This downregulation has been associated with distortion of the colonic basement membrane in UC [127].

Genetic correlates with macrophage and DC homing have been associated with CD only. Neutrophil homing genes have been associated with both CD and UC. Such polymorphisms within the peritoneal phagocytosis-inducing macrophage stimulating 1 (MST1) gene have been associated with CD in multiple large GWAS [128, 129]. The homing receptor chemokine receptor 6 (CCR6) is expressed by immature dendritic and memory T cells and has also been associated with CD on GWAS [115]. The expression of the neutrophil homing mediator, mucosal addressin cell adhesion molecule-1 (MAdCAM-1), has been demonstrated to be overexpressed in the gut epithelium during active CD and UC [79, 87, 100]. This discovery has led to the use of MAdCAM-1 and other related integrins as therapeutic targets for some newer IBD pharmacological treatments (see Chap. 46 on IBD treatment) [87].

Pathogen Recognition and Autophagy

NOD2/CARD15

Genes within the autophagy pathway were the first genes to be associated with IBD. The identification of these genes and further study into their functional roles in the pathobiology of IBD linked the fields of microbiology, immunology, and genetics. The most commonly studied autophagy-associated genes in IBD are nucleotide-binding oligomerization domain-containing protein 2 (NOD2, also known as caspase recruitment domain-containing protein 15 or CARD15), autophagy-related protein 16-like 1 (ATG16L1), and immunity-related GTPase family M protein (IRGM). Generally, a stronger association with CD vs. UC with these genes has been demonstrated.

The first step in autophagy is antigen recognition. Functional studies have demonstrated significantly higher expression of the PRR, TLR4 within the intestine of both UC and CD patients when comparing inflamed colonic mucosa with non-inflamed controls [130]. NOD2/CARD15, located on chromosome 16, was the first gene discovered to be associated with IBD in 2001 [66, 131]. To date, it has the strongest, most commonly replicated gene association with IBD, especially CD [132]. The NOD2/CARD15 gene is expressed in several cell types involved in the pathobiology of IBD including intestinal epithelial cells, Paneth cells, dendritic cells, and monocytes. The CARD15 protein is

involved in the recognition and binding of muramyl dipeptide (MDP, a bacterial cell wall component) at the protein's leucine-rich repeat nucleotide-binding domain [132]. Thus CARD15 is a PRR. Two main pathways, the nuclear factor kappa B (NFκB) and mitogen-activated protein kinase (MAPK) pathways, are activated when NOD2/CARD15 is activated through the binding with MDP [27]. NF-κB plays a key role in the regulation of several genes responsible for the production of proinflammatory factors, cytokines, chemokines, adhesion molecules, and growth factors including interleukins1β, 8, 6, and 12 and TNFα, a potent proinflammatory cytokine highly involved in IBD pathogenesis. TNFα is a critical target of a whole class of biologic drugs that bind both free and cell-associated TNFα, known as TNF antagonists which are highly effective in both UC and CD (see Chap. 47 on treatment). MAPKs are heterogeneous enzymes which phosphorylate serine and threonine amino acids causing the propagation of downstream inflammatory signals [133].

Despite having the strongest IBD association, not all IBD patients have a NOD2/CARD15 mutation. In fact, the three most commonly IBD-associated SNPs or single-base substitutions within the NOD2 gene (R702W, G908R and 1007 fs) are rarely found in Asian CD patients and is only found in, at most, 40 % of European and North American CD patients vs. 10–15 % of the non-IBD population [134]. Interestingly, these three SNPs are all located either near or directly within the leucine-rich repeat sequence area of the gene where MDP is detected. The presence of any one of these SNPs has been demonstrated to cause impaired activation of the NFκB pathway and the subsequent production of inflammatory cytokines [135].

Besides activating the second messengers NFκB and MAPK, NOD2/CARD15 also recruits the autophagy-associated protein, ATG16L1, to the cell membrane [131, 132]. Both NOD2/CARD15 and ATG16L1 must be functional in dendritic cells for autophagy to occur [86]. Found on chromosome 2q37, ATG16L1's protein product is expressed by APCs, T cells, intestinal epithelial cells, and macrophages and is involved in the formation of the autophagosome. Paneth cell abnormalities, an impaired ability to breakdown intracellular bacteria, and increased levels of inflammatory cytokines have been demonstrated in both CD patients with mutations in ATG16L1 and ATG16L1 murine knockout models [19, 86]. Although more commonly associated with CD, meta-analysis has shown a small, but statistically significant, association with UC although with an odds ratio of only 1.08 [136].

An association between the IRGM gene and IBD was discovered at the same time as ATG16L1. Located on chromosome 5, IRGM encodes immunity-related GTPases required for the IFNγ-mediated clearance of intracellular pathogens. Similar to ATG16L1, the knockdown of IRGM in animal models has been shown to result in defective autophagy and the survival of several pathogens including *Toxoplasma gondii*, *Listeria monocytogenes*, and *Mycobacterium tuberculosis* [137, 138]. Three IRGM SNPs (rs13361189, rs4958847, and rs10065172) have been associated with IBD in early GWAS and confirmed in CD but not UC in a 2013 meta-analysis of 25 studies inclusive of 20,590 IBD cases and 27,670 controls. When stratified by ethnicity, a significantly increased CD risk was demonstrated in Europeans vs. Asians [139]. The presence of SNPs in the IRGM gene has been associated with earlier disease recurrence after ileocolectomy in CD [140].

The Adaptive Immune System

The human leukocyte antigen (HLA), also known as the MHC, involved in the presentation of antigen to T cells has been the focus of much study in IBD with a particular focus on HLA-DR subtypes. Although these genes are conventionally thought of as UC associated, subtypes of HLA genes such as DRB3, DR7, and DQ4 have also been associated with CD [141–144]. An association with DR2, DR9, and DRB1 and UC has been demonstrated by meta-analysis [142]. The HLADRB1 gene has been associated with the extraintestinal manifestations of IBD [141].

Several known IBD-associated genes including tumor necrosis factor superfamily member 15 (TNFSF15, also known as the TNFSF ligand 1A/TL1A and vascular endothelial growth inhibitor/VEGI), signal transducer and activator of transcription (STAT5), and T cell activating Rho GTPase-activating protein (TAGAP) are involved in T cell differentiation which occurs after activation [95]. The TNFSF15 gene, found on chromosome 9q32, is one of the earliest genes associated with both CD and UC through GWAS which has been subsequently confirmed with smaller studies [94]. TNFSF15's protein product, tumor necrosis factor (TNF)-like cytokine 1A (TL1A), is expressed in macrophages, endothelial cells, and gut lamina propria lymphocytes [145] and acts as a ligand binding the death domain receptor 3 (DR3) which is mainly expressed on T lymphocytes [94, 145]. Interestingly, TNFSF15/TL1A also has a regulatory, angiostatic effect in the vasculature [146]. Roles in apoptosis and the induction of metalloproteinases involved in intestinal barrier function have also been demonstrated [147, 148]. Stimulation occurs through the NFκB pathway. Downstream effects in IBD patients include an enhanced IFN gamma and IL-2 production by T cells [149, 150] and a preferential differentiation into Th1 and Th17 subsets [94, 149, 151]. Additionally, overexpression of TL1A in T cells has also been associated with a dysregulated immune response with increased numbers of Tregs noted [147, 152]. Interestingly, SNPs in this gene have also been associated with surgical diverticulitis [153].

The STAT5 gene encodes a protein member of the STAT family of transcription factors which are described above in the innate immunity/epithelial barrier function section. In contrast to TNFSF15, STAT5 inhibits differentiation into

Th17 and Tregs subsets and is associated with dysregulation of Th1 cells through the alteration of the IL-2 receptor and enhanced proinflammatory IL-4 secretion by mast cells [112, 154–159]. A key role for STAT5 in the functions of both the innate and adaptive immune systems, namely, tight junction permeability and mucosal healing [158] and the development of T, B, and NK cell [112, 159], has been demonstrated in STAT5 knockdown animal models.

The TAGAP gene, which is co-regulated with the proinflammatory cytokine IL-2 [160], plays a role in both T cell migration and activation [161–163]. Originally believed to be exclusively associated with CD, Toedter et al. demonstrated variations in TAGAP expression (as well as several other genes) before and after anti-TNF treatment in the colonic tissue of UC patients [164]. TAGAP's protein product is a member of the Rho GTPase–activating protein (GAP) family. This class of molecules is involved in several immune-modulating processes including actin formation. Actin formation affects cell motility, the establishment of cell-cell contacts, and the formation of the immunological synapse [165]. Interestingly, TAGAP propagates the inactive form of the Rho molecule [163, 166], thus impairing its interaction with downstream effectors resulting in changes in the T cell cytoskeleton which are critical to cell shape, movement, and contractility [167]. Like POU5F1 and several other IBD-associated genes, the TAGAP gene is also associated with other immune-mediated diseases such rheumatoid arthritis, celiac disease, and type 1 diabetes mellitus [160]. It has also been associated with anal Crohn's disease and has been shown to vary its expression along the course of the colon [168, 169].

Several cytokines are involved in the pathways involved in IBD. Some maintain these pathways while others induce or disrupt them. Several of these cytokines are mentioned in the above sections. The most well-known IBD-associated cytokine is IL-10. This cytokine is unique since it has anti-inflammatory properties. Therefore, mutations within the gene or its receptor which disrupts its function result in inflammation which is often very severe. IL-10 receptor (IL-10R) gene mutations were famously associated with extremely severe, early onset medically refractory CD with severe anal involvement at the Royal Free Hospital in 2009, a discovery which has since been replicated [170, 171]. This small cohort of patients with IL-10R mutations responded well to bone marrow transplantation suggesting the possibility of an actual cure for CD, by effectively reversing the specific genetic defect responsible for the disease in this highly unique subpopulation of patients.

IL-23 is secreted by DCs, monocytes, and activated macrophages and is involved in the Th17 differentiation of naïve T cells and the release of other proinflammatory cytokines including TNFα, IL-1, and IL-6 from monocytes and macrophages, also known as the IL-23–Th17 axis [172]. The IL-23 receptor (IL-23R) is a key linking molecule between the innate and adaptive immune systems. IL-23R is expressed by NK, memory T, and cytotoxic T cells. Particularly high levels are found in Th17 cells [92]. Binding of IL-23 to the IL-23R activates the JAK2 protein leading to the downstream recruitment and dimerization of the two subunits of the transcription activator, STAT3. STAT3 is then able to translocate into the cell nucleus and promote the transcription of proinflammatory mediators as described as above [172].

The IL-23 signaling pathway also activates an additional pathway with a key role in T helper cell differentiation, the retinoic acid-binding orphan receptor-γt (ROR-γt) pathway. The cytokines produced when this pathway is activated (IL-17A, IL-17F, IL-6, and TNFα) are proinflammatory and propagate naïve T cell differentiation into Th17 cells [172]. This pathway is particularly important in the pathogenesis of IBD as multiple polymorphisms located within several genes in this pathway are associated with the disease [92, 173]. The IL-23 gene is also associated with other immune-mediated diseases including rheumatoid arthritis and ankylosing spondylitis [92] as well as extraintestinal manifestations in UC [174].

The Molecular Basis of Malignant Degeneration

Both UC and CD patients are at an increased risk of developing CRC. An earlier onset of CRC and an increased risk of synchronous and metachronous neoplasia are found in both UC and CD patients when compared to the general population. Risk is significant and generally underappreciated by caregivers since up to 15 % of IBD patients die from CRC [175]. Despite the demonstrated increased risk of UC-associated CRC and the poor performance of colonoscopic surveillance protocols, no genetic or serological marker has been identified or shown to be effective in clinical practice; thus colonoscopy, including chromoendoscopy, continues to be the mainstay of surveillance practice.

Inflammation is a known risk factor for dysplasia, metaplasia, and progression to carcinoma. Thus IBD-associated dysplasia and CRC are found predominately in tissues with evidence of current or past inflammation [175–179], and risk is therefore also related to disease extent and duration [175]. Typically, inflammation progresses to low-grade dysplasia (LGD) with which it shares pathologic features. LGD then progresses to high-grade dysplasia (HGD), with shared features with CRC and then to CRC. In IBD, however, this progression is unpredictable and, unlike sporadic CRC which typically takes 10 years to develop, varies in rate and does not always occur in the aforementioned order [176, 179–183].

Like sporadic CRC, IBD-associated CRC involves p53 and adenomatous polyposis coli (APC) mutations and microsatellite instability. However, the sequence of these mutations in progressive malignant degeneration is different between IBD-associated malignancy and conventional CRC (Figure 44-6) [184, 185]. APC mutations are involved in the

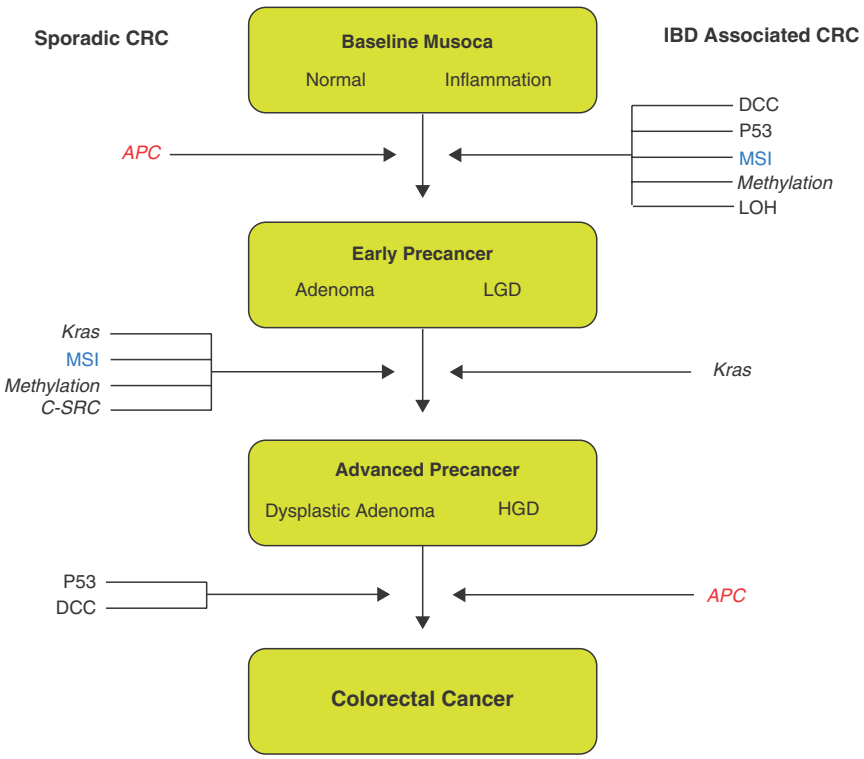

FIGURE 44-6. Malignant degeneration in the setting of IBD vs. sporadic colorectal cancer.

first step of progression from normal tissue to sporadic cancer. However, APC mutations are involved relatively late in the progression from inflammation to IBD-associated cancer. An increased frequency of p53 mutations in LGD in UC and decreased frequency of APC mutations in UC-associated CRC patients compared with sporadic neoplasia patients were demonstrated in an early study of 33 UC-associated neoplasias and 23 sporadic neoplasias [186].

The discovery of a genetic predictor of progression to CRC in IBD could potentially affect surveillance regimens and provide the opportunity to offer a prophylactic colectomy to patients at high risk [187]. To date, only a few small studies have been performed in this field of research, and results are conflicting [188, 189]. An SNP within the OCTN1 genes (discussed above in the Genetic Correlates section) was found to be associated with UC, UC-associated CRC, and early onset of sporadic CRC in a large cohort of over 600 Italian patients. However, only two genes (OCTN1 and OCTN2) were investigated [190]. In a study of over 300 known IBD-associated SNPs comparing carefully matched UC and UC-neoplasia patients, no correlation between any of these IBD SNPs and neoplasia was found suggesting a stronger role for sporadic CRC-associated mutations [191].

A more significant association with UC-associated cancers (57 %) vs. sporadic cancer (36 %) has been demonstrated in cases of promoter region methylation of the e-cadherin encoding gene CDH1 gene which is involved in epithelial junctions [192]. Houlston et al. subsequently demonstrated an association between CDH1 and both sporadic CRC and UC, suggesting a link between the two pathologies. However, UC-associated CRC patients were not included in the study [193, 194]. The process of methylation is the best studied epiphenomena in IBD-associated CRC [195]. Interestingly, methylation levels have been demonstrated to be higher in human UC-CRC vs. sporadic cancer [189], and known key mediators of IBD-associated inflammation including IL-6 and IFNγ have been shown to induce DNA methylation, possibly explaining why the risk of cancer increases with the duration of UC inflammation [189]. Mouse models of colitis have demonstrated the presence of DNA methylation prior to tumor development [188, 196]. However, though methylation in UC-associated cancer appears to play a potentially significant role, utilizing this to identify patients at risk for UC-associated CRC has not been done.

Surgical Genetics in IBD

The novel field of "surgical genetics" utilizes clinical and genotype data to predict operative outcomes [197]. Due to the unpredictable nature of IBD both in surgical outcome and disease recurrence, the identification of specific genetic factors that might predict surgical outcome is attractive. Other examples could include the identification of patients that will fail medical treatment, require repeat segmental resections for Crohn's, or experience severe or develop debilitating pouchitis after ileal pouch-anal anastomosis for UC. Some early studies have been performed that identify possible genes of relevance to the surgical management of IBD patients.

There are several gene alleles that suggest a predisposition to early surgery in IBD. Increased expression of the drug efflux pump, multidrug resistance (MDR) gene in peripheral blood lymphocytes, was associated with failure of corticosteroid treatment and the need for surgery in a study of over 200 IBD patients [198]. A TNFα polymorphism (308A allele) was associated with an OR of 2.1 for requiring surgery due to medical failure in pediatric IBD patients [199]. In the largest surgical genetics study to date, utilizing genotyping results from greater than 70 known IBD loci in over 1000 CD patients, Dubinsky et al. associated three loci, IL-23R, IL-12B, and chromosome 11 open reading frame 30 (a regulator of transcription), with the requirement for early surgery (within 5 years of IBD diagnosis) [200].

Utilizing an SNP array with over 70 IBD-associated SNPs, the presence of the IRGM SNP rs4958847 was associated with the more frequent need for repeat ileocolectomy [140]. In a study evaluating only three NOD2 SNPs in 80 small bowel CD patients, the 1007 fs variant was associated with a the requirement for surgery for stenotic disease in over 60 % of patients with the variant [201]. SNPs in the PTGER, NOD2, and TNFSF15 have also been associated with Crohn's-like pouch complications (i.e., fistula, abscesses) and severe pouchitis after IPAA [202–204]. Much like the increasing role of genetic determinants in defining chemotherapy for CRC, genetic alleles will likely soon be used to assist the surgeon in deciding the type and timing of operative intervention in IBD patients.

45
IBD Diagnosis and Evaluation

Matthew M. Philp and Howard M. Ross

Key Concepts

- Familiarity with modes of clinical presentation of ulcerative colitis and Crohn's disease allows the clinician to promptly select the most efficient combination of tests.
- Knowledge of histologic findings of ulcerative colitis and Crohn's disease facilitates discussion with other physicians of the care team and tailors specific medical and surgical therapies.
- Serologic tests such as ASCA, pANCA, and fecal markers such as calprotectin are increasingly becoming utilized for diagnosis and treatment effectiveness monitoring.
- High definition images, chromoendoscopy, confocal laser endomicroscopy, and double balloon enteroscopy add to the ability to diagnose and treat ulcerative colitis and Crohn's.
- Capsule endoscopy, computerized tomography and computerized tomography enterography, magnetic resonance imaging, and magnetic resonance enterography provide previously unimagined ability to visualize disease and are revolutionizing the care of the IBD patient.

Inflammatory Bowel Disease: Diagnosis and Evaluation

Historical Context

The purpose of this chapter is to describe modalities and points of information that will aid the surgeon in the diagnosis and evaluation of the inflammatory bowel diseases.

Crohn's disease and ulcerative colitis are collectively referred to as inflammatory bowel diseases. Inflammation plays a significant role in each entity. Though largely different in the distribution of disease and the manner in which inflammation affects the gastrointestinal tract, occasionally the diseases overlap both in behavior and in their responses to similar treatments.

The consideration of ulcerative colitis and Crohn's disease together as inflammatory bowel diseases is beautifully described in a historical review in the Mt. Sinai Journal of Medicine, "Although clinical descriptions of diarrhea with or without blood go back thousands of years, clear distinctions between enteritis and ulcerative colitis were possible only in the nineteenth century." [1] The term "ulcerative colitis" was mentioned in 1888 by Dr. Hale-White in his paper, "On simple ulcerative colitis and other rare incidental ulcers" [2]. As described by Dr. Lockhart Mummery in 1905, the introduction of the electric sigmoidoscope made it possible to make proper diagnosis of ulcerative colitis and distinguish it from infective dysentery, membranous mucous or catarrhal colitis, and nervous diarrhea [3]. The entity now known as Crohn's disease has a politicized origin. Drs. Ginzburg and Oppenheimer "in conjunction with Dr. Burrill B. Crohn" presented a definitive paper, "Non-specific Granulomata of the Intestine," on May 2, 1932, to the American Gastro-Enterological Association and the paper "Regional Ileitis: A Pathologic and Chronic Entity," under the authorship of Crohn, Ginzburg, and Oppenheimer," was published later that year [4].

Ulcerative Colitis

The classic presentation of ulcerative colitis is the new passage of bloody diarrhea. The work-up must include a careful history. The importance of rapidity of onset, fecal consistency, frequency of defecation, continence, and exposure to infectious agents, weight loss, other concurrent associated symptoms, and family history are all important and may hint at diagnosis. The goal of investigation is to make a specific, prompt diagnosis to facilitate early treatment. Past medical history is always crucial. Patients with prior immunosuppression, foreign travel, or antibiotic use may be more likely to have an infectious colitis and prior perianal infection may suggest Crohn's disease. Physical exam is important to evaluate signs of toxicity that might mandate prompt surgical

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_45

TABLE 45-1. Extra-intestinal manifestations of ulcerative colitis [6]

Site	Manifestation	% of UC patients
Skin	Erythema nodosum	3
	Pyoderma gangrenosum	1.4–5
	Aphthous stomatitis	4
Hepatopancreatobiliary	Primary sclerosing cholangitis	5
	Cholangiocarcinoma	Rare
	Primary biliary cirrhosis	Rare
	Autoimmune hepatitis	Rare
	Portal vein thrombosis	Rare
	Pancreatitis	Rare
Musculoskeletal	Peripheral arthritis	20–40
	Axial	5
	Metabolic bone disorders	2–40
	Myopathy	Rare
Ocular	Episcleritis	Rare
	Uveitis	Rare
	Scleritis	Rare
	Optic neuritis	Rare
Hematologic	Anemia	8–73
Vascular	Venous thromboembolism	Rare
Genitourinary	Urolithiasis	Rare
Pulmonary	Bronchiolitis	Rare
Cardiac	Pericarditis	Rare

evaluation and treatment. Evaluation of vital signs is critical looking for tachycardia specifically. Careful abdominal examination and rectal exam must be performed. External anal examination should be performed evaluating signs of anal Crohn's disease (waxy thickened skin tags, fistulae). Rectal tone should be evaluated and documented. The nature of the anus should receive focus. Is there any sign of anal structuring or fibrosis, or is the musculature supple? Is there a mass? The contents of the rectal vault should be noted for stool consistency and the nature of the bleeding.

Infectious colitides that mimic ulcerative colitis must be evaluated via stool culture. Shigella, Salmonella, Yersinia, Clostridia *difficile*, and Cytomegalovirus must be specifically queried (see Chap. 52 for further details about infectious colitides).

The colon must be evaluated by colonoscopy. The extent of disease and characteristics of the mucosa are critical. Classically, ulcerative colitis begins in the distal rectum and extends proximally. The inflammation progresses in a confluent manner and affects only the mucosa, without fissuring, or skip areas. An activity index for ulcerative colitis is seen in Table 45-1 [5]. Extra-intestinal manifestations can be associated with both ulcerative colitis and Crohn's disease (Table 45-2) [6].

TABLE 45-2. A simple clinical colitis activity index. Scoring system for the Powell-Tuck Index [5]

Symptoms and signs		Score
Symptoms		
Bowel frequency	3–6	1
	>6	2
Stool consistency	Formed	0
	Semi-formed	1
	Liquid	2
Abdominal pain	Before/after bowel motions	1
	Prolonged	2
	Anorexia	1
	Nausea/vomiting	1
General health	Normal	0
	Slightly impaired	1
	Activities restricted	2
	Unable to work	3
Extracolonic manifestations	One/mild	1
	More than one/severe	2
Signs		
Abdominal tenderness	Mild	1
	Marked	2
	Rebound	3
Body temperature (°C)	<37.1	0
	37.1–38	1
	>38	2
Blood in stool	Trace	1
	More than trace	2
Sigmoidoscopy	Non-hemorrhagic	0
	Friable	1
	Spontaneous bleed	2

Crohn's Disease

Crohn's disease can affect anywhere in the digestive tract from the mouth to the anus and the inflammatory process of Crohn's involves the full thickness of the bowel wall.

TABLE 45-3. Macroscopic features used for the diagnosis of IBD [13]

	Ulcerative colitis	Crohn's disease
Localization GI tract	Especially colon and rectum	Whole GI tract
Ileum	Not except in backwash ileitis	Often involved
Colon	Left > right	Right > left
Rectum	Commonly involved	Typically spared
Distribution GI tract	Diffuse (continuous)	Segmental (discontinuous)
Ulcers	Superficial ulcers	Aphthoid ulcers, confluent deep linear ulcers
Pseudopolyps	Common	Uncommon
Skip lesions	Absent	Present
Cobblestone pattern	Absent	Present
Deep fissures	Absent except in fulminant colitis	Present
Fistulae	Absent except in fulminant colitis	Present
Mucosal atrophy	Marked	Minimal
Thickness of the wall	Normal	Increased
Fat wrapping	Absent	Present
Strictures	Uncommon	Present

These properties contribute to the clinical behavior of the disease and the varied manners of presentation.

The most common site of Crohn's disease is an ileocolic distribution though anal, intestinal, or colonic disease alone are also regularly seen. As Crohn's disease involves the full thickness of the bowel wall, stricture and obstruction, fistula formation, and abscess formation are important sequelae that might result in presenting symptoms, point to diagnosis, and might mandate intervention. Discontinuous skip areas of involvement are common and a clear differentiating behavior from ulcerative colitis.

The work-up of Crohn's disease begins similarly to ulcerative colitis. History and physical exam provide evidence of the diagnosis.

IBD Histology

A basic knowledge of the histological features in inflammatory bowel disease is essential for the practicing colorectal surgeon. The combination of clinical disease activity, endoscopic findings, and histology generates accurate diagnosis. Communication with an experienced IBD pathologist is vital for making correct treatment decisions in many situations.

Ulcerative Colitis

The classic macroscopic finding in ulcerative colitis (UC) is contiguous mucosal inflammation extending from the rectum proximally for a variable distance in the colon. Other portions of the gastrointestinal tract are not involved. Macroscopic features of UC are shown in Table 45-3. Clinicians should be aware of certain instances where macroscopic inflammation in UC may not be in a continuous pattern. These situations are often confused with Crohn's disease. The cecal cap or patch is an isolated area of inflammation surrounding the appendix [7, 8]. Backwash ileitis is contiguous ileal inflammation in UC from reflux through the ileocecal valve. It is correlated with severity of cecal inflammation. The incidence of backwash ileitis is decreasing, likely due to improved medical management and reductions in severe right-sided colitis [9]. Patchy or noncontiguous ileal involvement should raise suspicion for Crohn's disease. Rectal mucosal sparing is often thought to result from enema topical therapy. Among medically treated UC patients, both oral and per rectum, 33–44% have been shown to have some patchy distribution of inflammation [10].

The hallmark of microscopic ulcerative colitis is widespread crypt distortion in a continuous pattern of inflammation (Figure 45-1). The severity of inflammation is worse distally in the colon. It is mucosal limited, with occasional extension into the superficial submucosa. In situations of fulminant UC, ulcer penetration to the muscularis propria with serositis can occur, making it difficult to discriminate from Crohn's disease. Crypt abscesses occur more frequently in UC (41%) than in Crohn's disease (19%) [11]. Mucin depletion is much more common in UC than in Crohn's [12]. Basal plasmacytosis is an early feature of UC and can be used to help differentiate it from infectious colitis [13].

Crohn's Disease

Crohn's disease (CD) can affect any portion of the gastrointestinal tract. Mostly commonly the ileocolon is involved. "Creeping fat" at the mesenteric edge of the bowel is due to transmural inflammation and is strongly correlated with Crohn's. "Creeping fat" is nonspecific and is found in other inflammatory conditions, including diverticular disease [14]. Aphthous ulcers are one of the early gross mucosal findings in Crohn's. Ulcers are often surrounded by edematous, but otherwise normal tissues. Coalescence and spread of the ulcers leads to the classic cobblestoned mucosal appearance (Figure 45-2). Inflammatory pseudopolyps caused by inflammation and

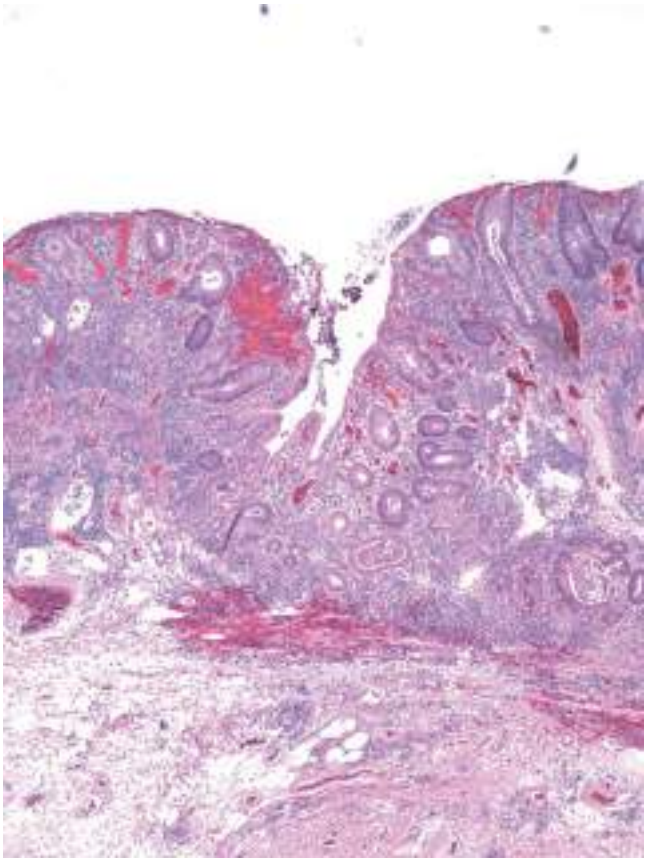

FIGURE 45-1. Low-power view of ulcerative colitis showing inflammatory infiltrate confined to the mucosa.

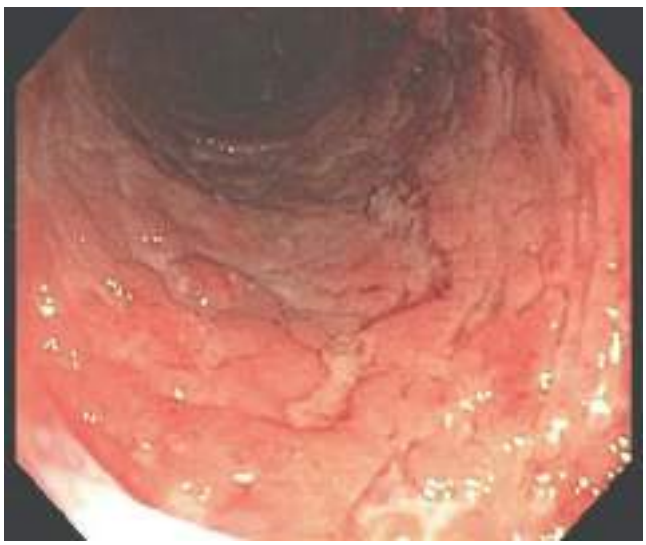

FIGURE 45-2. Crohn's disease with cobblestone appearance of the mucosa.

FIGURE 45-3. Pseudopolyp in Crohn's disease.

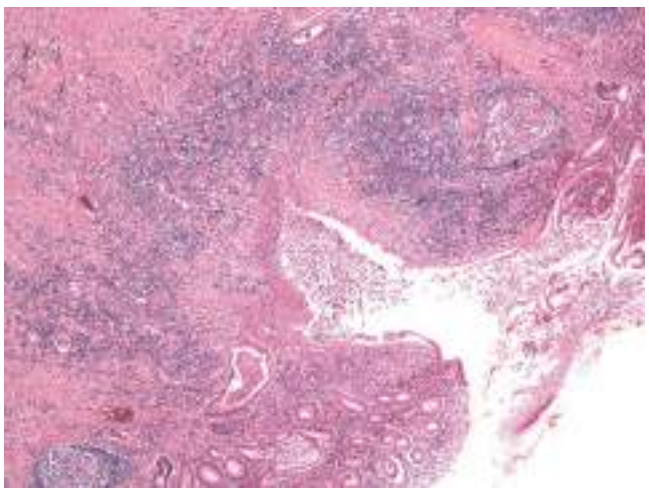

FIGURE 45-4. Low-power view of Crohn's disease with lymphocytic infiltration and mucosal ulceration.

reactive hyperplasia, although more common in UC, also occur in Crohn's colitis (Figure 45-3).

Focal chronic inflammation, granuloma, and localized crypt distortion are some of the commonly accepted microscopic features in Crohn's. Plasma cells and lymphocytes in the lamina propria are hallmarks of colonic inflammation (Figures 45-4 and 45-5). Lymphoid aggregates are common and transmural. Granulomas, although highly suggestive, are not specific for Crohn's, being present in a few as 18% of samples in some studies (Figure 45-5) [11]. Granulomas can

occur at the site of ruptured crypts in UC and are also found in infectious colitis and intestinal tuberculosis. Microscopic differences between UC and CD are listed in Table 45-4.

Indeterminate Colitis

Often the clinical and histologic features of a patient's disease course may share that of both UC and Crohn's. One common situation is fulminant UC mimicking CD with deep transmural inflammation. Indeterminate colitis (IC) was first described by Kent in 1970 [15] and more formally by Price in 1978 [16]. The Montreal Working Party recommended that the term indeterminate colitis should be reserved only for those cases where colectomy has been performed and pathologists are unable to make a definitive diagnosis of either CD or UC after full examination [17]. The term "inflammatory bowel disease, type unclassified" (IBDU) is suggested for patients in whom there is evidence on clinical and endoscopic grounds for chronic inflammatory bowel disease affecting the colon, without small bowel involvement, and no definitive histological or other evidence to favor either CD or UC [17].

The distinct delineation of disease carries becomes surgically relevant when considering a patient with an IC or IBDU diagnosis for a restorative proctectomy. Higher rates of pelvis sepsis, pouch fistula, and pouch failure have been reported in patients with IC undergoing ileal pouch-anal anastomosis (IPAA), compared to a UC cohort [18]. When the patients ultimately diagnosed with CD were excluded, outcomes for the IC patients were similar to the UC group. Functional status and quality of life have been reported to be similar between IC and UC patients post-IPAA, along with similar pouch failure rates [19].

Ultimately, most patients with an initial IC diagnosis will be found to have UC [20]. In the absence of current or historical clinical features of Crohn's disease, most IC patients could be considered for IPAA, with expectations of functional outcome and pouch retention rates similar to that of UC patients [21].

Serology and Markers of Disease

ASCA and pANCA

Anti-*Saccharomyces cerevisiae* antibodies (ASCA) and perinuclear anti-neutrophil cytoplasmic antibodies (pANCA) have been extensively studied as biomarkers in IBD. Due to

TABLE 45-4. Microscopic features used for the diagnosis of IBD [13]

	Ulcerative colitis	Crohn's disease
Crypt architectural irregularity	Diffuse (continuous)	Focal (discontinuous)
Chronic inflammation	Diffuse (continuous) Decrease proximally	Focal (discontinuous) Variable
Patchiness	Uncommon	Common
Localization	Superficial Transmucosal Sometimes in submucosa	Transmural
Serositis	Absent except in fulminant colitis	Present
Lymphoid aggregates	Frequent in mucosa, submucosa	Common, transmural
Granulomas	Absent, except with ruptured crypts	Present
Acute inflammation	Diffuse (continuous)	Focal (discontinuous)
Crypt epithelial polymorphs	Diffuse (continuous)	Focal (discontinuous)
Crypt abscesses	Common	Uncommon
Mucin depletion	Present, pronounced	Uncommon, mild
Neuronal hyperplasia	Rare	Common
Muscular hypertrophy	Absent	Present
Paneth cell metaplasia	Present	Uncommon
Pyloric gland metaplasia	Rare	Present

their presence in other inflammatory conditions, such as vasculitis or rheumatoid arthritis, they are not useful as screening measures. pANCA-positive values range from 2 to 28% in CD patients, while 20–85% of UC patients are positive for pANCA, resulting in a sensitivity of 56% and a specificity of 89% in UC patients [22]. ASCA positivity is found in 39–69% of CD patients and in 5–15% of UC patients [22]. One clinical situation where biomarkers could be extremely useful would be in indeterminate colitis. Unfortunately, in one study of 97 IC patients nearly half (48.5) were ASCA−/pANCA−, thus providing no useful clinical information [23]. ASCA+/pANCA− status was able to predict CD in 80% and ASCA−/pANCA+ predicted UC in 63.3%. One small study of IPAA patients showed ASCA+/pANCA− patients had 44% of developing postoperative fistulas and were more likely to have their diagnosis changed to CD [24]. Elevated levels of pANCA in UC patients undergoing IPAA have been shown to predict the incidence of chronic pouchitis. The cumulative risk of developing chronic pouchitis among patients with high-level pANCA (56%), defined as >100 EU/ml, before IPAA was significantly higher than in patients with medium level (22%), low level (16%), and those who were pANCA−ANCAsi [25].

Fecal Markers

Calprotectin is a small calcium-binding protein, found in abundance in neutrophilic granulocytes, in which it accounts for 60% of the cytosolic fraction, as well as in monocytes and macrophages [26]. Calprotectin is stable in feces for up to 7 days at room temperature and is homogenously distributed [26]. The presence of calprotectin in stool implies mucosal inflammation, which is nonspecific, and can also occur with mucosal bleeding. This can occur in non-IBD situations like NSAID damage or malignancy. Lactoferrin is similar to calprotectin in that it is neutrophil derived and found in the stool. Like calprotectin, it can be measured by commercial ELISA. Lactoferrin testing tends to be more affordable than calprotectin [27]. Calprotectin has been used in a variety of clinical situations for IBD patients, including diagnosis, prediction of clinical course, monitoring response to therapy, and postoperative surveillance. Although primarily assayed via stool sample, measurement via serum samples has been studied, but correlation to stool values is weak [28].

Initial use of fecal calprotectin was in attempting to differentiate between patients with IBD and irritable bowel syndrome, a non-inflammatory condition. This has been fairly extensively studied in both the adult and pediatric populations, with a goal of reducing the need for invasive testing. A meta-analysis showed good sensitivity (93%) and specificity (96%) of fecal calprotectin to diagnose IBD in adult patients, although specificity (76%) was much lower for pediatric patients [29]. The authors calculated in a hypothetical population of 100 adults with suspected inflammatory bowel disease (and an overall mean prevalence of 32%) three patients without the disease would go on to have endoscopy and two patients with the disease would be missed [29]. They conclude that increased fecal calprotectin levels could be used to guide more urgent endoscopic evaluation, but caution that negative values in a patient with persistent rectal bleeding do not exclude the presence of IBD.

There is mounting evidence that mucosal healing is a better target in IBD treatment, rather than clinical symptom control, as it can alter the course of disease, reducing hospitalizations and rates of future surgery [30]. Calprotectin would be a desirable marker for following mucosal healing, as repeated endoscopic evaluation is not practicable for patients. One study of IBD patients in clinical remission with normalized calprotectin levels showed 38 of 45 had complete mucosal healing [31]. Data from the STORI trial showed that of CD patients in stable remission on infliximab and immunomodulator who stopped biologic treatment, 43.9% would relapse at 1 year [32]. Fecal calprotectin ≥300 μg/g was shown to be predictive of relapse on multivariable regression (hazard ratio 2.5). In general, fecal calprotectin has been more effective in predicting the clinical course of UC patients or in CD patients with colonic involvement [26].

Fecal calprotectin has also been studied in the surgical IBD cohort. In a prospective study of 90 patients admitted with acute UC, calprotectin was shown to be predictive of the need for colectomy [33]. All patients received high-dose steroid therapy, with 23% receiving infliximab. 34.4% of patients required colectomy due to failure of medical management. Fecal calprotectin was significantly higher in patients who had failed medical therapy compared to those who escaped surgery (1200.0 vs. 887.0 μg/g; $P=0.04$). Using a cutoff point of 1922.5 μg/g at mean follow-up around 1 year, 87% of patients required colectomy. In post-resection CD, fecal calprotectin >200 μg/g has been shown to be predictive of endoscopic recurrence after 12 months [34]. Recurrence after surgical resection for CD may also be predicted by calprotectin levels. In a prospective study, levels of calprotectin greater than 100 μg/g indicated endoscopic recurrence with 89% sensitivity and 58% specificity and a negative predictive value of 91% [35]. Calprotectin was superior to CRP and a clinical disease index (CDAI) for detection of recurrence and monitoring response to treatment. Serial calprotectin measurement may represent a less invasive and costly method for the postoperative management of CD patients.

Inflammatory Markers

C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and albumin are three common serum measures of the acute phase of inflammation. IBD intestinal inflammation is clearly a trigger for elevation of these measures, but remains nonspecific, as other inflammatory conditions can

elevate them as well. Albumin has a long half-life (5 days), limiting its clinical usefulness. CRP is made by hepatocytes, and a primary trigger for release is IL-6. CRP has a short half-life (19 h) compared with other acute-phase proteins and will therefore rise early after the onset of inflammation and rapidly decrease after resolution of the inflammation [36]. CRP tends to be elevated more in CD, rather than UC [37]. ESR is the rate at which erythrocytes settle in the plasma. ESR is an indirect measurement of plasma acute-phase protein concentrations and can be greatly influenced by the size, shape, and number of erythrocytes, as well as by other plasma constituents such as immunoglobulins or fibrinogen [38]. Compared with CRP, ESR will peak much less rapidly and may also take several days to decrease, even if the clinical condition of the patient or the inflammation resolves [36].

These inflammatory markers have been studied in a variety of clinical IBD situations. They allow for excluding IBD diagnosis in patients with functional bowel disorders without invasive study, in whom there may be some overlap of clinical symptoms. One study of patients presenting with abdominal symptoms showed elevations in CRP and ESR in all patients eventually diagnosed with CD and in 50% of those eventually diagnosed with UC [39]. No patients with functional bowel disorders had elevated inflammatory markers. A more recent study showed a cutoff value of 2.3 mg/l had a sensitivity of 100% and a specificity of 67% in differentiating functional disease from new cases of IBD [40]. CRP tends to be a less reliable predictor of endoscopic disease in the postoperative CD patient [35, 41].

Genetic-Based Testing

In 2001, two groups simultaneously reported on NOD2/CARD15 gene mutations on chromosome 16 that conferred susceptibility to Crohn's disease [42, 43]. NOD2 plays a role in the nuclear factor NF-κβ pathway that is responsible for the cellular response to bacteria. This has provided a genetic model for the dysregulated response of the immune system that occurs in IBD. In retrospective clinical studies, NOD2 mutations have been shown to be more frequently associated with ileal CD and severe pouchitis in UC patients after IPAA [44, 45]. NOD2/CARD15 mutations are actually quite common in asymptomatic patients, with prevalence between 2.4 and 11.5% in a white population, with wide geographic variability [46]. Even patients with double NOD2/CARD15 mutations did not have elevated risk of IBD [46]. This underscores the fact that genetics in conjunction with environmental exposure is necessary for the clinical expression of IBD. In fact, another burgeoning area of genetic research in IBD involves the microbial environment of the gut [47]. Although the clinical utility of genetic testing remains limited currently, it is clear that research in this field will shape the future of IBD diagnosis and treatment.

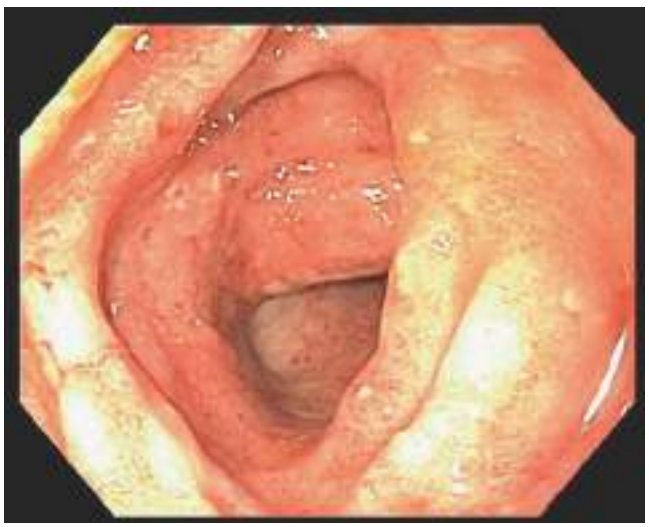

FIGURE 45-7. Sigmoid colon in ulcerative colitis.

Endoscopy in IBD

Flexible Endoscopy

Flexible endoscopy remains a gold standard technique in the initial diagnosis and follow-up management of patients with suspected or established inflammatory bowel disease. Figures 45-6 and 45-7 show the endoscopic appearance and subtle differences between Crohn's colitis (patchy) and ulcerative colitis (diffuse and contiguous). Endoscopy allows for mucosal inspection and, importantly, tissue sampling for histology. Therapeutic interventions, such as balloon dilations of strictures, can also be performed. Patients with symptoms suggestive of IBD should undergo colonoscopy. Intubation and biopsy of the terminal ileum is especially

important in patients with suspected Crohn's disease. Endoscopically abnormal areas of the colon should be sampled. Biopsy of normal areas is important as well, as presence or absence of microscopic colitis can aid in differential diagnosis. Particular attention should be made in areas of colonic stricture, with historical studies showing 24% of UC and 6% of CD strictures may be malignant [48, 49]. Colonoscopy is overall a safe procedure, but it is invasive and carries risk of serious complications. IBD patients are known to carry higher risks of procedural complications. This is especially true in patient with advanced age, severe colitis, or during therapeutic interventions. Risk of perforation in one national database study for IBD patients was 1%, with age, female gender, and therapeutic dilation being predictors of complication [50]. Upper endoscopy plays a role in the smaller subset of Crohn's patients who present with esophagogastroduodenal involvement. Newer techniques of single and double balloon enteroscopy allow advanced endoscopists to reach far into the small bowel, in both antegrade and retrograde directions. Double balloon enteroscopy has been shown to be similar to CT enterography for the evaluation of Crohn's small bowel disease [51]. Double balloon enteroscopy is invasive, however, and carries risk of perforation, with major complication rates of around 1% and interventional procedure complication rates of 4–5% [52]. One major advantage is that it can be used for stricture dilation or retained video capsule removal, with relatively good rates of success [53, 54]. Double balloon enteroscopy remains an advanced endoscopic technique and may not be available in all centers.

Beyond initial diagnosis, endoscopy is used for evaluating the response of IBD to medical therapy, for monitoring recurrence after surgery, and for dysplasia surveillance in UC. There are no specific guidelines for routine colonoscopy during medical therapy for IBD [55]. Colonoscopy is indicated when there is a major change in symptoms. It is debated whether colonoscopy should be done for the clinically asymptomatic patient. It is well established that clinical symptoms and endoscopic findings may not be congruent, and clinicians are often poor at predicting disease extent based on symptoms alone. Colonoscopy is useful in the decision to withdraw medical therapy in stable CD [55]. Endoscopic mucosal healing has been shown to reduce twofold the risk of relapse after infliximab withdrawal in CD patients on immunosuppression with steroid-free remission [32]. Colonoscopy is recommended 6–12 months after surgery for CD, as anastomotic recurrence (Figure 45-8) is common (60–90% at 1 year) [55]. Fecal calprotectin may be a useful screening trigger to prompt earlier colonoscopy (see Fecal markers section) [55]. Early medical intervention in the postoperative CD setting is associated with lower rates of endoscopic recurrence and higher rates of complete mucosal healing [56]. There are a number of endoscopic grading systems used to describe mucosal findings in CD, including the Crohn's Disease Endoscopic Index of Severity (CDEIS) and the Simple Endoscopic Score for Crohn's Disease (SES-CD) [57, 58]. None are widely or routinely used outside of research settings. However, it is important to standardize endoscopic reporting including severity, location and extent of inflammation, and presence of strictures or other lesions. The Rutgeerts endoscopic score (Table 45-5) has been shown to predict the recurrence of symptoms and need for repeat surgery based on the endoscopic appearance of the neoterminal ileum and ileocolonic anastomosis [59]. 85% of patients with i0 or i1 lesions 6–12 months postoperatively will have no endoscopic progression at 3 years [60]. i3 or i4 patients had progressive or very severe endoscopic progression 92% of the time [60]. Clinical recurrence occurred in less than 5% of patients with i0/i1 lesions, 15% with i2, 40% with i3, and >90% with i4 [60]. There are at least 9 endoscopic scoring systems described for UC [30]. Two of the most commonly used are the Baron and Mayo scores (Table 45-6) [61, 62]. The Baron score relies on the assessment of mucosal bleeding during colonoscopy, and the Mayo score evaluates the overall appearance of the mucosa, with respect to erythema, vascular pattern, friability, bleeding, erosions, and ulcerations.

FIGURE 45-8. Anastomotic recurrence 2 months after ileocolic resection.

Colonoscopy is recommended for patients with chronic colitis for dysplasia surveillance. The risk of colorectal cancer surpasses that of the general population after 8–10 years of disease [63]. It is important to note that this period begins at the onset of symptoms, rather than time of histological diagnosis. Although a meta-analysis demonstrated the cumulative risk of colorectal cancer for UC patients to be 2.1% at 10 years, 8.5% at 20 years, and 17.8% at 30 years, population-based series have reported lower annual incidence rates of 0.06–0.2%. Despite this, it is generally

TABLE 45-5. Rutgeerts score of postoperative endoscopy for CD [59] and corresponding CTE scoring system for postsurgical examination [92]

Rutgeerts	Endoscopic findings	CTE	CTE findings
i0	No lesion in the neoterminal ileum	CTE0	No findings
i1	<5 aphthoid ulcers	CTE1	Minor mucosal irregularities with slight wall thickening and mural contrast enhancement
i2	>5 aphthoid ulcers with normal mucosa in between, or skip areas or larger lesions related to anastomosis	CTE2	Mucosal hyperdensity with distinct bowel wall thickening, no stenosis, or stenosis without prestenotic dilatation
i3	Diffuse aphthoid ileitis, with mucosa extensively inflamed	CTE3	Major mucosal abnormalities, distinct bowel wall thickening with target sign and extravisceral signs such as perienteric stranding, comb sign, fibrofatty proliferation, stenosis with prestenotic dilatation, and/or the presence of complications
i4	Diffuse inflammation, large ulcers, nodules, and/or stenoses		

TABLE 45-6. Baron and Mayo scores for ulcerative colitis

	Baron score	Mayo score
Score 0	Normal mucosa, ramifying vascular pattern clearly visible throughout, no spontaneous bleeding, no bleeding to light touch	Normal or inactive disease
Score 1	Abnormal but not hemorrhagic: appearances between "0" and "2"	Mild disease (erythema, decreased vascular pattern, mild friability)
Score 2	Moderately hemorrhagic: bleeding to light touch, but no spontaneous bleeding seen ahead of instrument on initial inspection	Moderate disease (marked erythema, absent vascular pattern, friability, erosions)
Score 3	Severely hemorrhagic: spontaneous bleeding seen ahead of instrument at initial inspection, and bleeds to light touch	Severe disease (spontaneous bleeding, ulceration)

accepted that chronic UC is associated with an increased risk of malignancy [64]. Studies on dysplasia and cancer in UC are more widely available than those on CD; thus surveillance and treatment paradigms are often similar in the two groups despite the differing disease pathophysiology [65]. The Crohn's and Colitis Foundation of America (8–10 years), the American College of Gastroenterology (8–10 years), and the American Society of Colon and Rectal Surgeons (8 years) all have similar recommendations for initial surveillance colonoscopy in chronic colitis [64, 66, 67]. After a negative study, most recommend 1–2 year interval for repeat examination. After two negative exams, follow-up time can be 1–3 years. After 20 years of disease, recommendations are again every 1–2 years [66]. Patients with primary sclerosis cholangitis (PSC) have higher rates of malignancy and should undergo yearly evaluation [68].

The traditional recommendation for endoscopic biopsy for dysplasia surveillance is four-quadrant sampling every 10 cm [64, 66]. Particular attention should be paid to raised lesions or strictures, with sampling of any normal surrounding areas to allow for histologic comparison. Significant pseudopolyposis may make surveillance unreliable by obscuring the mucosa or being too numerable to sample [67]. Particularly in UC, consideration of sampling every 5 cm in the distal colon is reasonable given the worsening severity of inflammation and higher rates of malignancy in this area [66]. A typical endoscopic biopsy samples 0.05% of the mucosal surface [69]; accordingly multiple samples must be taken for adequate sampling. A minimum of 33 random biopsies has been shown to result in 80–90% sensitivity for detecting dysplasia, with 64 required for 95% [70].

Recent advances in endoscopic technology are changing how dysplasia surveillance is performed. The American Society for Gastrointestinal Endoscopy (ASGE) has recently made strong recommendations that high definition video equipment be used when using traditional white-light colonoscopy [71]. One retrospective study showed twice as many dysplastic lesions were detected with high definition equipment rather than standard definition [72]. Chromoendoscopy involves the use of dye applied to colonic mucosa to improve epithelial surface detail and allow for targeted sampling. Diluted indigo carmine and methylene blue are the two most commonly used dyes. Two prospective tandem colonoscopy studies have shown the increased ability of chromoendoscopy to detect dysplastic lesions, being 1.8–3.5 times more likely positive than conventional four-quadrant biopsy technique [71, 73, 74]. One study found no dysplasia in 2904 non-targeted biopsies, versus 9 in 157 chromoendoscopy-targeted biopsies [73]. The improvement in efficiency using chromoendoscopy is clear. It is not clear that this has had any effect on reducing rates of progression to cancer. The St Mark's Hospital recently reported on the outcomes of their UC surveillance screening program originating in 1971. From 2002 to 2012 twice as many dysplastic lesions were found using chromoendoscopy (8.4%) vs. white-light colonoscopy (4%) [75]. The post-colonoscopy colorectal cancer rate was lower following chromoendoscopy compared with white-light endoscopy, although this did not reach statistical significance [75]. Chromoendoscopy has been given a strong recommendation over white-light colonoscopy by the ASGE [71]. Currently there is no evidence to support routine use of digital enhancement techniques, such as narrow band imaging (NBI).

One study of NBI vs. white-light colonoscopy actually found fewer total dysplastic lesions were detected with NBI [76].

Confocal laser endomicroscopy (CLE) is a newly introduced modality which captures images of "virtual histology" of the gastrointestinal mucosa during endoscopy [77]. At present, CLE can be performed with two devices: one integrated into an endoscope (Pentax, Tokyo, Japan) and one as a mini-probe through the scope (Cellvizio, Mauna Kea Technologies, Paris, France) [77]. Confocal microscopy consists of focusing a laser ray onto the mucosal surface and filtering the returned light by means of a small pinhole which rejects out-of-focus light [77]. This technology allows for real-time interpretation of histology and, in theory, could eliminate the need for endoscopic biopsy. It can also detect microscopic evidence of ongoing inflammation in normal appearing colonic mucosa. One study found 4.75-fold more dysplastic lesions using chromoendoscopy-guided CLE with 50% fewer biopsy specimens [78]. This technique will require further investigation and study before it can be considered for integration into screening paradigms.

Capsule Endoscopy

Video capsule endoscopy (VCE) was introduced in 2001 as a noninvasive method to evaluate the small bowel that remains outside the reach of contemporary flexible endoscopy [79]. The technique consists of a pill-sized device with self-contained lighting, video capture, and transmission capability. After a 12 h fast, the patient consumes the camera with a sip of water. Bowel preparation regimens are variable, but a meta-analysis showed a combination of polyethylene glycol and simethicone provided optimum image quality [80]. Patients should abstain from NSAIDs for a month prior to examination, as these can induce mucosal ulcerations and confound image interpretation. Patients wear image capture sensors and belt, avoid consumption of fluids for 4 h, and do not have to limit physical activity. The capsule itself passes naturally with bowel movement and is usually excreted within 24–72 h [79].

For the IBD patient, evaluation of small bowel CD is the most common indication for VCE. Meta-analysis has shown VCE to have higher diagnostic yield than colonoscopy, push enteroscopy, conventional enterography, and CT enterography [81, 82]. VCE was found to be similar to MR enterography in those same reviews. One important consideration in many VCE studies is that patients with suspected or known structuring CD were excluded, due to fear of capsule retention. Capsule retention is a rare, but feared, complication of VCE. Reported rates of capsule retention in CD patients are around 13%, with one review showing that established CD diagnosis increased the risk of capsule retention ninefold [83, 84]. A slowly dissolvable patency capsule exists (Agile PC, Given Imaging) and is intended to assess patency of the small bowel prior to VCE [79]. The European Society of Gastrointestinal Endoscopy (ESGE) has recommended that VCE be done if deemed necessary to change management in CD and only after cross-sectional imaging and patency capsule evaluation are done to exclude stricture [83].

FIGURE 45-9. Fluoroscopic enterography study showing terminal ileal stricture in Crohn's disease.

Radiology in IBD

Plain Radiography

Plain radiographs remain a standard for rapid assessment of the IBD patient presenting with acute abdominal symptoms. Free air from hollow viscus perforation, toxic megacolon, or small bowl obstruction from stricture or adhesion are diagnoses that can rapidly and inexpensively be confirmed. Fluoroscopic gastrointestinal imaging, once the gold standard for IBD evaluation, has rapidly been supplanted by advanced imaging techniques and flexible endoscopy. In the 1960s and 1970s, before CT or MRI, single contrast and then double contrast enema imaging was the primary method to evaluate both the upper and lower GI tracts. Historically, small bowel follow-through (SBFT) studies have been the standard approach to assess active disease [85]. Early mucosal changes and strictures can be seen with fluoroscopic studies (Figure 45-9). Although well-supervised SBFT studies allow for excellent visualization of the bowel mucosa, small bowel enteroclysis offers a more sensitive and accurate assessment of mucosal abnormality and strictures [85]. Standard enteroclysis is typically performed with placement of a nasojejunal tube with fluoroscopic guidance. Barium along with air or methylcellulose, for double contrast, is instilled to provide opacification and distension of the small bowel [86].

Computed Tomography

Computed tomography (CT) imaging has revolutionized the diagnosis and management of abdominal diseases. Findings of small and large bowel mural thickening, abscess, and

fistulae were evident on the earliest generation of CT scanners in early studies of IBD patients [87]. CT imaging for UC patients is mostly limited to situations of severe or fulminant colitis. CT for CD allows non-interventional assessment of the small and large bowel, as well as possible extra-intestinal manifestations of disease. In addition to standard axial image acquisition, CT enteroclysis and enterography are also possible. CT scanning is a primary modality for image-guided percutaneous biopsy of abscesses in CD. A study using a nationwide database showed 29% of CD abscesses were treated with percutaneous drainage in 2007, up from 7% in 1998 [88]. In that same time period, surgical drainage fell from 59 to 32%.

CT enterography (CTE) requires specialized preparation. Neutral intraluminal contrast agents (such as water) are required to enable adequate visualization of enhancing mucosal lesions which would otherwise be masked by positive contrast agents such as barium [85]. Because luminal collapse can mimic bowel wall thickening, large volume ingestion is necessary. A typical prep consists of 1 L of a polyethylene glycol solution followed by 1 L of water. This can be consumed orally (enterography) or via nasojejunal tube (enteroclysis) given 1 h before scanning. Intravenous contrast is given to enhance inflammatory changes in the mesentery and bowel wall. Anti-spasmodics are often given to reduce bowel motion artifact.

CTE has been shown to be as specific as conventional enteroclysis in diagnosis of Crohn's small bowel lesions, with somewhat less sensitivity [89]. Enteroclysis can pick up some early changes of disease (thickened folds, aphthoid ulcers) that CTE does not have the resolution to identify, and there may be clinical situations where a combination of the techniques is helpful. CTE has been shown to alter clinical decision making in CD. One cohort study of 273 established or suspected IBD patients showed CTE changed management in 51% of cases [90]. Of those with established disease, 48% had management change, including 24% with medication changes. Another study showed poor correlation between CTE findings and clinical assessment of IBD symptoms [91]. 16% of CTE identified strictures in this study were not suspected by expert clinical assessors. No scoring systems for CTE are in wide use, but one has been developed for imaging postsurgical resection [92] (Table 45-5). This has been evaluated prospectively, and been shown to accurately predict need for reoperation, similar to Rutgeerts endoscopic score [93].

MRI

Magnetic resonance imaging (MRI) allows for acquisition of images, similar to CT, but does so by manipulating the nuclear properties of hydrogen atoms and thereby avoids exposing the patient to the ionizing radiation that CT requires. MRI also allows for obtaining images with specific contrast profiles to allow for differentiation between inflammation and fibrosis or suppressing surrounding fatty tissues. One issue with MRI is increased complexity, longer time for image acquisition, and generally more limited availably, when compared to CTE. The increased soft tissue resolution delivered by MRI over CT has made it the preferred imaging technique when imaging is required for complex fistulizing perianal CD.

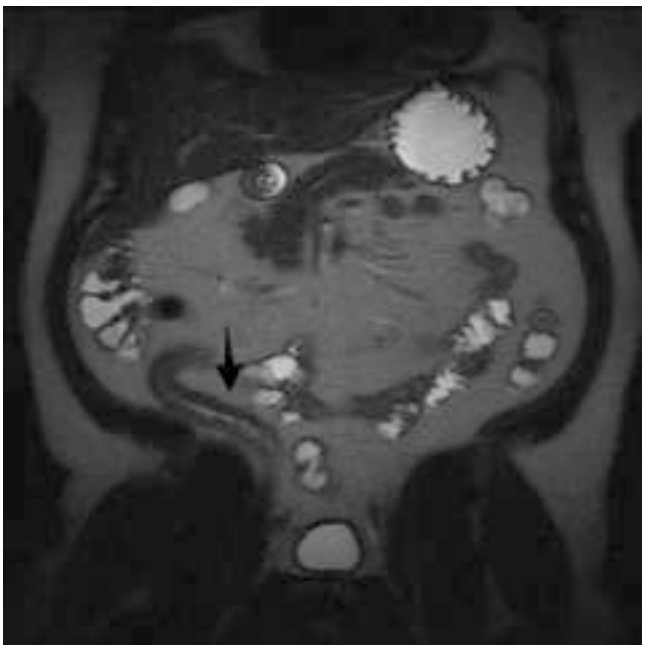

FIGURE 45-10. MRE in Crohn's disease. Coronal T2-weighted images demonstrate segmental mural thickening of the terminal ileum (*black arrow*).

Patient preparation for MRE is similar to that of CTE. Oral purgatory solution and large volume negative contrast solution are consumed. MR enteroclysis can be performed, but enterography is preferred by patients and has been shown to produce similar image quality [94]. Gadolinium is used as an IV contrast medium. MRE is much more sensitive to motion artifacts than CTE, so 1 mg of glucagon is often used. Multiple image acquisition sequences are taken including T1, T2, and diffusion weighted (Figures 45-10, 45-11, and 45-12). Breath holding is necessary for most sequences and the entire time of image acquisition takes around 30–35 min [94].

The presence of bowel wall thickening in conjunction with asymmetric mural hyperenhancement is essentially pathognomonic for Crohn's disease images (Figure 45-10) [95]. The "comb sign" refers to engorgement of the vasa recta and is highly suggestive of active inflammation [95]. The ability of MRE and CTE to detect Crohn's lesions is similar. One study showed sensitivity of MRE to be 90.5% and 95.2% in CTE for detecting active small bowel Crohn's disease [96]. In this study, MRE image quality scores were rated significantly worse than CTE, underlying the increased technical challenge of image acquisition for MRE. Three indexes of activity based on adequate external references have been proposed: the

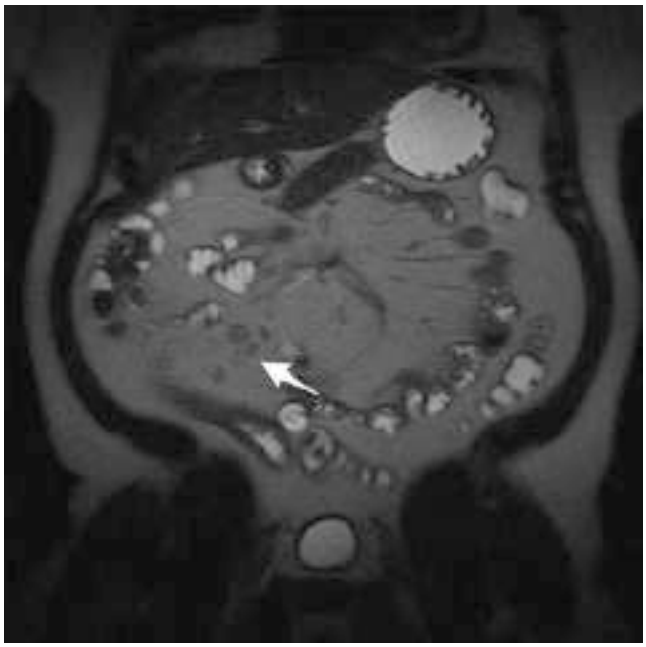

FIGURE 45-11. MRE in Crohn's disease. Coronal T2-weighted images with surrounding fibrofatty proliferation and ileocolic lymph nodes (*white arrow*).

FIGURE 45-12. MRE in Crohn's disease. Gadolinium-enhanced coronal T1-weighted image demonstrate mucosal hyper-enhancement as well as enhancement of the ileocolic lymph nodes, indicative of active Crohn's disease (*arrows*).

Magnetic Resonance Index of Activity (MaRIA) score, the Crohn's disease MRI Index (CDMI) score, and the Nancy score [97]. The MaRIA and CDMI scores are the most commonly used in research settings, but neither has yet transitioned to routine clinical practice [97]. The accuracy of the MaRIA, CDMI, and Nancy scores for detecting inflammatory activity is in the range of 80–90%, with MaRIA accuracy of predicting mucosal healing being 83% [97].

Ultrasound

Ultrasound (US) could, in theory, represent an ideal imaging technique for the IBD patient. US is widely available, is relatively low cost, is noninvasive, and does not require ionizing radiation. However, US is a highly operator-dependent imaging method and correct interpretation of sonographic findings requires adequate experience in abdominal and bowel sonography [98]. Both oral and intravenous contrast agents are available to enhance images. Bowel wall thickness >3–5 mm detected with US is the primary cutoff for postoperative CD recurrence in many studies, with a wide range of sensitivity and specificity reported [99]. One study looked at bowl wall thickness of the anastomosis in postoperative CD, showing patients with thickness >3 mm had twice the risk of further surgical intervention [100].

Nuclear Medicine

Currently nuclear medicine plays a limited role in the initial imaging assessment of patients with CD, depending on local practice [85]. Radiolabeled white cells have been used to quantify degree of bowel inflammation, but are limited by poor anatomical correlation and failure to detect strictures and fistulae [85]. PET/CT has also been evaluated in CD, with higher standardized uptake values (SUV) correlating with worsening inflammation [101]. One small study of 13 patients showed the addition of PET to CTE was able to detect additional areas of inflammation or fistula in 23% of patients [102]. In general, concerns over radiation exposure have limited the use of many nuclear medicine techniques in routine clinical practice.

Evolving Role of CTE and MRE

There has been recent concern among medical professionals and the media regarding increasing exposure of patients to ionizing radiation and subsequent risk of malignancy. IBD patients represent a cohort at particular risk for repeated studies employing ionizing radiation. The young IBD patient represents a particular concern. Younger patients are inherently more radiosensitive and have longer life spans for radiation-induced cancers to develop [103]. One retrospective study looking at radiation exposure in children with IBD

estimated that 60% would exceed 50 mSv by age 35 [104]. There is direct evidence from epidemiologic studies that organ doses in the range of 30–90 mSv result in an increased risk of cancer [103]. Given the similar clinical usefulness of both CTE and MRE, many advocate for the use of MRE in most situations where imaging is required, especially in the adolescent IBD patient. Surgeons, gastroenterologists, and emergency medicine physicians caring for IBD patients should be particularly aware of this issue and coordinate care so that unnecessary radiologic studies can be avoided.

Medical Management of Chronic Ulcerative Colitis

Stefan D. Holubar and Mattias Soop

Key Concepts

- CUC is highly prevalent in North America and Europe, and its incidence is increasing globally.
- CUC has an unknown etiology, but the pathogenesis is believed to be multifactorial, with an impaired mucosal immune regulation and unknown environmental conditions or trigger(s).
- The incidence of colorectal cancer in CUC is increasing, and the presence of low-grade dysplasia is an indication for colectomy given an unacceptably high rate of synchronous or metachronous cancers.
- Surgeons must be familiar with the numerous medical treatments for CUC, including their side effects.
- Mild-to-moderate CUC is typically treated in a bottom-up manner with oral aminosalicylates, and if steroids are required for flares, then the patient is transitioned to AZA/6MP or a biologic agent to wean the steroids.
- Moderate-to-severe disease is typically treated in a top-down manner with combination therapy with a biologic agent and immunomodulator, often under the cover of temporary steroid treatment.
- Medical patient who may require surgery should be aggressively optimized in terms of anemia, malnutrition, and VTE prophylaxis.
- Pouchitis is common and responds promptly to oral antibiotic use. Patients with "Crohn's-like" picture of the pouch (indeterminate pouchitis) may benefit from additional medical therapy.

Electronic supplementary material: The online version of this chapter (doi:10.1007/978-3-319-25970-3_46) contains supplementary material, which is available to authorized users.

Part 1: Defining CUC

Introduction

Chronic ulcerative colitis (CUC) is an idiopathic, recrudescent chronic disease of colonic mucosal ulceration (Figure 46-1) with a prevalence of well over 600,000 affected persons in North America [1]. CUC is one end of the spectrum of idiopathic inflammatory bowel disease (IBD) (Figure 46-2). Although the etiology of CUC remains idiopathic, it is generally accepted that the pathogenesis of CUC is multifactorial, with an impaired mucosal immune regulation and unknown environmental conditions or trigger(s) playing complementary roles.

The vast majority of patients with CUC will require multiple medications to control disease over the course of their lifetime. Surgeons managing patients with IBD must be intimately familiar with medical management as the risks and benefits of surgery must be weighed against those of continued medical treatment in both elective and acute settings. In this chapter, in Part 1 we will discuss the definition and severity classifications of CUC, and we will review the epidemiology. Part 2 will review the armamentarium of medications currently available. In Part 3 we will present an algorithmic approach to CUC treatment based on severity and extent, as well as that of pouchitis. This chapter, intended for a surgical audience, aims to be a pragmatic clinical overview with clinical pearls rather than being an exhaustive review.

Wilks & Moxon at Guy's Hospital, London, originally described CUC in 1875. Symptoms include chronic diarrhea, often bloody, accompanied by tenesmus and defecatory frequency and urgency. The urge incontinence that many patients experience is one of the more troubling symptoms, and CUC patients will often report needing to "run to the bathroom" and knowing the location of "every bathroom on the interstate." Other common disease manifestations including anorexia related to spasmodic/crampy abdominal pain and systemic signs such as weight loss, fever, arthralgia, and

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_46

fatigue/malaise related to anemia and disrupted sleep patterns due to diarrhea. Extra-intestinal manifestations are numerous and summarized in Figure 46-3.

Diagnosis

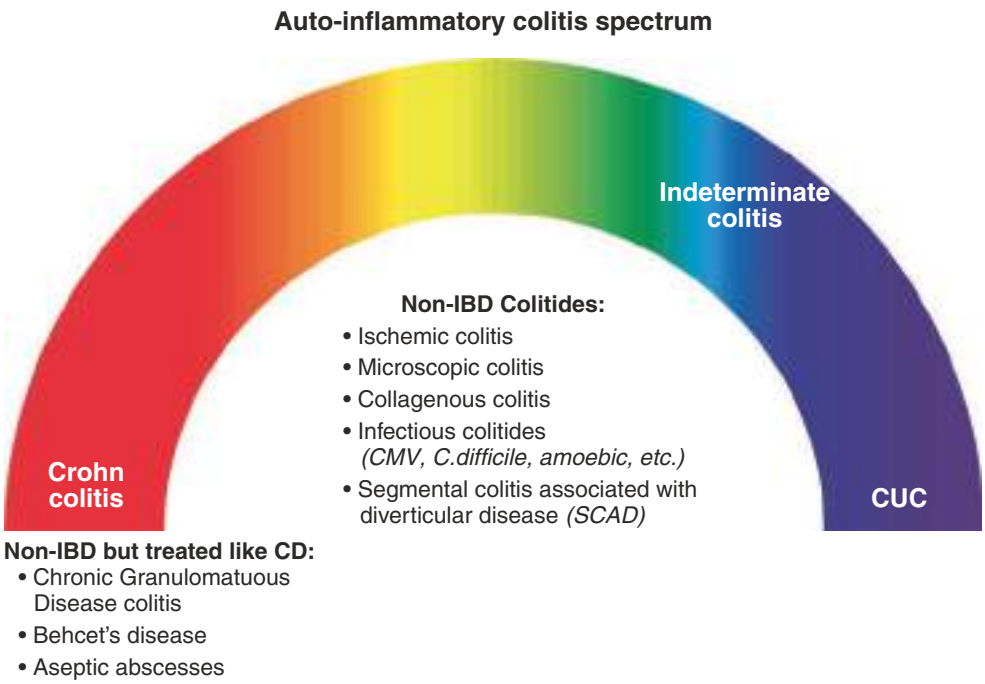
CUC is diagnosed using a combination of history, physical exam, and colonoscopic and histologic appearance (Figure 46-4). History should include baseline bowel function and continence or prior anorectal manifestations that may suggest Crohn's disease (both these could obviate future IPAA). Other conditions that should be ruled out include irritable bowel syndrome, celiac sprue, and the other colitides seen in Figure 46-2. Family history is important, as it is generally appreciated that although IBD is not a genetic disease, there is clearly an "auto"-inflammatory component, with haplotype B27 and other similar genes leading to a predisposition. Relatives and siblings of patients with IBD may also have either CUC or Crohn's disease. Physical exam should assess for anemia, malnutrition, stigmata of CD, abdominal tenderness and scars, rectal tone, masses, and pelvic floor dysfunction. Pelvic floor dysfunction should be treated with physical therapy preoperatively as it can result in suboptimal IPAA function.

FIGURE 46-1. Operative specimen, gross photo. Note ulcerated, hemorrhagic mucosa with severe pseudopolyposis and exposed muscularis, slightly (chronically) thickened bowel wall.

Colonoscopy

Mucosal assessment is crucial to diagnosing CUC, with continuous (i.e., no skip areas) mucosal inflammation starting in the rectum (not the anus) and progressing proximally a variable distance, from only the rectum, to pancolitis with backwash ileitis. Inflammation may be mild, with a granular mucosa with contact bleeding, to more severe with linear ulcerations, to fulminant with severe pseudopolyposis characterized by "islands of mucosa in a sea of muscularis" (Figure 46-1). In patients with long-standing disease, the colon may be foreshortened, ahaustral ("lead-pipe colon"), and although a mucosal only disease, there may be full-thickness hypertrophy and even strictures. Biopsies will

FIGURE 46-2. Auto-inflammatory colitis spectrum.



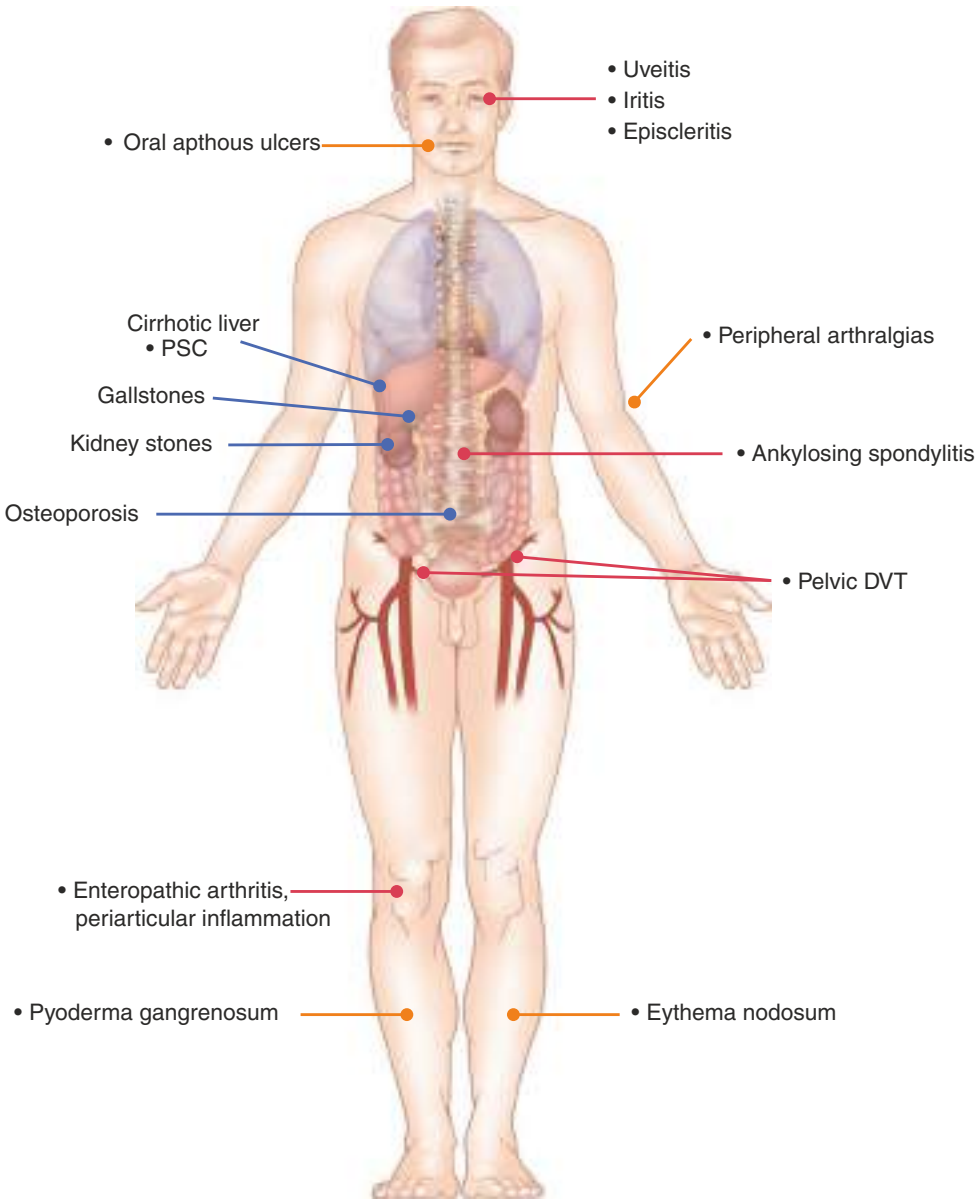


FIGURE 46-3. Schematic representation of common extra-intestinal manifestations in CUC.

demonstrate inflammatory acute and/or chronic colitis, with inflamed lamina propria and distorted crypt architecture. The presence of granuloma on biopsies indicates CD (Figure 46-4: photomicrograph of CUC vs. CD with granuloma). Regarding the role of colonoscopy in CUC surveillance, please see below colorectal cancer section.

Imaging

Cross-sectional imaging is part of the standard initial work-up of patients suspected of having IBD. These may include fluoroscopic small bowel follow-through, magnetic resonance enterography (MRE, Figure 46-5), computed tomographic enterography (CTE, Figure 46-6), or occasionally capsule endoscopy (Video 46-1) to evaluate the small intestine for stigmata of Crohn's disease. CTE and MRE and will typically also demonstrate the extent and severity of colitis. Inflamed bowel will typically demonstrate an edematous, thickened rectal and colonic wall with mucosal hyperenhancement, as well as lead-pipe changes.

MRE is preferred given long-term concerns over harmful levels of cumulative radiation exposure for patients with IBD [2]. MRE has the added benefit of the additional sequences in which the enteric contrast can be made to appear as either positive contrast or negative contrast to enhance visualization of mucosal detail. Of note both CTE and MRE use a larger than standard volume of enteric contrast. MRE uses IV gadolinium which is slightly more nephrotoxic than CT IV contrast, and patients with chronic diarrhea should be well hydrated to prevent contrast-induced nephropathy associated with either CTE or MRE.

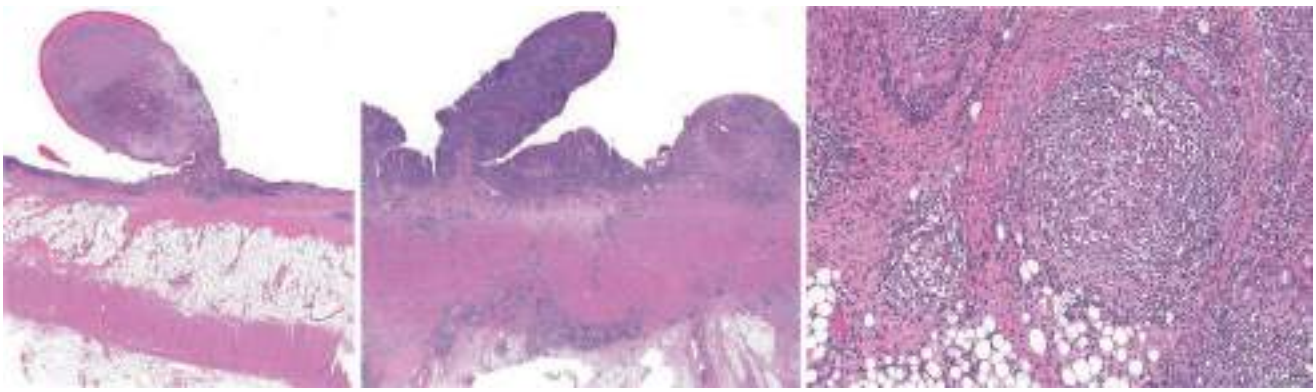

FIGURE 46-4. Photomicrograph of CUC vs. CD. H&E stain. *Top panel* shows severe transmural inflammation and granulomas consistent with Crohn's Disease.; *middle panel* shows severe mucosal ulceration consistent with ulcerative colitis; *bottom panel* shows mucosal inflammation and a pseudopolyp consistent with ulcerative colitis. Courtesy of Dr. Anthony Senagore.

FIGURE 46-5. Magnetic resonance enterography, LAVA sequence 70 s post-contrast. Note the normal appearance of the small bowel wall in a CUC patient prior to total colectomy. Specifically the small bowel wall is of normal thickness, and the lack of mucosal or bowel wall hyper-enhancement, with no demonstrable fistula, strictures, or abscesses. This patient also had marked proximal colonic dilation due to left-sided CUC.

FIGURE 46-6. Computed tomographic enterography. Note the normal appearance of the small bowel wall in a CUC patient prior to total colectomy. Specifically the small bowel wall is of normal thickness, and the lack of mucosal or bowel wall hyper-enhancement, with no demonstrable fistula, strictures, or abscesses.

Serology

Ancillary studies include serial measurement of nonspecific serologic inflammatory markers including white blood cell count (WBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). Both ESR and CRP are sensitive markers of inflammation, inexpensive, and available in most centers. The main difference is ESR's longer half-life. More recently, fecal calprotectin, a measure of colonic mucosal macrophage activity, used in conjunction with ESR and CRP can predict and follow the trajectory of disease flares, and a falling calprotectin can predict mucosal healing [3].

Often clinicians are confronted with IBD patients who are difficult to diagnose with IBD or who do not fit nicely into the category of CD or CUC. In these patients, Prometheus® antigen testing panel has been used as a diagnostic aid. Now in its fourth generation the panel assesses nine antigens, Prometheus testing is reserved for helping to diagnose

cases that are difficult to classify based on traditional testing. Prometheus testing is most helpful in ruling out IBD, but may also have a role in differentiating between CUC vs. indeterminate colitis vs. CD, although it may not have adequate specificity for that indication [4]. As additional antigens are added to the panel, this test is likely to become more clinically useful in the near future.

Infectious Work-up

For newly diagnosed patients with bloody diarrhea, and especially for those with severe disease activity, it is crucial to rule out infectious colitides. These include standard stool studies for ova and parasites mainly to assess for *Giardia lamblia* (more common in those with a history of hiking/camping). Others include cryptosporidium (more common in immunosuppressed patients). *Clostridium difficile* is seen with increased frequency in IBD, and may be related to prior antibiotics or to immunosuppression, and can be assessed by endoscopic appearance (Figure 46-7) or molecular testing. Assays can detect either *C. difficile* antigens or toxins (toxin A and/or toxin B). Cytomegalovirus (CMV) colitis (Figure 46-8) with its characteristic "punched-out" ulcerations is also seen with increased frequency and may also be related to immunosuppression; CMV colitis is usually diagnosed by colonoscopic biopsy. Both C. diff and CMV are more common in patients with CUC who are already on immunosuppressive medications, and these coinfections should be ruled out prior to proceeding to surgery.

FIGURE 46-8. Colonoscopic appearance of CMV colitis in a patient with CUC. Note the classic "punched-out" ulcerations (bottom center of photo) in a background of peudopolypsis. Courtesy of Dr. Anthony Senagore.

Epidemiology

The epidemiology of CUC is relatively well defined. North America has a relatively high incidence of 8–15 cases per 100,000 persons per year [5]. It is estimated that 50,000 new individuals are diagnosed in these regions yearly, and it has an estimated point prevalence of more than 600,000 persons at any given time in the North America. The incidence of CUC in Western societies continues to rise, lending indirect support to the hygiene hypothesis of pathogenesis of CUC (see below). Furthermore, since CUC does not typically shorten the life span of patients, the prevalence continues to rise as well. Risk factors for CUC are summarized in Table 46-1.

Overall, approximately 70–75% of CUC patients will never require colectomy. Some 50% of those who do not undergo colectomy are in remission, and 50% have active disease. Unfortunately, the proportion of patients with prolonged remission is only 10%, highlighting the recrudescent, waxing and waning nature of this illness. Approximately 1% of patients live with continuously active disease [6].

Hygiene Hypothesis and Fecal Microbiome

Although the etiology is as yet undefined and CUC remains idiopathic, mounting evidence suggests that the hygiene hypothesis may pull together many epidemiological features of the disease into a unified theory [7]. This hypothesis, which may also apply to other autoimmune/auto-inflammatory diseases such as diabetes and asthma, suggests that lack of exposure to environmental pathogens sets the stage for future development of hypersensitivity to normally harmless pathogens by lack of tolerance induction. This hypothesis is supported by a number of findings, including

TABLE 46-1. Epidemiologic risk factors for development of CUC

Category	Risk factor(s)	Comments
Age	Median age of diagnosis = 33 years	Larger studies have disproven bimodal distribution
Gender	Slight male preponderance	–
Genetics	Monozygotic twin concordance = 14–19%, dizygotic concordance 0–7%	If one sibling with CUC, other sibling(s) with 7–17 relative risk of CUC
Geography	Higher prevalence in Northern, developed countries but is worldwide	Highest risk areas appear to be North America, UK, Northern Europe, Scandinavia; rising incidence of CUC in developing countries typically precedes that of CD by 1–2 decades
Race/ethnicity	Caucasians, Ashkenazi Jewish ("Jews of Europe"); incidence rising in Asians and Hispanics	Migration studies suggest that geography is a more important risk factor than race as low-risk groups who migrate to higher prevalence areas and then develop a higher prevalence independent of race
Socioeconomic status (SES)	Possible association between increased SES and increased risk of CUC	–
Cigarette smoking	Highly characterized strong, inverse relationship current smokers @ 40% risk reduction for development of CUC	Current smokers with CUC less likely to require hospitalization or colectomy relative to nonsmokers
Appendectomy	Highly characterized strong, inverse relationship with patients who have had appendectomy with a 70% risk reduction for development of CUC	Patients who have had appendectomy who do develop CUC may have less severe disease
Antibiotics	Oral antibiotics in prior 2–5 years modestly increase the risk of IBD development	Probable dose–response relationship, i.e., the more prescriptions for prior antibiotics, the higher the likelihood of developing IBD
Oral contraceptives	No significant relationship for CUC	Earlier studies suggested a modest increased risk for CUC if prior oral contraceptives
Diet	No significant relationship for CUC	Some studies suggested a link between refined sugar and CD not CUC
Infection	No significant relationship for CUC	Conflicting data for CD but no effect for CUC

Adapted from Loftus EV, Epidemiology of inflammatory bowel disease [76]

geographic variation in incidence (more developed countries having increased incidence), socioeconomic status, migration studies (which show that persons who migrate from low-incidence areas to high-incidence areas are at increased risk), and others, the penultimate being a correlation to clean households.

Another area of intense research at this time that may lead to etiologic clues focuses on the characterization of the fecal microbiome (the mass of colonic bacteria in the colonic lumen and on the mucosa) in individuals with and without IBD [1, 8]. At this time, it is unknown whether observed differences in microbiomes between affected and unaffected individuals are etiologic in nature or *secondary* to the disease and/or its treatment. Nevertheless, manipulating the fecal microbiome is a promising line of inquiry.

Colorectal Adenocarcinoma

Aside from confirming the clinical diagnosis, severity, and extent of CUC, colonoscopy also has an important role in surveillance. Patients with CUC are at increased risk of developing colorectal cancer. A rule of thumb is the risk of developing colorectal cancer (CRC) in CUC is 0.5–1% per year after the first 10 years of disease. Currently it is recommended that surveillance should commence 8–10 years after onset of colitis (rather than the time of diagnosis) [2, 9]. However, some 20% of cancers in CUC occur within the first 8 years of disease, emphasizing the importance of early colonoscopy and continued vigilance and low threshold for repeating endoscopy as the clinical situation demands [3, 10]. A number of factors increase the risk of dysplasia and cancer development and hence should inform the frequency of surveillance colonoscopy. These include young age at diagnosis, longer disease duration, severity and extent of inflammation, family history of CRC, and presence of primary sclerosing cholangitis (PSC) [4, 11]. Of note patients with CUC with neoplasia and PSC are also at increased risk for pouchitis after IPAA. The importance of timely surveillance cannot be underemphasized, as the incidence of colorectal adenocarcinoma in CUC appears to be increasing over the last 40 years [5, 12].

For patients with multiple diarrheal bowel movements per day, less bowel preparation is needed, and the patients should be aware *a priori* that multiple mucosal biopsies will be taken. The endoscopist should intubate the terminal ileum for a minimum of 5–10 cm in order to evaluate for backwash ileitis versus Crohn's ileitis. The mucosa and any lesions are biopsied, as is the mucosa in multiple segments, such as eight biopsies from the right colon (and labeled as such), eight from the transverse colon, and eight from the left colon.

A more sensitive approach to neoplasia surveillance is chromo-endoscopy and narrow-banding imaging (NBI). Chromo-endoscopy uses dilute methylene blue sprayed onto mucosa using a standard endoscope, while in NBI a filter narrows the white light to blue. The resulting increased contrast facilitates detection of subtle, especially flat lesions not visible to white-light endoscopy, and directed instead of random biopsies. Although more time-consuming, chromo-endoscopy has a higher adenoma detection rate in CUC [6, 13].

Patients with low-grade dysplasia in flat or non-polyp-like lesions (formally called dysplasia-associated lesions or masses—DALMs) should be advised to undergo colectomy due to a 20–30% risk of these patients already harboring unrecognized colorectal adenocarcinoma and >50% risk of developing cancer within 5 years of the diagnosis of low-grade dysplasia [7, 14].

Classification of CUC

The severity and extent of CUC ultimately is what directs the treatment, so in this section we will review the different methods of assessing disease activity. Historically, disease activity was measured by the criteria outlined by Truelove & Witts in their landmark 1955 study of corticosteroid therapy for the treatment of CUC [15]. These widely used criteria, based on signs, symptoms, and ESR, are shown in Table 46-2.

More recently the Montreal classification of IBD, a revision of the Vienna classification, has become the preferred way to specify disease activity, both in clinical usage and in research studies (Figure 46-9) [16]. The advantage and utility of this system is that it stratifies patients not only by disease severity but also by extent:

Severity

- S0 = clinical remission
- S1 = mild disease: <4 bowel movements per day, no serologic or systemic signs of inflammation
- S2 = moderate: >4 stools per day, some signs of inflammation
- S3 = severe: >= 6 bloody stools daily, pulse >90 beats per minute, temperature >37.5 °C, hemoglobin <10.5 g/100 ml, and ESR >30 mm/h)

TABLE 46-2. Modified Truelove and Witts Criteria

Variable	Mild disease	Severe disease	Fulminant disease
No. of stools/day	<4	4–10	>= 10
Blood in stool	Intermittent	Frequent	Continuous
Temperature	Normal	>37.5	>37.5
Pulse	Normal	>90	>90
Hgb	Normal	<75% of normal	Requiring transfusions
ESR (mm/h)	Normal =< 30	>30	>30
Abdominal X-ray	Normal	Edema/thumbprinting	Dilation
Abdominal pain	None	Mild diffuse tenderness	Distension and tenderness

Note moderate disease with features of mild and severe disease
Adapted from Mahadevan Clin Colon Rectal Surg 2004 [75]

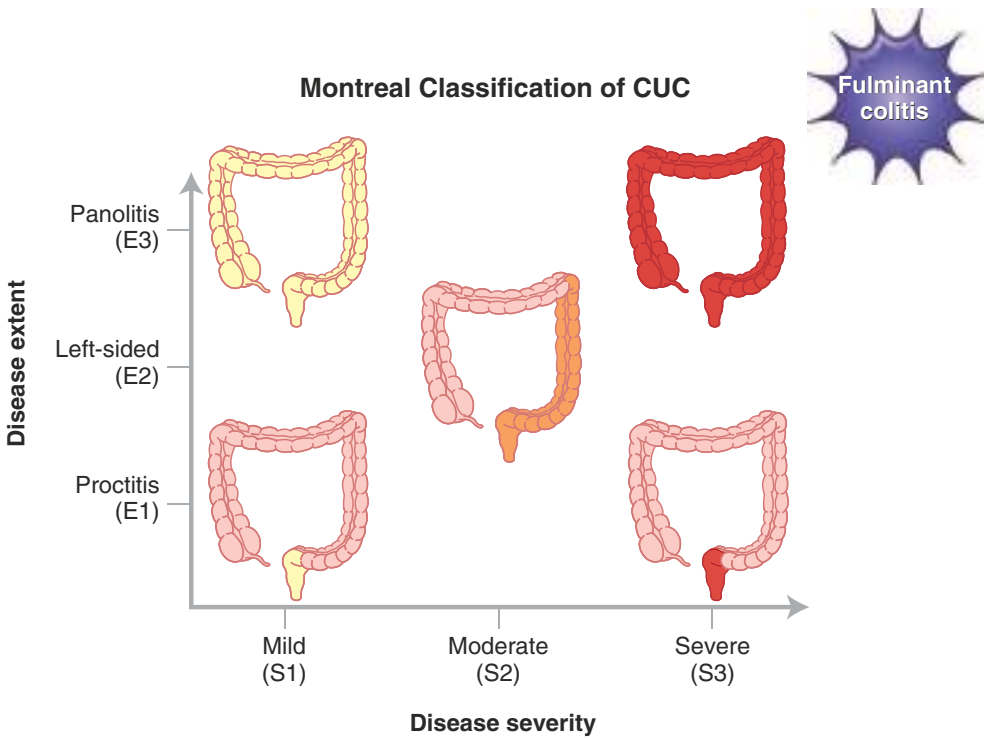

FIGURE 46-9. Diagrammatic representation of the Montreal classification of CUC disease severity and extent.

Extent

- E1 = ulcerative proctitis
- E2 = left-sided colitis
- E3 = pancolitis

Other recommendations of the Montreal Working party was that the clinical term *indeterminate colitis* should be renamed *IBD-unclassified (IBDU)* and that use of the term indeterminate colitis should be reserved for use in the post-colectomy patient in which the pathologist cannot categorize the colitis as either CD or CUC.

Endoscopic classification is facilitated by the Mayo Severity Index (also called the Mayo Clinic Score and Disease Activity Index, Table 46-3). This assesses symptoms, the degree of mucosal inflammation, and the physicians' global assessment of patient well-being [17]. The Simple Clinical Colitis Activity Index (SCCAI, Table 46-4) is also useful clinically for following patient's symptoms over time [18].

Treatment Endpoints

The goals of medical therapy for CUC include induction of remission, avoiding steroids, and improving quality of life (QoL), while avoiding toxicity and preventing neoplasia. Remission is defined as an absence of symptoms that typically accompanies mucosal healing. Maintenance of remission often requires ongoing medical therapy. Symptomatic improvement can objectively be assessed using the above scores, but can also be assessed by measuring quality of life (QoL). Instruments to assess QoL may include measures of overall QoL (such as the SF-36 or EuroQoL 5D VAS [Figure 46-10]), disease (IBD-Q), or symptom-specific (FISI/FIQL) QoL. These can be used both clinically and for research studies.

Cost Considerations

Both the direct and indirect costs of therapy for CUC have been studied and must be considered when determining the optimal treatment for CUC. Overall CUC is known to be a costly disease with medical patients consuming on average $6,586 dollars per year, increasing to $15,732–$20,131 in the years prior to surgical intervention [19, 20]. The cost-effectiveness of surgery for CUC compared with biologic therapy has also been studied, and early colectomy was found to be a cost-effective treatment compared to maximal medical therapy [21]. A subsequent study, including the long-term costs of medical and surgical complications, did find that infliximab (IFX) therapy was initially cost-effective. However, as shown in Table 46-5 (a sensitivity analysis of a model of the effect of time in years on the cost-effectiveness of infliximab and surgery for severe CUC), after 2 years of IFX therapy surgery became the dominant strategy (more effective and less costly), increasingly so as time goes on towards age 70 years [22].

Part 2: Specific Treatments

Bottom-up Versus Top-Down Strategies

An overview of available medical therapy is shown in Table 46-6. In general, there are two competing therapeutic strategies, namely the traditional "bottom-up" (additive) therapy in which less expensive, less effective medications are sequentially added until the desired clinical endpoint is achieved. An emerging approach is the "top-down" (subtractive) strategy in which patients are initially placed on the more aggressive therapies in order to achieve rapid remission, and then agents are sequentially weaned.

TABLE 46-3. Mayo severity index

Variable	Points (Range 0–12)			
	0	1	2	3
BM frequency	Normal	1–2 BM > normal	3–4 BM > normal	>= 5 > normal
Bleeding	None	Streaks < 50% of BM's	Obvious blood with most BM's	Blood alone
Endoscopy	Normal	Mild: Erythema, decreased vascularity, mild friability	Moderated: marked erythema, lack of vascular pattern, friability	Severe: Spontaneous bleeding, ulceration
Physicians Global Assessment (PGA)	Normal	Mild	Moderate	Severe

Adapted from Schroeder NEJM 1987 [17]

TABLE 46-4. Simple clinical colitis activity index

	Points (range 0–15)				
Symptom(s)	0	1	2	3	4
Daytime BM frequency	1–3	4–6	7–9	>9	
Nocturnal DM frequency	None	1–3	4–6		
Fecal urgency	None	Hurry	Immediately	Incontinence	
Bloody stools	None	Trace	Occasional frank	Usually frank	
General well-being	Very well	Below average	Poor	Very poor	Terrible
EIM's	1 point per extra-intestinal manifestation

*Quality-adjusted life years based on EuroQoL-5D Visual analog scale

An example of top-down therapy would be inducing the patient on a biologic and a thiopurine and then attempting to remove the biologic after the patient is clinically improved.

Aminosalicylates (5-ASA Moieties)

Sulfasalazine is the prodrug of the 5-ASA class of medications. Multiple forms of 5-ASA medications have been developed, mainly in an attempt to reduce side effects. 5-ASA medications are administered via enteral (e.g., tablets or time-release "caplets") or topical (e.g., Canasa® suppositories) formulations. There are three release mechanisms: pH (e.g., Asacol®, Lialda®), time release (e.g., Pentasa®), and bacterial cleavage release (e.g., Azulfadine®), and these mechanisms dictate the target area of bowel (ileum, colon, or rectum). To determine the proper dose for a given 5-ASA product, the prescribing provider must the calculate "5-ASA delivered dose." Doses are typically in the 2–4 g by mouth per day range.

Oral 5-ASA products have been shown to be effective for induction of remission in mild-to-moderate CUC (see Part 3 below) [23]. Overall no difference in remission rates was demonstrated between the different preparations. These findings support the conclusion that use of an *adequate* dose is

TABLE 46-6. Overview of clinical pharmacotherapy for CUC

Class (effect)	Indication	Examples	Dose
5-aminosalicylates (enteric/topical anti-inflammatory)	Induction *and* maintenance of remission for mild-to-moderate colitis/proctitis	Sulfasalazine	4–6 g PO daily
		Mesalamine	PO: 2.4–4.8 g PO daily
		Canasa®suppositories	PR: 500 mg–1 g per rectum daily
		Olsalazine	1.5–3 g PO daily
		Balsalazide	6.75 g PO daily
Topical corticosteroids (anti-inflammatory)	Maintenance of remission for mild-to-moderate colitis	Budesonide	9 mg PO daily; rectal foam now available
Thiopurine immunomodulators (block purine metabolism)	Induction *and* maintenance of remission for moderate-to-severe colitis	Azathioprine (AZA) 6-MP	AZA: 2.5 mg/kg PO daily (50–150 mg PO q24)
			6MP: 1.5 mg/kg daily
Biologics agents (block TNF or leukocyte rolling and adhesion)		Anti-TNF-alpha Antibodies	IFX: 5–10 mg/kg, weeks 0, 2, 6 then every 4 weeks
			Adalimumab: 160 mg week 1, 80 mg week 2, then 40 every other week
		Anti-integrin Antibodies	Golimumab: 200 mg week 0, then 100 mg every other week
			Vedolizumab: 300 mg IV weeks 0, 2, 6, then every 8 weeks
Systemic corticosteroids (anti-inflammatories)	Rescue therapy for severe colitis[a]	Prednisone	5–40 mg PO daily
		Hydrocortisone	20–300 mg IV daily
Calcinurin inhibitors (immunosuppressives)	Rescue therapy for steroid refractory severe colitis[a]	Cyclosporine	2–4 mg/kg daily
		Tacrolimus	0.05 mg/kg twice daily

[a]indicated for induction of remission *not* maintenance of remission. Inability to wean from these agents is an indication for surgery

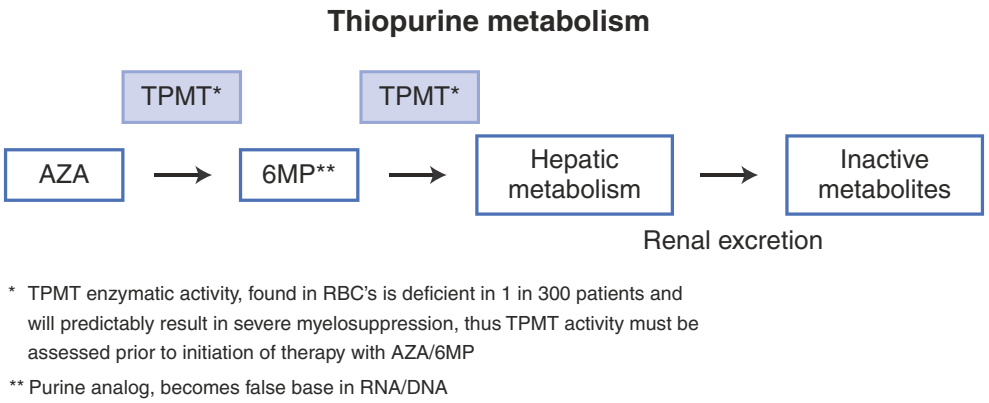

FIGURE 46-11. Schematic representation of in vivo thiopurine metabolism.

more important than preparation, emphasizing the concept of "5-ASA delivered dose." Overall it appears high-dose oral 5-ASA, which is associated with increased side effects, is *not* more effective at induction of remission than moderate dose in CUC patients [23]. Regarding the maintenance of remission, 5-ASA medications are effective for maintenance, but only by maintaining, not lowering the dose. Despite their efficacy in inducing and maintaining clinical remission, 5-ASA class medications are not protective for development of colorectal cancer [24]. "Bidirectional therapy" with both enteral and per rectal preparations is well known to be more effective than either alone and makes clinical sense as essentially all CUC patients have distal disease. However, patients are often resistant to the daily use of suppositories or enemas.

Side effects, which are dose dependent, are mainly dermatologic and gastrointestinal toxicity. Sun exposure can lead to severe sunburn as sulfa moieties can be found in the dermis and can be activated by sunlight.

Immunomodulator Therapy (6-MP, Azathioprine)

Azathioprine (AZA) is the prodrug of 6-mercaptopurine (6-MP), and both act as immunomodulator or weak immunosuppressant. Thiopurines (TPs) are metabolized as shown in Figure 46-11. In summary, the prodrug AZA is first converted by the enzyme TPMT into 6MP, which in turn is then converted by TPMT into other metabolites.

It is important to understand the TMPT metabolic pathway in order to prevent severe toxicity, including life-threatening leukopenia, pancreatitis, and hepatitis [25]. Specifically, the TMPT genes, expressed in red blood cells, are present either in its wild-type form (normal metabolizers) or as deficient genes (prevalence 1 in 300 persons). In TMPT-deficient patients, active metabolites are not efficiently degraded resulting in supra-therapeutic AZA concentrations, frequently leading to myelosuppression.

Thus, TMPT testing is an integral part of initiating TP therapy, and CBCs are monitored for signs of myelosuppression [26]. Since TPs are immunosuppressive, any active infections must be treated prior to initiating therapy. Other side effects include hypersensitivity reactions such as fever, nausea, pancreatitis, and influenza-like symptoms. Finally, immunomodulator therapy may be associated with a marginally increased risk of lymphoma, but the absolute risk is small [27]. It should be noted that IBD patients are at baseline-increased risk of lymphoma due to their chronic inflammatory state (see IFX side effects below for additional discussion).

TPs are effective steroid-sparing medications. They are seldom used by themselves and are often started upfront with steroids (top-down or step-up therapy) to induce remission in a top-down manner. The steroids are then weaned, and the TP used as a maintenance drug. TPs have also been used in combination with biologic agents as they are known to increase biologic efficacy; the increased efficacy of "SONIC-style" combination therapy may be due in part to prevention of anti-TNF immunogenicity [28]. Thiopurines, in the setting of combination therapy, may also represent an "exit strategy" from chronic biologic therapy [29].

Biologic Agents

Anti-TNF-Alpha Antibodies

Infliximab (Remicade®)

IFX is chimeric mouse/human monoclonal anti-Tumor Necrosis Factor (NTF) alpha antibody. IFX was FDA approved for CUC in 2005 and is now indicated for the treatment of mild-to-severe UC in both adults and children. In the ACT-1 and ACT-2 randomized trials assessing the efficacy of IFX for inducing and maintaining remission (defined as reduction of Mayo score by 3 points), 60–69% of patients have successful induction, compared with 29–37% response for placebo [30]. The typical loading dose is 5 mg/kg IV at week 0, 2, and 6, switching to maintenance dose of 5 mg/kg IV every 8 weeks starting at week 14. If a loss of responsiveness occurs and symptoms flare, then the IFX dose can be increased to 10 mg/kg IV every 4–8 weeks. Serum drug trough levels are monitored to assure proper dosing, ensuring adequate trough levels may be associated with increased efficacy and decreased risk of colectomy. The best outcomes of IFX therapy are seen in combination with other medications such as TPs as demonstrated by the UC-SUCCESS trial with 40% of patients achieving a steroid-free remission, compared with only 2% on monotherapy with either agent; similarly mucosal healing was observed in 63% of combination therapy patients compared with 55% on IFX alone [31].

The most widely recognized side effect of IFX is activation of latent infections most notably TB. Thus, prior to initiation of IFX therapy patients are screened with the QuantiFERON® gold assay [32]. IFX can also make active infections worse and can exacerbate hepatitis B. Other adverse reactions include infusion reactions, which can result in flash pulmonary edema or hypersensitivity including anaphylaxis; thus, these patients must be administered the drug in an infusion center. Demyelinating central nervous system disorders and other neurologic side effects such as optic neuritis and multiple sclerosis have been reported, and *young males receiving combination TP therapy may be at increased risk of hepatocellular T-cell lymphoma, an otherwise rare, lethal disease*. It is unknown whether IFX independently increases the risk of other forms of lymphoma as IBD patients IBD are generally at increased risk due to their chronic inflammatory state [33].

It is highly controversial whether or not biologic agents, and IFX in particular, increase the risk of surgery. Both Mayo Clinic and Cleveland Clinic have shown increased perioperative risk in patients on biologics, and the Crohn's and Colitis Foundation has recently published a position paper regarding perioperative management [34–36]. One consideration is the half-life of the agents (Figure 46-12). This schematic, which *assumes first-order elimination pharmacokinetics*, may provide some guidance for timing of surgery for patients requiring elective surgery.

Adalimumab (Humira®)

The second in class, this humanized form represents an attractive alternative to infliximab.

Similar to IFX albeit less powerful, adalimumab is indicated for induction and maintenance of remission in adults with moderate-to-severe CUC; an additional indication is loss of response to IFX. The ULTRA-1, 2, and 3 trials demonstrated that in patients with moderate-to-severely active CUC, adalimumab is efficacious in both short-and long-term

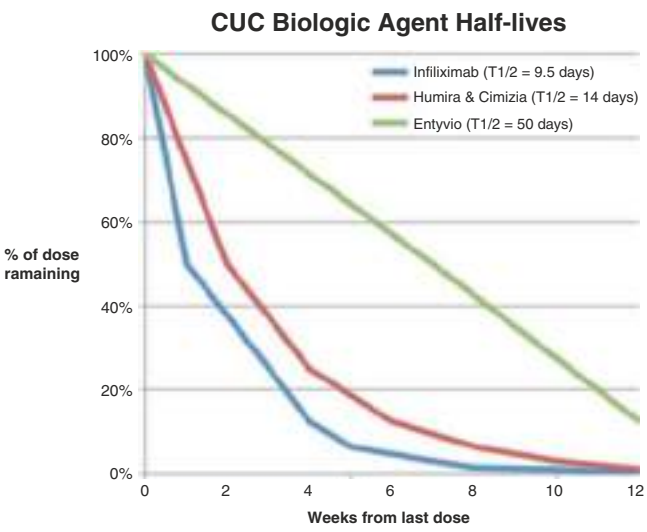

FIGURE 46-12. Graphical representation of the theoretical in vivo half-lives of biologic agents used to treat CUC. Note this graph assumes first-order elimination pharmacokinetics.

maintenance of remission for up to 4 years in 60% of patients. Loading doses are used (week zero 4 shots = 160 mg, week two 80 mg, maintenance week four 40 mg SQ every other week subcutaneously). If a suboptimal response is observed the dosing interval is often increased to weekly. As in IFX, trough levels can be used to monitor and optimize therapy, such as by increasing the dose to 40 every week or 80 every other week. Also as in IFX, the best outcomes are seen with combination therapy with TPs. Humira may be more convenient for patients since they self-administer, but some patients may be less compliant because patients may not be self-medicating.

The humanization of the antibody has greatly reduced the side-effect profile of this medication relative to IFX. Adverse reactions are generally similar to those of IFX and also include local, injection-site reactions and loss of responsiveness.

Certolizumab Pegol (Cimzia®)

This was the third in class of anti-TNF-Ab agents indicated in IBD in adults. It is a partially humanized Fab' fragment of an anti-TNF antibody, which is PEGylated (the pegol acts as a carrier for the Fab' fragment which is lacking the Fc fragment). Presently it is FDA approved for CD (and RA), *but not approved for CUC*. Patients with CUC refractory to other agents may be offered this medication on-study or off-label.

Golimumab (Simponi®)

Simponi is another humanized anti-TNF-Ab which was FDA approved for CUC in 2013 for the induction and maintenance of remission in adults and for patients with loss of responsiveness to IFX and Humira. In the PURSUIT-SC study, Golimumab has been shown to be effective for the induction of remission in moderately-to-severely active CUC with >51% of patients achieving remission compared with 30% of placebo patients, and over 47% of patients maintaining remission, compared with 30% in the placebo arm [37, 38]. Dosing is usually 200 mg subcutaneously at week zero and then 100 mg subcutaneously every other week. Trough level assays are not yet available.

Anti-Integrin Antibodies

Vedolizumab (Entyvio®)

Entyvio is an intravenously administered monoclonal antibody to integrin **α**4**β**7, also known as lymphocyte Payer's patch adhesion molecule 1 (LPAM-1). Blocking this receptor results in the upregulation of anti-inflammatory pathways [39]. In 2014 it was FDA approved for the induction and maintenance of remission of both CUC and CD in adults and also for patients with loss of responsiveness to the above medications. In the GEMINI-I and -II studies, vedolizumab resulted in the induction of remission in 47% of patients, compared with 25% of placebo and maintenance of remission in 41% vs. 15% with placebo [40]. Dosing, which is intravenous, is 300 mg IV at week 0, 2, 6 and then every 8 weeks, and trough levels are not yet available. The adverse drug reactions are similar to IFX and also include a warning regarding the potential the risk of PML (see natalizumab below).

Natalizumab (Tysabri®)

In May 2015, natalizumab is only FDA-approved biologic agent for the treatment of CD. Although *not FDA approved for the treatment of CUC patients at this time*, but it presented here as (a) some patients refractory to the other biologic agents may be offered treatment on- or off-trial (off-label), and (b) natalizumab may become approved for CUC in the future. Given the lack of FDA approval at this time, and the potential for PML, the role of natalizumab for CUC is off-label and unclear. Some experts, in patients with inflammatory bowel disease refractory to other strategies, have used natalizumab to induce remission and, once remission has been achieved, transition the patient to vedolizumab or other non-first-line biologic agent [41].

Natalizumab is associated with JC virus activation or infection that can be a lethal neurological condition progressive multifocal leukoencephalopathy (PML). PML is caused by the JC virus, although an immunocompetent immune system will typically prevent disease development. Prior to initiation of treatment with natalizumab, serologic testing for JC virus is performed. If a patient has negative serologic testing, then the risk of developing PML with treatment is approximately 1 in 10,000. However, if a patient has positive JC virus serology, then the risk increases by two orders of magnitude to the range of 1 in 500 and as high as 1 in 100 with prolonged treatment. Given the severity of the PML illness, this is real cause for concern and the patient must be counseled carefully. Thus, main contraindication to it use is known or suspected PML [32].

"Rescue" Therapy

Corticosteroids

Corticosteroids represent the mainstay of rescue therapy for otherwise medically refractory CUC. Their mechanism of action is that of nonspecific immunosuppression and immunomodulation. Steroids are associated with significant side effects and they should not be used for maintenance therapy. Corticosteroids are glucocorticoid steroid hormones that bind to glucocorticoid receptors, which are ubiquitous in all animal (vertebrate) cells [42]. After binding they result in anti-inflammatory protein upregulation and downregulation of pro-inflammatory proteins. They are metabolized in the liver and excreted in the urine. Various formulations are converted to hydrocortisone equivalent doses using readily available online conversion calculators.

Effects of steroids include adrenal suppression, water retention, moon-like facies, psychological distress (ranging from agitation and insomnia to frank psychosis), rosacea, buffalo-hump, abdominal striations, and osteoporosis. One of the most serious and potentially nonreversible adverse effects is osteoporosis, which may not be responsive to calcium or vitamin D supplementation. Patients on repeated courses of corticosteroids need bone density monitoring with dual-energy X-ray absorptiometry (DEXA) scans.

Enteric or topical budesonide has been shown to be effective for CUC. The CORE-1 study showed that budesonide MMX 9 mg was effective at indication of remission in mild-to-moderate CUC but more limited in maintenance of remission [43]. Newly available Budesonide foam, released February 2015, was shown to decrease symptoms [44]. Long-term (2 years) Budesonide use was shown to be safe based on bone density and protective if steroid naive [45].

Oral forms are typified by prednisone. Most patients with CUC respond to oral steroids, with only 16% not responding acutely [46]. However, systemic steroids have no role for maintenance of remission due to their relatively severe side-effect profiles. Long-term (>1 year) corticosteroid treatment is contraindicated and the inability to wean off chronic steroids represents an indication for surgery.

IV steroids are indicated for those refractory to outpatient medical therapy. Maximum-effective dose is 300 mg hydrocortisone per day. An estimated 60% of patients will respond, usually within 5–7 days. Please see "Severe CUC" section below.

Oral or intravenous (IV) steroids can also be used to prevent immune hypersensitivity to the antigens of infliximab. Effective IV steroid premedication for infliximab dosing was shown to be single dose of 300 mg [47].

Tapering, also called weaning, is done to prevent Addisonian crisis after times of physiologic stress. Rapidity of weaning depends on the duration of use—in general patients treated with steroid for only days to a few weeks can be weaned rapidly (50% reduction per day), while patients on more long-term steroid therapy must have slow tapers of 5–10 mg per week. A common scheme for patients on 40 mg prednisone equivalents per day is 40 for 7 days, 30 for 7 days, 20 for 7 days, 10 for 7 days, then 5 for 7 days, and if no symptoms of withdrawal (lethargy, sluggishness) then off versus 5 every other day or 2.5 every day for an additional 1–2 weeks. Finally, patients weaning from steroids should anticipate symptoms of physical and emotional withdrawal from the steroids such as decreased energy and mood.

Regarding the perioperative management of steroids, a recent Cochrane analysis found no evidence for or against a protective effect for stress dose steroids [48]. Although case reports have identified cases with Addisonian crisis, based on more recent data, no stress-dose steroids are needed [49]. However, clinicians opting not to use them should still monitor these patients for signs and symptoms such as fever, tachycardia, and fluid-resistant hypotension in the perioperative period and treat accordingly.

Some centers advocate for Vitamin A (60,000 IU PO, IV, or IM per day for 5 days) supplementation immediately postoperatively to optimize wound healing. It has been shown in animal studies to prevent the inhibition of collagen-cross-linking and the obvious deleterious effects on wound healing. Although the level of evidence is weak, this treatment is both safe and inexpensive; thus, the potential benefits outweigh any risks.

Cyclosporine/Tacrolimus

These drugs, used for prevention of graft rejection in solid-organ transplantation, are calcinurin inhibitors. These medications bind to a T-cell receptor, inhibiting calcineurin-mediated cytokine release, essential to promote T-cell-mediated immune-competency.

Given its position as a major immunosuppressive agent, calcinurin inhibitors are reserved for use as a rescue agent for severe, otherwise medically refractory CUC [50]. Please see the "Severe Colitis" section below.

These medications carry a risk of opportunistic infections and are associated with a host of specific adverse reactions. These latter include constitutional and gastrointestinal symptoms, and they are potentially nephrotoxic, hepatotoxic, and neurotoxic and exacerbate hypertension and hyperlipidemia. Finally, they are potentially carcinogenic; these drugs taken long term can increase the risk of skin squamous cell carcinoma.

Methotrexate

Methotrexate (MTX) is an anti-metabolite, specifically inhibiting folic acid metabolism by competitive inhibition of dihydrofolate reductase (DHFR). Since folic acid metabolites such as tetrahydrofolate are a required cofactor for DNA synthesis and repair, blockage of this path inhibits rapidly dividing or growing cells. MTX undergoes extensive hepatic metabolism and are renally excreted. Aside from being hepatotoxic and myelosuppressive, MTX is also an FDA Category X drug, meaning it is teratogenic, resulting in birth defects, and has been used as an abortifacient.

Given its success in rheumatoid arthritis and psoriasis, MTX held promise as an alternative to biologics or corticosteroids for IBD. Although MTX may be used in the treatment of CD, at present there is *no evidence supporting the use of MTX for induction or maintenance of remission in CUC* [51, 52]. Current trials are under way (MERIT-UC and METEOR) which may further define its role in CUC.

Part 3: Medical Management of Mild-to-Severe CUC

Mild-to-Moderate Distal Colitis/Proctitis (Figure 46-13)

Topical mesalamine is the first-line treatment for both inducing and maintaining remission of distal mild or moderate colitis [53]. The formulation chosen is tailored to the extent of disease: suppositories are appropriate for proctitis without proximal involvement, foams reach the sigmoid colon, and enemas may even reach the splenic flexure, but compliance can be an issue. Although oral aminosalicylates are less effective than topical mesalamine [53], most patients prefer oral formulations. In moderately severe cases, combining topical and oral therapy is more effective than topical mesalamine alone in both achieving and maintaining remission [54]. Clinical effects of oral aminosalicylates are apparent after 2–4 weeks and overall some 60–80% of patients have a response [55].

Topical corticosteroids have similar efficacy in achieving remission in active disease and are an alternative to topical mesalamine. They should not be used for maintenance, however. The roles of oral corticosteroids, TPs, and biologics in cases where aminosalicylates fail to induce or maintain remission in distal colitis are similar to those in extensive colitis, as discussed below.

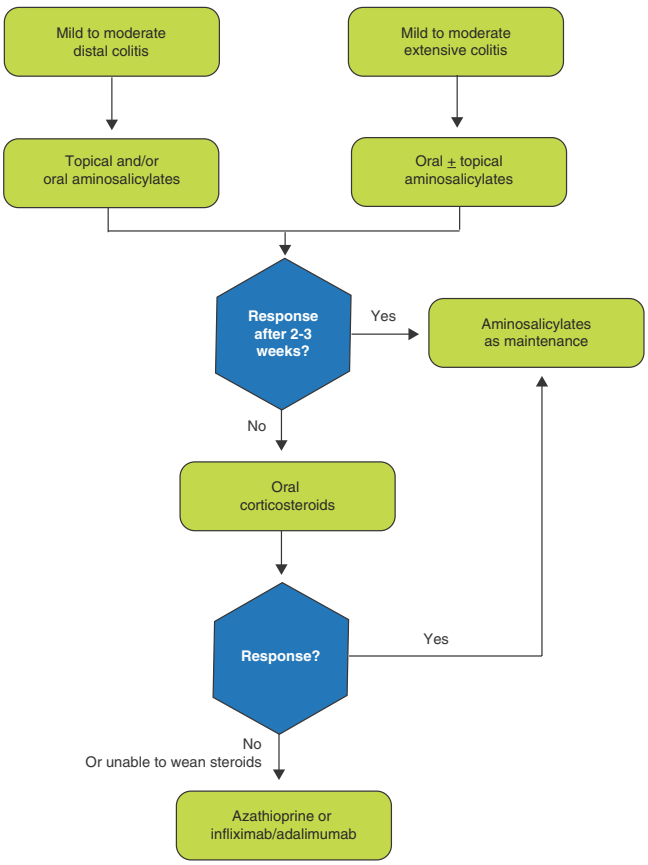

FIGURE 46-13. Standard "Bottom-up" approach to the management of mild-to-moderate CUC (based on the American College of Gastroenterology 2010 Practice Guidelines).

Mild-to-Moderate Extensive Colitis (Figure 46-13)

For mild or moderate colitis, oral salicylates induce clinical improvement in 60–80% of cases within 4 weeks of therapy [55]. Efficacy is dose related, but due to common adverse effects such as nausea and anorexia, and the risk of less common but severe adverse effects such as hepatotoxicity, pancreatitis, and nephrotoxicity, daily doses of sulfasalazine are commonly started at 1–2 g and increased as tolerated up to 4–6 g. Non-sulfonamide aminosalicylates, such as mesalamine, are more expensive but may be better tolerated [17]. The highest recommended dose for these compounds is 4.8 g daily.

In either distal or extensive colitis not responding to 4 weeks of aminosalicylate therapy, a course of oral steroids is indicated. This is usually started at 40–60 mg of prednisone per day. When a clinical response has been achieved, the dose is tapered over several weeks, typically reducing the daily dose by 5–10 mg every week until a daily dose of 20 mg is reached, and by 2.5–5 mg thereafter. Due to its well-known and wide-ranging acute and chronic toxic and adverse effects, corticosteroid therapy should be used judiciously and is only indicated for active colitis. Although the response rate is around 70%, some 20% overall develop steroid dependency and cannot be weaned without relapse of symptoms [46].

In nonresponders, and in patients who become steroids dependent, a third-line therapy should be started to aid in weaning of prednisone. The two main options at this stage are TPs and biologics. Azathioprine is effective in inducing and maintaining remission, but its effects are slow with the time of onset measured in months, requiring overlap with an extended course of oral prednisone.

Infliximab has been well studied in steroid-refractory mild and moderate colitis. Trials have established the efficacy of the 5 mg/kg intravenously administered dose at 0, 2, and 6 weeks in inducing remission, and every 8 weeks to maintain remission [30]. Some 69% of patients respond to induction treatment. The drug is discontinued in nonresponders after two doses, as later response is very unlikely. Co-administration of infliximab and azathioprine may be associated with an increased clinical response rate and mucosal healing in moderate and severe steroid-refractory colitis compared to monotherapy with either drug [31]. Synergy may be due to the thiopurine-related inhibition of hypersensitivity reactions against the biologic agent's antigens. However, such patients may be at increased risk of immunosuppression-related infections.

Remission in mild and moderate extensive colitis can be maintained either by oral aminosalicylates, TPs, or inflix-

imab. Alternately, patients with a single episode of mild disease may opt for clinical observation alone. The choice of maintenance therapy is chiefly determined by the method by which remission was induced. Responders to aminosalicylates or oral steroids are typically subsequently maintained on oral aminosalicylates. These can be given as sulfasalazine or a non-sulfonamide derivative, although recent evidence does not support any benefits of those more expensive derivatives either in efficacy or adverse events [23]. Overall, some 59% of patients remain in steroid-free remission at 12 months on oral aminosalicylates [23].

When treatment with infliximab or azathioprine, or a combination, is used to induce remission, the same therapy is continued as maintenance. Infliximab is infused every 8 weeks. In initial responders who develop symptoms during maintenance therapy, a dose increase to 10 mg/kg is often effective. Some 74% of patients will require one or more additional courses of oral corticosteroid over a maintenance period of 54 weeks [30]. Steroid-free remission during 12 months is achieved in some 56% of patients on azathioprine on meta-analysis of randomized trials [56]. Long-term efficacy of a combined TP and biologic therapy is unknown. Similarly, the rationale of switching from infliximab to a newer anti-TNF drug such as adalimumab or golimumab is unclear.

Severe Colitis (Figure 46-14)

Most patients with severe colitis require hospitalization for stabilization and a course of intravenous corticosteroids, regardless of the extent of disease. Selected patients with severe disease who partially have responded to oral medications and, importantly, are systemically well with no signs of toxicity can be started on infliximab as outpatients [30]. A course of intravenous steroids has been the standard therapy for severe ulcerative colitis since the 1950s [15] and is currently given in a daily dose of 300 mg hydrocortisone or equivalent. A course of 3–5 days is given with close clinical observation. Ideally consultation with a colorectal surgeon and a stoma therapist is advisable during this stage, so that the patient can be in a position to make an informed decision about the next steps by day 3–5 should steroid therapy fail, especially since overall some 20–40% of patients with severe UC will fail to improve on IV corticosteroids. Persistence of colonic or systemic manifestations after this period is labeled steroid-refractory disease and mandates surgical consultation.

During these first days, several additional measures need to be taken to reduce morbidity and prepare for so-called rescue therapy should this be necessary. In addition to initial fluid and electrolyte resuscitation, patients with significant weight loss will often need supplemental parenteral nutrition support. Continued oral diet is encouraged in most patients, due to the theoretical advantages of short-chain fatty acid provision to the colon. However, bowel rest may be indicated if bowel movements are excessive.

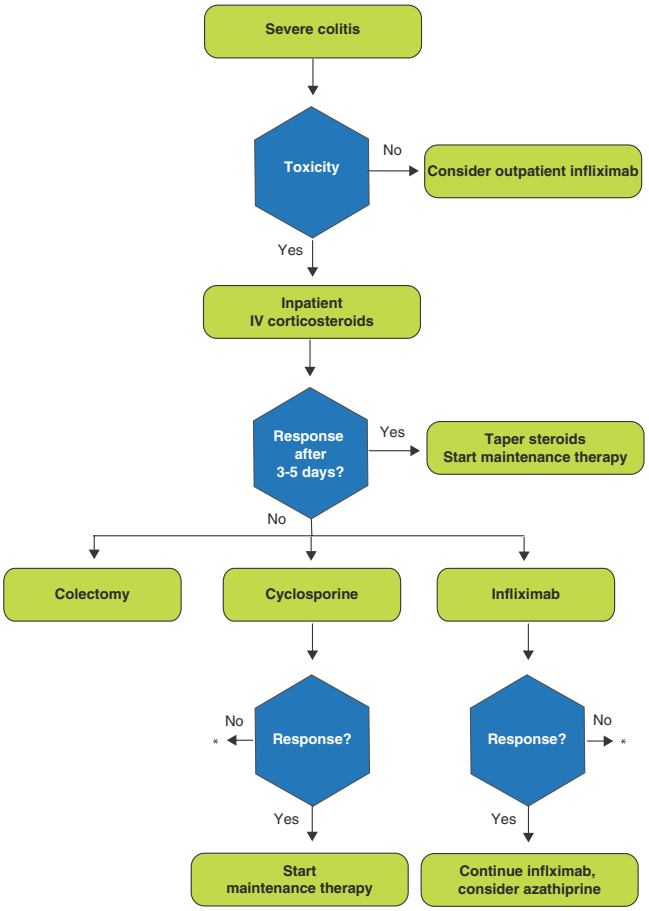

FIGURE 46-14. Standard "Bottom-up" approach to the management of severe CUC (based on the American College of Gastroenterology 2010 Practice Guidelines).

Thromboembolic prophylaxis is routinely given and anticholinergic and opioid medications are avoided.

Importantly, gut infections may exacerbate ulcerative colitis and treating those aggressively is thought to facilitate induction of remission. Stool samples are therefore cultured for *Salmonella*, *Yersinia*, and *Shigella* and tested for *C. difficile* toxin. Some 25–36% of patients with steroid-refractory UC have CMV disease in colonic biopsies [57]. Colonic CMV disease is best demonstrated by immunohistochemistry of classic "punched-out" mucosal ulcer biopsies obtained on flexible sigmoidoscopy, although leukocyte CMV PCR is sometimes used as a surrogate marker. Importantly, positive CMV antibody titers merely signal current or previous CMV infection (worldwide prevalence of CMV is in the order of 50%), but negative IgM titers means that the patient is highly unlikely to carry CMV and sigmoid biopsies are not required. CMV colitis is usually treated with IV ganciclovir at 5 mg/kg q12 h × 14–21 days and then transitioned to 5 mg/kg daily or 1000 mg PO three times daily.

Broad-spectrum antibiotics are often given to patients with toxicity over fear of bacterial translocation. There are no data to support this, and it is known that portal or venous bacteremia is rare in severe UC even during colectomy [58].

Patients with megacolon (often defined as colonic dilatation to a diameter >6 cm) require additional caution. Oral intake is stopped, abdominal signs are closely monitored, and daily plain abdominal films obtained to assess progression. In this subgroup of severe CUC, failure to respond to corticosteroids is an indication for urgent colectomy already after 24–48 h, as is progressive dilatation. Fulminant colitis is the advanced form of severe, acute colitis and is typically defined as toxic colitis, i.e., colitis with signs of systemic toxicity such as peritonitis, hypotension, impending perforation, and/or end-organ damage such as renal failure.

Rescue therapy for steroid-refractory severe UC falls into three main categories. In historical order, these are colectomy, cyclosporine, and infliximab. For a complete discussion on the indications and technical aspects of colectomy in this context, please refer to Chap. 48.

In randomized trials and large uncontrolled studies, intravenous cyclosporine is highly effective in steroid-resistant severe UC, with response rates of up to 82–83% [59, 60]. On the other hand, it has proven difficult to maintain remission in responders, with up to 54% of patients subsequently requiring colectomy [60]. Responders are typically started on maintenance azathioprine, often with the addition of an oral aminosalicylate. The issue of recrudescence of colitis following rescue therapy with cyclosporine, in combination with a significant toxicity profile, has led to a reduction in its usage in the biologic era, and presently it is only offered at select centers.

More recently, infliximab has emerged as a widely used rescue therapy in the recent decade, despite support by relatively small studies, with response rates in the 50–71% range [61, 62]. One important advantage is that infliximab can be continued long term to maintain remission. A direct comparison confirmed that both cyclosporine and infliximab have high initial response rates when used as rescue therapy in steroid-refractory severe colitis (85 vs. 86%), and in this trial colectomy rates were also similar at 3 months (18 vs. 21%) [63]. Selected patients who fail either cyclosporine or infliximab may respond to the alternate therapy, although this is associated with risks and should only be undertaken in selected patients in specialized IBD units [64]. Specifically two other alternative rescue therapies that have been used anecdotally with success include cigarette smoking and hyperbaric oxygen, the latter of which is under study.

Preoperative Optimization of the Medical CUC Patient

When a patient is refractory to maximal medical therapy, or has CUC-associated neoplasia (colorectal cancer or high-grade dysplasia), or patient refusal of additional medical therapy, then surgery is indicated. Note we use the term "refractory to maximal medical therapy" in lieu of "failure of medical therapy" as the latter has negative connotations for both the patient and referring gastroenterology provider. Overall medically refractory disease is the indication in 88% of colectomies for CUC, while neoplasia the remaining 12% [65]. A third category, not frequently indicated, is colorectal cancer prophylaxis (without dysplasia).

Given the overall success of medical therapy for CUC, surgery has often been relegated to a therapy of last resort. This is often due to patient and (referring) physician concern over surgical complications and fear of permanent ileostomy. However, a recent population-based study from the UK demonstrated that the strategy of surgery as last resort may actually increase CUC-related mortality [66]. Furthermore, delay in surgery has been shown to increase postoperative complications [67]. Clearly surgery should not be relegated to this position, and ideally at the time of CUC diagnosis, referring gastroenterologists should refer patients to colorectal surgery not just for surgery but also for appropriate education in the event that they ultimately do require surgery. Demystification of surgery, and in particular of ostomy-related and post-IPAA lifestyle/functional concerns, can dramatically change patient perception of surgery and make it a more acceptable option. In addition to local or regional colorectal surgeons and Wound and Ostomy Care nurses, resources for patients include the Crohn's and Colitis Foundation of America literature, including camp Oasis for children and young adults with IBD, the American College of Surgeon's Ostomy Education series (available on YouTube®), as well as the recently developed CUC Medical Therapy and CUC Surgical Therapy (Emmi Solutions, Inc.) online educational modules.

VTE Prophylaxis

Perioperative venous thromboembolism (VTE) is known to be particularly prevalent in patients undergoing surgery for IBD due to decreased mobility and a pro-inflammatory state. The perioperative incidence is 2.7% in this population and is higher than the incidence among patients having colorectal resection (2.1%) [68]. Randomized studies support the use of extended VTE prophylaxis postoperatively after abdominopelvic cancer [69, 70]. The authors' preference is prophylaxis with enoxaparin 40 mg once daily for a total of 4 weeks postoperatively.

However, it is also well recognized that hospitalized *medical* CUC patients are also at increased risk of VTE, and there can be little doubt that some CUC patients who come to surgery bring to the table unrecognized preoperative VTE [71]. It is important that medical teams, including colorectal surgeons, who are caring for CUC patients are aware of this significantly increased risk and treat appropriately with aggressive ambulation and chemo-prophylaxis *before* surgery.

Anemia

Patients with CUC are also at increased risk for anemia, and similar to VTE represents an opportunity for preoperative prevention of postoperative complications. Oral ferrous sulfate (325 mg PO, two to three times daily) given with concurrent vitamin C (500 mg PO, two to three times daily) doubles the rate of iron absorption. Other adjuncts for oral anemia treatment in CUC include folic acid (1–2 mg per day PO), thiamine, or multivitamin supplements daily. For more severe cases, intravenous iron (Venofer, 100–300 mg per infusion) or transfusion of packed cells may be indicated. Erythropoietin is generally not indicated and may also be prothrombotic. Auto-transfusion is also typically not recommended because it will worsen the patients' existing anemia. In addition to the above treatments, nutritional optimization will aid in reversal of anemia. New, more effective forms of supplemental iron are expected in the very near future.

Nutrition

Protein-calorie malnutrition represents another preoperative comorbidity, which CUC patients may bring to the table that is recognizable, and usually treatable, in medically treated CUC patients. The most readily available markers of malnutrition include history of weight loss, serial office-based weight, and clinical indicators such as temporal wasting. Unfortunately, all of these may be confounded by steroid-induced water-weight gain; thus, serologic assessment has an increased role of importance in this patient population. Serum markers such as prealbumin and albumin are acute phase reactants and thus fluctuate based on the underlying inflammatory state. In the near future, radiographically assessed sarcopenia (lack of skeletal muscle) assessment using traditional MR or CT images with additional semi-automated tissue compartment assessment is likely to become an additional, practical tool (e.g., Slice-o-matic®, Materialize®, others) for use in this patient population.

For malnourished patients who are able to tolerate PO, nutritional supplementation 2–4 times per day with formulations for several weeks may stabilize and or reverse mild-to-moderate malnutrition. For patients with severe disease who may not be able to tolerate enteric supplementation, parental nutritional therapy is indicated. For the pre-surgical patient, peripherally inserted central access catheters (PICC) placed for TPN, especially if dual lumen, can be maintained and used for perioperative access as well; patients should be aware of the risk of line-sepsis and upper extremity DVT.

Medical Therapy for the Postsurgical Patient: Ileostomy and Pouch issues

A significant number of readmissions after surgery for CUC are for dehydration. Dehydration is more common in ostomates who are age >50 or who required diuretics prior to discharge [72]. Recent work has shown that ileostomy discharge carepaths, including educational materials and access to Wound and Ostomy Care Nurses, discharge coordinators, and social workers, can successfully decrease readmissions for dehydration [73]. A practical pathway of educations instructions to "thicken it up, and slow it down" using fiber, a BRAT diet, and over-the-counter Imodium, as well as instructions to eat salty foods and drinks, such as "potato chips and Gatorade®." The patient and family should also be educated about signs and symptoms of dehydration.

Pouchitis is an acute inflammatory state of the pouch that typically responds to oral antibiotics therapy. In some cases, pouchitis can be antibiotic dependent, and in others antibiotic refractory. Pouchitis must be differentiated from several other medical conditions: cuffitis, which is inflammation limited to the anal canal mucosal cuff left behind and which typically responds to topical Canasa, Crohn's enteritis—which is typically obvious endoscopically, and irritable pouch syndrome, which may be due to a fixed pelvic pouch or primary or secondary pelvic floor dysfunction. For additional pouch-related complications, please see Chap. 51.

A meta-analysis of treatments for pouchitis found that both ciprofloxacin and metronidazole were effective for inducing and maintaining remission of pouchitis in most patients [74]. There is some evidence that probiotics in the form of VSL#3 are effective for maintaining antibiotic-induced maintenance.

Pouch surveillance with flexible pouchoscopy is recommended annually to biannually, but pouch neoplasia is exceptionally rare, and its utility may be more for early diagnosis of Crohn's-like pouch changes; for patients with a Crohn's-like picture of the pouch, the authors prefer the term "*indeterminant pouchitis*". Random biopsies of the pre-pouch ileum, pouch body including afferent and efferent limb, and pouch-anal anastomosis and anal transition zone are recommended. Mild-to-severe pouch-anal anastomotic strictures can be dilated at the time of pouchoscopy with sedation, using either Hagar dilators or via pneumatic balloon dilation (Video 46-2).

Summary

Medical therapy will continue to be the mainstay of treatment for the vast majority of patients, and we should expect new, more efficacious agents, with varying side-effect profiles, to be released in the near future, as the etiology of CUC is elucidated.

Medical Management of Crohn's Disease

Scott A. Strong

Key Concepts

- Crohn's disease is classified by age at diagnosis, disease location, and disease behavior.
- Disease severity is stratified using a clinical or endoscopic scheme that assesses symptoms and signs or endoscopic appearance, respectively.
- Medical therapy (e.g., 5-aminosalicylate compounds, glucocorticoids, immunomodulators, and biologic agents) should be approached in a "step-up" or "top-down" manner to balance efficacy and toxicity.
- 5-aminosalicylate compounds are of limited value in the induction and maintenance of remission.
- Glucocorticoids can successfully induce remission, but short- and long-term adverse effects largely limit their usage to management of acute episodes.
- Immunomodulators are of limited use for induction of remission, but successfully maintain remission in many patients.
- Biologic agents can induce and maintain remission in patients with moderate-to-severe disease, but the efficacy and safety varies among the different medications.
- Disease prophylaxis after surgery should be individualized according to the patient's risk for recurrence.

Introduction

The appropriate treatment of Crohn's disease includes a combination of medical and surgical therapy to safely resolve inflammation, lessen symptoms, improve quality of life, and minimize the risk for short- and long-term complications. Therapy is usually guided by the age of the patient, anatomic extent of inflammation, disease behavior, symptom severity, treatment response, and risk for adverse effects. Treatment can be intended to induce remission in patients with active disease or maintain remission in others. Operative intervention is generally reserved for patients with disease-related complications or disease that is refractory to medical therapy with the later indication being quite common. Consequently, it is important for the surgeon to understand the indications, dosing, benefits, and risks of the various types of medications used to treat intestinal Crohn's disease.

Disease Classification

Initial attempts to classify Crohn's disease were fraught with problems that instigated a World Congress of Gastroenterology Working Party to develop the Vienna classification [1] and its modification, the Montreal classification [2–4]. The Vienna scheme was prospectively designed to be a simple phenotypic classification system based on objective and reproducible clinical variables that include age at disease diagnosis, anatomic location of disease, and disease behavior. However, controlled trials showed that experts could not independently agree on disease phenotype using the Vienna classification [5]. Therefore, the Montreal classification introduced modifications within each of the variables, but did not alter the three primary categories (Table 47-1).

This newer classification system introduced a subgroup for patients with early onset of disease (i.e., ≤16 years of age) because several centers have demonstrated that specific genotypes or serotypes are more frequently found in early-onset Crohn's disease.

With respect to disease location, ileal disease is defined as involvement limited to the lower third of the small bowel with or without involvement of the cecum. Colonic disease is disease between the cecum and rectum without ileal disease. Ileocolonic disease is understood to be disease of the terminal ileum and colon. Upper gastrointestinal disease represents disease located proximal to the terminal ileum. Moreover, the upper gastrointestinal disease description can be used alone or as a modifier of the ileal, colonic, or ileocolonic subgroups because upper gastrointestinal disease is recognized to coexist with more distal disease.

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_47

TABLE 47-1. Vienna and Montreal classification for Crohn's disease

	Vienna	Montreal
Age at diagnosis	A1 below 40 years	A1 below 16 years
	A2 above 40 years	A2 between 17 and 40 years
		A3 above 40 years
Location	L1 ileal	L1 ileal
	L2 colonic	L2 colonic
	L3 ileocolonic	L3 ileocolonic
	L4 upper	L4 isolated upper disease[a]
Behavior	B1 non-stricturing, non-penetrating	B1 non-stricturing, non-penetrating
	B2 stricturing	B2 stricturing
	B3 penetrating	B3 penetrating
		p perianal disease modifier[b]

[a]L4 is a modifier that can be added to L1–L3 when concomitant upper gastrointestinal disease is present

[b]"p" is added to B1–B3 when concomitant perianal disease is present

The behavior variable is defined as inflammatory, stricturing, or penetrating behavior. Perianal disease is a separate subgroup because experts recognize that perianal fistulizing disease is not exclusively associated with intestinal penetrating disease.

Initial application of the Vienna classification to clinical practice showed that phenotype evolves over time for an individual patient [6–9]. Specifically, 80% of individuals with inflammatory disease ultimately exhibit stricturing or penetrating behavior, whereas only 15% of patients experience a change in anatomic location. Although the Montreal classification has demonstrated significant potential because of good interobserver agreement [10, 11], a system that combines genotype and phenotype characteristics will likely emerge as we better understand genetic linkages associated with Crohn's disease [12].

Disease Severity

Crohn's disease is caused by immune dysregulation that leads to chronic intestinal inflammation manifesting itself as symptoms including abdominal pain, bleeding, and diarrhea and signs such as anemia. Although medical therapy is targeted towards controlling inflammation, disease activity is commonly assessed by composite indices that largely measure symptoms and signs with the former preferred in everyday clinical practice. The traditional approach to monitoring therapy accordingly relies on the consequences instead of the causes of inflammation. The problem with this strategy is that substantial overlap exists between the symptoms of Crohn's disease and other conditions, such as adhesive disease, bacterial overgrowth, bile salt diarrhea, irritable bowel syndrome, and steatorrhea. Some clinicians now argue that the newer goals of therapy should include induction and maintenance of mucosal and histologic healing.

The Crohn's Disease Activity Index (CDAI) has long been the primary outcome measure used in clinical trials to study the impact of new medications for the treatment of Crohn's disease. Regressing 18 clinical items against a 4-point global rating of disease activity created the CDAI [13]. Eight independent predictors were identified including liquid/soft stool frequency, abdominal pain severity, general well-being, extraintestinal symptoms, need for antidiarrheal drugs, presence of an abdominal mass, hematocrit, and body weight. Regression coefficients for each of the eight predictors were ascertained to generate an overall CDAI score that ranges from 0 to 600. Benchmarks for disease activity were established as follows:

Clinical remission	CDAI <150
Mild disease	CDAI 150–219
Moderate disease	CDAI 220–450
Severe disease	CDAI >450

Clinical response has been subsequently defined as a reduction from the baseline score of more than 70–100 points. The majority of the CDAI score stems from items recorded in a symptom-based, 1-week diary (i.e., stool frequency, pain, well-being). Further studies have proven that the CDAI can be simplified to these patient-reported variables without a significant compromise in the instrument's responsiveness [14, 15].

The Harvey–Bradshaw Index (HBI) was derived to simplify calculation of the CDAI. The HBI consists of five descriptors including general well-being, abdominal pain, number of liquid stools, abdominal mass, and complications. Remission has been defined as a score of <5 [16]. A 3-point change in the HBI correlates with a 100-point change in the CDAI. An HBI ≤4 corresponds with a CDAI score ≤150 [17].

Clinicians have more recently attempted to use mucosal healing as a marker of disease activity with the thought that mucosal inflammation often precedes the onset of clinical symptoms. The Crohn's Disease Endoscopic Index of Severity (CDEIS) was accordingly created using regression modeling and weighting of independent items that correlated with the global evaluation of lesion severity [18]. Four descriptors (i.e., superficial ulceration, deep ulceration, ulcerated stenosis, and non-ulcerated stenosis) are summed with the estimated extents of both ulcerated and diseased areas in each examined segment (i.e., ileum, right colon, transverse colon, left colon, rectum). The total CDEIS score ranges from 0 to 44. Complete endoscopic remission has been somewhat arbitrarily defined as a score of <3, endoscopic remission as a score of <6, and endoscopic response as a decrease of >5 points [19]. Mary and others (1989) have argued different scores, and the tool remains incompletely validated with an undefined responsiveness to change despite being associated with a high level of interobserver agreement [20].

Just as the CDAI can be cumbersome for measuring clinical disease activity, the CDEIS has been argued as awkward. Consequently, a Simple Endoscopic Score in Crohn's Disease (SES-CD) was developed to overcome the unwieldy nature of the CDEIS [21]. The four descriptors selected from the CDEIS for use in the SES-CD are ulcer size, proportion of surface covered by ulcer, proportion of surface covered by other lesions, and stenosis. Each descriptor is graded 0–3 and is scored in five segments (i.e., ileum, right colon, transverse colon, left colon, rectum). The total score is calculated as the sum of all the items in each segment and can range from 0 to 60. The SES-CD demonstrates a high degree of interobserver agreement and well correlates with the CDEIS. Benchmarks for disease activity have been described as follows:

Remission	0–2
Mild inflammation	3–6
Moderate inflammation	7–16
Severe inflammation	>16

Unfortunately, both the CDEIS and SES-CD demonstrate a weak correlation with the CDAI [21–23], and legitimate grading of disease activity remains an unresolved issue. This shortcoming is underscored by concerns that no valid patient- or clinician-reported outcome instruments have yet been created according to criteria established by the US Food and Drug Administration. In fact, the Food and Drug Administration recently indicated that the CDAI is no longer acceptable as a measure of disease activity in clinical trials related to Crohn's disease [24].

Medications

Probiotics, antibiotics, 5-aminosalicylate compounds, glucocorticoids, immunomodulators, and biologic agents are all therapies approved by the US Food and Drug Administration for the treatment of Crohn's disease depending upon the clinical scenario. Each drug within these therapeutic groups is distinguished by dosing parameters, short- and long-term side effects, and expected response intervals. Before initiating therapy with any medication, patients should be comprehensively counseled about these characteristics. Moreover, objective criteria for disease response should be initially discussed and then measured after a reasonable time interval. If the desired response is not achieved, prohibitive side effects ensue, or noncompliance transpires, the drug has failed, and another medication should be trialed. When all suitable medical management has proven unsuccessful, operative intervention is generally indicated. The continuation of ineffective drug therapy risks the development of further disease complications that may adversely impact surgical outcome.

Some patients will instead seek an operation before trialing all available medical modalities because they have concerns regarding the alternative drug(s). Interestingly, a survey of outpatients with Crohn's disease, gastroenterologists, and colorectal surgeons quantified this behavior [25].

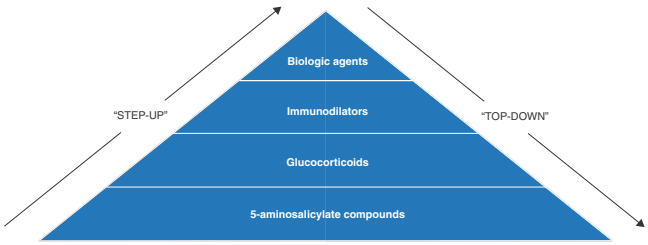

FIGURE 47-1. "Step-up" versus "top-down" models of therapy.

Participants were interviewed to measure their preferences for six scenarios by using a prospective preference measure, and significant differences were seen between patients and gastroenterologists for three of six scenarios. Although 72% of gastroenterologists were willing to gamble life expectancy to avoid a laparoscopic ileocolic resection, only 36% of colorectal surgeons and 37% of patients were willing to similarly gamble. Conversely, 85% of patients were willing to gamble to avoid a proctocolectomy and permanent ileostomy compared to 75% of surgeons and 91% of gastroenterologists.

The current model for the medical treatment of Crohn's disease is referred to as "step-up" therapy whereby patients are initially managed with drugs associated with fewer side effects, but might not be as effective as more potent medications linked with greater potential for toxicity. If the initial treatment fails, therapy will be escalated using stronger drugs with the process repeated until the disease is adequately managed or an operation is warranted. The patient's relative severity of disease dictates which therapeutic group is initially trialed. However, debate exists as to whether an alternative approach should be employed. The "top-down" method is predicated on the hypothesis that using more effective medications from the outset may alter the natural history of Crohn's disease while reducing the likelihood for disease exacerbations, hospitalizations, and operations. As we gain an enhanced understanding of the disease and identify risk factors associated with a more aggressive disease behavior, we will be better positioned to use an individualized approach that finds an acceptable balance between efficacy and toxicity (Figure 47-1).

Probiotics

Probiotics are beneficial microorganisms that can potentially impact the gut's microbiota composition, metabolic activity, and immunomodulation to confer host benefit. These bacteria and fungi can alter microbial diversity through competitive inhibition of other microbes, enhance mucosal barrier function via the production of short chain fatty acids, and interact with intestinal dendritic cells to instigate an anti-inflammatory response. The microorganisms must be of human origin, nonpathogenic, and able to survive the gastrointestinal transit in

order to be beneficial. Unfortunately, recent meta-analyses suggest that probiotics are ineffective for both the induction and maintenance of remission in patients with Crohn's disease [26–28].

Antibiotics

Antibiotics are felt to benefit patients with Crohn's disease through the inhibition of pathogenic bacteria and reduction of overall bacterial burden. The principal shortcomings associated with antibiotic therapy include lack of specificity associated with therapy, poor insight as to which bacteria should be targeted, and the potential for antibiotic resistance. The majority of studies demonstrate improvement with antibiotics only when disease is limited to the colon [29]. Metronidazole, which is active against anaerobic bacteria and some parasites, and ciprofloxacin, especially active against *Enterobacteriaceae* and *Escherichia coli*, are the most frequently used antibiotics. Multiple randomized clinical trials employing metronidazole or ciprofloxacin for induction of disease remission have suggested that metronidazole is effective for active colonic and ileocolonic disease, but not upper gastrointestinal tract inflammation [30]. Five randomized controlled studies evaluating the efficacy of ciprofloxacin alone or in association with metronidazole for active Crohn's disease have yielded mixed results [30].

A recent meta-analysis reviewed trials that compared antibiotic therapy prescribed for at least 3 months duration with placebo; outcomes were defined as remission in patients with active disease and relapse in patients with inactive disease [31]. Sixteen trials examining 13 treatment regimens in 865 patients were included. Three trials of nitroimidazoles demonstrated benefit with a combined odds ratio of 3.54 [95% confidence interval (CI), 1.94–6.47] and four trials of clofazimine had an odds ratio of 2.86 (95% CI, 1.67–4.88). For patients receiving nitroimidazoles, the number needed to treat was 3.4 (95% CI, 2.3–7.0) and 6.1 (95% CI, 5.0–9.7) for patients with active and inactive disease, respectively. The corresponding numbers for clofazimine were 4.2 (95% CI, 2.7–9.3) and 6.9 (95% CI, 5.4–12.0). A separate review found that rifamycin derivatives, which are minimally absorbed and active against gram-positive and gram-negative bacteria either alone or in combination with other antibiotics, have a significant impact related to inducing remission in active Crohn's disease [32]. None of these antibiotics are specifically approved by the US Food and Drug Administration for the treatment of Crohn's disease.

Metronidazole therapy is associated with several side effects that are dose dependent and occur in up to one-half of patients. These include gastrointestinal intolerance, headaches, metallic taste, and vertigo. Peripheral neuropathy is a rare complication, but may be irreversible. Side effects linked to clofazimine include abnormal pigmentation, gastrointestinal upset, and pruritus from clofazimine crystal deposits. Rifaxamin has been associated with gastrointestinal intolerance, headaches, and rectal tenesmus.

5-Aminosalicylate Compounds

A number of 5-aminosalicylate (ASA) compounds are available with active 5-ASA released at various locations throughout the intestinal tract depending on the design of each specific drug. These compounds work by activating a class of nuclear receptors involved in the control of apoptosis, cell proliferation, inflammation, and metabolic function. These gamma forms of the peroxisome proliferator-activated receptors are found at particularly high levels in colon epithelial cells, where their expression appears to be at least partially stimulated by gut bacteria. Sulfasalazine is the original 5-aminosalicylate and is compromised of 5-ASA bound to a sulfapyridine moiety that detaches when the drug reaches the bacteria of the colon. Sulfasalazine has a number of side effects due to the sulfapyridine moiety, including symptoms such as gastrointestinal upset and headaches. Rare side effects include bone marrow suppression, fever, hemolytic anemia, hepatitis, hypersensitivity reactions, pancreatitis, pneumonitis, and rash. Patients who take sulfasalazine must also take folic acid (1 mg daily) because the medication depletes folic acid stores.

These agents were once a mainstay in the medical management of Crohn's disease, but are now rarely recommended for disease treatment [33, 34]. A recent meta-analysis looked at six placebo-controlled randomized controlled trials with standard criteria in defining clinical remission (CDAI < 150) [35]. The trials included 910 patients with active Crohn's disease treated by 5-ASA compounds for 6–17 weeks. Remission of disease was not achieved in 68% of 5-ASA group compared to 74% of patients allocated to placebo (relative risk of failure: 0.89; 95% CI, 0.80–0.99). The number needed to treat to obtain clinical remission was 11. Furthermore, the role of 5-ASA as a maintenance medication is equivocal at best and clearly of no benefit in patients with glucocorticoid-induced remission [36]. In the previously mentioned meta-analysis, 11 trials of 5-ASA compounds versus placebo or control therapy in quiescent disease revealed 53% of the 5-ASA patients relapsed compared with 57% of the controls (relative risk: 0.94, 95% CI, 0.87–1.01) [35].

Glucocorticoids

Glucocorticoid drugs were first used for the management of Crohn's disease several decades ago and their benefit originates from an ability to modulate the immune response, inhibit expression of adhesion molecules, and decrease trafficking of inflammatory cells to the intestine. However, the traditional glucocorticoids are associated with significant

short- and long-term adverse effects that limit their usage to management of acute episodes. Budesonide, a glucocorticoid with an extensive first-pass metabolism, was consequently developed because it maximizes the amount of glucocorticoid locally available in the distal ileum and proximal colon, but theoretically has minimal systemic accessibility making it ideal for the treatment of ileocolonic Crohn's disease.

Prednisone is generally prescribed in dosages of 40–60 mg daily for 2–6 weeks to induce remission, although no appropriate dose-ranging studies have been performed. The daily prednisone dose is then tapered by 5–10 mg/week until a level of 20 mg daily is reached. The daily dosage is thereafter reduced by 2.5–5 mg weekly until discontinuation of the medication. Budesonide is started at 9 mg daily for up to 8 weeks with courses repeated for recurring episodes of active disease. Once symptoms are controlled, the drug is tapered to 6 mg daily for maintenance tapering to complete cessation attempted if symptom control is maintained for 3 months.

Resistance and dependency are major concerns when treating patients with glucocorticoids. On average, one-half of patients treated for active symptoms with a glucocorticoid will be "steroid resistant" or "steroid dependent" [37, 38]. Studies further suggest that younger patients, smokers, and those with colonic disease are at highest risk of becoming dependent on glucocorticoid therapy [39]. The occurrence and severity of most side effects are related to the dose and duration of treatment. Common findings include abdominal striae, acne, cataracts, fluid retention, glaucoma, hyperglycemia, hypertension, insomnia, mood disturbances, moon facies, and weight gain. Musculoskeletal complications, such as myopathy, osteonecrosis, and osteoporosis, are additional side effects. Lastly, adrenal suppression can occur during the course of treatment and contribute to physiologic dependence.

A recent meta-analysis limited to randomized controlled trials identified two trials using standard oral glucocorticoids to induce remission in active Crohn's disease that included a total of 267 patients [40]. Overall, 53 of 132 patients (40%) assigned to oral glucocorticoids failed to achieve remission compared with 93 of 135 (69%) prescribed placebo. Moreover, the number needed to treat to achieve remission in one patient with standard glucocorticoids was 3 (95% CI, 2–11). The same analysis reported the effect of budesonide on active disease after reviewing two trials involving 458 patients with ileal, ileocolonic, or right-sided colonic disease [35]. They found that 192 of 351 patients (55%) randomized to budesonide failed to achieve remission compared with 81 of 107 (76%) receiving placebo. The number needed to treat with budesonide to achieve remission in one patient was 5 (95% CI, 3–9). One trial reported the rates of adverse events that were thought to be glucocorticoid related; identical proportions (26%) in both treatment arms experienced an event. Another six trials directly compared standard glucocorticoids to budesonide in patients with active disease involving the ileum, ileocolon, or right colon. Overall, 116 of 304 patients (38%) receiving standard oral glucocorticoids failed to achieve remission compared with 173 of 365 (47%) managed with oral budesonide. The number to treat with standard oral glucocorticoids compared with budesonide to achieve remission in one patient was 11 (95% CI, 6–50). However, 62% of patients treated with standard glucocorticoids experienced glucocorticoid-related adverse events compared with only 37% of patients prescribed budesonide; the number needed to harm was 4 (95% CI, 3–6).

Although traditional glucocorticoids are not used for maintenance therapy, the role of budesonide has been evaluated in selected patients. Budesonide has been compared to placebo in five randomized controlled trials containing 559 patients with at least 70% of patients afflicted with isolated ileal disease [40]. Overall, 200 of 319 patients (63%) randomized to oral budesonide experienced a relapse of disease activity compared to 167 of 240 (70%) receiving placebo. When the efficacy of budesonide 6 mg daily was compared to 3 mg daily, no benefit was seen with the higher dose (59% versus 63%, respectively). In addition, the relative risk of glucocorticoid-related adverse events was significantly higher in budesonide-treated patients with a number needed to harm of 6 (95% CI, 4–25). Therefore, it appears that budesonide at any dose to maintain remission is no more effective than placebo, but significantly more toxic [41].

Immunomodulators

The thiopurines and methotrexate are immunomodulators that can be used to induce remission in patients with active disease, allow glucocorticoid tapering in patients with "steroid-resistant" or "steroid-dependent" disease, and maintain remission in patients with quiescent disease.

Thiopurines Azathioprine and 6-mercaptopurine (6-MP) are thiopurines with azathioprine being the precursor of 6-MP. Although their exact mechanism of action in patients with Crohn's disease is uncertain, they are known to cause immunosuppression by interfering with nucleic acid metabolism in the immunological sequence that follows antigenic stimulation. Azathioprine is prescribed at 2.0–2.5 mg/kg and 6-MP is dosed at 1.0–1.5 mg/kg for daily maintenance therapy. Clinical benefit may not be evident until 6–12 weeks after initiation of therapy, but tends to be durable. Genetic polymorphisms of thiopurine methyltransferase (TPMT), the primary enzyme responsible for 6-MP metabolism, have been identified and drug metabolite levels can be measured. These clinical assays allow monitoring and dosing of the medications according to measurements of the metabolites 6-thioguanine and 6-methylmercaptopurine. Prior to starting thiopurine therapy, TPMT enzyme activity or genotype should usually be determined because the drugs should be avoided in patients with TPMT deficiency. Patients with heterozygous genotype of intermediate activity should begin

therapy at reduced doses that are one-half the usual recommendations. If TPMT activity or genotype cannot be assayed in advance of initiating treatment, the drugs should be cautiously dosed at the outset with careful monitoring for leukopenia.

While the most common side effect linked to azathioprine and 6-MP is nausea, adverse events associated with these drugs include liver function abnormalities, leukopenia, and pancreatitis. Pancreatitis typically presents during the first 8 weeks of therapy, and reintroduction of either agent should be avoided because pancreatitis will likely recur. Routine monitoring of complete blood counts is recommended at 1–2 week intervals initially and subsequent to a dose change and then at least every 3 months thereafter to detect evidence of acute or delayed bone marrow suppression. Rare hypersensitivity reactions characterized by fever, liver dysfunction, and rash may occur. A slightly increased risk of lymphoma has also been reported [42, 43].

A recent review addressed the role of immunomodulators in inducing and maintaining remission in patients with Crohn's disease [44]. Five randomized controlled trials containing 380 patients compared azathioprine or 6-MP with placebo for the induction of remission [45]. The majority of studied patients had ileal or ileocolonic disease for at least 3–4 years and had previously received medical therapy or undergone an intestinal operation. Tapering doses of glucocorticoids were generally prescribed in both groups. Compared with placebo, thiopurine therapy showed a trend towards fewer failures to achieve remission at 12–17 weeks (relative risk: 0.87; 95% CI, 0.71–1.06).

Three randomized controlled trials evaluated maintenance of remission with azathioprine continuation versus azathioprine withdrawal. More patients maintained remission in the group that continued therapy than in the group that ceased treatment (relative risk of failure to prevent disease relapse: 0.39; 95% CI, 0.21–0.74) [31]. This translates into 201 fewer disease relapses per 1000 patients for those continuing azathioprine compared with azathioprine withdrawal.

Data related to the risk of serious infections were obtained from a large prospective, observational cohort study of 6273 patients with a mean follow-up of more than 5 years [46]. On multivariate analysis, thiopurine therapy was associated with a trend towards an increase in serious infections (adjusted odds ratio: 1.23; 95% CI, 0.96–1.57). Patients treated with thiopurines had ten more serious infections per 1000 patients compared with patients who were not managed with thiopurines.

Methotrexate Methotrexate and its polyglutamate metabolites are folic acid analogues that demonstrate inhibitory activity against many enzymes in the metabolic pathway of folic acid. Chronic low-dose methotrexate therapy inhibits the production of thymidylate, purines, and methionine and leads to the accumulation of adenosine, a potent anti-inflammatory purine nucleoside. These actions decrease formation of antibodies, inhibit cellular proliferation, and reduce the production of inflammatory mediators. Methotrexate (25 mg) is weekly administered by subcutaneous or intramuscular injection. Folic acid (1 mg daily) should be concomitantly prescribed. After remission has been achieved, a dose of 15 mg weekly may be effective. The most frequent side effects reported with methotrexate are gastrointestinal upset and stomatitis. Leukopenia can also occur, but much less frequently than seen with thiopurine therapy. Rare complications of methotrexate therapy include hepatic fibrosis and hypersensitivity pneumonitis.

Two randomized controlled trials have compared methotrexate with placebo for the induction of remission. Compared with controls, a trend towards fewer failures of remission was seen with methotrexate versus placebo (relative risk: 0.82; 95% CI, 0.65–1.03) [45]. Accordingly, methotrexate therapy results in 143 fewer failures per 1000 patients compared to placebo. Another two randomized controlled trials examined the utility of methotrexate in patients with quiescent disease. A pooled analysis reported that methotrexate therapy was associated with fewer relapses (relative risk: 0.74; 95% CI, 0.54–1.0), and methotrexate therapy would result in 168 fewer relapses compared with placebo. Unlike the experience with thiopurines, there is insufficient data to determine the risk of infection and lymphoma in patients with Crohn's disease treated with maintenance methotrexate.

Three small randomized controlled trials have compared methotrexate with thiopurines for the induction of remission. In general, methotrexate failed to show or exclude a beneficial or detrimental effect on failure of remission at 24–36 weeks (relative risk: 1.17; 95% CI, 0.82–1.67) [47]. However, methotrexate therapy would be expected to produce 68 more failures of remission per 1000 patients compared to thiopurine treatment.

Moderate quality evidence indicates that methotrexate at a dose of 15 mg weekly is superior to placebo for maintenance of remission in Crohn's disease and appears to be safe [48]. Conversely, low-dose oral methotrexate (12.5–15 mg/week) does not appear to be effective for maintenance of remission.

Biologic Agents

Anti-tumor necrosis factor (TNF) agents The anti-TNF agents are designed to block the effects of TNFα, and three such medications (i.e., infliximab, adalimumab, certolizumab pegol) are currently approved for the treatment of Crohn's disease. Infliximab is permitted for the treatment of moderate-to-severe Crohn's disease that does not respond to standard therapies. Adalimumab is accepted for the treatment of moderate-to-severe disease that does not respond to con-

ventional medications and for patients who have lost response to or are intolerant of infliximab. Certolizumab was approved for therapy in patients with moderate-to-severe disease who have failed conventional treatment.

Infliximab (5 mg/kg) is parenterally administered and usually well tolerated. After the initial infusion of infliximab, patients are generally administered another dose 2 and 6 weeks later and then at consistent 8-week intervals. If patients lose their initial response to infliximab, the medication dose can be increased (10 mg/kg) or the interval between infusions can be decreased (every 6 weeks). Infusion reactions are not uncommon, and most are successfully managed without discontinuing the infusion or preventing further use of infliximab.

Adalimumab (40 mg) is given as a single subcutaneous injection every other week after an initial induction regimen of four injections the first week and two during the third week. Although adalimumab may prove highly effective in the initial treatment stages, some patients lose response over time and the medication may need to be administered each week. Certolizumab (400 mg) is indicated for inducing or maintaining a clinical response in patients with moderate-to-severe disease who have had an inadequate response to conventional therapy. The drug is given by subcutaneous injection initially and at weeks 2 and 4. If the disease responds, the injections continue every four weeks.

Side effects associated with the anti-TNF agents are well recognized and include an increased risk of infections, such as tuberculosis, as well as autoimmune reactions, heart failure, liver dysfunction, lymphoma, and multiple sclerosis. Ongoing infection is an absolute contraindication to treatment with any TNF inhibitor. Prior to initiating treatment with an anti-TNF agent, patients should be screened to assure that they do suffer from occult infection secondary to hepatitis B or tuberculosis.

Integrin receptor antagonists Natalizumab is indicated for inducing and maintaining clinical response and remission in patients with moderate-to-severe Crohn's disease who have demonstrated an inadequate response to or are unable to tolerate conventional therapies and anti-TNF agents. Natalizumab (300 mg) is intravenously infused every 4 weeks. If patients have not experienced a therapeutic benefit by 12 weeks of induction therapy or cannot discontinue glucocorticoids within 6 months of starting therapy, the drug should be discontinued. Natalizumab should not be used in combination with immunomodulators or anti-TNF medications due to the risk of developing progressive multifocal leukoencephalopathy.

Vedolizumab is another integrin receptor antagonist indicated for patients with moderate-to-severe who have failed glucocorticoid or immunomodulator therapy. After an initial infusion of vedolizumab (300 mg), patients are administered another dose 2 and 6 weeks later and then at consistent 8-week intervals. If patients have not experienced a therapeutic benefit by 14 weeks of induction therapy or cannot discontinue glucocorticoids within 6 months of starting therapy, the drug should be discontinued.

A recent systematic review of randomized controlled trials compared these biologic agents with placebo or one another for inducing and maintaining clinical remission in patients with moderate-to-severe disease [48]. Of the 17 randomized controlled high-quality trials comparing six biologic agents with placebo in biologic-naïve patients, network meta-analysis revealed that infliximab and adalimumab, but not certolizumab pegol, natalizumab, and vedolizumab, were more likely to induce remission than placebo. Similar results were observed for maintenance of remission (Table 47-2). Infliximab showed the greatest probability of being ranked as the most effective agent for induction of remission and adalimumab for maintenance of remission at 86% and 48%, respectively. Unfortunately, few comparative efficacy studies exist.

TABLE 47-2. Pooled relative risk of inducing and maintaining remission with biologic agents in biologic-naïve patients with moderate-to-severe disease

		Remission induction		Remission maintenance	
Biologic agent	Usual maintenance dose	Relative risk	95% CrI	Relative risk	95% CrI
Infliximab	5 mg/kg IV every 8 weeks	6.11	2.49–18.29	3.31	0.98–14.01
Adalimumab	40 mg SQ every 2 weeks	2.98	1.12–8.18	5.16	1.78–18.00
Certolizumab	400 mg SQ every 4 weeks	1.48	0.76–2.93	2.26	0.38–13.57
Natalizumab	300 mg IV every 4 weeks	1.36	0.69–2.86	4.26	0.71–25.49
Vedolizumab	300 mg IV every 8 weeks	1.40	0.63–3.28	2.20	0.37–13.54

Induction and Maintenance of Remission

Several guidelines have been published that detail recommendations for the induction and maintenance of active Crohn's disease based on disease location and severity [33, 49–52]. As discussed earlier, the long-term use of glucocorticoids, including budesonide, is associated with unacceptable side effects and they cannot be safely used for chronic therapy. Thiopurines and methotrexate should not be offered as monotherapy, but may be added to glucocorticoid therapy when two or more disease flares have occurred in a 1-year period or the glucocorticoid cannot be tapered. Biologic agents are commonly prescribed when a patient's disease is steroid resistant or dependent. In most instances, anti-TNF therapy should be used only after active disease has been objectively confirmed by laboratory tests (e.g., C-reactive protein), imaging studies, or endoscopy.

A recent meta-analysis identified 39 randomized controlled trials comparing thiopurines, methotrexate, infliximab, adalimumab, certolizumab, vedolizumab, or combined therapies with placebo or an active agent for the induction and maintenance of remission in patients with Crohn's disease [53]. They reported that infliximab, the combination of infliximab plus azathioprine, adalimumab, and vedolizumab were superior to placebo for the induction of remission in active disease. In comparisons of anti-TNF agents, infliximab plus azathioprine and adalimumab alone were superior to certolizumab for induction of remission. In addition, all treatments were superior to placebo for maintaining remission, except for the combination of infliximab plus methotrexate. Infliximab, infliximab plus azathioprine, and adalimumab were superior to a thiopurine alone for maintenance of remission. Infliximab plus azathioprine and adalimumab alone were superior to certolizumab, and adalimumab was superior to vedolizumab.

Induction of Remission

Mild disease Mildly active Crohn's disease limited to the ileum is best managed with budesonide (9 mg daily); mesalamine and antibiotics in this setting are associated with minimal and no benefit, respectively. Some selected patients with ileal disease and only mild symptoms can be appropriately managed with no medical therapy. For mild disease of the colon or ileocolon, sulfasalazine or systemic glucocorticoids can be used. Extensive upper gastrointestinal Crohn's disease should be treated with systemic glucocorticoids and immunomodulators. Patients with clinical features indicative of a poor prognosis should be offered thiopurines, methotrexate, or anti-TNF therapy used alone or in combination.

Moderate disease Moderately active disease of the ileum should be treated with budesonide (9 mg/day) or systemic glucocorticoids. Antibiotics should be added if features of localized sepsis are noted. Systemic glucocorticoids plus an immunomodulator is also a viable alternative. Anti-TNF therapy should be considered as an option for patients with active disease that has previously been steroid resistant or dependent.

Moderately active colonic disease should be treated with systemic glucocorticoids. Anti-TNF therapy with or without thiopurines or methotrexate is an appropriate option for patients who have relapsed with moderately active disease. For some patients with only occasional relapsing disease, reintroduction of glucocorticoids with an immunomodulator may be more appropriate. Before initiating anti-TNF or immunomodulator therapy, surgical options should be discussed with the patient.

Extensive, moderately active upper gastrointestinal disease should be handled with systemic glucocorticoids and immunomodulators. For patients who have relapsed, anti-TNF therapy with or without thiopurines or methotrexate is an appropriate option. Surgical management should be considered and discussed at an early stage.

Severe disease Severely active ileal Crohn's disease should be initially managed with systemic glucocorticoids. For patients who have relapsed, anti-TNF therapy with or without an immunomodulator is an appropriate alternative. However, patients with infrequently relapsing disease may be best treated with glucocorticoids in combination with an immunomodulator. Surgery is also a reasonable option for some patients and should be discussed.

Severe disease of the colon may be treated with systemic glucocorticoids. Patients who have relapsed can be appropriately handled with anti-TNF therapy with or without an immunomodulator, but glucocorticoids with an immunomodulator may be warranted if the disease is infrequently relapsing. Before initiating thiopurine, methotrexate, or anti-TNF therapy, surgical options should be discussed with the patient.

Extensive upper gastrointestinal Crohn's disease should be managed with systemic glucocorticoids and immunomodulators. For patients who have relapsed, anti-TNF therapy with or without immunomodulators is an appropriate option. Surgical alternatives should also be considered and discussed at an early stage. Patients who demonstrate clinical features predictive of a poor prognosis seem to be the most suitable candidates for early introduction of anti-TNF therapy and thiopurines.

Maintenance of Remission

If remission of an initial presentation has been achieved with a glucocorticoid, a thiopurine or methotrexate should be considered, but no maintenance treatment is an option for some patients. If a patient has a relapse, escalation of the maintenance treatment can be considered. Surgery should always be considered as an option in localized disease. Oral 5-ASA compounds have not been consistently proven effective in maintenance of remission.

Patients who relapse on thiopurine should be evaluated for therapy adherence and have their dose escalated according to 6-thioguanine and 6-methylmercaptopurine concentrations or until leukopenia develops. A change in their maintenance therapy to methotrexate or an anti-TNF agent is an alternative, and surgery should always be considered as an option in localized disease.

If remission has been achieved with an anti-TNF agent, maintenance with regular anti-TNF therapy should be offered. Patients in a scheduled-treatment regimen with regular infliximab infusions appear to do better compared to patients managed using an episodic strategy. Thiopurine monotherapy may be also considered if the patient is naïve to thiopurines. However, combination therapy with infliximab plus a thiopurine is of greater efficacy in achieving and maintaining glucocorticoid-free remission than either infliximab or thiopurines used alone in patients naïve to both medications. Some clinicians feel that patients managed with long-term anti-TNF agents should have their disease annually assessed to determine whether ongoing therapy is still clinically justified.

The relapse rate following immunomodulator cessation in patients receiving immunomodulator monotherapy for maintenance of remission is nearly 20% at 1 year [54]. In patients receiving an immunomodulator plus infliximab for at least 6 months, the relapse rate following discontinuation of the immunomodulator seems to be equivalent to the risk of relapse in patients maintained on combination therapy at 20% over 2 years. However, cessation of the anti-TNF agent in combination therapy is associated with a 50% recurrence rate after 2 years. These findings suggest that a deescalating treatment strategy should be largely limited to patients with a high risk for severe adverse events and patients in deep remission. Deep remission for a patient on maintenance thiopurine is often considered 4 years of remission, while the most appropriate duration of treatment with methotrexate or anti-TNF agents is unknown.

Medical Prophylaxis After Surgery

The cumulative risk for surgery in patients with Crohn's disease is estimated to be 16%, 33%, and 47% at 1, 5, and 10 years, respectively [55]. Endoscopic recurrence has been reported in 54% of patients at 5 years, and clinical recurrence follows endoscopic recurrence with a prevalence of 28–45% by 5 years [56]. Clinicians have accordingly attempted to use medical therapy to prevent this almost inevitable recurrence of disease, and a recent view summarized 21 trials comprised of more than 2000 patients comparing seven treatment strategies to placebo.

Antibiotics, immunomodulator monotherapy, immunomodulator plus antibiotics, and anti-TNF monotherapy but neither mesalamine nor budesonide reduced the risk of endoscopic recurrence [57]. Similarly, antibiotics, mesalamine, immunomodulator monotherapy, immunomodulator plus antibiotics, and anti-TNF monotherapy but not budesonide reduced the risk of clinical recurrence. Overall, anti-TNF monotherapy was the most effective pharmacologic intervention for postoperative prophylaxis, as evidenced by large effect sizes relative to all other strategies. Moreover, the relative risk of medication discontinuation as a result of adverse events did not significantly differ between antibiotics, immunomodulator monotherapy, immunomodulator plus antibiotics, and anti-TNF monotherapy.

Conclusions

Crohn's disease is a complex inflammatory condition of the intestine that is best managed through collaboration among the patient, physician, and surgeon. Medical therapy is commonly the first-line treatment and typically managed by the physician, but the surgeon must be familiar with the medications and their characteristics to understand when operative intervention is in the patient's best interest. While most patients are currently treated in a step-up manner, a top-down approach is gaining support in an effort to alter the disease's long-term outcome. This change in strategy coupled with the development of new medications directed at specific molecular targets will likely lead to a reduced need for operative intervention for patients suffering from this potentially debilitating disease.

Anorectal Crohn's Disease

Stephen R. Gorfine

Key Concepts

- Crohn's disease is an incurable inflammatory condition of unknown cause that can involve any portion of the GI tract. Anorectal involvement is estimated to occur in 25–35 % of cases.
- Common manifestations of anorectal Crohn's disease include skin tags, abscesses, fissures, ulcers, fistulas, and strictures. Cancers, both adenocarcinomas and squamous carcinomas, are also possible, occurring with more frequency than that seen in the general population.
- Evaluation of the Crohn's patient with anorectal disease usually involves examination under anesthesia and imaging studies such as pelvic MRI or ERUS in addition to colonoscopy, enterography, and laboratory studies.
- Any undrained sepsis must be addressed promptly. Incision and drainage of abscesses and placement of drains or setons under general anesthesia are often required.
- Once sepsis has been controlled, medical therapy, which usually includes antibiotics, immunomodulators, and biologics, in combination or as single agents, is generally instituted. Corticosteroids are ineffective in anorectal Crohn's disease and should be avoided. Close collaboration with the medical team is mandatory.
- Fistulizing anorectal Crohn's disease occurs commonly. Fistulas are classified as simple or complex. Simple fistulas can often be treated by lay-open fistulotomy. Complex fistulas are usually treated medically with biologics, often in combination with immunomodulators. Surgical management of complex fistulas can include permanent seton, fibrin glue, fistula plug, endorectal advancement flap, and LIFT procedure. Surgical interventions should be used judiciously as these incur a risk of incontinence and nonhealing wounds.
- Long-standing fistula tracts and strictures should be routinely biopsied to exclude malignant degeneration. Cancers, when found, are generally treated in the same manner as those found in the general population. Total proctocolectomy is a consideration in a patient with extensive Crohn's colitis of long duration found to have a rectal adenocarcinoma.
- Diversion and/or proctectomy are required in about 10–20 % of cases.

Introduction

Crohn's disease (CD) is an inflammatory condition of unknown etiology that can affect any portion of the GI tract. The terminal ileum is most commonly involved [1] and perianal disease occurs in about 25 % of cases. Crohn's disease was first described in 1932 [2]. The first association of ileitis with perianal disease was described by Bissell in 1934 [3] and confirmed by Penner and Crohn in 1938 [4]. Crohn's disease is marked by transmural inflammation of the affected portion of the gut.

Incidence and Natural History

Perianal Crohn's disease is defined as inflammation at or near the anus. Various perianal lesions are commonly associated with Crohn's disease. These include external tags, fissures, ulcers, abscesses, fistulas, and strictures. Anal cancer, either adenocarcinoma or squamous carcinoma, may also complicate perianal CD. Symptoms of perianal CD include pain, bleeding, drainage, and incontinence. Risk factors for perianal involvement include colonic and especially rectal disease and young age at CD onset [5–7]. Hellers et al. reported that 12 % of patients with small bowel CD had perianal disease [8]. The same report showed that 41 % of patients with CD colitis with rectal sparing and more than 90 % of patients with colitis and rectal involvement had perianal disease [8]. The incidence of perianal CD occurring in the pediatric population has been estimated to be between 14 and 62 % [9].

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_48

In the majority of cases, intestinal manifestations of Crohn's disease will precede anorectal involvement. However, in a small number of patients, perianal disease will be the first manifestation of CD [10]. The presence of perianal disease suggests a more aggressive CD phenotype [11]. The natural history of perianal CD depends upon the type of disease present. Simple fissures and ulcers are often amenable to medical treatment. Superficial fistulas can usually be resolved by simple surgical techniques. Complex fistulas, destructive ulcers, and stenosis often present therapeutic challenges that may be solved only by anoproctectomy. CD patients who have perianal involvement generally fare less well than those who do not. Perianal disease is associated with more disability [11], more frequent extra-intestinal manifestations [12], and more steroid resistance [13].

Etiology

The cause of Crohn's disease is unknown. The reason for a predilection for perianal involvement is also unclear. There appears to be an underlying autoimmune process based upon genetic predisposition and microbiota influence that is responsible for perianal involvement in CD patients. Genetic factors associated with fistulas and abscesses have been associated with specific gene variants at the susceptibility locus on chromosome 5q31 (IBD5), including OCTN [14] and IRGM [14–16]. OCTN and IRGM both play roles in the development and preservation of intracellular pathogen killing, among other functions. The association between NOD2/CARD15 genotype and perianal Crohn's disease has also been studied with no conclusive correlation established [6, 17]. The influence of various bacteria has also been studied. A variety of microorganisms have been associated with perianal disease, but none have been linked conclusively. Changes in the microbiota among patients with perianal CD may be primary phenomena or secondary changes.

Crohn's disease is characterized by a transmural inflammatory process which may lead to perforation, abscess, and fistula formation at the anus or at other intestinal locations. One postulated mechanism regarding the pathogenesis of perianal abscesses and fistulas hypothesizes that Crohn's-related inflammation causes a shallow mucosal ulceration which subsequently extends to deeper structures by the action of exposure to stool and the pressure of defecation [18]. A second hypothesis implicates infection of anal glands with penetration of the infective process beyond the intersphincteric space [19].

Anatomy

The anus is the most terminal portion of the gastrointestinal tract. It opens on the perineum distally and becomes the rectum proximally. It has two muscular layers, the internal and external anal sphincters. The internal sphincter is a continuation of the circular smooth muscle of the rectum. It is an autonomic structure, not under voluntary control. The external anal sphincter is a skeletal muscle, a continuation of the puborectalis and levator ani muscles. It is subject to voluntary control. The perianal skin is a stratified squamous epithelium, similar to hair bearing skin elsewhere on the body until it approaches the anal verge. At the anal verge, the pigmented, keratinized perianal skin of the buttocks becomes the anal canal epithelium, the anoderm, which is also pigmented and keratinized but does not have skin appendages (hair, sweat glands, and sebaceous glands). The surgical demarcation between the rectum above and the anal canal below is the anorectal ring, where the puborectalis muscle forms a sling around the posterior aspect of the anorectal junction.

The anal canal is about 4–5 cm in length. The dentate line, a scalloped demarcation formed by the anal valves at the inferior-most ends of the anal columns, is located about 1–2 cm proximal to the anal verge. The anoderm changes from stratified squamous epithelium of the perianal skin of the anal verge to the columnar epithelium of the rectum at a point just proximal to the dentate line. This area is called the anal transition zone. The anal glands, located within the intersphincteric space, drain into the anal crypts. The anal crypts are located at the distal end of the columns of Morgagni, which are 6–10 longitudinal mucosal folds in the upper part of the anal canal (Fig. 48.1).

The anal or hemorrhoidal cushions are present in the left lateral, right anterolateral, and right posterolateral positions. These cushions contain fibromuscular connective tissue as well as branches of the middle and inferior rectal arteries. The ischiorectal fossae are located lateral to the anal canal below the pelvic diaphragm. In men, the prostate and seminal vesicles and the vagina and cervix in women lie anteriorly to the anal canal separated by Denonvilliers fascia. Posteriorly the anococcygeal ligament communicates with the presacral fascia of Waldeyer. The entire anal canal is completely extra-peritoneal.

Clinical Presentation

Perianal Crohn's disease is manifest as five, often overlapping, conditions. These are anal skin tags, tissue destruction in the form of fissures and ulcers, infective complications consisting of fistulas and abscesses, anorectal strictures, and anorectal cancers. Clinical manifestations are exceedingly variable ranging from mildly bothersome anal tags to destructive perianal lesions causing sepsis and incontinence.

Diagnosis

In order to effectively manage perianal Crohn's disease an understanding of the extent of intestinal disease is required. In addition to a history and physical exam, including a thorough anorectal exam, when possible, a colonoscopy and

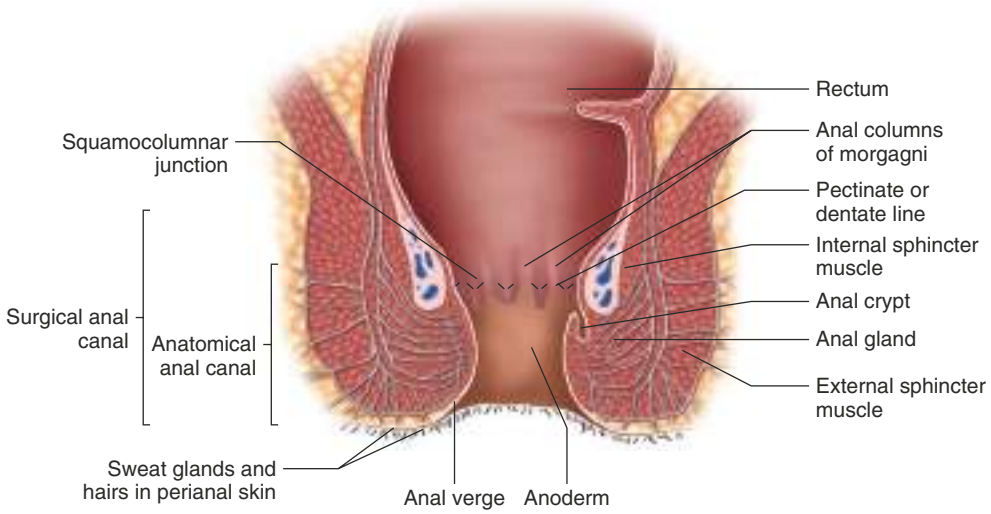

FIGURE 48-1. Anal anatomy.

small bowel evaluation, usually by CT enterography, will be required. The anorectal exam usually includes inspection of the anus and perianal areas, digital anorectal exam, and anoproctoscopy. This exam may be limited by patient discomfort and examination under anesthesia (EUA) may be required.

In the evaluation of perianal abscess and fistulous disease, a combination of magnetic resonant imaging (MRI) of the pelvis, endorectal ultrasound (EUS), and exam under anesthesia has been shown to yield 100 % diagnostic accuracy [20]. These exams, in combination, have gained increasing importance in arriving at management decisions. EUA involves inspection, palpation, and probing of fistulous tracts as well as anoproctoscopy with rigid or flexible instruments. The source of fistulous disease may be aided by the injection of dilute hydrogen peroxide into the external fistulous openings and observing the anal canal for bubbling. Alternatively, intra-operative EUS may also be augmented by injection of hydrogen peroxide.

Classification

In 1978, Hughes [18] proposed an anatomic and pathologic classification for perianal Crohn's disease (the Cardiff classification, later modified [21]) in which each major manifestation of perianal Crohn's disease (ulceration, fistula, and stricture) is graded on a scale of 0–2 (0, absent; 2, severe); fistulas are classified as low (not extending above the dentate line) or high (extending above the dentate line, sometimes to the levator muscles), and other associated anal conditions, the intestinal location of other sites of Crohn's disease, and a global assessment of the activity of the perianal disease are noted [18, 21]. Neither the Cardiff classification nor a more recent perianal Crohn's disease scoring system developed by Pikarsky and colleagues [22] has been reproduced or prospectively validated using clinically meaningful end points. These classification systems are not widely used because of a perceived lack of clinical relevance [23].

A more widely used clinical classification proposed by the American Gastroenterological Association (AGA) identifies each type of lesion [24, 25]. Ulcerations are divided into fissures and ulcers similar to the simplified Cardiff classification. Only irreversible and fibrous anorectal strictures are included in the AGA classification and may be short, annular, diaphragm-like strictures less than 2 cm in length, or longer tubular strictures arising from rectal inflammation. Anal skin tags are either type 1 (large edematous and cyanotic lesions) or type 2 corresponding to flat and broad or narrow, soft painless lesions [25].

Skin Tags

Skin tags have been classified into two types [25]. Type 1 are edematous, hard, often cyanotic, tender or not, typically arising from a healed anal fissure, ulcer, or hemorrhoid. These skin tags are caused by lymphedema secondary to lymphatic obstruction. They often occur in concert with intestinal inflammation. Type 2 lesions are raised, broad or narrow based, single or multiple, soft or firm, and painless (often referred to as "elephant ears"). Elephant ear tags (Fig. 48.2) are usually multiple and are generally asymptomatic except for patient complaints of difficulty cleaning and poor cosmesis. A study by Bonheur et al. [26] found that type 2 tags were more frequently found among CD patients when compared to patients with ulcerative colitis. There was a trend toward greater incidence of these tags among CD colitis patients compared to CD patients with ileitis and ileocolitis. These tags are fairly common among CD patients. Peyrin-Biroulet and colleagues [27] found in a population-based cohort study that the ten-year cumulative probability of developing tags from time of diagnosis was

FIGURE 48-2. "Elephant Ear" tags.

18.7 %. Taylor and colleagues [28] investigated excisional biopsies of anal skin tags in 26 patients with known CD and found noncaseating granulomas in almost 30 %.

Management

Skin tags associated with CD are generally best managed with benign neglect. There is no effective medical management of these lesions. Excision in some cases can lead to non-healing, persistent surgical wounds and a substantially worse problem. The AGA Institute states that most colorectal surgeons should avoid excision of skin tags, particularly type 1, owing to problems with wound healing. Fibroepithelial polypoid tags and "elephant ear" tags can be excised locally if clinically indicated in patients experiencing difficulty with perianal hygiene and in whom there are no concerns about wound healing [25].

Hemorrhoids

Symptomatic hemorrhoidal disease is remarkably uncommon in the setting of Crohn's disease. A study by the St Mark's group [29] showed that among more than 50,000 patients treated for hemorrhoids, only 20 had Crohn's disease. Results of surgery within the CD group were uniformly poor, and the authors concluded that hemorrhoidal surgery was contraindicated in the setting of CD. A more recent report [30] showed better results following hemorrhoidectomy among CD patients with symptomatic hemorrhoids. A review found that the incidence of complications after hemorrhoidectomy or removal of tags was high among CD patients [31]. CD patients contemplating hemorrhoid surgery should be free of active anorectal involvement.

Management

Hemorrhoidal disease in the setting of CD is best managed expectantly. Dietary modifications, antidiarrheal medications, and limiting toilet time, when possible, are useful adjuncts. Topical medications or suppositories have not been proven effective, but have limited downside potential. Surgical interventions such as rubber band ligation and excisional procedures should only be undertaken when conservative measures have failed and the anorectum is otherwise free of evidence of CD.

Anal Fissure and Ulcer

An anal fissure is a cut, tear, or defect in the anoderm. In the setting of CD, anal fissures can be idiopathic, similar to those seen in non-CD patients, or "atypical," being Crohn's related. An idiopathic anal fissure is located in the anterior or posterior anal midline at the anal verge (Fig. 48.3). About 90 % of idiopathic fissures occur in the posterior midline and 10 % occur in the anterior midline, areas with a characteristically poor blood supply [32]. These fissures are located distal to the dentate line and rarely extend beyond the anal verge. The resting anal sphincter tone is generally elevated. Anal hypertonicity is thought to decrease anodermal blood flow leading to non-healing of chronic fissures [33].

Characteristically, idiopathic fissures will cause modest bleeding with BMs and cause pain for some time (usually hours) following the movement. Idiopathic anal fissures can be acute or chronic. Acute fissures have the appearance of a simple slit or cut of the anoderm. Chronic fissures will often expose the fibers of the internal sphincter muscle at the fissure base and show "heaped up" edges. A skin tag or "sentinel pile" may be present at the distal margin and an hypertrophied anal papilla may be present at the proximal margin.

Atypical fissures and ulcers are more common among patients with CD. These lesions are often located off the anterior and posterior midline. In many cases there are multiple fissures or ulcers [34]. These fissures have granulating bases and overhanging edges (Figs. 48.4 and 48.5). They can extend beyond the anal verge to the perianal skin. Large cavitating ulcers with significant tissue destruction are also seen (Figs. 48.6 and 48.7). A majority of patients with these lesions will present with anal pain and bleeding. These lesions are painful in up to 70 % of cases [34, 35]. Discharge, pruritus, and bleeding are frequent associated symptoms. Biopsy of these lesions will show non-necrotizing epithelioid cell granulomas, characteristic of CD, in up to 77 % of cases [36]. Patients with noncaseating granulomas in perineal biopsies have more severe disease [36].

These fissures and ulcers are thought to result from a direct involvement of the perianal tissues with Crohn's-related inflammation and are not related to internal anal sphincter hypertonicity. Among those patients not known to have intestinal CD, other ulcer-forming anal diseases need to

FIGURE 48-3. Idiopathic chronic anal fissure. Note "heaped up" edges and internal sphincter fibers at base.

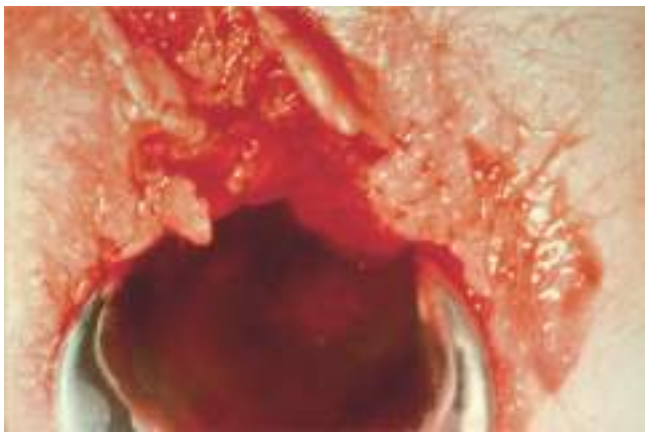

FIGURE 48-4. Fissure in Crohn's disease.

be excluded. These conditions, including syphilis, herpes, acquired immunodeficiency syndrome (AIDS), *Neisseria gonorrhea*, *Chlamydia trachomatis*, tuberculosis, and leukemic infiltrates [37]. Carcinoma and prior radiotherapy may also cause anal ulcerations [37]. Biopsy and microbiologic studies may be necessary to establish the diagnosis.

Management

Idiopathic fissures in CD patients can be treated in a fashion similar to that used in non-CD patients. Limiting toilet time and use of antidiarrheal medications, when appropriate, are useful. "Chemical sphincterotomy" with topical nitroglycerin, calcium channel blockers, and injected Botulinum toxin have been used to treat chronic anal fissures [38, 39]. Control of pain has been demonstrated with the use of these agents in numerous studies involving non-CD patients [40–45]. Healing rates of chronic fissures in non-CD patients with use

of these medications are somewhat better than those seen with placebo [39]. Use in CD patients has not been studied, but the risk among these patients appears to be low.

Healing rates of idiopathic anal fissures after lateral internal anal sphincterotomy have been shown to be superior to those seen with medical management among non-CD patients [39, 46]. In a small series of CD patients, Fleshner and colleagues found that "judicious" use of lateral internal sphincterotomy appeared to be safe and more effective than medical management [34]. Surgical treatment should be reserved for CD patients with a single, "characteristic" midline fissure, elevated resting sphincter tone, and a disease-free rectum.

Crohn's associated fissures and ulcers present more of a therapeutic challenge. Topical treatments have been used with varying degrees of success. Topical metronidazole 10 % showed improvement in the Crohn's Disease Activity Index and improvement with regard to pain, discharge, and induration at 4 weeks in an open-label study [47]. Similarly, topical tacrolimus 0.1 % was shown to improve these lesions in early studies (Fig. 48.8) [48].

Systemic medications including corticosteroids, antibiotics, aminosalicylates, and 6-mercaptopurine have been studied as treatments for CD perianal ulcerations [35, 49–51]. Improvement of these lesions has been inconsistently observed. None of the clinical studies of thiopurines in perianal Crohn's disease have examined perianal Crohn's disease as the primary efficacy endpoint [52]. Thalidomide [53], cyclosporine [54], and hyperbaric oxygen [55] as well as local infiltration of infliximab [56] and granulocyte colony-stimulating factor (GM-CSF) [57] have also been used effectively in small uncontrolled studies.

Infliximab and potentially other anti-TNF antibodies have become the "gold standard" in the treatment of perianal CD. In a recent large retrospective study 42.5 % of patients with ulceration had a complete clinical response after anti-TNF induction [58]. Resolution of symptoms, including anal pain and soiling, occurred rapidly after initiation of infliximab therapy.

FIGURE 48-8. Response to topical tacrolimus for two separate patients (**a** and **b**). Before *left*, after treatment on *right. With permission from Hart AL, Plamondon S, Kamm MA. Topical tacrolimus in the treatment of perianal Crohn's disease: exploratory randomized controlled trial. Inflamm Bowel Dis 2007; 13(3):245-253 (49) © Wolters Kluwer 2007.*

After a median follow-up period of 175 weeks, healing of ulcers was maintained in 73 % of cases [58]. Anti-TNF therapy should be considered as first-line therapy for cavitating ulcers as the long-term outcome is poor, with the risk of anoproctectomy approaching 83 % in some studies [59].

Abscess and Fistula

Abscess

Perirectal and perianal abscesses can be expected to occur in up to 80 % of CD patients [60]. Abscesses about the anus and rectum can form in four distinct anatomical locations. These are the perianal space, the ischiorectal (or perirectal) space, the intersphincteric (or submucosal) space and the supralevator space (Fig. 48.9). The majority of abscesses involve the perianal and ischiorectal spaces. The patient will often present with constant anorectal pain, worsened by sitting, coughing, walking and bowel function. Fever, chills and signs of systemic sepsis may also be present. Physical exam shows erythema and swelling of the affected side. The diagnosis of perianal abscess (Fig. 48.10) and ischiorectal abscesses (Fig. 48.11) is usually fairly easy to establish, whereas submucosal and supralevator abscesses may require imaging studies, such as MRI [61], computed tomography (CT) [62] or endorectal ultrasound [63]. Induration and tenderness are common findings. Fluctuance is generally a late sign. Examination under anesthesia is often required for diagnostic and therapeutic purposes.

Management

When the diagnosis of an abscess has been established, surgical drainage is indicated. Unless the abscess is quite superficial, this is usually best accomplished under general anesthesia in the operating room. Superficial perianal abscesses can be drained under local anesthesia in the clinic or emergency department. A cruciate incision will often prevent premature closure of the skin edges. Recovered purulence may be sent for microbiologic cultures, although growth of mixed flora is the rule rather than the exception [64]. Cultures are more useful when there is extensive surrounding cellulitis. Antibiotic therapy is often added, but is not a substitute for adequate surgical drainage.

The site of incision for drainage of an ischiorectal abscess should be placed on the buttock, just outside the sphincter complex. Most of these abscesses will result in fistula formation, and an incision site closer to the anorectum results in a shorter fistula tract. Placement of a mushroom or Malecot catheter or a draining seton, if the internal opening of a causative fistula is found, is preferred. "Packing" the abscess cavity is contraindicated in virtually all cases, as the packing actually impedes drainage.

Submucosal abscesses can be successfully drained into the anorectum by incising the overlying mucosa and internal

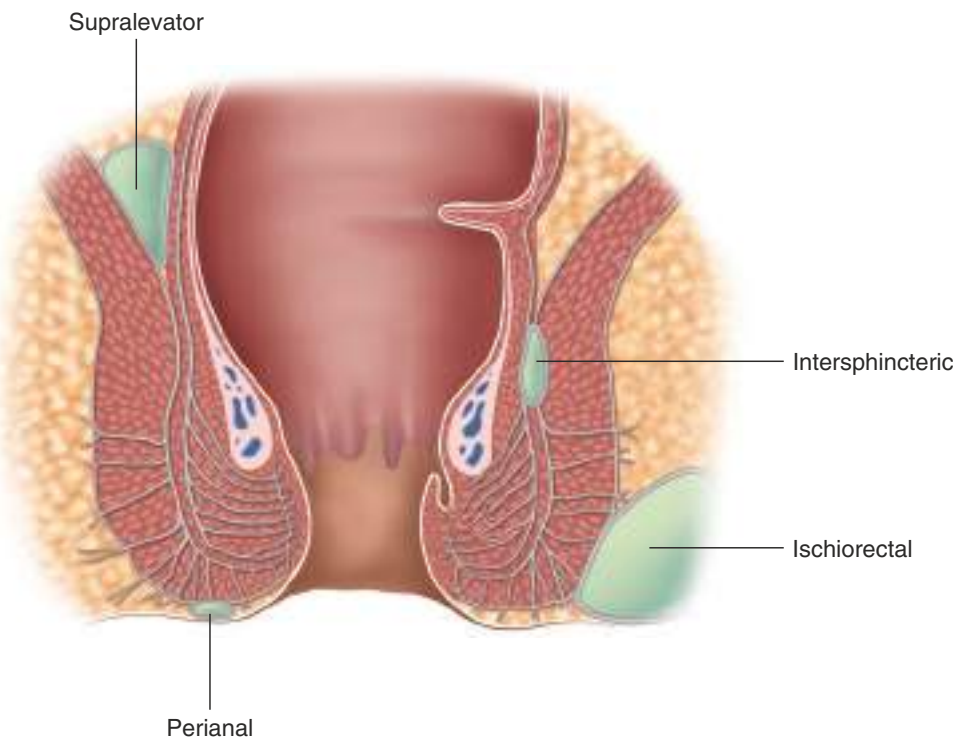

FIGURE 48-9. Location of abscesses.

FIGURE 48-10. Perianal abscess.

FIGURE 48-11. Left perirectal or ischiorectal abscess. Notice *left*-sided erythema and fullness.

anal sphincter muscularis. Division of the internal sphincter, however, may result in impaired anal continence. This potential complication should be explained to the patient before surgery. Supralevator abscesses may originate from a cryptoglandular focus or from an intra-abdominal source. Every effort should be made to differentiate the origin of this type of abscess. Supralevator abscesses originating within the abdominal cavity can be successfully drained into the rectum. Supralevator extensions of abscesses of cryptoglandular origin should be drained with a mushroom catheter via a perineal incision (Fig. 48.12) [65]. Non-palpable supralevator abscesses may require drainage by interventional radiology under CT or MRI guidance or by the surgeon under EUS guidance [63]. Abscesses will often lead to anorectal fistulas, whether drained surgically or not.

Fistula

A fistula is an abnormal communication between two epithelial lined surfaces. Fistulas arising from the anus or rectum can terminate on the perianal or buttock skin, the vagina and

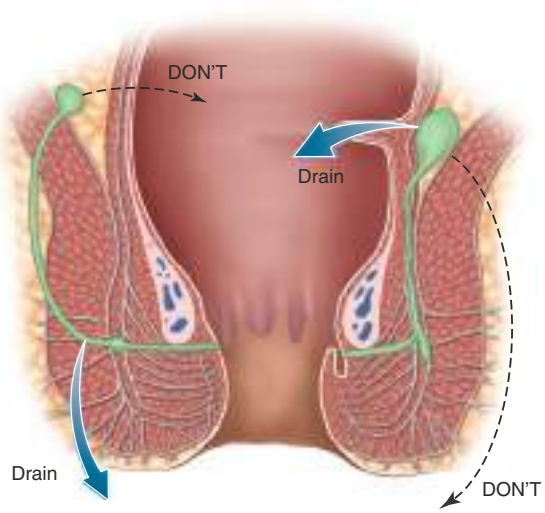

FIGURE 48-12. Drainage of supralevator abscess.

labia, the scrotum and penis, or the thighs, groins, and even further from the anus. Fistula formation is probably the most common complication of perianal CD. After 10 years of CD, the cumulative incidence of anal fistulas is reported to be up to 33 % and after 20 years it is about 50 % [66]. Among CD patients presenting with perineal disease, 29 % will have anal fistulas without antecedent abscesses [59].

Various classification schemes have been devised for perianal fistulas. Parks' classification [67] is perhaps most descriptive but also the most complicated. CD patients often have complex, branching, and interconnected series of fistulas that are not easily defined, much less objectively classified. A simpler scheme devised by Bell and colleagues [68] divides fistulas into two groups: simple and complex. A simple fistula has a low intersphincteric or transphincteric location, and a single, short tract (Fig. 48.13). The internal opening is at or caudad to the dentate line, and the external opening is near the anal verge. Vaginal involvement and abscess are not present. A complex fistula has a single internal opening above the dentate line or multiple internal or external openings. A complex fistula is present when any one or more of a vaginal extension, an abscess, multiple openings, an anorectal stricture, or active anorectal CD are present (Figs. 48.14 and 48.15) [25, 68]. Goodsall's rule, which predicts the tract of a fistula and the location of the internal opening within the anorectum based upon the relationship of the external fistulous opening to a transverse anal line, is notoriously inaccurate in the setting of perianal CD. Combining modalities such as EUA with MRI or EUS increases diagnostic accuracy [20] which can aid in therapeutic decision making. Transperineal ultrasonography is an alternative to EUS when EUS is not tolerated [69]. CT and fistulography are considered inferior studies for these purposes [70, 71].

Management

The goals of management of perianal fistulous disease include preservation of continence, complete healing, a reduction in the number of septic events, and improvement

FIGURE 48-13. Simple Crohn's disease fistula.

FIGURE 48-14. Complex Crohn's disease fistula.

in the patient's quality of life. Obviously, these goals are not always met. As a general rule, control of diarrhea, perianal hygiene by showers or sitz baths, and application of protecting barrier creams are always appropriate [72]. Successful treatment will often involve a close collaboration among surgeons, gastroenterologists, and radiologists, among others.

FIGURE 48-15. Complex Crohn's disease fistula.

Medical Therapy

Aminosalicylates and Corticosteroids

Clinical data suggest that aminosalicylates are more effective than placebo in achieving remission of mildly to moderately active intestinal CD [73, 74]. Their effectiveness, however, is influenced by the site of disease activity. Similarly, corticosteroids have been considered first-line treatment in patients with moderately to severely active CD. This approach is based largely on the findings of large clinical studies demonstrating the efficacy of steroids in mild-to-moderate intestinal CD [73, 74]. Despite these findings, there is no evidence that aminosalicylates play any role in the treatment of perianal CD. Steroids are similarly ineffective and may be contraindicated in the setting of fistulizing perineal disease.

Antibiotics

Despite a lack of convincing evidence, antibiotics are often used as initial treatment in the setting of CD-related fistulous disease [25]. In a small study, Bernstein and colleagues [75] treated CD patients with metronidazole at relatively high doses. More than half of these patients had complete healing with rapid onset of symptom resolution. Decreased pain and tenderness were noted in all study patients. However, long-term treatment with metronidazole was associated with a variety of adverse reactions including nausea, peripheral neuropathy, and paresthesias. Symptoms recur when metronidazole therapy is discontinued [76]. Ciprofloxacin has also been studied in the setting of perianal CD. In a small pilot study comparing ciprofloxacin and metronidazole to placebo, CD fistula response and remission rates were greater among those patients treated with ciprofloxacin [77]. The difference, however, did not reach statistical significance. A recent meta-analysis of 15 randomized, placebo-controlled trails of the efficacy of antibiotic treatment in CD found, that compared to placebo, ciprofloxacin exhibited significant clinical benefits in patients with perianal fistulas [78]. Antibiotics are

perhaps best used as an effective bridge to immunosuppressive therapy [79].

Immunosuppressives

Immunosuppressive medications used in the treatment of fistulizing perianal CD include 6-mercaptopurine (6-MP), azathioprine, methotrexate, cyclosporine, and tacrolimus. There are no controlled clinical trials in which the efficacy of immunosuppressants in treating fistulizing perianal CD was considered the primary end point [80]. Several small studies have assessed perineal healing by azathioprine and 6-mercaptopurine as secondary endpoints. A meta-analysis of this data found that significantly more patients responded to these immunosuppressants than those responding to placebo [52].

Tacrolimus and cyclosporine are calcineurin inhibitors that suppress T-cell activation and interleukin-2 production. Tacrolimus was compared to placebo in a randomized, controlled study where fistula closure was defined as either the absence of spontaneous drainage or the ability to express drainage with "gentle compression" [81]. The authors concluded that oral tacrolimus is effective for fistula improvement, but not fistula remission, in patients with perianal CD. Significant adverse events were also noted in the tacrolimus group. In another small, exploratory series, Hart and colleagues [48] found that topical tacrolimus was ineffective in treating CD-related perineal fistulas. Multiple small studies have shown value in treatments with cyclosporine A and thalidomide [54, 82–85]. However, use of these agents is limited owing to significant side effects.

Biologics

Tumor necrosis factor alpha (TNF-α) antagonists specifically target the elevated concentrations of TNF-α that contribute to the pathological inflammation in CD. Anti-α4 integrins belong to a newer class of drugs which also show promise in treating CD.

Infliximab

Infliximab is a chimeric monoclonal antibody to TNF-α. It is administered by intravenous infusion. Infliximab is the best studied of all the biological agents. Efficacy of infliximab in the treatment of fistulizing perineal CD has been demonstrated in multiple randomized, controlled studies. In the first published study, Present and colleagues [86] randomized 94 patients (85 with perianal fistulas) to receive either 5 mg/kg of infliximab or 10 mg/kg of infliximab or placebo at weeks 0, 2, and 6. The primary end point was a reduction of 50 % or more from base line in the number of draining fistulas observed at two or more consecutive study visits. A secondary end point was the closure of all fistulas. At the end of the study 55 % of the patients assigned to 5 mg/kg of infliximab had a closure of all fistulas, compared with 13 % of the patients assigned to placebo. Sands and colleagues [87] demonstrated the superiority of infliximab over placebo in maintaining long-term fistula healing. Despite these positive results, 11 and 15 % of patients enrolled in these trials developed abscesses during the study period. This was probably due to an early closure of the cutaneous opening of the fistula tract. To minimize this complication, a combined surgical and medical approach has been proposed. Small studies [88, 89] reported a better response rate, a lower recurrence rate, and a longer time to recurrence among patients who had a seton placed prior to infliximab treatment when compared with patients receiving infliximab alone. The seton is removed after the second infliximab infusion. Although the initial response to infliximab tends to be very good, the median duration of fistula closure is approximately three months and repeated intravenous infusions of infliximab are usually necessary. Long-term maintenance therapy (as opposed to episodic therapy) may be necessary to prevent fistula relapse [90]. Despite impressive rates of patient improvement, radiographic evidence of complete fistula healing occurs in a minority of patients [91]. Patients who received surgery and infliximab had a shorter time to fistula healing and a longer mean time to relapse compared to those who received infliximab or surgery alone. Discontinuation of infliximab therapy is associated with fistula recurrence.

Alessandroni and colleagues [92] reported a small series of CD patients with complex fistulas treated by core-out fistulectomies plus local injections of infliximab. Results were generally good, but long-term closure of fistulas was observed in a minority of patients.

Adalimumab

Adalimumab is a completely humanized monoclonal antibody to TNF-α. It is administered by subcutaneous injection. The CHARM study [93] was a 56-week, randomized, double-blind, placebo-controlled trial with a 4-week open-label induction period. Patients successfully completing CHARM could enroll in an open-label extension, the ADHERE study [94]. In the ADHERE study, fistulas were assessed for spontaneous drainage or drainage with gentle compression at each study visit. Complete fistula healing was defined as the absence of drainage under both of these circumstances. Of 117 enrolled patients (113 with perianal fistulas), adalimumab therapy was associated with progressive increases in fistula closure over time. Rates of complete closure differed between placebo and adalimumab groups as early as 2 weeks after randomization and reached statistical significance at 16 weeks. Baseline immunosuppressant or CD-related antibiotic use had no apparent effect on the rates of fistula closure in patients receiving adalimumab or placebo at weeks 26 or 56. In addition, whether patients were naive to or experienced with TNF antagonists before receiving adalimumab did not appear to effect fistula healing. Adalimumab was effective in patients who were infliximab nonresponders or had become infliximab refractory [94]. In the CHOICE trial [95], patients receiving adalimumab had draining fistula counts decrease by 41.3 % at the last visit compared with

baseline and approximately 38.6 % of patients had complete fistula healing at the last visit.

Certolizumab Pegol

Certolizumab pegol is the PEGylated Fab' portion of a recombinant humanized monoclonal antibody to TNF-α. It is administered by subcutaneous injection. Certolizumab pegol has also been shown to be effective in the treatment of CD in a number of well-controlled clinical trials [96–99]. Schreiber and colleagues [100] reported on a series of patients with CD fistulas from the PRECISE 2 [99] study. After open-label induction with certolizumab pegol at weeks 0, 2, and 4 responders were randomized at week 6 to receive either certolizumab pegol or placebo every 4 weeks. At week 26, 36 % of the patients in the certolizumab pegol group had fistula closure compared to 17 % among the placebo group; however, protocol-defined fistula closure was not statistically significant between the two groups. The authors concluded that when compared to placebo, continuous treatment with certolizumab pegol improves the likelihood of sustained perianal fistula closure.

Natalizumab

Natalizumab is a humanized monoclonal antibody against the cell adhesion molecule, α4-integrin. It is administered by intravenous infusion. Natalizumab is indicated for both induction of remission and maintenance of remission for moderate to severe Crohn's disease [101]. Natalizumab is largely reserved for CD patients with extensive ileocolonic disease who have failed conventional immunosuppressants and at least two anti-TNF-α agents [102]. Data concerning fistula healing is limited to open-label, retrospective studies [102]. Fistula disease responded to natalizumab in about half of treated patients [102]. Data concerning this agent is limited because of the association with the rare but usually fatal condition, progressive multifocal leukoencephalopathy (PML). Natalizumab should not be combined with an immunosuppressant or prolonged corticosteroids, because this may increase the risk of PML.

Vedolizumab

Vedolizumab is a humanized monoclonal antibody specifically designed to inhibit gut $\alpha_4\beta_7$ integrins. Blocking the $\alpha_4\beta_7$ integrin results in gut-selective anti-inflammatory activity [103]. It inhibits adhesion and migration of leukocytes into the gastrointestinal tract by preventing the $\alpha_4\beta_7$ integrin subunit from binding to mucosal addressin cell adhesion molecule-1 (MAdCAM-1). Because MAdCAM-1 is preferentially expressed on blood vessels in the intestinal tract, vedolizumab is theoretically more gut specific and therefore a more targeted form of immunosuppression. Vedolizumab is indicated for the treatment of moderately to severely active CD in patients who have lost response to biologic agents, immunosuppressive agents, or corticosteroids. A large randomized trial showed that vedolizumab was more effective than placebo in achieving remission but not a Crohn's Disease Activity Index-100 (CDAI-100) response, at week 6 [104]. There is no data concerning the use of vedolizumab in the treatment of CD fistulas. The risk of progressive multifocal leukoencephalopathy with this agent is thought to be less than that seen with natalizumab [105].

Surgical Therapy

Surgical therapy for fistulizing perianal disease needs to be tailored to each individual patient. While there are a variety of approaches available to the surgeon, it must be borne in mind that surgical interventions in CD patients can result in non-healing perineal wounds, incontinence, and significantly diminished quality of life. Surgical management of perianal CD should control perianal sepsis without resort to more extensive procedures when possible.

Seton

Placement of a loose, draining seton is often used as the first step in the management of fistulizing perianal CD. A silastic vessel loop passed through the fistula tract and tied to itself outside the anus works well (Fig. 48.16). The goal of the seton is to promote drainage and prevent recurrence of an abscess. Placement of the seton does not require division of the sphincter complex; hence the seton itself has essentially no impact on continence [106]. Draining setons are generally well tolerated by patients. Cutting setons should be avoided, as not only are they painful, but they can also lead to impaired control [107].

In the presence of active rectal CD, a seton can be used for many months [108] as a temporizing measure while medical therapy is instituted. Some authors advocate an "indwelling or permanent" seton for patients with CD-related complex fistulas [109].

FIGURE 48-16. Silastic seton.

Fistulotomy

Lay-open fistulotomy should be reserved for simple Crohn's fistulas. These will be either low transphincteric or intersphincteric fistulas (Figs. 48.17 and 48.18). The anorectum should be free of disease. This surgery is usually performed under general or spinal anesthesia with the patient in the lithotomy, left lateral decubitus, or prone jackknife position. A probe is passed from the external to internal opening and an estimate of the amount of muscle encompassed within the fistula tract can be estimated by palpating over the probe. Care must be taken to ensure that very little to none of the sphincter mechanism is involved. Granulation tissue at the base of the fistulotomy site is removed by curettage and the edges of the wound are then sewn to the edge of the fistulous tract with a running, locked absorbable suture. Healing rates between 80 and 100 % have been reported [25]. Healing rates are substantially worse when active proctocolitis is present [110].

Complex fistulas require a more cautious surgical approach. Muscle division in these cases carries a high risk of incontinence and non-healing perineal wounds [111]. Surgical alternatives to lay-open fistulotomy include a variety of surgical techniques with varying rates of observed success.

Fibrin Glue

Instillation of fibrinogen and thrombin causes a fibrin clot to form within the fistula tract. The clot is thought to promote hemostasis and angiogenesis while acting as "scaffolding" upon which fibroblasts can migrate, effectuating healing. This procedure is generally performed under general anesthesia. The fistula tract is gently curetted of granulation tissue and the fibrinogen/thrombin mixture is instilled into the fistula tract with a special, two-barreled catheter.

Despite promising healing rates shown in initial reports for patients with cryptoglandular fistulas [112], later results, especially among the CD population, have been disappointing. In a randomized, prospective, multicenter trial, Grimaud et al. [113] compared fibrin glue instillation to seton removal alone among 77 highly selected CD fistula patients. Forty-one patients had simple fistulas and 36 had complex fistulas. All patients had no recent surgery or biologic drug use and no evidence of local sepsis. Evaluation at 8 weeks showed clinical remission (absence of purulence with gentle compression) in 38 % of the fibrin glue group compared with 16 % in the observation group. Simple fistulas seemed to respond better than complex ones. At 16 weeks, two of 13 responders in the glue group experienced fistula recurrences. Fibrin glue injection was generally very well tolerated with no difference in the frequency of adverse effects between the fibrin glue and control arms. Incontinence did not occur in either group. The authors concluded that fibrin glue appears to be a simple, effective, and well-tolerated therapeutic option in the treatment of CD perianal fistulas. Neither the addition of antibiotics to the sealant [114] nor closure of the internal opening with sutures or a flap [115] has substantially improved results. It appears that fibrin adhesive achieves fistula healing in a minority of CD cases. However, given the minimal risk of incontinence it could be used in an attempt to avoid more invasive surgery or as an alternative to permanent seton placement.

Anal Fistula Plug

An anal fistula plug (AFP) is either a cone-shaped device made from lyophilized, rolled, porcine small intestinal submucosa (Cook®, Biodesign®) or a tubular, multi-legged, button made from bio-absorbable polymers (Gore® Bio-A®). As with fibrin sealant, the absorbable plug is designed to provide a matrix allowing for the in-growth of collagen producing fibroblasts. AFP is generally inserted under general anesthesia. The plugs are inserted through the fistula tract with the broad or button end inside the anorectum and the tapered end or legs through the tract. The end of the plug within the anorectum is designed to be fixed in place with

FIGURE 48-17. Simple fistulotomy.

FIGURE 48-18. Simple fistulotomy.

sutures and covered with mucosa. Of the two devices, the porcine plug is better studied.

Results with both plugs are variable and data is scant among CD patients. Garg and colleagues [116] performed a systematic review of the then available literature. A total of 25 studies were extracted and 12 (317 patients) were finally included in the systematic review. Fistula plugs were noted to have patient cure rates ranging from 24 to 92 % during follow-up periods between 3.5 and 12 months. Prospective studies among patients with complex fistulas yielded successful outcomes in 35–87 %. The success rate in patients with Crohn's disease was 29–86 %. Failure, often attributed to plug extrusion, occurred in 4–41 % of cases. More recent studies using the polymeric plug included only four patients with CD fistulas [117, 118]. It would appear that for CD patients the AFP procedure is safe and at least as effective as fibrin glue. The risk of incontinence and abscess appears to be minimal.

Adipose Tissue-Derived Stem Cells

Use of autologous adipose tissue-derived mesenchymal stem cells (ACSs) to treat CD-related fistulous disease was first described in a case report in 2003 [119]. The procedure involves injection of the fistula with stem cells recovered from the patient or a healthy donor, in the case of allogenic transplant. ACSs are recovered through a rather elaborate purification and cell culture process [120]. ASCs are cryopreserved until used. The ASC product consists of a cellular suspension of living adult stem cells. After curettage of the tract, the cells are injected into the fistula tract walls [120] and, additionally, in some studies, instilled into the tract with fibrin glue [121, 122]. ACSs are considered a promising tool for cell therapy due to their immunomodulatory capacity [123, 124].

A phase two trial reported healing of complex perianal fistulas in 71 % of 24 patients who received adipose stem cells mixed in fibrin glue [121]. A more recent, open-label multicenter study [122] involved 43 CD fistula patients. Tracts were curetted and irrigated and the internal openings were closed with sutures. ASC was injected into the fistula walls and the tract was filled with ASC mixed with fibrin glue. Fistula healing was assessed at 8 weeks after final treatment. Patients without complete closure of their fistulas at 8 weeks received a second injection of ASCs containing 1.5 times more cells than the first injection. A modified per-protocol analysis showed that complete fistula healing occurred in 27 of 33 patients (82 %) at 8 weeks after injection. Of the 27 patients with fistula healing, 26 completed an additional observational study for 1 year. Twenty-three of 26 patients (88 %) had maintained closure at the end of 1 year. There were no adverse events reported. The authors concluded that ASC injections for patients with Crohn's fistulas were well tolerated and showed a favorable and sustained 1-year outcome [122]. Other authors reported that over a longer, mean follow-up of 38 months, only seven of 21 patients (33 %) remained healed [125]. Longer follow-up also failed to report any instances of anal incontinence. While long-term study has reaffirmed a very good safety profile of ASC treatment, only a third of fistulas remained healed at a mean interval of about 3 years. These results suggest that ASC could be an effective, short-term treatment option for CD fistulas, but more evidence concerning durability of results is required.

Ligation of Intersphincteric Tract

First described by Rojanasakul [126], ligation of the intersphincteric fistula tract (LIFT) is a novel approach to anal fistulas. This procedure, usually performed under general or spinal anesthesia, approaches the fistula tract via an intersphincteric incision. Outpatient surgery is possible. The fistula tract, once isolated, is divided in the intersphincteric space at both the internal and external sphincters. The distal portion of the external tract is then curetted out, and the external opening is widened at the skin. Lastly, the skin incision overlying the intersphincteric groove is closed (Fig. 48.19a–f). In several small series, the LIFT procedure has been effective in healing 57–83 % of cryptoglandular fistulas [127, 128]. Incontinence has not been reported [129]. Failures are usually manifest as persistent drainage from the intersphincteric surgical site [130]. The procedure has been modified to include insertion of a bioprosthetic graft in the intersphincteric space (BioLIFT). In small series of non-CD patients, this technique reported healing rates of 60 and 94 % [131, 132].

Gingold and colleagues [133] enrolled 15 CD patients with trans-sphincteric fistulas in a prospective study of the LIFT procedure. Fistula healing and two validated quality-of-life indices were assessed two and 12 months after surgery. LIFT site healing and fistula closure were seen in nine patients (60 %) at 2-month follow-up. No patient developed fecal incontinence. LIFT site and fistula healing were seen in eight of the 12 patients (67 %) with complete 12-month follow-up. Patients who had successful operations also significantly improved their mean quality-of-life scores. The authors concluded that fistulas among CD patients may be successfully treated by LIFT with minimal perianal wound creation and sphincter injury [133].

Endorectal Advancement Flap

Treatment of CD fistulas by endorectal advancement flap is an attractive and well-studied option for CD fistula patients without anorectal stricture or inflammation. This procedure can often be accomplished in the outpatient setting under general or regional anesthesia. Advancement flap often will be performed after seton drainage of the fistula has allowed the tract to "mature." The internal opening of the fistula is identified within the anus and a "U"- or square-shaped incision is made in the mucosa around it. A flap of anoderm, submucosa, and a small portion of the internal sphincter is raised proximally so that the flap reaches beyond the

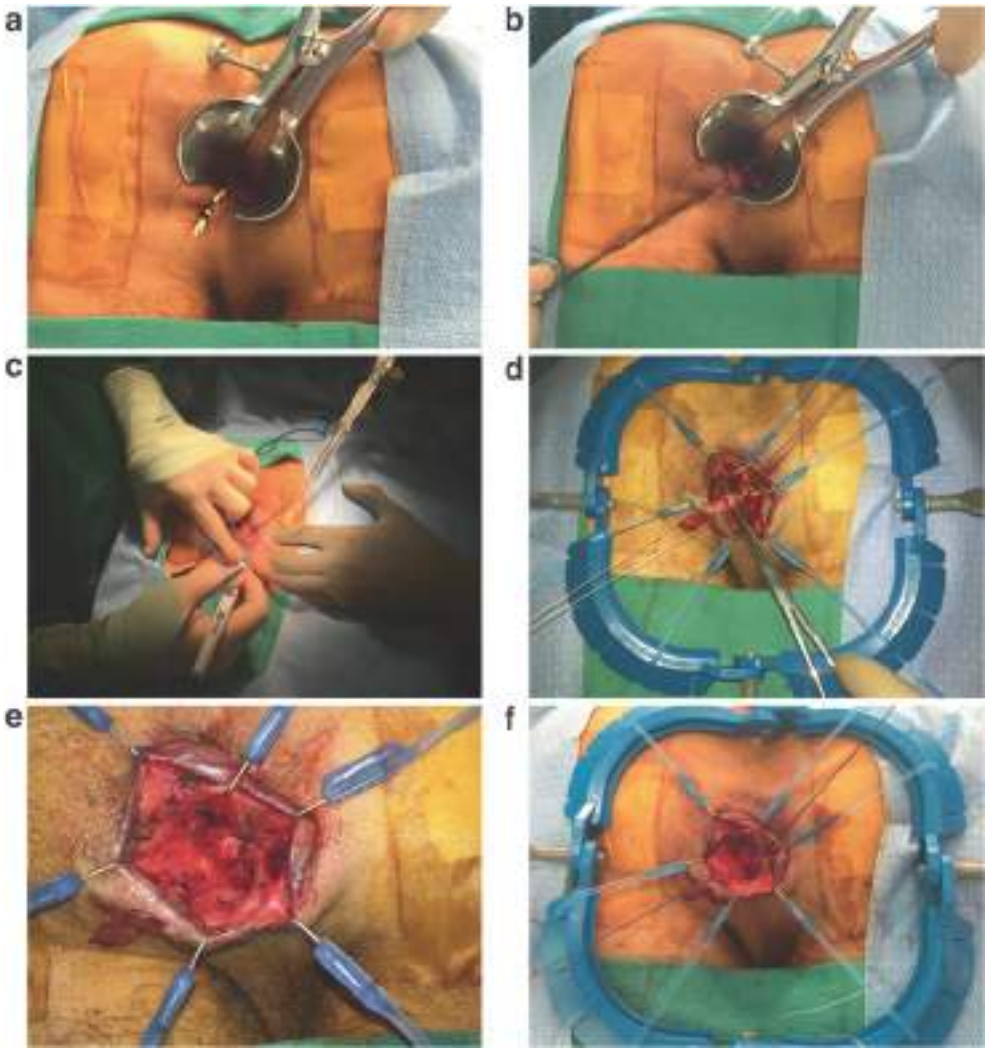

FIGURE 48-19. (**a**) LIFT: Seton in the fistula tract.; (**b**) LIFT: Identification of internal opening; (**c**) LIFT: Dissection in the intersphincteric groove. (**d**) LIFT: Isolation of the tract. (**e**) LIFT: Suture ligation of the tract. (**f**) LIFT: Ligation of the external sphincter.

muscular internal opening with no tension. The internal opening in the sphincter is closed with absorbable sutures. The distal end of the flap containing the mucosal internal opening is trimmed and the flap is sutured to the remaining anoderm (Fig. 48.20a–e).

Small series have demonstrated fairly good fistula healing rates after advancement flap in CD patients, but less than those seen in cryptoglandular disease [134]. In a systematic review of the then available literature, Soltani et al. [135] found 35 studies dealing with endorectal advancement flaps used in the treatment of CD and cryptoglandular fistulas. Of these, 23 consisted of retrospective case series, eight were prospective studies, and three were randomized clinical trials. Of 1654 patients available for pooled analysis, 91 had CD-related fistulas. Endorectal advancement flaps were more successful in cryptoglandular than in CD fistulas with weighted success rates of 80.8 % (range, 24.1 % to 100 %) in the cryptoglandular group and 64.0 % (range, 33.3 % to 92.9 %) in the CD group. The weighted average rate of incontinence was noted to be 13.3 % (range 0–35 %) in patients with cryptoglandular disease and 9.4 % (0–28.6 %) in patients with CD.

There are several reports concerning the effectiveness of endorectal advancement flap in rectovaginal fistulas with short-term healing rates reported between 42 % and 68 % [136–140]. The failure rates among CD-related rectovaginal fistula patients after endorectal advancement flap alone or in combination with levatorplasty were both about 50 % [141]. Successful trans-vaginal flap repairs of ano-vaginal fistulas have also been reported [142–144].

A retrospective, non-randomized study of patients with high anal fistulas of cryptoglandular origin initially treated with seton drainage demonstrated superiority of endorectal advancement flap over LIFT procedure [145]. In a multi-center, randomized trial of endorectal advancement flap versus anal fistula plug among non-CD patients, no differences

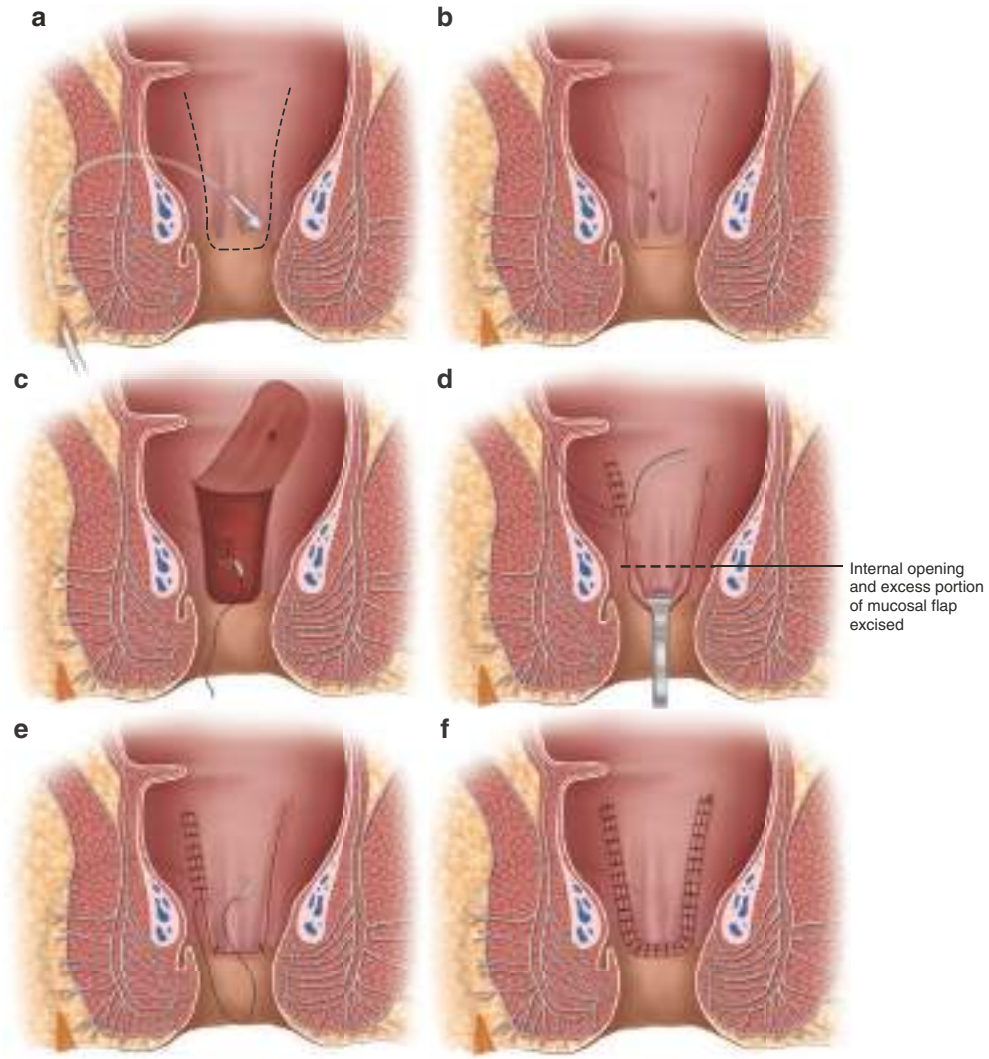

FIGURE 48-20. Endorectal advancement flap. (**a**) The probe or seton through the tract and the external opening is widened (**b**) The internal opening. were found in healing rates or continence scores [146]. At a median follow-up of 11 months the recurrence rate was 71 % in the anal fistula plug group and 52 % in the advancement flap group [146].

While some advocate that endorectal advancement flap is a good option for patients with complex CD anal fistulas [134], others point out that surgical outcome for complex CD fistulas remains disappointing, and recurrence is unpredictable [147].

Diversion

In situations where combined medical and local therapy is ineffective in controlling the symptoms of perianal Crohn's disease, fecal diversion, either on a temporary or permanent basis, has a role in patient recovery [148–151]. Ileostomy and colostomy have both been utilized for this purpose. Diversion of the fecal stream from the anorectum allows healing of those structures as well as amelioration or complete healing of perianal complications (Figs. 48.21 and 48.22a, b).

In a small, nonrandomized study [151] 13 of 39 patients underwent fecal diversion as treatment of severe perianal CD. At an average of 5 years follow-up, 11 of these patients (85 %) had complete resolution of their fistulas and only two (15 %) required proctectomy. In contrast, after local surgical procedures, only five of 26 patients (19 %) had complete resolution of perianal disease. Intestinal continuity was restored in six patients and three of these patients remained disease free. The authors concluded that fecal diversion was a viable treatment option for severe, perianal Crohn's disease and diversion may be associated with a higher rate of resolution than local surgical treatments alone [151]. Despite encouraging local control by diversion, only a minority of diverted patients ever achieve restoration of intestinal continuity.

In a recent report of 138 diverted patients [152], only 30 (22 %) came to stomal closure and 63 (45 %) underwent proctectomy with a permanent stoma. No particular treatment, including biological therapy, was associated with an improved outcome among these patients [152, 153]. While diversion usually causes the perineal disease to become quiescent, leaving the unused and diverted rectum in place as a Hartmann pouch poses its own set of risks. Cancers have been reported under these circumstances despite ongoing surveillance [154]. Proctectomy is strongly recommended in instances where the rectum is unlikely to be restored to continuity.

Proctectomy

In some instances, perineal CD is so severe that proctectomy with permanent diversion is the only viable option. About ten to 20 % of cases will require this intervention [155]. The presence of anal stricture and active colonic CD is associated with increased risk of proctectomy and permanent diversion [156]. This procedure usually involves two surgical fields, abdominal and perineal. Whenever possible, the perineal approach should utilize an intersphincteric dissection so as to lower the risk of non-healing of the perineal wound. Primary closure of the perineal wound is generally indicated [157–159]. Perineal wound problems can be expected to occur in up to 35 % of cases after abdominoperineal resection (Fig. 48.23) [160]. Non-healed perineal wounds have been managed with a variety of techniques including skin grafting [161], gracilis [162], and rectus abdominis myocutaneous flaps [163]. As perineal disease can be extensive, a staged approach is often warranted. Abdominal proctectomy with rectal transection at the level of the levators will allow perineal disease to heal or improve and permit a subsequent, second-stage, perineal anoproctectomy of a more limited scale [164].

FIGURE 48-23. Non-healed perineal wound 4 years after surgery.

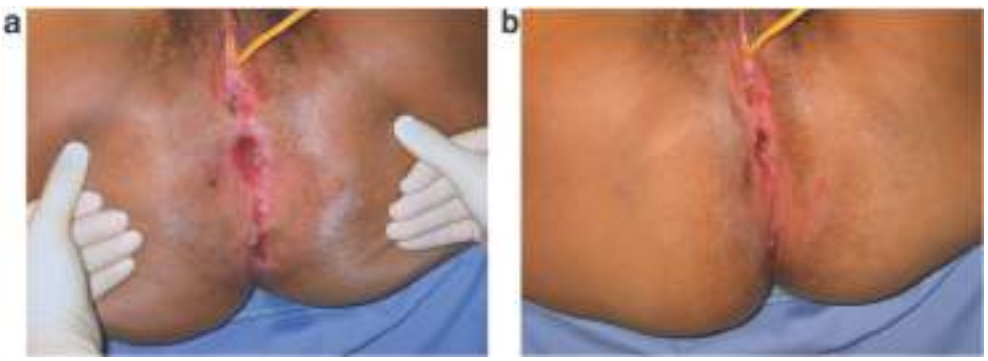

FIGURE 48-22. (**a**) Perineal wounds after diversion (**b**) Near complete healing a few months later.

Anorectal Stricture

Anal or rectal strictures are thought to arise as a consequence of transmural inflammation occurring in those structures. Stricture of the anorectum has been reported in 17 % of patients with perineal CD [59]. Linares and colleagues [165] reported on 44 patients with CD-related strictures of the anorectum. Of 48 strictures, 22 were in the rectum, 15 were in the anus, and 11 were anorectal. Proctitis and perianal disease were present in nearly all of these patients. While some strictures may be asymptomatic, the most common reported symptoms were hematochezia, constipation, perineal pain, and incontinence [165]. The diagnosis is often easily established by digital exam or anoproctoscopy.

Management

Asymptomatic strictures require no specific therapy. Any associated proctitis should be treated medically with systemic and/or rectal preparations. Symptoms of obstructed defecation often can be managed with dilatation using the finger, coaxial balloon, or Hegar dilators [165]. Effective management by rectal sleeve advancement has also been reported [166]. Despite these measures, about half of these patients will eventually come to proctectomy [156, 165].

Anal Cancer

Patients with Crohn's disease are at greater risk for colorectal carcinoma [167]. Long-standing perianal disease increases the risk of both anal squamous [168] and adenocarcinomas [169]. These lesions can occur within the anal canal or within chronic fistula tracts (Fig. 48.24). Diagnosis is made by biopsy. Cancers are relatively uncommon, but are often discovered late [170]. For this reason, routine, periodic biopsy of all persistent, perianal lesions is highly recommended [167]. A change in drainage or increased pain in a persistent fistula tract should raise suspicion of malignant degeneration. Physical exam is often unrewarding and misleading in these cases as scarring, induration, and distorted anatomy are often coexistent.

Management

Management of anorectal cancers in CD patients should follow generally accepted practices applicable to any patient. Pretreatment evaluation should include appropriate imaging studies to rule out metastatic spread. Squamous cancers generally are best treated with combined chemoradiation (Fig. 48.25). Wide local excision is possible if the lesion is small. Adenocarcinomas may require neo-adjuvant chemoradiation and then abdominoperineal resection. Consideration should be given to total proctocolectomy in these situations.

Summary

Perianal Crohn's disease is an all too common problem. Early treatment of perineal sepsis is required in all cases. Simple problems such as tags, hemorrhoids, and simple fistulas can often be managed in routine fashion if the anorectum is otherwise free of CD inflammation. More complicated problems will usually require combined medical and surgical therapy. Thorough understanding of the anatomy and extent of disease and expected risks and benefits of therapy are mandatory. Close collaboration between the surgeon and gastroenterolo-

gist, as well as other specialists, is essential. Crohn's disease is not curable. Therapy of perianal disease should be directed toward complete healing when possible, maintenance of rectal function and continence, elimination of sepsis, and overall improvement in quality of life. An algorithm of suggested management is presented in Fig. 48.26.

Crohn's Disease: Surgical Management

Roberta Muldoon and Alan J. Herline

Key Concepts

- Crohn's Disease is a chronic inflammatory bowel disease which primarily affects the terminal ileum and colon; however, it can involve all portions of the GI tract.
- Surgery is utilized in the treatment of Crohn's disease when medical therapy fails to control the disease or when there are complications from the disease (obstruction, perforation, fistulization, bleeding).
- Preoperative evaluation including appropriate imaging, nutritional assessment, as well as consideration of current medications and comorbidities will play a key role in operative planning and potential surgical outcome.
- Surgical intervention for Crohn's Disease should seek to alleviate symptoms while preserving small bowel length whenever possible.
- An ileocolic resection is the most common operative procedure performed on Crohn's patients.
- In cases of toxic colitis, aggressive medical therapy includes corticosteroids and/or rescue infliximab. If the patient fails to respond, total colectomy with end ileostomy is necessary. Delay in treatment can have dire consequences.

Surgery in the Treatment of Crohn's Disease

Crohn's disease is a chronic transmural inflammatory condition that primarily affects the terminal ileum and colon; however, it can involve all portions of the gastrointestinal tract. The course that the disease takes is variable, often manifesting acute attacks on a chronic underlying potentially debilitating condition. The severity of the disease is also variable ranging from a few flares with long periods of remission to constant unrelenting crippling symptoms. The transmural inflammation leads to the complications that are attributed to this disease including strictures, obstructions, fistula, and abscesses. Although Crohn's disease, at this time, is not curable, the goal of treatment is to induce and maintain remission of the disease to control symptoms as well as decrease the complications from this disease. This is accomplished primarily through medications; however, surgery plays an important role in the treatment of this disease. The specific goals of surgery are to determine the ideal timing of surgery and avoid delays in treatment, maximize patient conditioning to decrease postoperative complications, preserve as much small bowel as possible, and decrease recurrence rates. This complex disease does require thorough planning and preparation to have the best outcome from surgery. Special attention needs to be given to the patient's preoperative state including their overall health status, nutritional status, and current medication, as all of these factors can affect the outcome of surgery. The location of the disease, severity of disease, effect on the surrounding organs/tissue, and the patient wishes will all affect which procedure will be in the best interest of the patient. Surgery can have a profound effect on the well-being of the patient with >90 % of patients having significant relief or complete resolution of their symptoms after surgery [1].

Changing Trends in the Era of Immunomodulators and Biologics

There have been significant advances in the diagnosis and treatment of Crohn's disease over the past few decades. This has included an improvement in our ability to diagnose the disease at earlier stages with the use of CT enteroclysis and MRI. In addition to this, there have been significant advances in the medical therapies used to treat the disease over the years including the use of immunomodulators as well as

Electronic supplementary material: The online version of this chapter (doi:10.1007/978-3-319-25970-3_49) contains supplementary material, which is available to authorized users.

S.R. Steele et al. (eds.), *The ASCRS Textbook of Colon and Rectal Surgery*, DOI 10.1007/978-3-319-25970-3_49

biologics. Studies have not only looked at this effect with regard to the natural history of Crohn's disease, but also how these medications have influenced surgical intervention.

Overall, there has been an increase in the incidence and prevalence of Crohn's disease over the last five decades [2]. The highest incidence of Crohn's disease has been reported in Northern Europe, the United Kingdom, and North America [2, 3]. The incidence of Crohn's disease in Olmsted County, Minnesota, was 5.8/100,000 from 1940 to 1993; however, it increased to 7.9/100,000 from 1990 to 2000 [4, 5]. In Northern Denmark, the incidence rate for women with Crohn's disease increased from 4.1/100,000 in 1978–1982 to 10.7/100,000 in 1998–2002. For the same time period, the incidence for men with Crohn's disease increased from 3.2/100,000 to 8.5/100,000 [6]. The incidence rates for North America between 1981 and 1999 ranged from 3.1/100,000 to 14.6/100,000. The prevalence of patients with Crohn's disease in North America ranged from 26 to 198.5 cases per 100,000 from 1988 to 1999 [7]. Again, we see an increase in the prevalence over the years. The prevalence of Crohn's disease in 1991 in Olmsted, Minnesota, was 133 per 100,000, which was 46 % higher than that seen in 1980 [4]. The rate continued to increase in 2001 to 174 cases per 100,000 [5]. The prevalence in northern Denmark was 151 per 100,000 in 2002.

The rate of surgical intervention for Crohn's disease has also changed over the years. Prior to 1995, the reports of Crohn's patients requiring operations ranged from 35 to 78 % with the majority of the resections being done within the first year of diagnosis [8–14]. Ramadas et al. studied the natural history of Crohn's disease in a population-based cohort from Cardiff, Wales. They compared the incidence of surgery for Crohn's disease between three groups based on the year of diagnosis: Group A: 1986–1991, Group B: 1992–1997, and Group C: 1998–2003. The rate of surgery was 59 %, 37 %, and 25 %, respectively [15]. Jess et al. reviewed the population-based cohort of patients from Copenhagen, Demark. Three cohorts of patients were identified: those diagnosed with Crohn's disease during 1962–1987, 1991–1993, and finally 2003–2004. They found that the time from onset of symptoms to diagnosis was significantly longer in the first cohort compared to the second or third cohort. This difference may be due to the introduction of better imaging allowing earlier diagnosis of the disease. Interestingly, they also found the crude rate of intestinal resection was 35 % in cohort 1 versus 28 % in cohort 2 and only 12 % in cohort 3. They attributed this to a more aggressive medical therapeutic approach for the third cohort compared to the first cohort [16]. A similar study was performed in Denmark. Patients in cohort 1 (1979–1986) had a 50.3 % risk of surgery compared to those patients in cohort 4 (2003–2011) who had a 23.3 % risk of surgery [17]. Reported rates of surgical intervention for treatment of Crohn's disease after 1995 range from 20 to 44.3 % [1, 17–21].

A number of studies have looked at the cumulative risk of surgery for Crohn's disease over time. Bernell et al. performed a retrospective population-based study with a cohort of 1936 patients who were diagnosed with Crohn's disease between 1955 and 1989. They found 73.6 % of patients required at least one bowel resection. The absolute cumulative frequency of surgery was 44 % (95 % CI, 42–47 %), 61 % (95 % CI, 59–63 %), and 71 % (95 % CI, 69–73 %), at 1, 5, and 10 years after diagnosis [9]. Vester-Anderson et al. studied patients with Crohn's disease in a prospective population-based study in Denmark. All patients diagnosed with CD between January 2003 and December 2004 were included and then followed through to December 2011. They found 29.1 % of the patients required surgery within the follow-up period. The cumulative risk of first resection during that time period was 14.6 %, 24.6 %, and 28.5 % for 1, 5, and 7 years, respectively [18]. Similarly, in Norway, the cumulative probability of surgery was 13.6 %, 27 %, and 37.9 % for 1, 5, and 10 years, respectively [20]. Comparable numbers were seen in France with cumulative probabilities of first Crohn's disease-related abdominal surgery at 6.5 %, 25.9 %, and 44.3 % for 1, 5, and 9 years, respectively [19]. These studies demonstrate that the longer a patient has the disease the more likely they are to need surgical intervention.

Further evaluation of the natural history of Crohn's disease with regard to surgery revealed that there are factors associated with a higher risk of requiring surgery. Patients who are younger than 40 years of age at the time of diagnosis are more likely to require surgical intervention for treatment of their Crohn's disease [8, 20, 22]. Also, patients with terminal ileal or ileocecal disease are more likely to require surgery compared with those who present with colonic disease [9, 10, 12, 20]. Bernell et al. found that patients with small bowel disease or solely ileocolic disease have a relative risk of 3.2 for undergoing surgery compared with those patients with colorectal disease [9]. Lastly, those with a stricturing, penetrating pattern of disease are more likely to require surgery [20]. Sands et al. evaluated 345 patients who had surgical procedures for Crohn's disease. The study revealed that 20 % of patients required surgery with 50 % of those needing it within the first 6 months after diagnosis. Factors that were found to be associated with earlier need for surgery included smoking, disease of the small bowel without colonic involvement, nausea, vomiting, and abdominal pain at presentation, neutrophil count, and steroid use in the first 6 months of diagnosis [21].

Great strides have been made in the medical treatment of Crohn's disease. The question raised is: have these medications changed the need or the timing of surgery for the treatment of Crohn's disease? Numerous studies have been done, looking at the effect these new medications have had on the outcome of the disease. D'Haens et al. performed a randomized trial including centers from Belgium, Holland, and Germany from 2001 to 2004. They compared patients who received conventional therapy, which was considered treatment with corticosteroids followed by azathioprine followed by infliximab, to those who received combined infliximab and azathioprine. They found that at week 26, 60 % of those in the combined immunosuppression group were in

remission without steroids or surgery compared to 35.9 % in the conventional group [23]. Other studies also support this finding that the long-term use of anti-TNF therapy does decrease the risk of surgery for the treatment of Crohn's disease [19, 24]. Not all studies support this finding. Burke et al. reviewed the national trend of intestinal resection in Ireland. They found that the rate of small bowel or right side resection as well as proctectomies remained the same. The rate of left colon procedures decreased, while the rate of total colectomies increased. This shift may be more a reflection of a change in practice rather than an effect of medication [25]. If one looks at the population-based studies before and after the induction of anti-TNF medication, one will find that the rate of surgical procedures before anti-TNF ranged from 27–61 % at 5 years compared to 25–33 % at 5 years in the era of anti-TNF, suggesting a modest to no decrease [26].

There has been a significant decrease in the need for surgery for the treatment of Crohn's disease since it was first described in 1932; however, the largest drop predates the introduction of biologics and is reflective of the increased use of corticosteroids for treatment of the disease. The continued decrease seen over time is more likely multifactorial. Though there is some data that suggests that immunomodulators and biologics have decreased the need for surgery, the data available needs to be viewed carefully as many studies have short follow-up, include patient that have had the disease for a long period of time prior to starting the anti-TNF, or have already had one or more surgical procedures. All of these factors can complicate data analysis. In addition to this, over the years, we have seen improved diagnostics, which have led to earlier detection of the disease. With earlier detection, the disease may be diagnosed in a milder state and thus not be as likely to need surgical intervention. Earlier detection would also lead to earlier treatment, which could decrease the complications developed from the disease and thus decrease the need for surgical treatment. Continued study of large population-based cohorts with long follow-up will help to shed more light on the effect of biologics on the natural history of the disease.

Indications for Surgery

Crohn's disease is a very complex and heterogeneous disease. Surgeons are called upon to treat Crohn's disease in both the emergent and elective settings. The timing is critical. A multidisciplinary approach including the gastroenterologist, radiologist, and colorectal surgeon is ideal. Non-emergent indications for surgery include failure of medical therapy, chronic obstruction, fistulas, abscesses, cancer, and occasionally quality of life issues. The most common of these is failure of medical therapy to adequately control symptoms. Emergent indications include acute obstruction, perforation, hemorrhage, and toxic colitis.

Failure of Medical Management

Thirty-three to 47 % of patients have surgery for Crohn's disease due to failure of medical management [14, 27]. There are numerous medications used to treat Crohn's disease including corticosteroids, 5-aminosalicylate products, antibiotics, immunomodulators, and biologics. Each of these medications has benefits, but also carries with it risks and side effects. They each also have different time frames to reach maximum effectiveness. When one medication fails, others are tried. Ultimately, when medical options are exhausted, surgery is considered. Failure of medical therapy, therefore, not only includes failure of the medications to control symptoms, but also includes those patients who have symptom control but are experiencing unacceptable side effects or reactions from the medications. Inability to wean off corticosteroids within 3–6 months is also considered failure of medical management [28]. In a population-based study, 173 patients were evaluated with 43 % being treated with steroids. Twenty-eight percent of these patients were found to be steroid dependent at 1 year [29]. It is important to strike a balance between exhausting medical management and avoidance of surgery. Often patients are so determined to avoid surgery that they ultimately suffer with a severe decline in their overall general health and well-being. Timing is important to avoid a worsening health status, development of malnutrition or weight loss, or need for escalating steroid dosages, which all could have significant deleterious effects on surgical outcomes. Scott et al. surveyed patients to evaluate the timing of surgery from the patient perspective. Seventy-four percent stated that they would have preferred the surgery to have been carried out at an earlier time. The reasons given were severity of disease in 97 %, ability to eat normally after the resection in 86 %, feeling of well-being after the resection in 62 %, and cessation of drugs in 43 % of the cases [30].

Obstruction

Approximately 20–25 % of surgeries for Crohn's disease are secondary to obstruction [14, 27, 31]. Transmural inflammation causes bowel wall thickening which over time can fibrose and cause scarring. This stricturing can lead to a chronic obstructive type picture. Since these strictures develop slowly over time, the bowel slowly accommodates to the obstruction. The patients may experience intermittent crampy pain, bloating, and intolerance to certain foods. With repeat acute attacks the scarring worsens, leading to a fibrotic stricture with potential worsening symptoms. Other etiologies of obstruction in Crohn's patients include anastomotic strictures or cancer.

When a patient presents with obstructive symptoms, it is beneficial to try to determine the etiology of the obstruction. Evaluation with CT scan is helpful. It is important to try to

differentiate between an inflammatory stricture, a fibrotic stricture, and an anastomotic stricture. An inflammatory stricture may respond to steroids with symptomatic improvement of the patient without emergent surgical intervention. Once the patient has recovered, they should be reassessed for a possible fibrotic component which may require elective surgical intervention to prevent further episodes of obstruction. Fibrotic strictures are more likely to require surgical intervention. If the obstruction is secondary to an anastomotic stricture, endoscopic dilation may be employed if in the elective setting.

Endoscopic balloon dilation can be considered as part of the therapeutic options for treatment of Crohn's obstructions secondary to strictures. Ajilouni et al. evaluated 83 strictures in 37 Crohn's patients. Thirty-one strictures were anastomotic with the remaining being primary in nature. Ninety percent of the strictures were successfully dilated with 77 % of patients requiring only a single dilation. Fifty percent of those who required a second dilation required no further intervention at 20 months. They found a high success rate (84 % per patient), low complication rate (3 %), low rate of recurrent symptomatic strictures (26 %), and low rate of subsequent surgery (13 %) [32]. Ferlitsch et al. evaluated balloon dilation for treatment of 46 Crohn's patients with strictures. Seven of the 46 were not successfully dilated (15 %) leaving 79 dilations in 39 patients to be evaluated. Ileocolonic anastomosis accounted for 59 % of the strictures with 41 % being primary Crohn's strictures. Two patients experienced perforation, requiring surgery for repair (5 %), and one patient experienced severe bleeding requiring transfusion, but ultimately resolved spontaneously. Thirty-one percent of patients were treated with a single dilation and did not require any further dilation or surgery. Sixty-two percent of patients required repeat intervention with a need for surgery in 33 % of the cases during the 21-month follow-up [33]. These studies do suggest that consideration of endoscopic dilation as a treatment option for Crohn's stricture is feasible, if there is a capable endoscopist to perform the procedure.

Perforation

Perforation is a rare indication for surgery for Crohn's disease occurring only 1–3 % of the time. When this does occur, it is usually associated with a complete obstruction or toxic colitis. Patients are often septic and require immediate surgical treatment. The location of the perforation will depend on the etiology of the perforation. If the perforation is associated with a complete obstruction secondary to a stricture of the small bowel, the site of perforation may be just proximal to the stricture. This is best treated with resection and primary anastomosis, with consideration of a proximal diversion. If however the etiology is a colonic stricture, the site of perforation may be in the cecum due to the thinness of the bowel wall in that location. This is best treated with total abdominal colectomy with end ileostomy. If the perforation is associated with toxic colitis, the perforation will be located at the site of necrosis of the bowel wall. This also should be treated with total abdominal colectomy with end ileostomy.

Bleeding

Massive hemorrhage is a rare event in Crohn's disease accounting for only 2–13 % of surgical indications for operations for Crohn's disease [27, 34–38]. The evaluation and treatment of this complication is similar to other etiologies of gastrointestinal bleed. At presentation, the patient should be resuscitated and stabilized. Next, an attempt to localize the source of the bleed is undertaken. This is typically done with endoscopic evaluation, bleeding scans, or the use of selective angiography. Identification of the source is particularly important in this group of patients so that excessive and unnecessary bowel resection is not performed. Localization with angiography is successful in 40–45 % of cases [35, 37].

Because of the rarity of this indication, there is limited literature on the rates and outcomes of massive hemorrhage in Crohn's patients. Most of the literature is from case reports of small cohorts of patients. Two of the larger studies do give us a glimpse at the seriousness of this complication. Robert et al. found that of the 1526 Crohn's patients treated at The Mount Sinai Hospital between 1960 and 1986, 21 patients presented with severe gastrointestinal hemorrhage. Six of these patients (28.5 %) were treated medically and had no further episodes of bleeding. Ten patients (48 %) were treated with surgical resection and did well. One patient treated initially with surgery rebled and required a second surgery. Thirty percent of those initially treated medically rebled. Of those, one required surgery and ultimately rebled and exsanguinated. Of those patients treated surgically, there was a 15 % incidence of rebleeding [35].

Cirocco et al. had similar findings. They evaluated their four patients in combination with 34 other cases found in the literature for a cohort of 38 patients who had severe hemorrhage with Crohn's disease. Five of the 38 patients exsanguinated (13 %). Excluding these patients, 91 % of patients required surgical intervention to control the bleeding. Ileocolectomy was the most frequent procedure performed in 53 % of the cases with a rebleeding rate after resection of 3.5 % [37].

Since localization of the source of bleeding is so important in these cases, there have been some recommendations regarding methods that can be employed to increase the chances of success. Leowardi et al. suggested leaving the angiocatheter in place and injecting isosulfan blue in the operating room to identify the bowel segment that needs to be resected [1]. Remzi et al. reported the use of provocative angiography with highly selective methylene blue injection to localize an occult small bleeding site. This may help to

identify the segment that needs to be resected when multiple diseased segments are present [39]. Finally, the addition of vasopressin to stop bleeding has been attempted; however, definitive cessation of bleeding has not been reliably accomplished. However, this drug may help to temporize, so that full resuscitation can occur prior to moving forward with definitive surgical treatment.

Abscesses

Abscesses are another common indication for surgery in the Crohn's patient. This accounts for 7–25 % of surgeries performed on Crohn's patients [27, 40–44]. The abscess forms as a result of a microperforation that originates from the transmural inflammation of the diseased bowel. The most common location in the abdomen for these abscesses to occur is the ileocecal region [31]. The size and location of the abscess will determine the best course of treatment. If an inflammatory "mass" is seen on CT or MRI, it first must be determined if the "mass" is an abscess versus a phlegmon. If there is an abscess, evaluation for possible percutaneous drainage should be considered. The majority of patients who develop a spontaneous abscess will ultimately require surgery to resect the diseased portion of bowel since 40 % of these abscesses will have an associated fistula [31]. If the abscess is too small, or not amenable to percutaneous drainage, then a trial of antibiotics could be attempted.

Garcia et al. evaluated 51 patients who presented with intra-abdominal abscesses secondary to Crohn's disease over a 10-year period. Of these patients, 10 were treated medically, 7 were treated with percutaneous drainage, and 34 patients underwent surgery to treat their abscess. Two patients died during the initial hospitalization, one in the percutaneous group and one in the surgical group, and were not included in the analysis. Recurrence of the abscess in each group was 50 %, 67 %, and 12 %, respectively. Fifty percent of those treated non-operatively ultimately required surgery whereas only 12 % treated with surgery required reoperation during the follow-up period [45].

Percutaneous drainage plays a critical role in the treatment algorithm. It is advantageous because it allows for clinical improvement of the patient as well as the possibility of converting an emergent surgery to an elective surgery. Ideally the abscess is drained with resolution of the infection prior to surgical intervention to remove the diseased segment of bowel. In addition, if the abscess is successfully controlled with percutaneous drainage, there is a significant decrease in the risk of septic complications following surgery. Over 90 % of percutaneous drainage procedures are technically successful and over 50 % of patients avoid surgery in the short term [31, 46]. Postoperative abscesses are also seen. These abscesses are more likely to be successfully treated with percutaneous drainage alone than spontaneous abscesses [46]. Multiple abscesses are more likely to require surgical intervention. If the patient either fails drainage or fails to improve, surgery intervention will be needed.

Fistula

It is not surprising that fistulas are associated with Crohn's disease being that it is a transmural inflammatory process. Interestingly, Steinberg found a 17 % incidence of fistula in his series. There is a decreasing trend when comparing his findings with other series that have been published in the past [41, 42, 47, 48]. This trend is potentially the result of heightened awareness regarding the disease as well as the advancement in the medical treatment of the disease. Fistulas can be internal or external. The internal fistulas may be enteroenteric but can also be from bowel to any surrounding structure or organ such as the bladder, vagina, or retroperitoneum. Enterocutaneous fistulas are considered external fistulas. Often there is a stenotic area in the bowel wall distal to where the fistula originates which increases the intraluminal pressure. This circumstance predisposes to the formation of these fistulas [1]. Only fistulas that are symptomatic require treatment. For example, a fistula that extends from terminal ileum to a closely adjacent loop of small bowel would not necessarily require treatment. However, a fistula that bypasses a long segment of bowel such as a gastrocolic fistula would more likely cause complications and require such intervention. Fistulas account for 15–24 % of surgeries performed for Crohn's disease [14, 27].

Enteroenteric fistulas are the most common type of abdominal fistula found in Crohn's disease with majority originating from the terminal ileum [1, 31]. The fistulas originate from the disease portion of bowel; however, these can penetrate into normal surrounding tissue. Ileosigmoid is the most common of this type of fistula [1, 27]. These are typically treated with excision of the diseased bowel, excision or division of the fistula tract, and repair of the non-inflamed bowel wall. Patients can also present with a psoas abscess which is the result of a blind ending fistula from the ileum to the retroperitoneum. These require excision of the inflamed bowel to treat and prevent recurrence [1].

Enterocutaneous fistulas can occur either spontaneously or as a result of prior surgery. These fistulas can be quite detrimental to the patient causing dehydration, metabolic abnormalities, and skin damage as well as interfering with daily activities secondary to uncontrolled output. The etiology of these fistulas determines the best treatment as well as the likelihood of success. Seventy-five to eighty-five percent of enterocutaneous fistulas occur in the post-op period and are secondary to either anastomotic leaks or inadvertent injuries to the bowel. Because this bowel is healthy, the fistula is more likely to close with conservative measures. Fifteen to twenty five percent are spontaneous enterocutaneous fistula

which is due to abnormal bowels which have been affected by Crohn's disease, radiation, or cancer. These types of fistulas are unlikely to heal without surgical intervention [31, 49, 50].

Poritz et al. did a retrospective review of 51 patients with Crohn's disease who underwent surgery for fistula between 1983 and 2000. They found that 64 % had enterocutaneous fistula, 21 % had colocutaneous fistula, and 14 % were associated with a prior anastomosis. The onset of the fistula was postoperative in 23 %, post-abscess drainage in 27 %, and recurrent disease in 50 %. Seventy two percent of the patients were treated conservatively first, in an attempt to control sepsis and inflammation. Eight of the 51 patients (16 %) had a recurrence of the fistula with a mean time to recurrence of 27.0 ±9.0 months with majority being farther out from surgery suggesting recurrence of disease [51].

Cancer and Dysplasia

Patients with Crohn's disease have an increased risk of developing cancer in their lifetime. A recent meta-analysis by Laukoetter et al. evaluated 20 clinical studies for a total of 40,547 patients with Crohn's disease-associated cancer (CDAC). They found the overall incidence of CDAC in any Crohn's patient was 0.8/1000 person years duration (pyd) (95 %CI, 0.6–1.0/1000 pyd). This means that during a one-year observation period, 0.8 Crohn's disease patients out of 1000 developed a Crohn's disease-associated cancer. Crohn's disease-associated colorectal cancer had a pooled incidence of 0.5/1000 pyd (95%CI, 0.3–0.6/1000). The prevalence was 0.24 % (95 %CI, 0.19–0.28). The pooled incidence of CD-associated small bowel cancer was 0.3/1000 pyd (95 %CI. 0.1–0.5). The prevalence was 0.16 % (95 %CI, 0.12–0.21). They found that the incidence of a cancer arising from a CD-associated fistula was 0.2/1000 pyd (95 %CI, 0–0.4/1000) [52]. In summary, a patient with CD has a two- to threefold increased risk of colorectal cancer compared to the general population [52, 53]. With regard to small bowel cancer, there is an 18.75-fold increase [52]. Von Roon et al. in their meta-analysis also found an increased risk of development of small bowel and colon cancer in patients with Crohn's disease; however, interestingly they did not see an increased risk of rectal cancer [54].

A number of studies have found a male predominance in the development of cancer in Crohn's disease [55, 56]. Studies have shown that the average age at diagnosis of CDAC was 49–56 years which is about 10–15 years younger than the average age for sporadic bowel cancers [24, 55, 57]. The mean duration of disease from the onset of Crohn's disease to diagnosis of cancer is 20 years [55]. Ribeiro et al. evaluated 30 patients with 33 adenocarcinomas of the large bowel. Fifty percent of the patients had ileocolitis, 27 % had colitis, and 23 % had ileitis only. Five patients had cancer in excluded bowel. They found that 73 % of the cancers were distal to the splenic flexure. Interestingly, 58 % of the cancer occurred in areas of active disease, whereas 42 % occurred in areas that were distant from active disease. Thirteen percent were associated with a fistula and synchronous cancers were found in 10–20 % of patients [55, 57].

Survival seems to be worse for patients with Crohn's disease. Overall five-year survival was 41.3–44 % [24, 55]. A subgroup analysis looked at the difference in survival for those cancers that were found in bypassed bowel versus those found in bowel that was in continuity. Five-year survival of those patients with cancer in bowel that was in continuity was 56 % compared to 0 % for those cancers in bypassed bowel [55]. Literature supports that there is a higher risk of developing cancer in bypassed bowel and that it comes with a poor prognosis. It is for this reason that bypass surgery should be avoided and that defunctionalized rectal stumps should be removed if there is no plan for the patient to be placed back in continuity. Lastly, there is an increased risk of developing cancer in the area of a stricture. Levasz et al. found the mean overall CRC incidence rate to be 7.73 per 10,000 patient years; however, this incidence rate increased to 56.9 per 10,000 patient years when the patients presented with stenosing disease in the colon [58]. This suggests that colonic strictures need to be closely monitored if not surgically resected.

High-grade dysplasia (HGD) found in patients with ulcerative colitis is an indication for colectomy. The same is true of Crohn's disease. Kiran et al. evaluated 50 patients who had undergone colectomy for CD-associated dysplasia. The predictive value of HGD for a final HGD or cancer diagnosis was 73 %. The predictive value of LGD on biopsy for HGD in the colectomy specimen was 36 %. Forty-four percent of patients who underwent a total abdominal proctocolectomy or a subtotal colectomy had multifocal dysplasia and 40 % of cancer patients had evidence of dysplasia remote from the cancer site [59]. Studies have shown the association of HGD with colon cancers in virtually all cases [57, 60]. In addition to this, examination of 100 bowel specimens resected for noncancer-associated Crohn's disease revealed only a 2 % incidence of mild dysplasia [61]. This supports the recommendation that the presence of HGD should prompt the discussion of colectomy.

Toxic Colitis

Severe colitis is a serious and potentially life-threatening condition if not treated appropriately and in a timely manner. Patients with severe colitis typically present with a flare of their disease with signs of toxicity. Truelove and Witts characterized toxic colitis by the presence of severe diarrhea (greater than 6 bloody bms per day) in addition to fever (>37.5 °C), tachycardia (>90 bpm), anemia (<10.5 g/dl), and an elevated erythrocyte sedimentation rate (>30 mm/h) [62]. The addition of dilation of the colon (toxic megacolon) to

Table 49-1. Diagnostic criteria for toxic megacolon

Radiographic evidence of colonic distension
At least three of the following:
Fever >38 °C (101.5 °F)
Heart Rate >120 bpm
Neutrophilic leukocytosis $>10.5 \times 10^9$/L
Anemia
In addition to the above, at least one of the following:
Dehydration
Altered consciousness
Electrolyte disturbances
Hypotension

this compilation of symptoms increases further the risk of complications and could lead to a potentially fatal outcome. The most widely used diagnostic criteria for toxic megacolon was proposed by Jalan et al. (Table 49-1) [63]. A multidisciplinary approach for the treatment of these patients is critical to effectively manage these patients. Accurate assessment of the disease severity and close observation of changes in the patient's clinical status are necessary to appropriately treat this disease. If a patient presents with evidence of severe hemorrhage, intestinal perforation, or septic shock with systemic instability, then emergent surgery should be performed as soon as the patient is adequately resuscitated [64]. If these conditions are not present, aggressive medical treatment is appropriate with close observation.

Initial medical management of these patients includes efforts to resuscitate the patient, including intravenous hydration and correction of electrolyte abnormalities, in particular potassium and magnesium. These need to be kept in the normal range as hypokalemia and hypomagnesemia may predispose to colonic distention. Blood transfusions may be necessary. Though there is no proven advantage to placing patients on bowel rest and total parenteral nutrition, if there is concern for the need for urgent operative intervention, patients should be made nil per os and nutritional assessment should be made [65, 66]. Total parenteral nutrition may be necessary to optimize the nutritional status of the patient. It is important to rule out other possible causes of diarrhea including *Clostridium difficile* as well as cytomegalovirus. This can be assessed by direct evaluation of the stool for microbes, evaluation of stool for *C. difficile* toxin, or careful, limited endoscopic examination. Full colonoscopy is contraindicated as this could potentially lead to perforation. Daily abdominal films should be obtained if there is presence of abdominal distension so colonic dilation can be assessed and monitored. Anticholinergics, antidiarrheals, and narcotics should be avoided in these cases as they can lead to worsening colonic atony and dilation. In the absence of proven infection, control trials have not shown a benefit of the addition of antibiotics in the treatment of severe colitis [67, 68]. However, if an infection is suspected, it may be appropriate to treat with antibiotics. Patients with inflammatory bowel disease have a higher risk for thromboembolic disease, so special attention needs to be made for prophylaxis of this potentially fatal complication.

The mainstay of medical therapy is the administration of corticosteroids in a daily equivalent dose of hydrocortisone 300 mg (in divided doses) or methylprednisolone 60 mg (in divided doses) [69]. There is no benefit to treat with higher daily dosages, which exposes patients to a higher potential rate of side effects with no proven benefit. Patients who do not respond to steroids have limited options, which include either rescue infliximab or colectomy. Several studies have shown infliximab as an effective rescue therapy for acute severe colitis in ulcerative colitis [70–72]. Jarnerot et al. randomized 45 patients with severe colitis to receive a single infusion of infliximab (5 mg/kg) or placebo beginning four days after steroid initiation. Twenty-nine percent of the infliximab group required a colectomy within 3 months of randomization versus 67 % of those who received placebo [71].

Those patients who do not respond to medical therapy or have a decline in their clinical status within 24–72 h of initiation of treatment require emergent surgery. Delay of surgery can lead to dire consequences and increased postoperative complications [73]. Mortality rates dramatically increase in those who have suffered a perforation, increasing from 2 to 8 % up to 27 to 40 % [74, 75]. The procedure of choice for these patients is a total abdominal colectomy with end ileostomy. Emergent proctectomy is avoided if possible for a number of reasons. Emergent proctectomy in an acutely ill patient increases the morbidity and mortality of the procedure. Secondly, some patients will be candidates for a restorative procedure if the rectal and perianal region is not involved in Crohn's disease. Resection at the initial operation would obviate any possibility of reconstruction. Lastly, if there is a question as to the diagnosis, Crohn's versus ulcerative colitis, it is best to preserve the rectum for possible later restorative surgery should the patient choose that and pathology is favorable. Emergent proctectomy is rarely indicated; however, it is performed for rectal hemorrhage or rectal perforation. For those who do have a total abdominal colectomy with end ileostomy, majority will ultimately undergo a proctectomy. Harling et al. did a retrospective study looking at the outcome of the rectum after this procedure. They found that of the 84 patients they evaluated, 25 (30 %) patients ultimately underwent an ileorectal anastomosis. Of these, 16 patients (19 %) were functional at the end of the study period [76]. This suggests that a small select group of patients without rectal or perianal involvement may be candidates for a restorative procedure.

Surgical Considerations

Patients presenting with Crohn's disease, with either failure of medical management or complications from the disease, are a very heterogeneous group of patients. Their presentation may range from a simple terminal ileal stricture causing

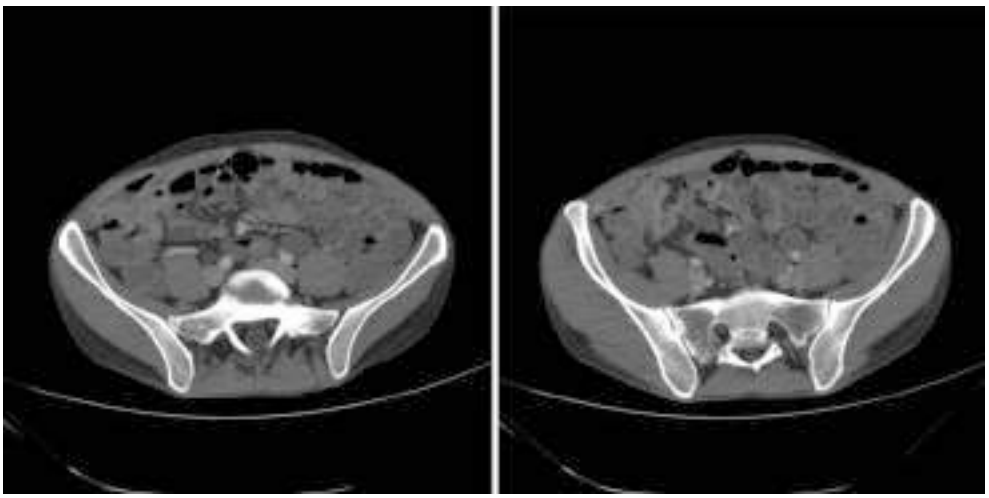

FIGURE 49-1. CT scan in a patient with Crohn's disease demonstrating fluid-filled bowel loops, thickened terminal ileum, and a subcutaneous right lower quadrant abscess.

minor obstructive symptoms, to a patient with a large inflammatory mass encompassing a significant portion of the bowel, to a patient who is hypotensive and septic from toxic megacolon. Each of these requires a different level of urgency as well as a different level of operative planning; however, all of them require careful consideration to details about the individual case as well as the optimal timing of the surgery. The basic goals of surgery in Crohn's disease are the same for all cases. Remembering basic axioms about the disease help to make sound surgical decisions when caring for these patients. Surgery for Crohn's disease is not curative, so preserving the small bowel when possible is paramount. Recurrence occurs in the majority of patients so should be considered in operative planning. Careful preoperative evaluation includes attention to the patient's overall clinical status; specific attention needs to be made of their nutritional status, current medications, prior surgeries, current disease status, as well as patient wishes.

Preoperative Evaluation

Information obtained from the history and physical, past medical, and surgical records, endoscopy, as well as imaging studies will be critical to operative planning and timing. Nutritional assessment as well as medication usage deserves special attention as this will affect healing and may increase postoperative complications. Preoperative imaging will give information regarding severity, involvement of surrounding structures, current infections, resectability, and possible risk of short bowel syndrome which will ultimately dictate what preoperative measures need to be taken as well as determine the best timing for intervention (Figure 49-1).

The amount of inflammation noted on the CT scan will help to determine the amount of bowel involved and potentially the amount that may need to be resected. When a simple fibrotic stricture is seen that is symptomatic, surgery can be scheduled without delay. On the other hand, if there is a large phlegmon with significant bowel involvement, rushing in to perform surgery may put significant amount of normal bowel at risk of injury. These patients may benefit from a period of bowel rest, steroid administration, as well as total parenteral nutrition. This will allow some of the inflammation to settle and will decrease the morbidity of the procedure. The diseased bowel will still need to be addressed; however, the benefit of waiting is to minimize the amount of normal bowel that would be at risk.

History and Physical

Initial evaluation begins with a complete history and physical. Accurate and detailed information regarding the patient's current set of symptoms is very important and helpful in deciding if surgery is indicated. Asymptomatic patients should not undergo surgery. Understanding how and when their disease flares is also helpful in understanding their disease. Questions should be queried to the patient regarding possible current or past perirectal involvement. Included in this detailed history of present illness should be specific information regarding their diet, including any dietary restrictions they have put on themselves because of the disease, as well as any change in weight. Patients will often state they are "doing well" and only on specific questioning will it become evident that they are severely limited in their dietary consumption. A complete list of current and past

medications, comorbid conditions, smoking status, as well as a complete list of any prior surgeries should be obtained. Medical and surgical records including prior endoscopies and pathologic evaluations should also be obtained. Gaining as much information about prior surgeries as possible not only sheds light on the current anatomy but also how much bowel has been previously resected. Each of these pieces of information will play a role in what operation is indicated and when the timing is appropriate.

A complete physical exam should then be performed. The vital signs will indicate the acuity of the patient and need for potential resuscitation. During the abdominal examination, special attention is paid to areas of tenderness, prior scars, evidence of draining fistula, as well as palpable masses. The rectal examination may reveal perianal Crohn's disease with visible fistula, fissures, skin tags, or abscesses. Digital rectal exam may reveal anal stenosis, scarring, or bleeding. Knowledge of rectal or perianal involvement is very important when planning operative management.

Imaging/Endoscopy

Further testing is necessary to determine the extent and severity of the disease. Endoscopic evaluation of the entire colon and terminal ileum is necessary as well as upper gastroduodenoscopy if there is concern for upper tract involvement. Biopsies of the terminal ileum should be obtained. Additional biopsies should be taken to confirm areas of inflammation as well as to confirm areas that appear to be normal. Mucosal abnormalities should also be sampled to assess for dysplasia.

CT enterography (CTE) or MRI enterography (MRE) can both be useful in assessing the extent and severity of disease. Because both of these tests cannot only give information regarding the bowel wall but also about extraenteric structures, they have essentially replaced the use of barium studies as the preferred diagnostic tool. The technique to get optimal visualization consists of having the patient drink a large volume of neutral or low-density oral contrast (enterography) which will give adequate luminal distention. In addition, an intravenous contrast agent is given which will optimize bowel wall enhancement [77]. There are specific features on CTE that can help determine whether the disease seen is active inflammatory disease versus chronic fibrostenotic disease. The former is more likely to respond to medical therapy, whereas the latter is more likely to require surgical intervention.

Enteric findings such as mural hyperenhancement, bowel wall thickening, mural stratification, and extraenteric findings such as engorged vasa recta ("comb sign") and increased attenuation of the mesenteric fat are features of active inflammatory small bowel Crohn's disease [77]. Of these, mural hyperenhancement and bowel wall thickening is the most sensitive for active disease [78]. Increased attenuation of the mesenteric fat is due to edema and engorgement of the vasa recta. The "comb sign" refers to engorged vasa recta that penetrate the bowel wall perpendicular to the bowel lumen, giving the appearance of a comb. Strictures without hyperenhancement or other signs of active inflammation as well as mucosal fat deposition, fibrofatty proliferation, and sacculations are all CTE signs of chronic fibrostenosing disease. Sacculations occur due to preferential involvement of the mesenteric side of the bowel by the inflammatory process. This causes asymmetric fibrosis on the mesenteric side of the bowel. Increased intraluminal pressure then causes sacculations on the antimesenteric bowel wall. Areas of tethering of the bowel with enhancing tracts between bowel loops or other structures suggest evidence of a fistula [77]. Abscesses are readily identified by CTE.

CT enterography and MRI enterography both have their own pros and cons and as such have different clinical scenarios in which each is the preferred test. MRI enterography also reveals information regarding the presence of active inflammatory disease versus fibrostenosing disease; however, it does this without the exposure of ionizing radiation [79]. This is particularly important since this disease affects young patients who will potentially need many of these exams over the course of their lifetime. MRE is better at demonstrating endoluminal abnormalities and ulcerations. CTE, however, is better in the emergent setting in that it takes less time, does not require the patient to be able to hold their breath to the same degree as MRE, and is better at diagnosing perforations [80]. The sensitivity and specificity of MRE for detecting small bowel Crohn's disease is 74 % and 80 %, respectively, compared to 83 % and 70 % achieved with CTE. These differences do not reach statistical significance. Abscesses are accurately detected by both modalities. The sensitivities for detecting stenosis and fistula are relatively low in both modalities. Positive predictive values for both these modalities are good; however, negative predictive value in both is low [81, 82]. Surgeons need to be mindful of this and search for additional pathology which may not have been detected on preoperative imaging at the time of exploration. Patients also need to be counseled that additional findings discovered at the time of surgery may alter the operative plan.

Nutritional Assessment and Role of TPN in Crohn's Treatment

Poor nutrition has been linked to delayed wound healing, decline in physiologic and psychiatric function, altered immune function, and increased postoperative complications. Various markers of nutrition have been evaluated including weight loss, protein depletion, serum albumin, and pre-albumin to assess their predictive value. Each of these has shown a link between malnutrition and poor surgical outcomes [83–85]. Dr. Studley, in 1936, made a pivotal

observation that linked severe preoperative weight loss and postoperative mortality. He found that a loss of >20 % normal body weight preoperatively in patients results in a 33.3 % mortality rate compared to a 3.5 % mortality rate in those who had <20 % body weight loss [86]. Seltzer et al. reviewed 4382 elective surgical patients and compared those who had a >10 lb unintentional weight loss versus those who had a <10 lb unintentional weight loss. He found the mortality to be 5.8 % versus 0.3 %, respectively [87]. Others have found that weight loss in conjunction with physiologic impairment is an even better indicator of postoperative complications [83].

Hypoalbuminemia has also been shown to be a good predictor of postoperative morbidity and mortality. Gibbs et al. performed a prospective observational study including 54,215 patients. They found that a drop in serum albumin from a concentration >4.6 g/dl to less than 2.1 g/dl was associated with an exponential increase in mortality from <1 to 29 % as well as in morbidity rates from 10 to 65 % [88]. Similarly, Lindor et al. found that patients had a complication rate of 29 % with an albumin level <3.1 g/dl compared to only 6 % when the serum albumin was in the normal range [89].

It is estimated that 80 % of Crohn's patients will have some degree of malnutrition and that weight loss has been reported in 65–76 % of patients with Crohn's disease depending on the severity of disease [90]. Total parenteral nutrition is a treatment option to improve the patient's nutritional status when enteral feeds are not possible. Ideal administration includes a balance of carbohydrates, protein, fats, and minerals. Though TPN does replenish much-needed nutrients, there is insufficient data to clearly show its benefit as a sole primary treatment of the disease. Though some studies did show initial remission, the recurrence rate was very high [91–93]. Greenberg et al. specifically studied the utility of bowel rest as a means to control Crohn's disease. Fifty-one patients were randomized to TPN, partial parenteral nutrition (PPN) plus a liquid feed of a specific formula delivered via NG tube, or PPN with a regular diet. Remission occurred in 71 % of those on TPN, 58 % of those on PPN with the addition of the specific formula, and 60 % of those on PPN with regular diet. The probability of being in remission in 1 year was 42 %, 55 %, and 56 % respectively. This did not reach statistical significance and the authors concluded that bowel rest did not contribute to primary treatment of the disease [94].

These studies found that bowel rest and TPN is not an effective primary treatment of Crohn's disease. This is not to say TPN does not have its role in the treatment of Crohn's disease. Correction of malnutrition preoperatively to lessen the risk of postoperative complications has also been studied with promising results. Rombeau et al. found that patients who received preoperative total parenteral nutrition for at least 5 days had significantly fewer postoperative complications compared to those who did not [85]. Likewise, Jacobson et al. compared 15 CD patients treated with TPN for at least 18 days with matched controls. They found that there were no significant early postoperative complications in the TPN-treated group, whereas there was a 27.6 % complication rate seen in the control group [95]. It has also been shown that those patients treated with TPN preoperatively had less bowel resected when compared to those who did not get treated with TPN [96]. These results do have to be viewed cautiously as each of these studies has a small sample size. A larger study was performed by the Veterans Affairs Group who studied 395 malnourished patients who required laparotomy or noncardiac thoracotomy. They were randomly assigned to either receive TPN for 7–15 days before surgery as well as 3 days afterward or receive no perioperative TPN. The rates of major complications as well as mortality were similar between the two groups. Those treated with TPN did have a higher infectious complication rate compared to the non-TPN group (14.1 % vs. 6.4 %, respectively.) A subgroup was studied finding that severely malnourished patients who received TPN had fewer noninfectious complications compared to the controls (5 % vs. 43 %, respectively). This would suggest a more selective approach to the use of preoperative TPN [97].

TPN is used in Crohn's disease, not only to correct severe malnutrition prior to surgical intervention but also for the treatment of intestinal fistula, treatment of short bowel syndrome, and for nutritional support when enteric feeds are not possible. Treatment with TPN does not come without its own price. Complications can be divided into those related to access, gastrointestinal, metabolic, or infectious. Access-related complications include injuries sustained during insertion of catheters (i.e., vascular injuries, pneumothorax, etc.), thrombosis, and embolization. Liver complications are the most important gastrointestinal complication related to treatment with TPN. This includes cholestasis, cholangitis, liver dysfunction, as well as elevation of transaminases. Metabolic imbalances can occur with either excess or inadequate administration of water, glucose, electrolytes, amino acids, fats, and minerals. Close monitoring is necessary to avoid such complications. Lastly, there can be infectious complications with the most common being catheter-related infections [90].

In summary, patients should be evaluated for malnutrition. Assessment of body mass index, preoperative weight loss, as well as serum albumin, pre-albumin, and transferrin should be included [84, 85, 98]. Severe malnutrition is defined as a greater than 10 % loss of body weight as well as albumin <3.5 and pre-albumin <15 mg/dl. If severe malnutrition is confirmed, administration of preoperative total parenteral nutrition should be considered. If TPN administration is not feasible either due to confounding factors or necessity of urgent or emergent surgery, then consideration should be made to either proximal divert if an anastomosis is formed or the avoidance of an anastomosis with creation of an end stoma until the time that the nutritional status can be improved.

Medication Effects on Surgical Outcomes

When Crohn's was first described, the medical treatment options were limited and included primarily corticosteroids. Though steroids remain a key medication for the treatment of acute flares, numerous other medications have been introduced to control this disease. Immunomodulators came on the scene with the thiopurines being the most commonly used and have been shown to be effective in the treatment of Crohn's disease. These include 6-mercaptopurine as well as azathioprine. These are slower acting medications so are used primarily to maintain remission [99, 100]. Antitumor necrosis factor (anti-TNF) agents were introduced in 1997 and have been shown to be very effective in the treatment of Crohn's disease [101]. Currently, there are three anti-TNF agents available: adalimumab, certolizumab, and infliximab. These agents have been shown to not only induce and maintain remission but also promote mucosal healing. A major concern with each of these medications was what, if any, effect there may be on surgical outcomes.

It is generally agreed that corticosteroids negatively affect wound healing and therefore increase postoperative complications. There have been numerous studies that have shown a deleterious effect on wound healing as well as healing of bowel anastomoses [102–104]. Stuck et al. in a meta-analysis of 71 controlled clinical trials showed an increase in the rate of postoperative infection for those patients on steroids compared to controls, 12.7 % versus 8 %, respectively. The correlation was not seen in those whose steroid doses were <10 mg/day and the rate of infection increased as the dose of steroids increased [105]. Subramanian et al. reviewed seven observational studies which included 1532 patients and found that the risk of postoperative infections was 1.6 times higher in those patients taking corticosteroids compared to control groups [106]. Lastly, Aberra et al. also found a correlation with steroid use and increased postoperative infectious complications. They did not see an increase risk of complications with the addition of thiopurine medications [107]. There have been some studies whose data did not support these findings. Bruewer et al. evaluated 397 patients who had undergone surgery for Crohn's disease at their institution. They divided the cohorts based on steroid usage: no steroids, low dose, or high dose for at least one month prior to surgery. They did not find any association between those who were given steroids and those who were steroid free [108]. Mascarenhas et al. studied 791 patients who underwent either ileocolic resection or right hemicolectomy. Ninety three of these were patients with Crohn's disease. They found that the patients with Crohn's disease did not have an increased risk of postoperative complications compared to patients without Crohn's disease even with the use of steroids and biologics in the preoperative time period [109].

With the introduction of infliximab, yet another potential contributor to postoperative complications was added to the mix. As with the other medications, numerous studies have been undertaken looking at the potential association of anti-TNF medications and postoperative complications. The majority of the studies did not find an association between the use of anti-TNF agents and increase in postoperative complications [110–112]. Kunitake et al. examined a large IBD patient cohort (413 patients) comparing the postoperative complications in those patient who had received preoperative infliximab and those who had not. They found that infliximab was not associated with an increased rate of postoperative complications [110]. Colombel et al. evaluated 270 patients who had been operated on for Crohn's disease. Of these patients, 107 had received steroids, 105 had received immunosuppressive agents (AZA, 6-MP, methotrexate), and 52 had received infliximab. Nineteen percent of patients had a septic complication. Though they found a trend linking steroid use and postoperative infectious complications, it was not statistically significant. They did not find an association between either immunosuppressive medications or infliximab with postoperative complications [111]. There have been a few studies that have either shown a trend or a statistically significant association between the use of infliximab and increased postoperative complications [113, 114]. Appau et al. studied sixty of 389 Crohn's patients who had undergone an ileocolic resection and had received infliximab. Comparison to a matched group of patients who did not receive infliximab showed that the infliximab group had a higher rate of readmission, sepsis, and intra-abdominal abscess.

The potential effect of combination therapy has also been evaluated. Brafford et al. evaluated not only single medication effect but also combination therapy. Patients who received steroids within 6 weeks of surgery, thiopurines, or anti-TNF agents within 90 days of surgery or any combination had neither higher rates of overall morbidly nor septic complications when compared with those who did not receive these medications preoperatively. The finding that steroids did not show an association may be due to the relatively low doses of steroids the patients in this series received [112]. Ali et al. performed a meta-analysis in an attempt to gain a better perspective on this issue. Twenty-one eligible studies were included (20 retrospective and 1 prospective) with 6899 patients. Interestingly, when evaluated individually, most studies failed to find an association between preoperative immunosuppressive medications and postoperative complications. Only 2/14 (14 %), 4/13 (31 %), and 1/8 (13 %) found an association between postoperative complications and preoperative anti-TNF agents, steroids, and thiopurines, respectively. In the meta-analysis, however, both antitumor necrosis factor agents and corticosteroids were found to have a higher risk of postoperative infectious complications. Anti-TNF agents were also significantly associated with wound infections and septic shock. There was no association with use of thiopurines and postoperative complications [115].

These studies do need to be interpreted with some caution. The majority of the studies are underpowered as well as being case cohorts and retrospective in design. In addition to this, there are significant confounding factors associated with this particular area of study as well as numerous intrinsic limitations. From a practical standpoint, most of the time, it is not feasible to stop these medications prior to surgery without incurring the risk associated with a potential acute flare and worsening of the clinical status of the patient. In light of this, the best approach is to wean steroids when possible keeping in mind that trying to wean them too aggressively or stopping them may cause a relapse which may increase the operative morbidity and mortality. If steroids cannot be weaned, one should consider either avoidance of an anastomosis or protect a created anastomosis with a diverting loop ileostomy. There has not been shown a clear association between postoperative complications and the use of thiopurines so these can continue up to the time of surgery. With regard to infliximab, an attempt should be made to schedule surgery just prior to the next scheduled dose (i.e., at the end of the 8-week dosing schedule) which may limit complications.

Operative Considerations: Overview

The primary goal of surgery for patients with Crohn's disease is to alleviate symptoms while preserving as much small bowel as possible. Going into surgery with as much information as possible is helpful. This includes as much information about the patient's symptoms as possible as well as the extent of disease and possible other organs that may be affected. Depending on which other organs may be involved, it may be helpful to have other specialists available. If there is significant inflammation around the ureters, ureteral stents may be helpful. Lastly, it is important to understand the wishes of the patients, especially regarding the creation of stomas, since intraoperative decision-making is frequent and changes in the operative plan may be necessary if additional pathology is discovered.

A few general principles apply when operating for Crohn's disease. First, complete exploration of the abdomen should be performed, assessing the extent of disease as well as involvement of surrounding bowel or other structures. It is critical to understand the extent of disease prior to resecting any bowel. Diseased bowel is often visible; however, the assessment can be further confirmed with palpation of the bowel and the adjacent mesentery. Involved bowel will feel thickened as will the adjacent mesentery. Normal bowel will be supple with a clearly palpable mesenteric edge. Significant inflammation in the area of the diseased bowel can affect the surrounding normal bowel loops. Every attempt should be made to preserve this uninvolved bowel. Care should be taken when handling the bowel and its mesentery because, depending on the amount of inflammation, the mesentery can be quite friable and even gentle retraction can lead to disruption of the mesentery and troublesome bleeding. Fistulas are common and arise from disease bowel. These fistulas cannot only affect other diseased bowel loops but can also extend to normal bowel loops or other nearby structures, like the bladder or vagina. Typically the diseased bowel loop will need resection while the "innocent bystander" can be preserved with its fistula site being treated with wedge resection and primary closure. Determination of extent of resection is based on macroscopic disease alone so a small margin is all that is needed. There is no need to assess microscopic margins. Fundamental principles apply when creating an anastomosis in a Crohn's patient. The bowel should be fully mobilized to assure there is no tension on the anastomosis and the bowel should be assessed for adequate blood supply.

There have been a number of studies that have compared hand-sewn end-to-end anastomosis and stapled side-to-side anastomosis in Crohn's disease in an attempt to determine if one was superior. A Cochrane Review by Choy et al. searched for randomized controlled trials comparing the stapled and hand-sewn anastomosis in ileocolic resections. Seven trials with 1125 patients were included. They found stapled anastomosis was associated with significantly fewer anastomotic leaks compared to hand-sewn (S=2.5 %, HS=6 %, p=0.03) [116]. Numerous studies looking specifically at anastomoses created in patients with Crohn's disease have shown that the stapled side-to-side anastomosis has fewer anastomotic leaks, shorter OR time, as well as lower rate of reoperation for recurrence of disease [117–119].

The notion that the type of anastomosis created could influence the rate of recurrent disease prompted more studies. Ikeuchi et al. looked specifically at the long-term effects of hand-sewn versus stapled anastomosis in a small prospective randomized trial. They found no statistically significant difference in the recurrence of Crohn's disease at the anastomosis at 5 years; however, the reoperative rate was 8 % in the stapled group versus 25 % in the hand-sewn group. This rate continues to increase to 18 % and 49 %, respectively, at the 7-year follow-up [120]. A meta-analysis comparing conventional sutured end-to-end anastomosis and stapled side-to-side anastomosis in Crohn's disease was performed. This analysis did include both randomized controlled trials and retrospective trials. They found, as others had previously found, a significant difference in both the anastomotic leak rate and the overall postoperative complication rate favoring the stapled side-to-side anastomosis. They did not find a difference between the groups with regard to recurrence or need for reoperation [121]. McLeod et al. performed a multicenter, randomized controlled trial comparing stapled side-to-side (ST) and hand-sewn end-to-end (HS) ileocolic anastomoses in Crohn's disease patients. One hundred seventy patients were included in the analysis. They found that mean operative time as well as time to create the anastomosis was significantly shorter in the stapled group.

They did not find a difference with regard to overall complication rates (24 % HS, 20 % ST, $p=0.79$), leak rates (7 % HS, 7 % ST, $p=0.86$), or reoperative rates (7 %HS, 7%ST, $p=0.86$). Endoscopic recurrence was the primary end point. After a mean follow-up of 11.9 months, the endoscopic recurrence rate was 42.5 % in the hand-sewn group and 37.9 % in the stapled group ($p=0.055$). The symptomatic recurrence rate was 21.9 % in the hand-sewn group compared to 22.7 % in the stapled group ($p=0.92$). They concluded therefore that the type of anastomosis did not affect recurrence of the disease [122].

Laparoscopic Surgery and Crohn's Disease

Laparoscopic surgery has been shown to have proven benefit over open surgery with respect to return of bowel function, hospital stay, postoperative pain, as well as cosmesis. Surgeons have questioned the feasibility of performing laparoscpic surgery on patients with Crohn's disease due to the inherent challenges of the disease. The presence of extensive inflammatory adhesions, multiple areas of disease bowel, large inflammatory masses, and the presence of fistulas and abscesses can certainly increase the difficulty of the procedure even when it is performed with an open technique. Multiple studies have shown that using the laparoscopic technique in Crohn's patients is both feasible and safe [123–127]. Additional studies compared laparoscopic versus open ileocolic resection for Crohn's disease. They found that the laparoscopic group demonstrated a faster return of bowel function and shorter hospital stay with no increase in complication rates [127–130]. These findings were also seen when laparoscopic colectomy was studied [131].

The studies mentioned above are viewed with some hesitancy since they were nonrandomized studies and many had few subjects. A bias is inherent in these studies where there is no randomization, as it may be that the surgeon is selecting out noncomplex Crohn's cases to be done laparoscopically. Rosman et al. performed a meta-analysis including 16 studies, one of which was a randomized controlled trial and the remainder were nonrandomized studies. They found that the laparoscopic surgery required more operative time but resulted in a shorter duration of ileus and a decreased length of stay. Laparoscopic surgery was also associated with a decreased rate of postoperative bowel obstruction [132]. The other meta-analysis performed by Tan et al. found similar results [133].

There are two randomized control trials that compare laparoscopic versus open ileocolic resection for Crohn's disease. Milsom et al. studied 60 patients: 31 were assigned to the laparoscopic group while the other 29 were assigned to the open surgery group. They did not find a difference between the two groups with regard to postoperative pain, return of bowel function, or rate of major complications. They did find fewer minor complications and median length of stay was 1 day shorter in the laparoscopic group [134]. Maartense et al. performed the second randomized control study. They found median operating times were longer in the laparoscopic group (115 min vs. 90 min, $p<0.003$). In addition to this, they also found a shorter hospital stay (5 vs. 7 day, $p=0.008$) and a lower complication rate in the laparoscopic group (10 % vs. 33 %, $p=0.028$) [135].

The benefits of laparoscopic surgery would be expected with simple noncomplex Crohn's cases. Goyer et al. did a prospective study assessing the feasibility of laparoscopic ileocolonic resection for complex Crohn's disease (i.e., recurrent disease, presence of fistulas or abscesses). Fifty-four patients with complex Crohn's disease (Group 1) were compared to 70 patients with non-complex Crohn's disease (Group 2). As would be expected, the operative time was higher in Group 1 (214 min vs. 191 min, $p<0.05$) as was the conversion rate (37 % vs. 14 %, $p<0.01$) The main reason for conversion was technical difficulty secondary to the presence of a complex fistula or adhesions. This compares to conversion rates in the literature which ranges from 6 to 40 %. In addition, two-stage procedure with a diverting loop ileostomy was higher in group 1 (39 % vs. 9 %, $p<0.001$). Overall morbidity (17 % vs. 17 %) and hospital stay were comparable between the two groups [124–127, 130, 131, 135–137].

There still remain some contraindications for laparoscopic surgery in the Crohn's patient. These would include patients with hypotension and sepsis, those unable to tolerate pneumoperitoneum, those with a large inflammatory mass that would require a larger incision for extraction, and those with extensive adhesion. Complex disease such as the presence of an abscess or fistula has become a relative contraindication. It is often difficult to determine preoperatively who will be a laparoscopic candidate and who will not. The key to success in these complex cases is having an experienced laparoscopist who is knowledgeable in the treatment of Crohn's disease. They must be able to recognize when it is in the best interest of the patient to convert to an open technique and accept a higher rate of conversion (Video 49.1).

Operative Considerations for Specific Locations

Upper Small Bowel Disease

Upper small bowel disease includes any involvement of the small bowel proximal to the terminal ileum. Disease in this area, when present, can be quite extensive, as this phenotype has a poorer prognosis. When the upper small bowel is involved there may be multiple areas of diseased bowel between areas of normal bowel. The number of diseased segments, as well as their proximity to each other, will determine what the best course of action is to take to treat the problem. Surgical options include resection with primary

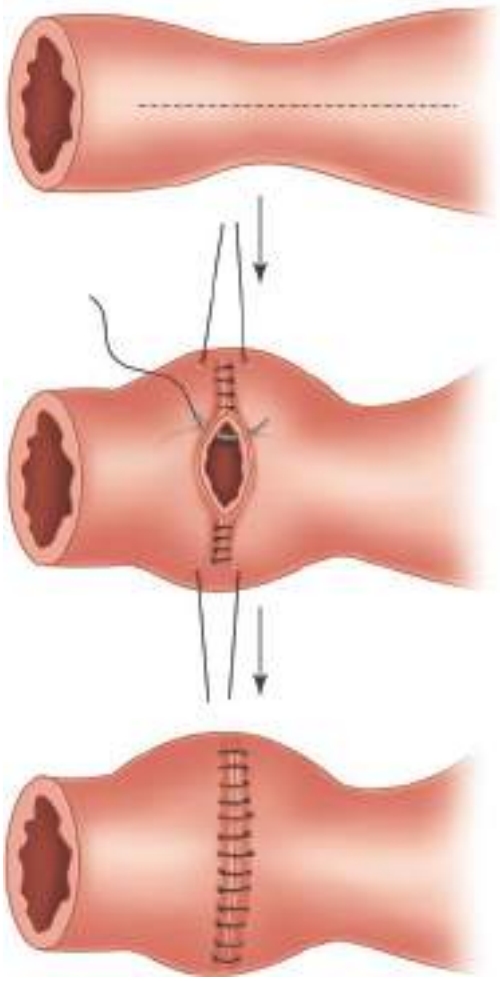

FIGURE 49-2. Heineke–Mikulicz stricturoplasty.

anastomosis, stricturoplasty, or in some instances, when there is significant distal disease present, proximal diversion. Internal bypass is rarely necessary and should be avoided if possible due to risk of bacterial overgrowth as well as higher risk of malignancy [138–140].

Resection with anastomosis is an acceptable option if the area to be resected is limited and the patient has not had significant small bowel resections in the past. Other segments of bowel that would require resection are those that have a perforation, an associated fistula or abscess, or significant inflammation. Resection may also be considered if there are multiple strictures in a short segment of bowel. Resection is carried out to gross negative margins. Fazio et al. performed a randomized control trial to evaluate the effect of surgical margins on the recurrence rates after resection for Crohn's disease. They found that recurrence rates do not increase even with microscopic evidence of Crohn's disease at the margin [141].

Since Crohn's disease is not curable and the majority of patients do undergo surgery for their disease, it is important that as much small bowel be preserved as possible. Stricturoplasty is a method by which an obstruction from a stricture in the bowel can be relieved without resecting that portion of bowel. There are multiple techniques by which this can be accomplished.

The Heineke–Mikulicz was first described by Hermann Heineke and Jan Mikulica-Radecki in 1886 for the treatment of a pyloric channel stricture. This is the most common stricturoplasty performed and is ideal for short strictures which are less than 10 cm in length. It is easy to perform with a low complication rate. This is performed by making a single longitudinal incision over the stricture with extension of the incision about 1–2 cm beyond the stricture on either side. The enterotomy is then closed in a vertical manner, thus relieving the obstruction (Figure 49-2). A variation of this type of stricturoplasty is the Moskel–Walske–Neumayer stricturoplasty and is ideal for those strictures that have a dilated proximal bowel with a stricture that is <10 cm. A "Y"-shaped incision is made over the stricture with the upper portion of the "Y" over the dilated portion of the bowel. This is then closed by advancing the dilated portion of the bowel to the base of the "Y," thus creating a "V" suture line. The advantage of this technique is that it addresses the bowel size discrepancy and is relatively easy to perform (Figure 49-3) [142, 143]

For those strictures that are slightly longer (>10 cm but <25 cm), a Jaboulay or Finney procedure is indicated. Mathieu Jaboulay, in 1892, proposed the technique of bypassing an obstructing stricture in the pylorus by performing a gastroduodenostomy. Finney later presented a modification of this technique also for the treatment of a pyloric stricture. The Jaboulay is created by folding the long strictured bowel on itself and making a longitudinal incision along the stricture on either side. These enterotomies are then sutured together. This does leave the central aspect of the stricture bypassed which can be problematic. Finney modified this technique to eradicate this bypassed segment of bowel. For the Finney technique, the strictured segment is folded on itself and a "U"-shaped incision is made along the entire length of the stricture. This is then sutured together, thus creating a large diverticulum. This may develop problems due to stasis if the created diverticulum is quite large (Figure 49-4) [142, 143].

For those strictures that are even longer (>20 cm), a Michelassi or Poggioli stricturoplasty is indicated. These, though technically more demanding, have the advantage of avoidance of resection of a significant amount of bowel without bypassing bowel or creating a blind loop. The Michelassi stricturoplasty is performed by dividing both the strictured bowel and its mesentery in the center of the stricture. The bowel is then advanced over the other end in a side-to-side manner. A longitudinal incision is made over both limbs of the stricture and sutured together (Figure 49-5) [144]. The modification to this technique that Poggioli proposed was to divide the bowel and mesentery at the distal end of the stricture. The normal bowel would then be advanced over the

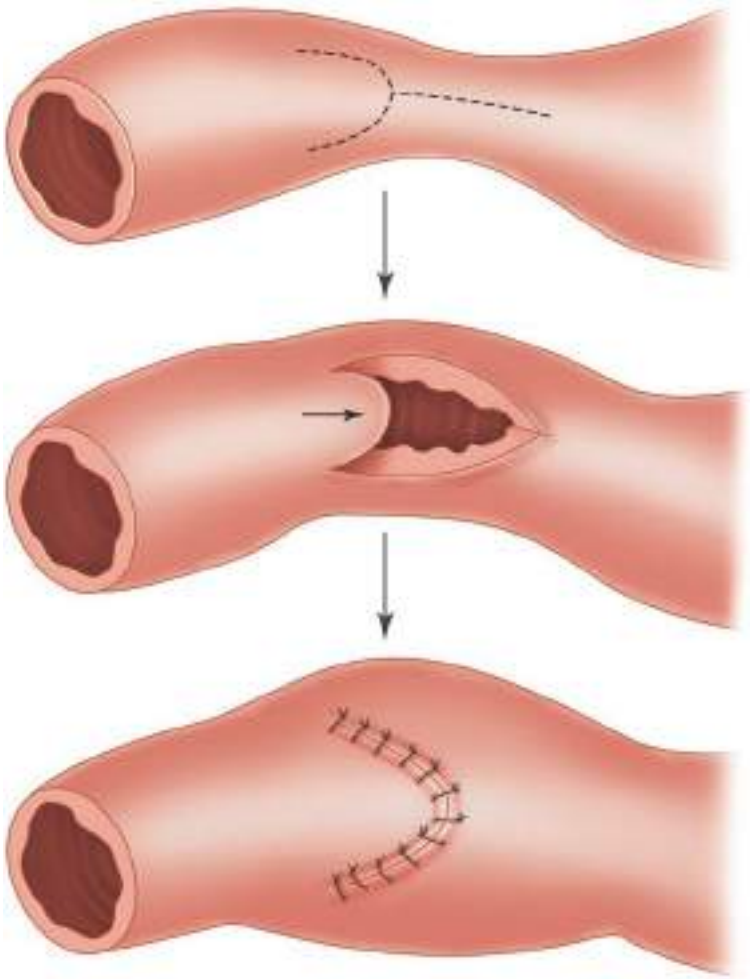

FIGURE 49-3. Moskel–Walske–Neumayer.

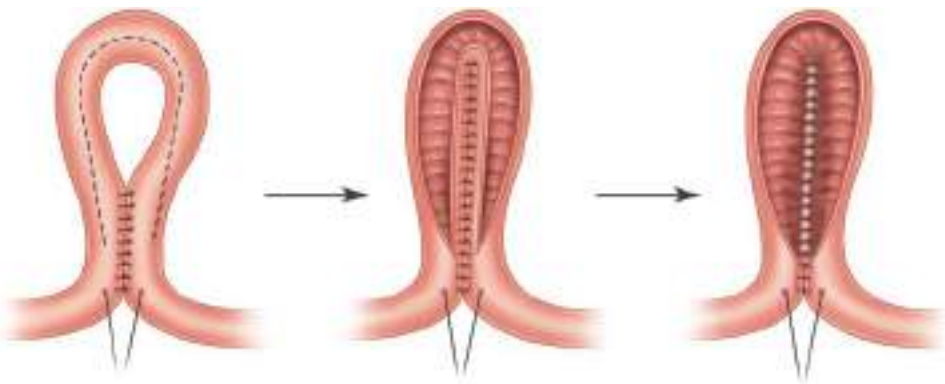

FIGURE 49-4. Finney stricturoplasty.

strictured bowel, opened via a longitudinal incision, and sutured together. This has the advantage of using normal bowel as part of the anastomosis. The normal bowel would be more pliable which may help in the execution of the stricturoplasty. It also has the disadvantage that if there is a complication, twice as much bowel will be lost, not only the strictured bowel but also an equal length of normal bowel [145, 146].

Indications for stricturoplasty include situations where there are multiple strictures involving a significant portion of bowel, previous significant small bowel resection (>100 cm), risk of short bowel syndrome, duodenal strictures or recurrent

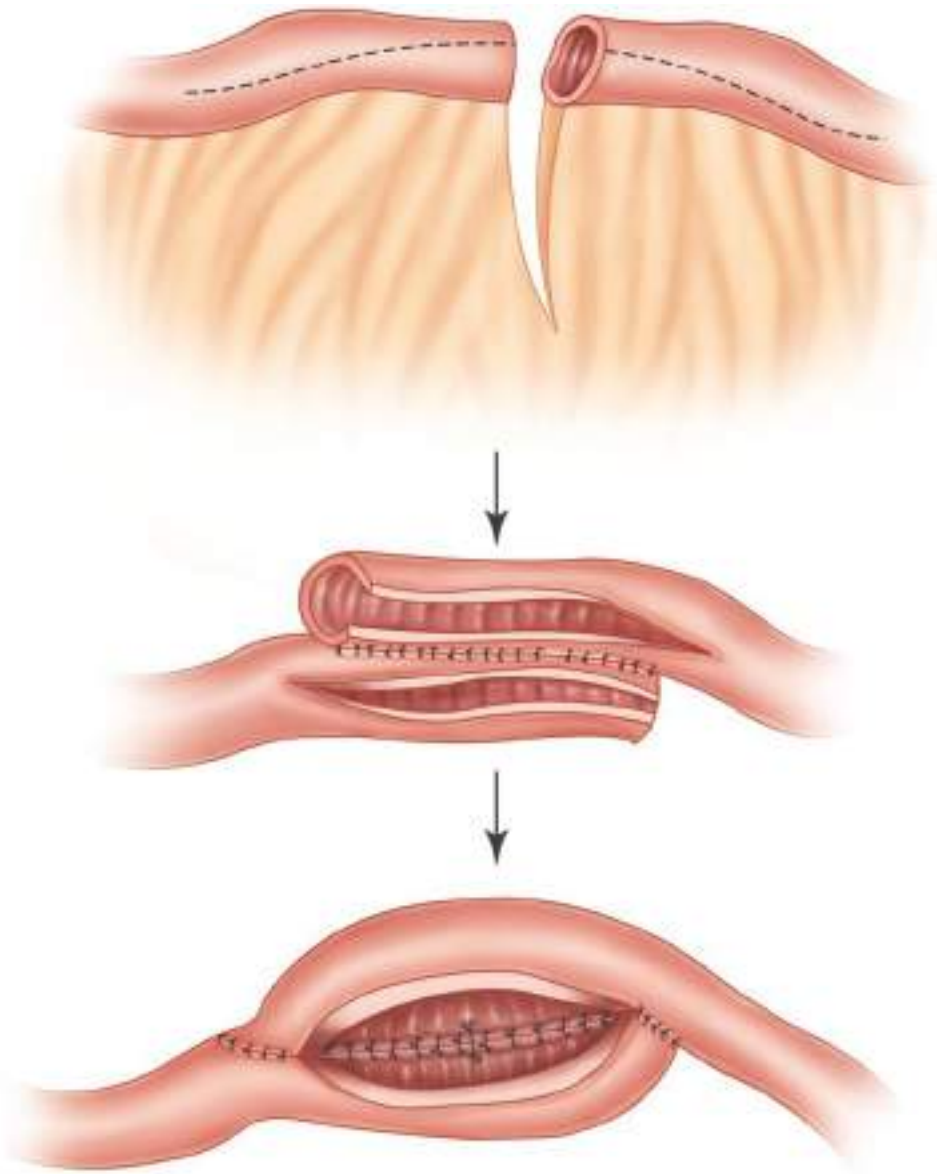

FIGURE 49-5. Michelassi stricturoplasty.

strictures, or recurrent strictures. It originally was thought unsafe to perform a stricturoplasty in a segment of bowel with active disease; however, recent studies have shown this is feasible and safe [147]. The contraindications to performing a stricturoplasty include severe inflammation, strictures associated with fistulas, abscesses, or a phlegmon, or those with diffuse peritonitis from a perforation. Stricturoplasty should also be avoided if there is concern for cancer, tension, or the area of the stricturoplasty is adjacent to an area of resection [148]. If when assessing the bowel wall, it appears to be either too fragile or thinned due to ulcerations, or so thick that there is minimal lumen left, stricturoplasty should be avoided [149].

There have been many concerns regarding performing stricturoplasties. The first is a concern regarding performing an anastomosis with bowel that is thickened and fibrosed and the potential for leaks or complications. The second main concern stems from leaving diseased bowel in situ and the potential risk of either recurrence or malignant transformation. Lastly, is it safe to perform stricturoplasties in those strictures that are >20 cm in length. Multiple studies have been done that have supported these procedures as being both feasible and safe. These studies found an overall complication rate of 5.7–20 % with a septic complication rate (fistulas, abscesses, or leak) of 2.9–6 % [148, 150–154]. A number of studies have specifically looked at the recurrence rates after stricturoplasty as well as location of recurrence when it did occur. Zuner et al. studied the effect of stricturoplasty on the recurrence rate as well as the location of the recurrence. One hundred and sixty-two patients underwent

191 operations for a total of 698 stricturoplasties (Heineke–Mikulicz 88 %, Finney 12 %). They found the five-year reoperative recurrence rate was 28 % which is comparable to what is found in the literature for reoperative recurrence rates after resection (32–53 %) [155, 156]. Multiple other studies have also confirmed comparable recurrence rate (12–36 %). In addition to that, they found a very low rate of recurrence at the site of a prior stricturoplasty (0.8–4.6 %) [149–154, 157]. Finally, Yamamoto et al., in their meta-analysis of 1112 patients found only two that had developed adenocarcinoma at the site of a prior stricturoplasty (0.02 %) [152].

In summary, it has been shown that Crohn's strictures can be safely and effectively treated with stricturoplasty using a variety of techniques based on the length of the stricture. The majority of the patients are treated with a combination of resection and stricturoplasty based on the findings at the time of operation. Of those undergoing stricturoplasty, 44–70 % of patients received at least one additional resection [142, 149, 151, 152].

FIGURE 49-6. Following laparoscopic mobilization, an energy device is being used to divide the thickened mesentery of a patient with Crohn's disease.

Terminal Ileal Disease

Since terminal ileal disease is the most common location for Crohn's disease to occur, it is not surprising that an ileocolic resection is the most common operative procedure performed on Crohn's patients. At the start of the operation, the abdomen is explored to assess the severity and location of disease. Careful observation looking for fistulas is also important considering the most likely origin of an enteric fistula is the terminal ileum. If disease is seen in the upper small bowel, decision regarding stricturoplasty versus resection is made. For the terminal ileal disease, the cecum and terminal ileum are fully mobilized. The small bowel is assessed to determine the point of bowel division. Again, the point of division is 1–2 cm beyond the palpable thickened bowel. Microscopic negative margins are not necessary. Care should be taken when dividing the mesentery, as it often is friable secondary to both the amount of inflammation and the use of steroids. The point of division of the colon is made just proximal to the ileocecal valve, preserving as much ascending colon as possible. Once the specimen is removed, it should be opened in the operating room to assess for any indications of malignancy which may require further resection (Figure 49-6 and 49-7).

Oftentimes there will be an inflammatory mass in the right lower quadrant with normal bowel adhered to the inflamed terminal ileum with possibly the presence of enteroenteric fistula. An attempt should be made to preserve as much small bowel as possible, though sometimes the amount of inflammation will preclude separation of the normal bowel from the diseased bowel and the entire mass will need to be resected en bloc.

Once the bowel has been resected, the decision is made to either create an anastomosis +/− a diverting loop ileostomy

FIGURE 49-7. Ileocectomy specimen in a patient with Crohn's disease.

versus creation of an end ileostomy. This decision is made by considering the risks factors that may lead to an anastomotic breakdown. These would include the hemodynamic stability of the patient, use of high-dose steroids, malnutrition, puru-

lent or fecal contamination secondary to a perforation, and/or bowel obstruction with markedly dilated bowel. Attempts, when feasible, to create an anastomosis is preferable, since taking down a loop ileostomy has lower morbidity, compared to an exploratory laparotomy for takedown of an end ileostomy. If it is deemed necessary to create a stoma, the time lapse until takedown of the ileostomy is somewhat dictated by the indication for the stoma. The goals to attain prior to takedown should be full recovery from the first operation, weaning off of the steroids, correction of malnutrition, as well as allowing time for the acute inflammation and adhesion from surgery to resolve. This may take 3–6 months.

Colonic and Rectal Disease

The operations used to treat Crohn's disease of the colon and rectum include total abdominal colectomy with end ileostomy, total abdominal colectomy with ileorectal anastomosis, total abdominal proctocolectomy with end ileostomy, and total abdominal proctocolectomy with micro Hartman's with an end ileostomy. The decision as to which of these procedures is going to be best for the patient is made by careful consideration of the preoperative status of the patient, location and severity of disease, use of steroids, age, sexual function, and patient wishes.

Patients who present acutely ill and are requiring an emergent operation for Crohn's colitis typically will need a total abdominal colectomy with end ileostomy regardless of the presence of rectal involvement. Attempting to perform a proctectomy in this setting is dangerous and unnecessary, as it will increase the morbidity and mortality of the procedure and is not necessary to improving the patient's overall health. In this setting, the entire colon is mobilized. The terminal ileum is divided as well as the upper rectum. The terminal ileum is then fashioned into an ileostomy. The rectum will be left in situ. If the rectum has significant inflammation, oversewing the staple line will help to decrease the risk of a dehiscence at the staple line. Even if the rectum has active disease present, typically once diverted, the disease in the rectum will improve as will the patient's symptoms. The decision to leave the rectum in situ, perform an ileorectal anastomosis, or perform a proctectomy can be determined at a later date.

The decision as to which operation to perform for a patient with Crohn's colitis in the elective setting is more involved as more options are available and need consideration. Patients who present with rectal involvement in addition to their colitis are not candidates for limited resection. For those patients with good nutrition, in good health, and not immunosuppressed, a total proctocolectomy with end ileostomy is the indicated procedure. This has the advantage of treating all aspects of the disease with one operation. This procedure offers the lowest recurrence rate; however, it does have potential for complications, the most common complication being perineal wound sepsis (36 %) [158]. For those patients with poor nutrition and/or on steroids, consideration of performing a total abdominal proctocolectomy with a micro Hartmann's and end ileostomy is a viable alternative. This has the advantage of removing majority of the disease however still avoiding a perineal incision and the increased risk of wound breakdown. At a later date, when the nutritional status is improved and the steroids have been weaned, a completion proctectomy can be performed via a perineal approach. A total abdominal colectomy with end ileostomy with delayed proctectomy might be considered in younger patients who are concerned about sexual function and are in their childbearing years. Surveillance of the rectum would be necessary until the time of the proctectomy.

For those patients with Crohn's colitis with rectal sparing, a more limited resection can be entertained. Ileorectal anastomosis or segmental resection has been proposed for selective patients. Numerous studies have looked at the outcomes of each of these procedures, though all are retrospective studies, so have inherent bias present. With regard to total colectomy with ileorectal anastomosis, mortality rates range from 0 to 7 % [159–162] with an anastomotic leak ranging from 3 to 16.7 % [159, 162, 163]. Recurrence rates at 5 years were found to be 55–58 % and at 10 years cumulative reoperative rates were 48–83 % [161, 162, 164]. Though these numbers are high, 77–87 % of patients had a functioning ileorectal anastomosis at 5 years, and 61–72.2 % had a functioning ileorectal anastomosis at 10 years [159, 161, 163–165]. Not surprising, those who had rectal sparing did better than those who had this procedure done in the setting of mild to moderate proctitis [166]. Those presenting with perianal disease, as well as those presenting with small bowel disease, had a higher rate of failure [164, 165, 167]. Reasons for failure, in addition to recurrence of disease, included poor functional control after surgery. O'Riordan et al. found that 22 % of the patients in their study who had undergone an ileorectal anastomosis ultimately had a proctectomy secondary to poor functional control [163].

Segmental resection for Crohn's colitis is controversial. Again, the studies looking at this are retrospective in nature, but do shed some light on this procedure and its potential place in the armamentarium. The majority of the studies compared segmental resection to total colectomy with ileorectal anastomosis. Polle et al. followed 91 patients who underwent a segmental resection for Crohn's colitis. Median follow-up was 8.3 years. They found that only 1/3 of patients required additional surgery. Of those that did recur, 2/3 ultimately underwent a total proctocolectomy. At the end of the study, patients were more likely to have a stoma if they had undergone a left colectomy versus those who required a right colectomy [168]. Andersson et al. evaluated 57 patients: 31 underwent a segmental resection and 26 underwent a total colectomy with ileorectal anastomosis. The cumulative re-resection rate was 55.3 % for the segmental group and 41.4 % for the colectomy group. Of those patients in the segmental group that had a re-resection, 50 % had additional

surgeries. No patient in the colectomy group required more than two surgical procedures. The median time to re-resection was 2.6 years and 7.3 years, respectively. The rate of permanent stoma in each group was 13 % and 19 %, respectively. The segmental group did have statistically significant fewer symptoms, fewer loose stools, and better anorectal function [169]. Prabhakar et al. evaluated 49 patients who had undergone a colon resection without a permanent stoma. Of these patients, 33 % required additional surgery, with 89 % of the recurrences being in the colon. Of these patients, 44 % ultimately had a permanent stoma. At the completion of the study, 86 % of the patients were stoma free [170].

In summary, patients with clear rectal involvement are not candidates for limited resection. For those patients with rectal sparing, consideration can be made for colectomy with ileorectal anastomosis or in some cases segmental resection. Both of these procedures have the advantage of avoiding a stoma and segmental resection has the added advantage of better functional results over IRA. Both of these procedures though have very high recurrence rates as well as high reoperative rates. These failure rates are even higher if there is perirectal disease or if the disease was localized to the left colon.

FIGURE 49-8. Coronal CT image in a patient with Crohn's disease demonstrating an ileal-sigmoid fistula from the thickened ileum to the sigmoid colon right above the level of the bladder.

Special Considerations

Ileal-sigmoid fistula

This is the most common abdominal fistula found. The origin of the fistula is from the diseased terminal ileum and ultimately the inflammation penetrates into the sigmoid colon. Most often, the sigmoid colon is not involved with Crohn's disease but happens to be adjacent to the inflamed bowel (Figure 49-8). If there is any question as to active Crohn's disease in the sigmoid colon, a flexible endoscopic exam during surgery should answer the question. In 54 % of patients, a polyp or cluster of polyps will be seen in the sigmoid colon and in no other location in the colon. This may signify the presence and location of the fistula [171]. The terminal ileum will need resection; however, the sigmoid colon can be treated with division of the fistula and primary repair of the fistula site. A wedge resection with primary repair is typically all that is needed. Occasionally, the inflammation will be so severe that wedge resection is not safe and in these cases a sleeve resection can be done to remove the short segment that has been affected.

Complex Perineal Wounds After Proctectomy

Perineal wound complications can be a devastating problem after proctectomy for Crohn's disease, leading to postoperative pain, significant wound care, and prolonged recovery. It has been estimated that the rate of unhealed perineal wounds after proctectomy for Crohn's disease ranges from 23 to 70 % [172–174]. The best approach to this problem is prevention. Strategies to prevent this complication include smoking cessation prior to surgery, improvement of the nutritional status of the patient, as well as preoperative management of sepsis. In cases of severe perianal disease, creation of a low Hartman's instead of complete proctectomy will avoid a perineal wound, yet still remove majority of the disease. This will allow resolution of the active sepsis and if necessary a perineal resection of the small rectal stump can be performed at a later time. When full resection is necessary, an intersphincteric dissection should be performed when possible. This decreases the amount of tissue removed as well as leaves well-vascularized muscle to bolster the closure.

At times, a wide excision is necessarily because of severe perianal disease, significant scarring, or the presence of cancer. In these cases, primary closure may not be possible; however, wound healing can be achieved with the use of advanced tissue flaps which bring viable healthy tissue to the wound. Various flaps have been described for this purpose including the gluteus maximus advancement flap, posterior thigh fasciocutaneous flap, chimeric posterior thigh flap, as well as the rectus abdominus myocutaneous flap. The gluteus maximus flap can be unilateral or bilateral and is ideal for smaller wounds. The posterior thigh fasciocutaneous flap is a good option for larger wounds. This provides significant soft tissue transfer as well as adequate skin for closure. The chimeric posterior thigh flap allows for two separate tissue transfers

with a single procedure. The gluteus maximus muscle can be transferred to fill dead space, while the posterior thigh flap can be used for perineal wound coverage. The most commonly used flap is the rectus abdominus myocutaneous flap. This flap provides muscle to fill the pelvic dead space as well as skin to close the perineal wound. This flap does require a laparotomy so is not used for completion proctectomies performed using the perineal approach alone [175, 176].

Recurrence of Disease

Recurrence can be described as being endoscopic, clinical, or surgical. Rutgeerts et al. followed a prospective cohort of patients and found that at 1 year, 73 % of patients had endoscopic evidence of recurrence in the neo-terminal ileum, though only 20 % were symptomatic. At 3 years, the endoscopic rate had increased to 85 % and the symptomatic rate had increased to 34 % [177]. Olaison et al. found even higher rates. They found 73 % of patients had endoscopic recurrence at 3 months, with 33 % being symptomatic. At 1 year, the endoscopic rate had increased to 93 % with a correlating symptomatic rate of 37 % [178]. Postoperative recurrence rates have been shown to be 33 % and 44 % at 5 and 10 years [9]. Frolkis et al. performed a meta-analysis of population-based studies to further evaluate the risk of second surgery in patients with Crohn's disease. They found the overall risk of second surgery to be 28.7 %. The five-year risk was 24.2 %, with the 10-year risk increasing to 35 % [179]. The rate of surgical recurrence ranged from 9.5 to 20 % at 5 years and 18.6 to 44 % at 10 years. The rate continued to increase to 57 % at 20 years [9, 14, 155, 180, 181].

Since the rate of recurrence is so high, much research has been done looking for risk factors that predict recurrence. The strongest predictor of postoperative recurrence is smoking [182–184]. Reese et al. performed a meta-analysis including 16 studies which included 2962 patients. They found that patients with Crohn's disease who smoke have a 2.5-fold increased risk of surgical recurrence and a twofold increased risk of clinical recurrence compared to patients who were nonsmokers [183]. Other risk factors that have been linked to a higher rate of recurrence include prior surgical resection and penetrating/perforating phenotypic disease type [182, 184–186]. Risk factors that have had mixed reviews in the literature regarding their predictive value for postoperative recurrence include gender and location of disease [9, 155]. Chardavoyne et al. found that patients who had the disease for 3–10 years before they underwent their first resection were more likely to have a re-resection compared to patients who had their disease for either less than 3 years or longer than 10 years [155].

As new medications become available, their usefulness in preventing postoperative recurrences is being studied. Steroids and probiotics did not show any role in the prevention of postoperative recurrences [187, 188]. Mesalamine has been shown to reduce the risk of clinical recurrence when compared to placebo in some studies but not all [189–193]. A randomized control trial demonstrated that those patients who received metronidazole for 3 months after ileocolic resection had a decrease in severity of early recurrence compared to placebo (13 % vs. 43 %) [194]. A second randomized, double-blind controlled trial investigated the effect of ornidazole (1 g/day) on clinical recurrence after ileocolic resection for Crohn's disease. The medication was given for 1 year after surgery. The clinical recurrence rate was 37.5 % in the placebo group compared to 7.9 % in the treatment group. Unfortunately, this effect was only seen when the drug was being administered and the side effects of the medication limit its prolonged administration [195]. Studies have shown a modest effect of the use of thiopurines with one study which showed that azathioprine seemed to delay endoscopic postoperative recurrence compared to historical series or placebo groups [187, 196–199].

Biologics have shown the most promise in reducing postoperative recurrence. Savarino et al. randomly assigned patients to receive adalimumab, azathioprine, or mesalamine. The endoscopic recurrence rates at 2 years were 6.3 %, 64.7 %, and 83.3 %, respectively. The clinical recurrence rate was 12.5 %, 64.7 %, and 50 %, respectively [200]. The studies on infliximab have been very promising. Regueiro et al. performed a randomized control trial investigating the effect of infliximab on postoperative recurrence and ileocolic resection. They found the endoscopic recurrence rate at 1 year was 9.1 % in the infliximab group compared to 84.6 % in the placebo group. Histologic recurrence was also lower in the infliximab group, 27.3 % compared to 84.6 % [201]. Yoshida et al. also found that infliximab had a beneficial effect. At 12 and 36 months, they showed that patients treated with infliximab postsurgery were 100 % and 93.3 % in remission, respectively, versus 68.8 % and 56.3 % in the placebo arm of the study [202]. Yamamoto et al. looked at the efficacy of infliximab on endoscopic recurrence as well as mucosal healing. Twenty-six patients who had been treated with mesalamine after surgery showed endoscopic evidence of recurrence at 6 months after surgery. These patients were treated with mesalamine, azathioprine, of infliximab. Clinical recurrence was seen in 0 % of the infliximab patients, 38 % in the azathioprine patients, and 70 % in the mesalamine patients. The rate of endoscopic improvement was 0 %, 38 %, and 75 %, respectively. Complete mucosal healing was seen in 0 %, 13 %, and 38 %, respectively [203]. These studies are relatively small but show great promise that perhaps infliximab can change the natural history of Crohn's disease. Larger randomized control trials will need to be performed to prove this.

Conclusion

In conclusion, surgery should not be viewed as a failure of treatment but rather as an integral treatment option for patients with Crohn's disease. Surgery can offer relief of

symptoms and an opportunity to return to a full and active lifestyle. Though the medical treatment has improved over the past decade, there has yet to be a significant drop in the number of surgeries performed. This may be explained by the increase in incidence of the disease. For now, surgery still plays a key role in the treatment of Crohn's disease.

Ulcerative Colitis: Surgical Management

Mukta K. Krane, Erin O. Lange, and Alessandro Fichera

Key Concepts

- Patients with ulcerative colitis should be managed by a multidisciplinary team of gastroenterologists, surgeons, pathologists, enterostomal therapists, and nutritionists.
- Preoperative weight management, improvement of nutrition, and optimization of medical therapy before proceeding with construction of the ileal pouch anal anastomosis are critical steps to achieve optimal long-term functional results.
- Laparoscopy should be considered the standard of care for elective surgery for ulcerative colitis
- While ileal pouch anal anastomosis should be considered the standard of care in the surgical treatment of ulcerative colitis patients, the surgical plan should be individualized both in terms of staged approach and restoration of intestinal continuity.
- Long-term follow-up of patients with an ileal pouch anal anastomosis is mandatory, even though the risk of malignant degeneration remains quite low.

Introduction

Ulcerative colitis (UC) is an inflammatory intestinal condition characterized by continuous colonic inflammation extending from the rectum proximally. Patients generally present in the second or third decade of life with manifestations of the disease including abdominal pain, diarrhea, rectal bleeding, and weight loss. While medical therapy is often first-line treatment, proctocolectomy is curative and therefore surgery has a pivotal role in the therapeutic armamentarium of UC. The aim of this chapter is to highlight the indications for surgery, principles of surgical decision-making, operative techniques, and special considerations.

Indications for Surgery

Approximately 25–30 % of patients with UC will undergo surgical intervention in their lifetime, with up to 10 % of patients requiring surgery within the first year of diagnosis due to a variety of elective and emergent causes (Table 50-1) [1]. The timing of surgery depends on the indication and severity of disease.

Elective Surgery

Elective indications for surgery include failure of medical management, complications or side effects associated with medications, dysplasia or invasive cancer, extraintestinal manifestations, and growth retardation in children and adolescents. Patients with active disease despite optimization of maintenance therapy are often in better general health than patients with fulminant colitis, but may undergo surgery in order to avoid corticosteroid dependency.

A diagnosis of high-grade dysplasia (HGD), dysplasia-associated lesion or mass (DALM), or invasive carcinoma in a patient with UC is an absolute indication for surgery. The diagnosis of dysplasia or cancer can be challenging in the setting of UC; therefore, it is imperative to obtain confirmation from two experienced GI pathologists [2]. The overall rate of colorectal cancer in patients with UC is 3.7 % with a risk of 2 % at 10 years, 8 % at 20 years, and 18 % at 30 years [3]. Synchronous and metachronous dysplasia and carcinoma are more common in patients with UC than in the sporadic colorectal cancer population. Kiran et al. recently reported a 14 % synchronous cancer and 55 % synchronous dysplasia rate in 176 UC patients with colorectal cancer [4]. The recommended procedure for UC patients with colorectal cancer or HGD is therefore proctocolectomy with end ileostomy or ileal pouch anal anastomosis (IPAA).

Table 50-1. Indications for surgery in ulcerative colitis

Elective	Emergent
Failure of medical management	Toxic megacolon
Complications/side effects of medications	Sepsis/fulminant colitis
Dysplasia	Perforation
Invasive cancer	Hemorrhage
Extraintestinal manifestations	
Growth retardation	

The need for and timing of surgery in patients with low-grade dysplasia (LGD) remains highly debated. The 5-year progression rate from LGD to HGD or colorectal cancer is reported to be as high as 54 % [5, 6]. In addition, patients may progress from LGD to colorectal cancer without intervening evidence of HGD. However, there are a number of small, observational studies which do not show a clear progression of dysplasia and have resulted in the recommendation by some that LGD can be followed with close endoscopic surveillance with surgery reserved for patients developing HGD or colorectal cancer. Recently, endoscopic mucosal resection and endoscopic submucosal dissection have emerged as possible therapeutic techniques in the treatment of UC-associated dysplasia [7, 8].

There are two widely accepted elective surgical options: total proctocolectomy with an end ileostomy or restorative proctocolectomy with ileal pouch anal anastomosis (RPC-IPAA), which may be performed in one, two, or three stages. Total abdominal colectomy with an ileorectal anastomosis is a third but rarely used option. The choice of elective procedure is individualized based on the patient and the clinical setting, and it will be discussed later in this chapter.

Emergent Surgery

Emergent indications for surgery include toxic megacolon, sepsis, or fulminant disease not responsive to medical therapy, perforation, and severe bleeding. Perforation and massive hemorrhage occur less frequently than fulminant colitis but are absolute indications for surgery, whereas toxic megacolon and severe acute flares may respond to intense medical therapy.

Toxic megacolon is a life-threatening complication of UC and there should be a low threshold for surgical intervention. An initial trial of conservative therapy with bowel rest, intravenous fluids, broad-spectrum antibiotics, and close monitoring for 24–48 h may be cautiously attempted. While infliximab and cyclosporine have been demonstrated to successfully treat toxic megacolon secondary to UC in 25–40 % of patients, associated morbidity and mortality rates are high [9]. Worsening clinical signs or evidence of increasing colon dilation with "thumb printing" or pneumatosis on radiologic imaging are indications for surgery.

Severity of UC can be characterized as mild, moderate, severe, or fulminant depending on the number of daily bowel movements, systemic symptoms, and inflammatory markers (Table 50-2) [10]. While advances in medical therapy have resulted in the avoidance or delay of surgical intervention in some patients with severe or fulminant disease, a colorectal surgeon should be consulted in these cases, particularly if the patient requires hospital admission. Early collaboration between the medical and surgical teams ensures that the patient understands that colectomy is an alternative if the colitis is refractory to medical management or if their clinical status deteriorates.

In patients admitted to the hospital with fulminant UC, steroids and other rescue therapies will often be initiated. It is important to objectively assess these patients on a regular basis by monitoring hematologic parameters, C reactive protein (CRP) levels, stool frequency, abdominal exams, and abdominal imaging. Colectomy is generally advocated for clinical deterioration or if there is no significant clinical improvement in 4–7 days [11]. Concomitant infection with cytomegalovirus or *Clostridium difficile* needs to be ruled out and appropriately treated if identified.

Critical examination of current practice reveals that the threshold for elective surgery is too high and it is important to consider surgery an alternative to medical therapy, rather than representing failed management [12]. Roberts et al. compared 3-year mortality in over 28,000 patients hospitalized for UC who had urgent or elective surgery versus medical management [13]. The elective colectomy group had the lowest mortality rate (3.7 %), while the medical management and urgent colectomy groups had similar mortality rates (13.6 % and 13.2 % respectively, $p = 0.001$). A recent review of the literature further illustrates the risks of urgent surgical intervention for severe colitis by reporting a 40.1 % morbidity rate [14].

In the emergent setting the most common procedure performed is a total abdominal colectomy with an end ileostomy, leaving the rectum in situ. Resection of the diseased colon eliminates the majority of the disease, alleviates symptoms, and usually allows the patient to discontinue immunosuppressive medications and return to an improved overall state of health. Completion proctectomy with or without an IPAA can then be addressed in an elective setting. Resection of the rectum at the time of emergent surgery should be avoided as it hinders future restoration of intestinal continuity and is associated with a higher risk of bleeding and injury to the autonomic nerves. Emergent proctectomy may also significantly increase the length of the procedure and the risk of postoperative complications.

Staged Operations

In the authors' experience, there are several indications for a staged approach to surgical therapy for UC patients (Table 50-3) and this strategy is commonly utilized in clinical practice in many major IBD centers [15]. Obesity and other patient comorbidities play a significant role in the decision tree and will be discussed throughout this chapter.

Table 50-2. Ulcerative colitis disease severity scale

	Mild	Severe	Fulminant
Number of bowel movements/day	<4	>6	>10
Rectal bleeding	Rare	Frequent	Profuse and continuous
Hemoglobin	Normal	<75 % of normal	Requiring transfusions
ESR (mm/h)	Normal	>30	>30
Body temperature (°C)	Normal	>37.5	>37.5
Heart rate	Normal	Normal to slightly tachycardic	Tachycardic

Modified from Truelove and Witts [10]

Table 50-3. Indications for a staged surgical approach

Indications for a staged surgical approach
Obesity
Medical treatment (Biologics, Steroids)
Fulminant disease/toxic megacolon
Patient comorbidities

In our practice, a two-stage approach (for both open and laparoscopic cases) includes a restorative proctocolectomy with an IPAA and diverting loop ileostomy as the first stage and reversal of the loop ileostomy at the second operation. A three-stage approach involves a total abdominal colectomy and an end ileostomy as the first stage, followed by a restorative proctectomy with an IPAA and diverting loop ileostomy as the second stage, and reversal of the ileostomy at the third and final operation.

The staged approach to pouch construction among complex UC patients seeks to decrease the incidence of pelvic sepsis, often related to a leak at the ileal-anal anastomosis [16, 17], and to minimize long-term sequelae of a postoperative septic complication including poor pouch function [18]. Pelvic sepsis is a frequent and serious complication of IPAA for UC and is reported to occur in up to 23 % of patients [19, 20]. Long-term outcomes after IPAA are worsened by the occurrence of pouch-related septic complications [16]. Although acceptable functional results can be achieved in highly motivated patients, multiple procedures are often necessary to achieve complete healing of an IPAA leak [17]. Hence efforts should be made to reduce such complications and to identify patients at risk of pouch-related sepsis.

Several risk factors have been postulated for postoperative pouch-related septic complications in UC including steroids [20, 21], infliximab [22, 23], and immunomodulators [24]. While the role of corticosteroids as a risk factor for postoperative complications has been described in various publications [16, 19–21], the role of infliximab has not been clearly defined to date [25–29]. Lim et al. reported that the use of corticosteroids was an independent risk factor for complications after IPAA in a dose-dependent fashion and concluded that patients receiving more than 20 mg/day of prednisone should undergo multistage pouch procedures [20]. Using this threshold as an indication for diversion, Gorfine et al. reported similar septic complication rates and functional results between patients on aggressive medical therapy and those taking no immunosuppressive and less than 20 mg of prednisone daily in the month preceding surgery [17, 30]. It is important to recognize that these studies were all conducted before the introduction of biologic therapy.

Since 2005, biologic therapy has become a significant component of medical therapy for many UC patients [31]. Unfortunately, aggressive medical management of acute flares of UC in the era of biologic therapy seems to be associated with increased postoperative infectious complications [23, 24], as patients are often referred to the surgeon malnourished, immunocompromised, and suffering from significant side effects of treatment.

Selvasekar et al. [23] found that UC patients treated with infliximab before IPAA have substantially increased odds of postoperative pouch-specific and infectious complications. In this study, the authors reported that anastomotic leaks ($p=0.02$) and pouch-specific ($p=0.01$) and infectious ($p<0.01$) complications were more common in the group receiving biologic therapy. Similar findings were demonstrated by Mor et al. [24]. The authors found that the odds of postoperative septic complications were 13.8 times greater ($p=0.011$) and the odds of late complications 2.19 times greater ($p=0.08$) in the group receiving biologic therapy. Although not in a standardized fashion, the surgeons involved in this study were 2.07 times more likely to perform a staged procedure for patients receiving biologic therapy ($p=0.011$) [24].

Ferrante et al. [21] reported their experience looking at 141 IPAA patients, 22 receiving biologic therapy. A moderate to high dose of corticosteroids ($p=0.003$) and an IPAA without ileostomy ($p=0.001$), but not the use of biologic therapy, were independent predictors of short-term postoperative infectious complications. However, they also noticed that patients on biologic therapy were more likely to undergo IPAA with a diverting ileostomy ($p=0.022$). Schluender et al. [22] reported that while preoperative biologic therapy alone did not significantly increase the incidence of postoperative complications, its use in combination with cyclosporine before colectomy in refractory UC was associated with higher surgical morbidity.

Finally a meta-analysis conducted by Yang et al. [32] on five studies and 706 patients found that biologic therapy increased short-term overall postoperative complications in UC, even if there was no association when analyzing separately short-term infectious and noninfectious complications,

except for a trend toward increased postoperative infections. This study was in part limited by the quality of the studies included and the small number of patients, further underpowered in the subgroup analysis.

The theoretical advantage of a three-stage approach is the opportunity to optimize the general medical condition, improve nutritional status, and wean off medical therapy during the interval following the total abdominal colectomy. While not extensively evaluated in the literature to date, this preparation period is considered important prior to attempting the more complex elements of surgical therapy, namely pelvic dissection with pouch construction and anastomosis, in order to reduce pouch-related septic complications and long-term pouch dysfunction. Recently this concept has been challenged by several authors [27, 33, 34], but this literature must be critically interpreted.

The series from Mount Sinai Hospital in Toronto concluded that preoperative treatment with TNF-alpha antagonists in IBD patients was not associated with early postoperative complications, after reporting similar rates of wound infection among patients with detectable preoperative infliximab levels compared with those with undetectable levels. However, this analysis included operations for both Crohn's disease and UC; among the 69 UC patients evaluated, only 11 pouches were constructed on patients on anti-TNF-alpha antagonists, thus limiting the validity of the conclusion for this specific subgroup [25]. Our own experience is similar: among 518 IBD surgical patients treated laparoscopically, we noted no differences in postoperative infectious complications. However, only 15 pouches (10.6 %) were constructed on patients while on infliximab [27].

In our practice, we have found that a more conservative surgical approach to UC patients with multiple comorbidities receiving aggressive medical management has allowed us to achieve excellent results with acceptable morbidity [35]. A retrospective analysis of our own prospectively collected data comparing a three- versus a two-stage approach in this population revealed no difference in overall postoperative complications. Despite significantly higher utilization of corticosteroids (96 %) and biologic therapy (43 %), as well as higher incidence of active *C. difficile* infection (14 % vs. 5.8 %) among patients in the three-stage group, we identified lower incidence of infection complications (21 % vs. 38.2 %. $p<0.05$) compared to the two-stage group [35]. In order to minimize complications, an accurate preoperative risk assessment, combined with the surgeon experience, is crucial to assign patients to the safest surgical approach. In our practice, patients receiving aggressive medical management undergo staged procedures, while single-stage pouch surgery is still offered only to the healthier, more elective group. Our interpretation of the data available in the literature suggests that by deferring the critical surgical step of the pelvic dissection with pouch construction and anastomosis to a time when patients are medically optimized, we are able to limit complications. Nevertheless, we believe that there are certain characteristics that define the group of patients who may benefit from the avoidance of a stoma and its complications [30]: young, healthy patients who are not on immunosuppressants or steroids preoperatively; surgical indication of dysplasia; uneventful operation; pouch with optimal blood supply and tension-free anastomosis. We usually leave a rectal tube in these patients for a few days to avoid pouch distension and discomfort due to the initial diarrhea and possible perianal skin irritation.

Operative Technique and Surgical Decision-Making

Once the decision is made to proceed with surgery, it is important to remember that, with UC patients, one size definitely does not fit all. In the following section, we will discuss the pros and cons of different approaches based on patient and disease characteristics and surgeon skill and judgment. While these opinions are based on the available evidence, there is a certain component of personal preference.

Preoperative Planning

The patient and family should meet with the surgical team prior to surgery to discuss the nature and necessity for the surgery, alternative options, risks and benefits of the procedure, and long-term functional outcomes. If a temporary or permanent ileostomy is planned, it is imperative that a certified enterostomal therapist evaluate the patient for preoperative marking. Preoperative anesthesia and medical consult evaluation may be needed preoperatively, depending on the patient's comorbidities, to optimize any underlying conditions and limit operative risk. Patients undergo bowel prep with a mechanical cleansing agent and oral antibiotics the day before surgery. In our practice, unless contraindicated, patients receive an epidural preoperatively as part of an enhanced recovery pathway. Antibiotics, thromboembolic prophylaxis, and in some cases stress-dose steroids are administered prior to induction of anesthesia.

Brooke Ileostomy

In 1952, Professor Bryan Brooke described his technique for everting an ileostomy in order to minimize skin excoriation [36, 37]. The Brooke ileostomy remains the preferred approach for patients who are not candidates for restoration of intestinal continuity in our practice.

When determining the placement of the ileostomy, the patient's abdomen should be assessed in the sitting and standing positions. The ideal location for the ileostomy is in

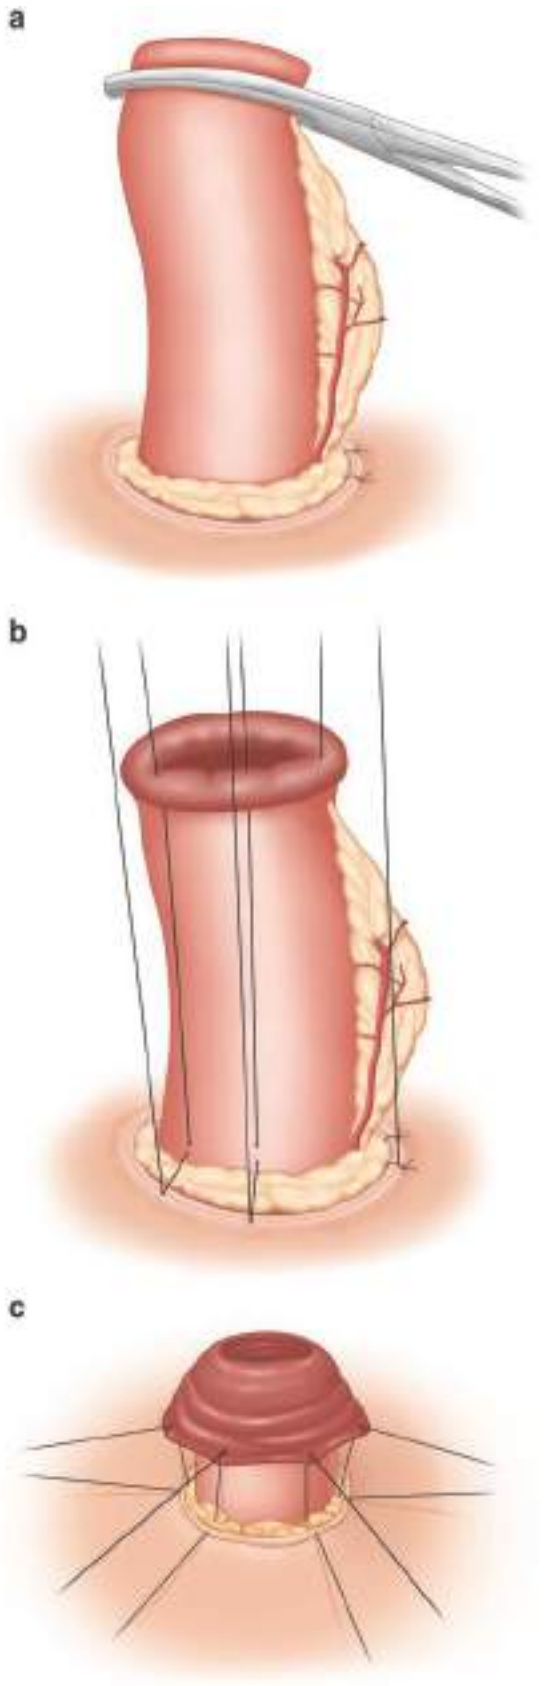

FIGURE 50-1. Construction of a Brooke Ileostomy. (**a**) The terminal ileum is extracted from the stoma site without tension on the mesentery. (**b**) Sutures are placed along the antimesenteric edge of the ileum and lateral to the mesentery allowing eversion of the bowel. (**c**) Everting sutures are tied and simple sutures are placed between the ileum and the dermis at the mucocutaneous junction.

a flat area over the right rectus muscle that is away from previous scars, deep abdominal folds or creases, and bony prominences. It is essential that a patient be seen by an enterostomal therapist to preoperatively mark the best site for the stoma [38].

Operative Details

A circular incision is made in the skin and carried down through the subcutaneous tissue until the anterior rectus sheath is encountered. The anterior rectus sheath is incised vertically and the rectus muscles are bluntly separated with handheld retractors. The posterior rectus sheath and peritoneum are then incised to create an opening that will accommodate two fingerbreadths. After ensuring no twisting of the bowel or mesentery, the terminal ileum is delivered through the opening (Fig. 50-1a). The ileostomy is matured with 3–0 chromic suture. A full thickness suture is placed at the open end of the ileum; a seromuscular bite of the bowel wall is then taken at the skin level and followed with a subcuticular bite through the dermis (Figure 50-1b). Four to five everting sutures are placed (Figure 50-1c), with particular care taken at the mesentery to avoid injury to the mesenteric vessels (a simple suture may be placed at this site). After placing the everting sutures, they are tied, and simple sutures are placed circumferentially between the cut edge of the ileum and the dermis to complete approximation of the mucocutaneous junction.

Operative Considerations

While obesity remains a relative contraindication to IPAA, management of obese patients with a stoma also presents significant challenges. Stoma-related complications occur in up to 36 % of patients [39], with obesity representing a key risk factor for stoma failure. Obese patients present technical difficulties caused primarily by mechanical factors: the foreshortened mesentery and the thick layer of the subcutaneous fat through which the intestine has to be placed. Stoma necrosis, retraction, parastomal herniation, and mucocutaneous separation are among the possible complications of a permanent end Brooke ileostomy, although not exclusively among the morbidly obese patients. In order for this group of patients to achieve the best possible long-term outcome, strict collaboration between the enterostomal therapist and the surgeon is critical. Revision of an ileostomy is often a very challenging operation in the obese patient; thus, proper placement, with appropriate preoperative evaluation for siting, is imperative. The impact of a poorly functioning ileostomy on patient's quality of life should not go

unnoticed, especially considering the fact that several of the UC patients are young with an active lifestyle.

Outcomes

To evaluate the Health-Related Quality Of Life (HRQOL) of patients who had a permanent Brooke ileostomy compared to the general population, Camilleri-Brennan et al. [40] conducted a mail survey using the quality of life questionnaire SF-36 version 2 (SF-36II) [41]. The authors evaluated the difference between patients and the general population for all dimensions and summary scores. The scores directly relating to physical well-being as well as the Physical Component Summary were similar between the two groups. Comparable results were also achieved for the energy and vitality dimension and pain scores. Scores in the mental health and role-emotional dimensions, as well as in the social functioning dimensions, and general health perceptions were analogous to that of the general population. This study suggested that despite the presence of a permanent ileostomy, HRQOL was very similar to that of the general population. The results clearly underscore the notion supported by other authors that a perceived negative impact of the ileostomy does not appear to affect HRQOL. Therefore, a permanent end ileostomy remains a viable option for UC patients requiring surgery and should always be discussed when counseling the patient regarding surgery.

Continent Ileostomy

There have been several modifications of the original description of the continent ileostomy popularized by Nils Kock in 1969 [42]. Creation of a continent ileostomy, or Kock pouch, requires an elaborate operation that involves the building of an ileal pouch with an internal valve to prevent and control the flow of enteric contents into the ostomy bag. With improvements in our understanding of inflammatory bowel disease and surgical technique, there are few patients today for whom the Kock pouch is an appropriate alternative to IPAA anastomosis following proctocolectomy. Specifically, this operation should be offered in specialized centers to patients with UC and a locally advanced low rectal cancer that will need adjuvant therapy postoperatively; patients who already have a Brooke ileostomy after proctocolectomy and wish to improve their quality of life; patients who are not candidates for an IPAA because of poor sphincter function; patients who prefer a continent ileostomy to an IPAA as a personal choice; and lastly, patients who have failed an IPAA but prefer a continence-preserving procedure to a Brooke ileostomy [43, 44]. Contraindications to this procedure include Crohn's disease, obesity, critically ill patients, and the psychologically unfit patients because of the inability to intubate. This procedure has also been performed in the pediatric population with satisfactory results [43–45].

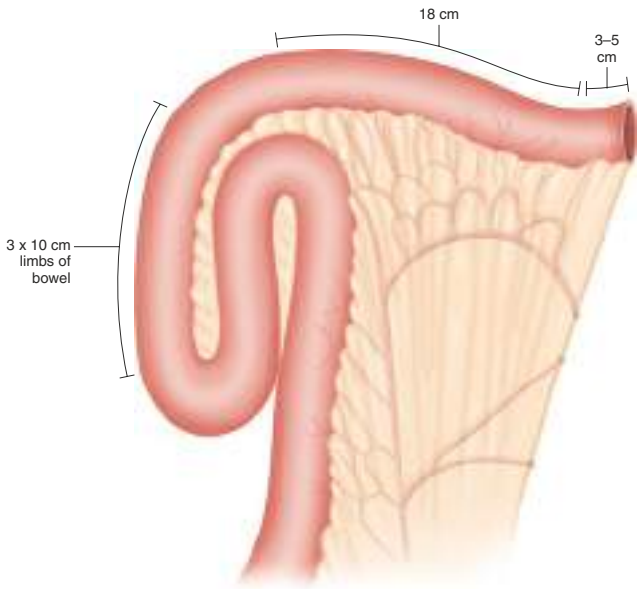

FIGURE 50-2. Construction of a Kock Pouch—about 50 cm of small bowel is used to create the Kock pouch. The distal 3–5 cm is used for the outlet, the middle 18 cm is used to construct the nipple valve, and the proximal 30 cm is utilized in creation of the pouch.

Operative Details

About 50 cm of small bowel is used to fashion a continent ileostomy (Kock pouch) (Figure 50-2). The outlet is constructed from the distal 3–5 cm of this segment, the nipple valve is created from the next 18 cm of bowel, and the remaining 30 cm is used for the pouch. Excising the peritoneum and mesentery on both sides of the arcade skeletonizes the mesenteric vessels of the small bowel used to build the nipple valve (Figure 50-3).

The pouch is generally created in an S-shape by folding the 30 cm length of small bowel into 10 cm limbs with one more cephalad to the other. A posterior row of sutures is placed between each limb and an enterotomy made along the S-shape (Figure 50-4). The incision will be antimesenteric along the middle limb and closer to the mesentery along the two outer limbs. A second posterior layer of sutures is created to re-approximate the cut edges (Figure 50-5). The nipple valve is then created with three passes of a GIA stapler without the knife (two along either side of the mesentery and one along the anterior aspect) (Figure 50-6). A two-layer closure of the anterior portion of the pouch is then performed. A circumferential row of interrupted sutures are placed between the outlet and the pouch to help maintain the position of the nipple valve (Figure 50-7).

To create the stoma aperture a small circular incision is made in the skin and carried through the subcutaneous tissue. A vertical incision is made in the fascia, the rectus muscle is retracted, and the peritoneum incised ensuring that the opening can accommodate two fingerbreadths. The outlet is brought

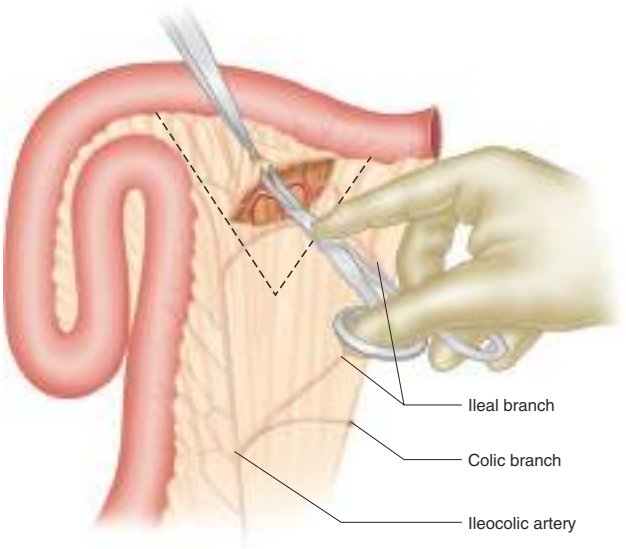

FIGURE 50-3. Construction of a Kock Pouch—the mesentery of the small bowel to be intussuscepted (marked by *dashed lines*) is skeletonized assisting formation of the nipple valve. The blood supply of this segment of bowel is identified with trans-illumination and the peritoneum and mesentery on either side of the vasculature is excised.

up to the opening and the pouch secured to the abdominal wall by placing sutures laterally and medially (Figure 50-8). The outlet is transected at a location that will enable the matured stoma to be flush with the skin. A curved Medina catheter is placed into the most dependent portion of the pouch and secured in place by suturing the rubber collar on the catheter to the skin (Figure 50-9).

Operative Considerations

The two main long-term problems with a continent ileostomy are malfunction of the valve and pouchitis. Malfunction of the valve causes incontinence and difficult intubation of the pouch and occurs in 11–20 % of patients [46–48]. When the continence mechanism fails, a traditional Kock pouch does not necessarily become a conventional ileostomy, but rather the "slipped valve" creates a functional obstruction requiring further surgery for revision or conversion to a standard Brooke ileostomy. Valve revision is successful in most patients. The incidence of pouchitis in Kock pouches is nearly identical to that after IPAA and management is similar.

Outcomes

Kock pouch procedures have recently fallen out of favor. The largest series were published in the late 1970s [46–48] and since the early 1980s fewer continent ileostomies have been performed as the great majority of appropriate patients choose to undergo an IPAA. However, recent data suggest

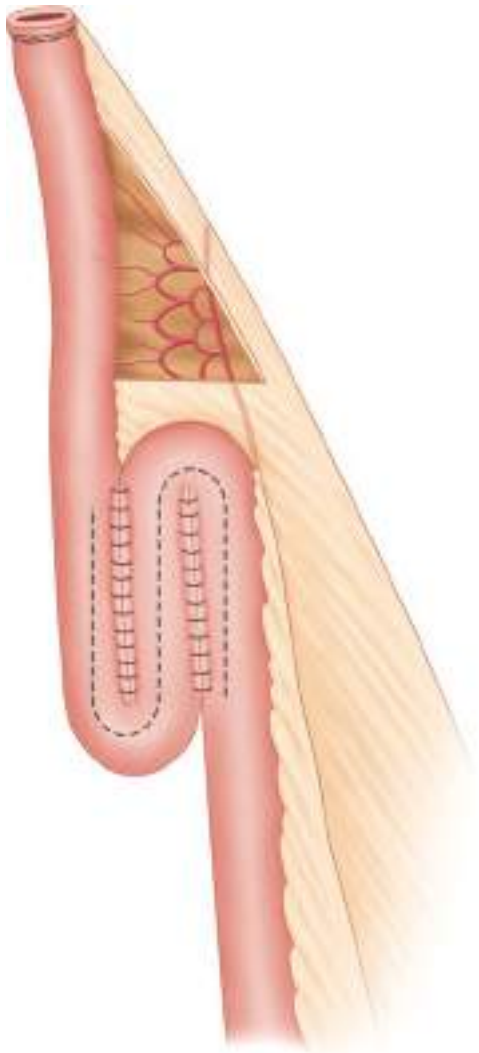

FIGURE 50-4. The S-shaped pouch is constructed by folding the proximal 30 cm of bowel into 3–10 cm limbs with sutures placed between the limbs. An enterotomy is made (*dotted line*) starting at the distal aspect.

that continent ileostomies in well-selected and properly motivated patients can be durable with long-term pouch survival rates approaching 80 % [49]. Overall long-term follow-up showed excellent results: between 70 and 89 % of patients have continence for gas and stool, and ultimately 95 % never had to wear an appliance [46–48].

Nessar et al. [50] reviewed the Cleveland Clinic continent ileostomy experience comparing HRQOL in continent ileostomy patients and those whose Kock pouch failed requiring removal and conversion to an end ileostomy. Results were evaluated using the continent ileostomy surgery follow-up questionnaire and the Cleveland Global Quality of Life (CGQL) scale. Patients with an end ileostomy were more than twice as likely to report social, work, and sexual restrictions and to require a higher antidiarrheal medication

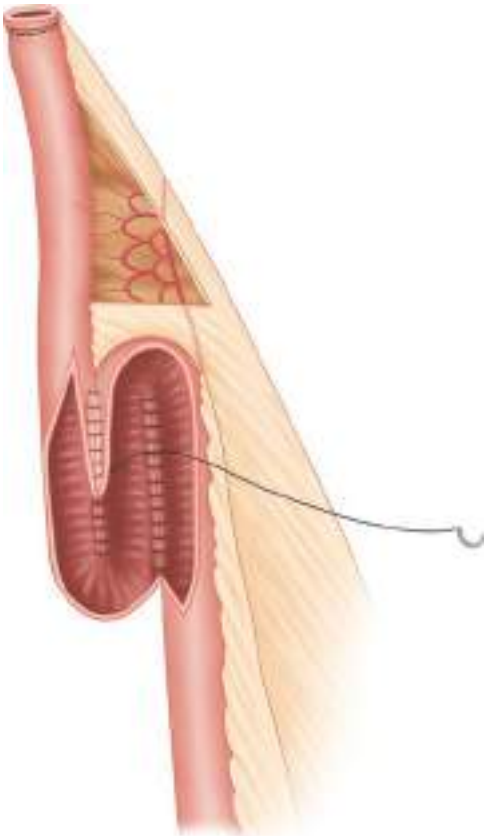

FIGURE 50-5. An inner posterior layer is created starting at the proximal end forming the pouch.

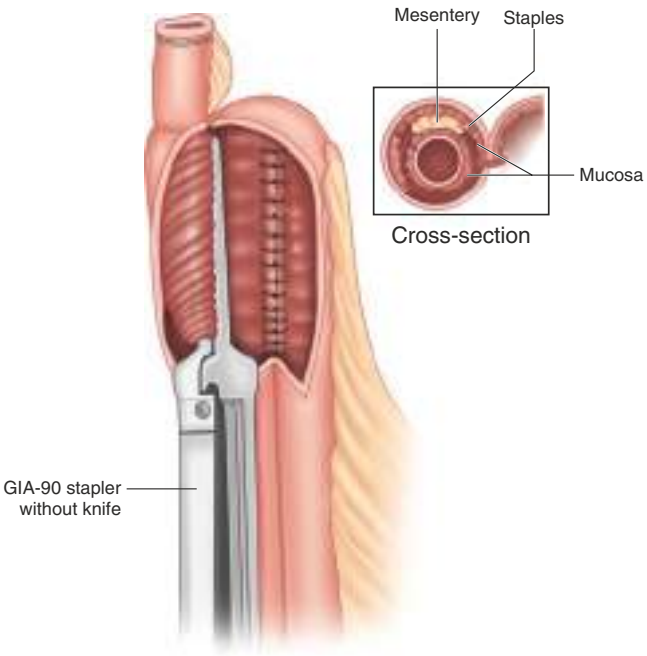

FIGURE 50-6. The nipple valve is created with three firings of a GIA 90 mm stapler without the knife.

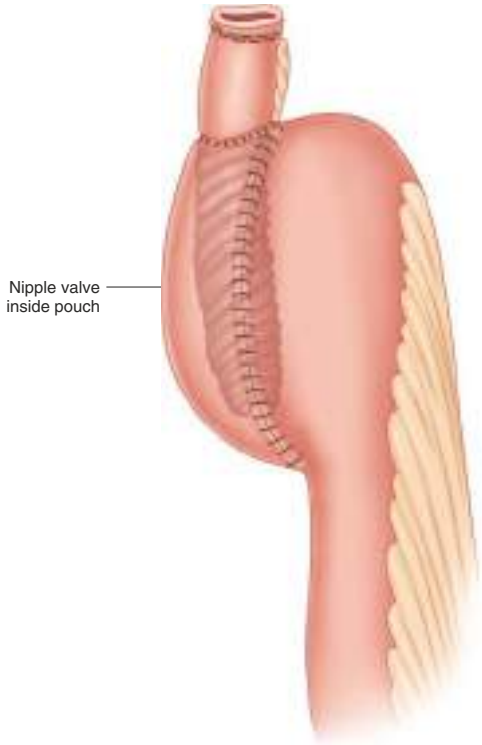

FIGURE 50-7. The anterior aspect of the valve is then completed with an inner and outer layer of sutures. To help maintain the nipple valve position a row of interrupted sutures is placed between the pouch and the outlet.

and fiber intake compared with patients with a continent ileostomy. Patients with a continent ileostomy reported having a better appetite and less abdominal pain than the end ileostomy group and rated a higher score for overall happiness. CGQL measurements were better on all scales as well as the summary scale in the continent ileostomy group. Kohler et al. compared quality of life between Brooke ileostomies, Kock pouches, and IPAA [51]. Patients with IPAAs had fewer restrictions in sports and sexual activities than those with Kock pouches, whereas those with Kock pouches had fewer restrictions in these activities but more restrictions in travel than those with Brooke ileostomies. In contrast, performance in the categories of social life, recreation, work, and family was similar between groups. They concluded that a well-functioning IPAA is superior to both Brooke ileostomies and Kock pouches in terms of overall quality of life.

Total Abdominal Colectomy with Ileorectal Anastomosis

Until the 1950s, total proctocolectomy with end ileostomy was the only available approach for UC patients failing medical management. In the 1940s reports of subtotal colectomy with

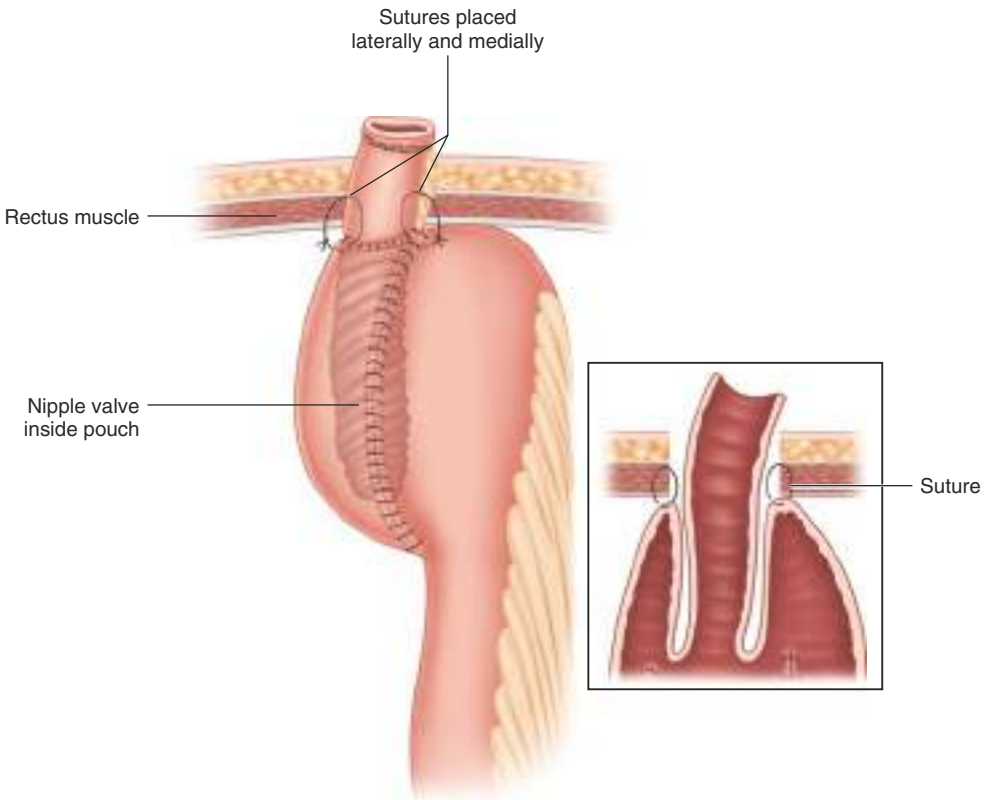

FIGURE 50-8. Sutures are then placed between the pouch outlet and the posterior sheath of the abdominal wall on the lateral and medial aspects.

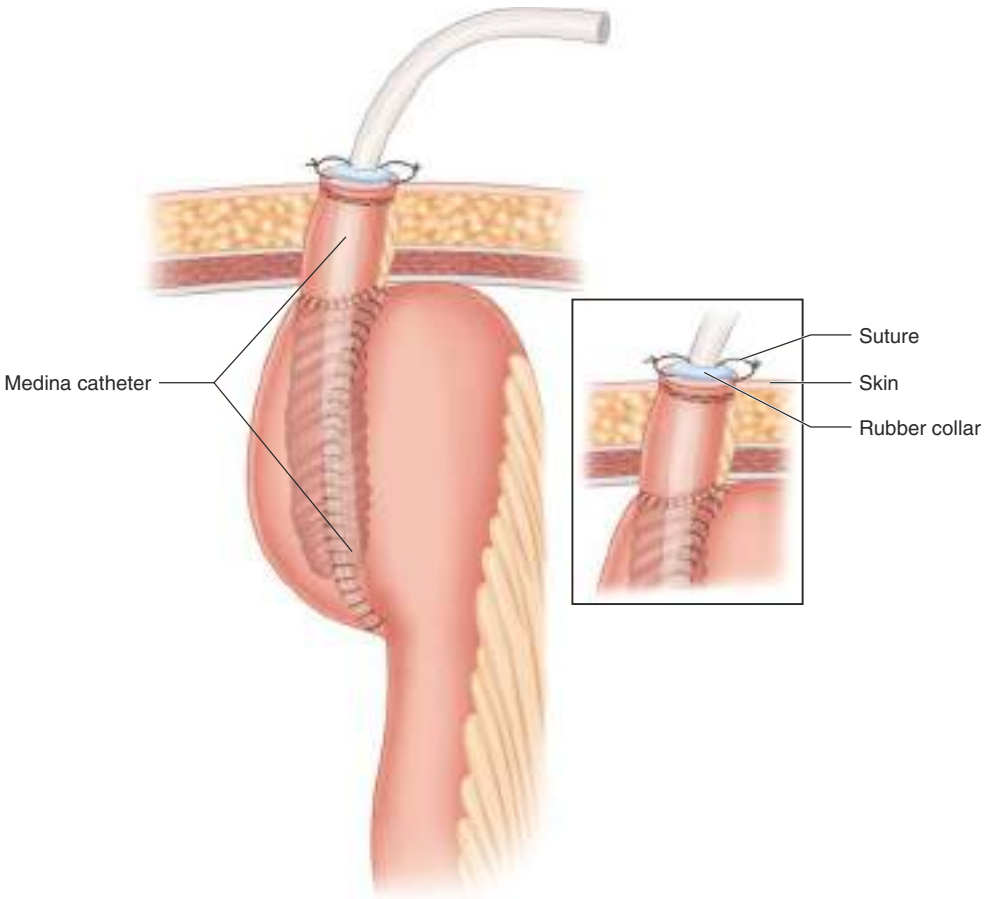

FIGURE 50-9. A Medina catheter is placed into the most dependent aspect of the pouch and secured to the skin.

ileorectal anastomosis (IRA) as an alternative to total proctocolectomy in selected patients were first published. Prior to the description of IPAA, this procedure quickly became a valid alternative to total proctocolectomy in highly selected patients with minimal rectal inflammation and adequate rectal compliance to avoid a permanent stoma [52, 53]. Advantages included lack of a permanent stoma, performance of a one-stage, less invasive operation, and avoiding pelvic dissection with its associated risk of sexual dysfunction [54].

In 1978, Parks et al. described the IPAA and Utsonomiya popularized it in the 1980s [55, 56]. Since then, IPAA has become the procedure of choice for patients affected by UC with excellent long-term functional results and a low risk of persistent cuff inflammation or neoplastic degeneration in the retained rectum [57, 58]. Consequently, many surgeons have abandoned IRA in favor of IPAA or total proctocolectomy in patients not candidates for IPAA. The pros and cons of the different surgical approaches are listed in Table 50-4 [17, 54, 59–61]. Patient selection is clearly critical in assuring long-term favorable outcomes in patients undergoing an IRA. Total abdominal colectomy with ileorectal anastomosis (TAC-IRA) is now generally reserved for patients with limited rectal involvement, good rectal compliance, and no dysplasia or cancer. Adequate rectal compliance and normal anal sphincter function are critical for good long-term results. This can be initially assessed by digital rectal examination, but is more accurately characterized by rigid/flexible proctoscopy and anal manometry. Patients with poor sphincter function, severe rectal disease, and a non-distensible rectum should not be offered an IRA. TAC-IRA may be done via a minimally invasive or open approach depending on the nature and severity of disease, previous surgical history, comorbidities, and surgeon experience.

Operative Details: Open Approach

The procedure is performed with the patient in the modified lithotomy position with the legs supported by stirrups, ensuring that all pressure points are appropriately padded. A vertical midline incision is made and the abdomen is explored with careful examination of the bowel for possible manifestations of Crohn's disease or the presence of malignancy.

The ascending colon and terminal ileum are fully mobilized by incising the lateral peritoneal reflection from the cecum up to the hepatic flexure. The right ureter and gonadal vessels and duodenum should be identified and separated from the mesentery to prevent inadvertent injury. The transverse colon is separated from its attachments to the stomach with or without preservation of the greater omentum. In our practice, the greater omentum is generally resected with the transverse colon (Figure 50-10). The lesser sac is entered and the omentum separated from the greater curvature of the stomach caudal to the gastroepiploic vessels. Dissection is carried to the splenic flexure exercising care to avoid splenic injury. Traction on the omental or colonic attachments to the splenic capsule may result in an avulsion injury and can often be avoided by dividing any omental attachments before applying traction. The dissection is then carried along the descending colon. Adhesions of the sigmoid colon to the abdominal and pelvic sidewall are divided and the lateral peritoneal reflection is incised. Care is taken to identify the left ureter and gonadal vessels to ensure their safety. Dissection is continued superiorly up to the splenic flexure, and with a combination of blunt and sharp dissection from the proximal and distal aspects, the splenic flexure is completely freed. At this point, full mobilization of the colon from the terminal ileum to the rectosigmoid junction has been accomplished.

The terminal ileum is transected with a GIA stapler and the mesentery of the colon is ligated and divided. If malignancy is not suspected, high ligation of the named vessels is not necessary and the mesentery can be divided close to the bowel wall. Larger vessels should be doubly ligated or divided with a vessel-sealing device. The inferior mesenteric artery is generally preserved in order to avoid injury to the hypogastric plexus and preserve adequate blood supply to the rectal stump. The rectosigmoid junction is divided at the level of the sacral promontory.

The ileorectal anastomosis can either be performed in an end-to-end or side-to-end fashion via a handsewn or stapled technique. We generally prefer to create a side-to-end ileorectal anastomosis. A flexible sigmoidoscopy is then performed to ensure that the anastomosis is patent, hemostatic, and healthy appearing, and an anastomotic leak test is conducted.

TABLE 50-4. Pros and cons in ulcerative colitis surgery

IRA	IPAA	TPC
+ Function	+ Low cancer risk	+ Cancer risk
+ One surgery	+/– Defecatory function	+ One surgery
+ Low risk of sexual/urinary dysfunction	– Risk of sexual/urinary dysfunction	– Permanent fecal diversion
– Recurrent disease	– Multiple surgeries	– Risk of sexual/urinary dysfunction
– Cancer risk	– Decreased fertility	– Decreased fertility

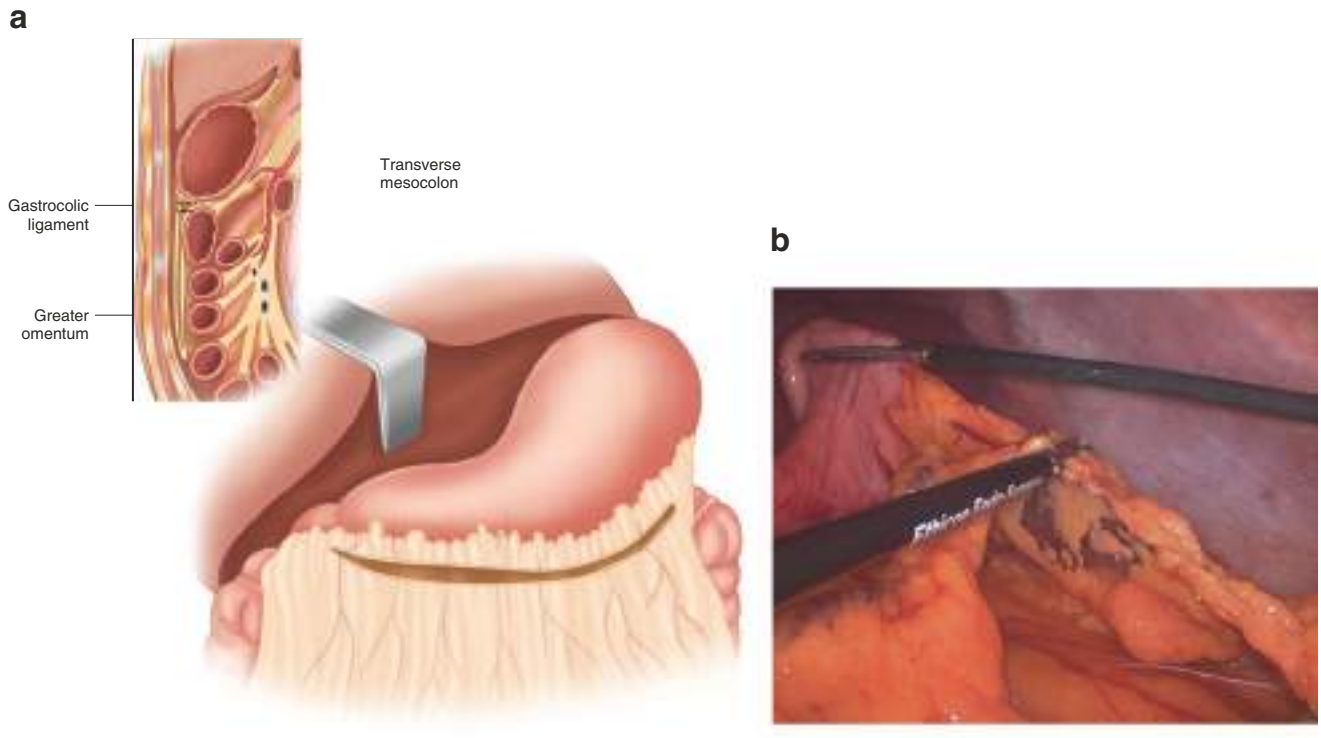

FIGURE 50-10. (**a** and **b**) The omentum is divided along the greater curvature of the stomach distal to the gastroepiploic arcade.

Operative Details: Laparoscopic Approach

The procedure is performed with the patient in the modified lithotomy position with the legs supported by stirrups and both arms tucked, ensuring that all pressure points are appropriately padded. An infraumbilical (supraumbilical for a hand-assisted procedure) port is placed via an open technique. The abdomen is explored with careful examination of the bowel for possible manifestations of Crohn's disease or the presence of malignancy and ability to perform the procedure laparoscopically is assessed. If a laparoscopic approach is feasible, then four additional trocars are placed in the right and left upper and lower quadrants for a straight laparoscopic procedure. If the surgeon elects to perform hand-assisted approach, two additional trocars in the bilateral lower quadrants and the hand-assisted port are placed via a Pfannenstiel incision about two fingerbreadths above the symphysis pubis.

The patient is then placed in the Trendelenburg position with the right side up. The cecum is retracted anterolaterally and the ileocolic artery and vein are identified (Figure 50-11). An incision is made just inferior to the vessels and a mesenteric window created. The duodenum should be visualized not only to avoid inadvertent injury but because it is an important landmark used to confirm correct identification of the ileocolic artery and vein. The vessels are then divided away from the origin if malignancy is not suspected. Mobilization continues superiorly, sweeping down the second portion of the duodenum and separating it from the posterior aspect of the transverse mesocolon (Figure 50-12). The dissection then continues laterally in the plane between the mesocolon and Gerota's fascia. The appendix is then retracted toward the splenic flexure and the lateral peritoneal reflection is divided from the cecum to the hepatic flexure until the site of medial mobilization is met (Figure 50-13). Care is taken to avoid injury to the duodenum.

Dissection continues with serial ligation and division of the transverse mesocolon and omentum caudal to the gastroepiploic arcade (Figure 50-14a, b). This mobilization may be aided by placing the patient in reverse Trendelenburg. In the presence of benign disease, the mesocolon can be ligated and divided close to the bowel wall with a vessel-sealing device. Through a combination of blunt and sharp dissection, the splenic flexure is mobilized ensuring no undue traction on the spleen (Figure 50-15a, b). The patient is placed with the left side up and the small bowel retracted toward the right side. The left mesocolon is serially ligated and divided and the left-sided peritoneal reflection is divided. The sigmoid colon is retracted medially and the lateral attachments of the sigmoid colon are incised taking care not to injure the left ureter or gonadal vessels. The sigmoidal branches are ligated and divided. Once the colon has been mobilized up to the rectosigmoid junction, it is extracted through a Pfannenstiel incision, the bowel is transected, and the anastomosis is created in the same way as the open approach.

Outcomes

In UC, an IRA is a safe procedure with a reported overall morbidity between 8 and 28 %[60–63] including small bowel obstruction, anastomotic leak, abdominal abscess, pulmonary embolism, sepsis, rectal bleeding, wound infection, abdominal wall dehiscence, urinary tract infection, transient urinary retention, hematoma, and stoma complication. In addition IRA does not involve extensive pelvic dissection, unlike IPAA or total proctocolectomy, minimizing the risk of sexual and urinary dysfunction. Hence, higher fertility rates may be expected in IRA patients compared to IPAA although definitive studies providing evidence for better fertility rates in UC patients are lacking. Nonetheless, IRA should be considered and discussed with women in their reproductive age [64].

Disease recurrence in the rectal remnant in continuity is significant and these patients should be monitored and followed up endoscopically. The cumulative probability of having a functioning IRA at 5 years has been reported as high as 84 % [63, 65], 69 % at 10 years [62, 65], and between 46 and 69 % at 20 years [64]. In the Cleveland Clinic series comparing 22 IRA with 66 IPAA patients matched for age, gender, and follow-up time, the cumulative probability of having a functioning IRA at 5, 10, 15, and 20 years was 81, 74, 56, and 46 %, respectively, in accordance with previously published work [60]. Functional results are typically described in terms of number of bowel movements and incidence of soiling or urgency. The Cleveland series of 22 IRA patients reported six bowel movements per day (range 2–11), 5 % incidence of nighttime seepage, and 68 % mostly/sometimes grade of urgency [60]. Pastore et al. described a median number of six bowel movements per day (range 2–20), with median number of one nocturnal bowel movement (range 0–10) among 90 patients undergoing total abdominal colectomy and IRA. Three patients had more than eight daily stools with frequent soiling and urgency. At the time of follow-up, antidiarrheal medications were taken by 53.3 % of patients, whereas 31.3 % required low doses of systemic or topical steroids. More than 90 % of patients considered that their health status had improved after the operation. Quality of life was improved in 84 % [63].

The main indication for proctectomy is recurrent proctitis refractory to medical management [60, 62, 63, 65], followed by dysplasia or cancer, and the development of Crohn's disease. Options for these patients include IPAA, Brooke ileostomy, or a continent ileostomy (Kock pouch). IPAA can often be safely performed in the majority of these patients, thus preserving bowel continuity and avoiding permanent fecal diversion [60]. Among 86 patients undergoing IRA for UC, 46 (53 %) required completion proctectomy for refractory proctitis

FIGURE 50-14. (**a** and **b**) Ligation and division of the transverse mesocolon and omentum caudal to the gastroepiploic arcade.

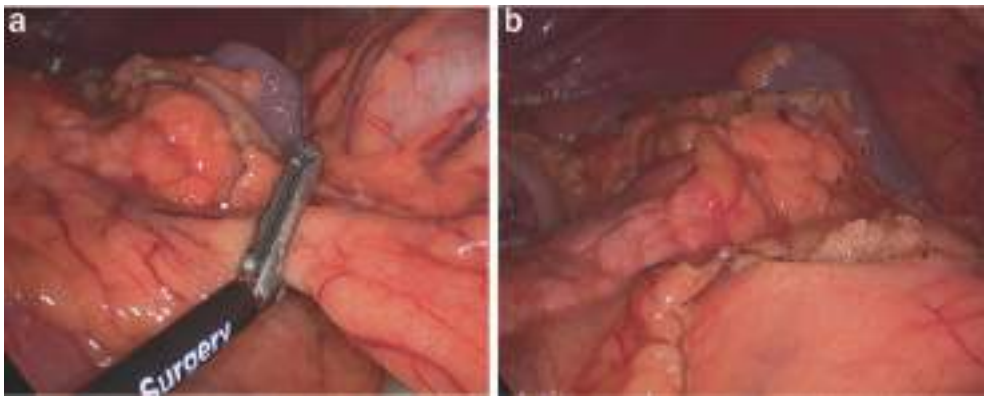

FIGURE 50-15. (**a** and **b**) Mobilization of the splenic flexure.

($n=24$), rectal dysplasia ($n=15$), and rectal cancer ($n=7$) at a median interval of 10 years (range 1–33) [60].

Endoscopic monitoring of the rectal remnant is essential given the high rate of disease recurrence, as well as the risk of dysplasia/cancer which increases with time. In the Cleveland Clinic series, the overall cumulative probability of rectal dysplasia in the retained rectum increases from 9 % at 10 years to 25 % at 20 years [60]. The overall incidence of rectal cancer after an IRA varies in the literature based on the length of follow-up, ranging from 0 to 8 %. In the Cleveland Clinic series, the incidence of cancer was 0, 2, 5, and 14 % at 5, 10, 15, and 20 years, respectively [60]. In the Scandinavian series, no cancer was reported at 13-year and 18-year follow-up, respectively [62, 65], thus emphasizing the importance of strict patient selection.

Most patients who develop rectal cancer in the retained rectum presented at an advanced stage (stages III–IV), suggesting the possibility of a more aggressive biology and making close surveillance imperative [60, 66]. Rectal biopsies every 6–12 months are advised following IRA in UC patients. If dysplasia is found, completion proctectomy is indicated. Patients with long-standing UC who are not able or willing to undergo surveillance should not be offered an IRA. It is also important to emphasize that colectomy with IRA should not be offered to patients with preexisting dysplasia or cancer due to the increased risk of further neoplastic degeneration [67]. However, patients with advanced metastatic disease may benefit from an IRA due to their short life expectancy and the palliative nature of their treatment.

Total Proctocolectomy with End Ileostomy

Proctocolectomy with Brooke ileostomy was the standard of care for the treatment of ulcerative colitis until the early 1980s when Utsonomiya popularized the IPAA [56]. While restorative proctocolectomy with IPAA with the intent of maintaining intestinal continuity is now the gold standard in the surgical management of UC, certain patients are not candidates for this procedure, typically due to patient or disease-related factors or personal preference (Table 50-5). Once these patients are referred to the surgeon with an indication for surgical intervention, they should be evaluated and offered a total proctocolectomy with a permanent ileostomy, or in certain circumstances an ileorectal anastomosis as discussed previously.

By removing all diseased epithelium, a proctocolectomy cures patient disease, eradicates the associated risk of malignancy, and eliminates the need for costly medications and time-consuming lifelong follow-up. The disadvantages of this operation include the presence of a permanent ileostomy, the potential for nerve injury during pelvic dissection, and

Table 50-5. Contraindication to IPAA

Absolute	Relative
Severe fecal incontinence	Severe morbid obesity
Locally advanced low rectal cancer involving the sphincters	Locally advanced low rectal cancer requiring neoadjuvant treatment
Perianal Crohn's disease	Crohn's disease
	Previous extensive small bowel resections
	Personal preference

IPAA—ileoanal pouch anal anastomosis

the risk of perineal wound healing problems. A proctocolectomy with an end ileostomy is indicated in patients who are not candidates for an IPAA (Table 50-5) or a Kock pouch. The operation may also be indicated if other medical problems make a more complex, longer operation too risky [68, 69]. Finally a total proctocolectomy should be considered in patients who desire a single operation for cure or whose work and other daily activities make an ostomy appliance easier to manage than frequent bowel movements.

There are no absolute contraindications to this procedure. However, in the emergent setting, it is advisable to stage the procedure with an initial abdominal colectomy. This strategy avoids the morbidity associated with rectal dissection, which can be potentially difficult and time-consuming in an unstable patient. This procedure can be performed through a laparotomy incision, single incision, hand or laparoscopic assisted, or totally laparoscopically as the authors have previously described [70]. There are no large studies comparing these approaches in this very selected group of patients. Intuitively, a totally laparoscopic approach should result in lower incidence of hernias, with the exclusion of parastomal hernias. As with an abdominal colectomy with ileorectal anastomosis, the choice of a minimally invasive or open approach is dependent on nature and severity of disease, previous surgical history, comorbidities, and surgeon experience.

Operative Details: Open Proctectomy

If the severity of disease or other patient factors necessitate a staged approach, the initial total abdominal colectomy proceeds as above, but rather than creating an ileorectal anastomosis, the rectal stump is left in situ and the terminal ileum is fashioned into an end ileostomy. The rectosigmoid is transected with a linear stapler at the sacral promontory (Figure 50-16). The staple line can be reinforced with interrupted Lembert sutures if there is increased concern for dehiscence, but this is not our common practice. A rectal tube is left in place for 5 days postoperatively to ensure adequate evacuation of rectal contents and decompression of the rectal stump. The proctectomy with or without ileal pouch can be performed several months later when the patient's overall health improves and they are no longer on medications.

Whether the rectal dissection is done at the same time as the colonic mobilization or as the second operation of a staged approach, the dissection begins with division of the terminal branches of the inferior mesenteric artery (the superior rectal arteries) and complete posterior mobilization of the rectum. Bilateral ureters and the sympathetic neural plexus, which lies directly posterior to the inferior mesenteric artery at the pelvic brim, are identified and swept free. The terminal branches of the inferior mesenteric artery and vein are ligated and divided at the level of the sacral promontory.

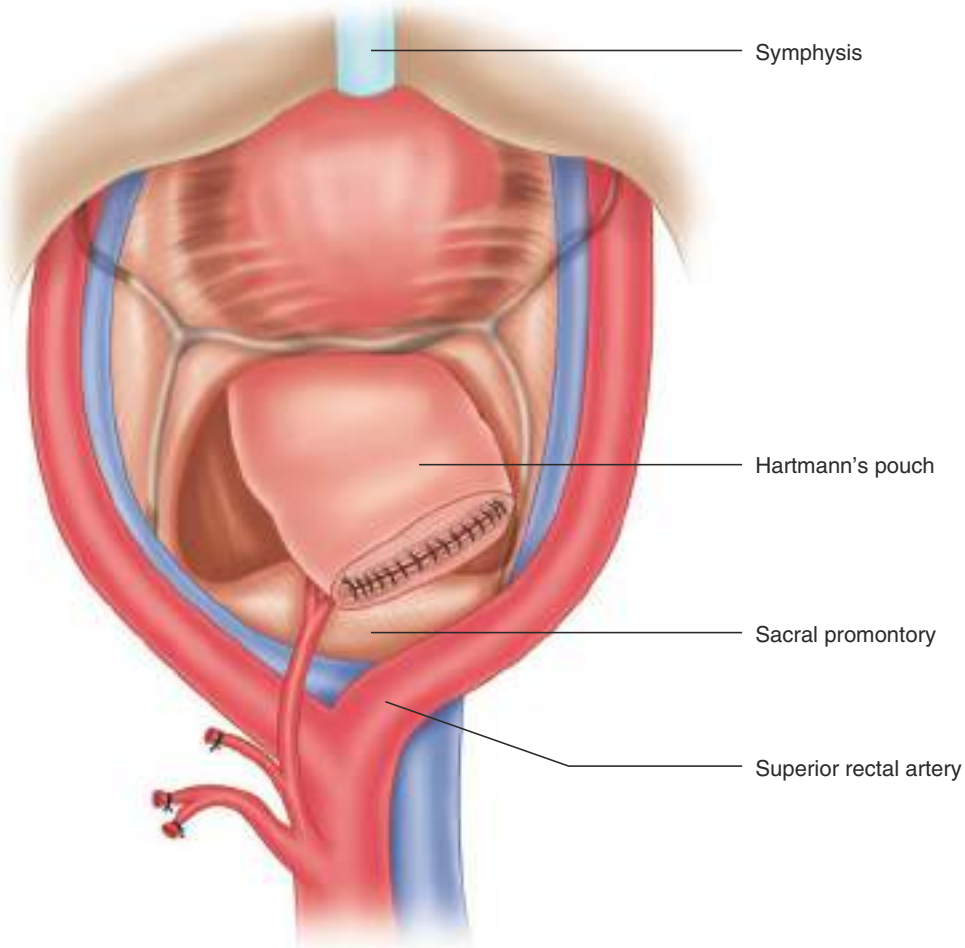
The parietal peritoneum is incised inferiorly and laterally to gain access to the presacral space between the fascia propria of the rectum and the presacral fascia. The rectum is retracted anteriorly and sharp dissection is carried out in the areolar tissue. Care must be taken to ensure that the presacral venous plexus remains covered to avoid bleeding that can often be difficult to stop and may be life-threatening. Dissection should be carried down in the posterior plane beyond the coccyx and Waldeyer's fascia is incised. The lateral rectal stalks are then divided as close to the rectal wall as possible to avoid injury to the pelvic plexus. Attention is then turned to anterior dissection in the rectovaginal or rectovesicular space posterior to Denonvilliers' fascia. At this point, the rectum should be circumferentially mobilized to the levator ani muscles. If the colectomy had not been done at a prior operation, the terminal ileum is transected at its junction with the cecum with a GIA stapler. Then the abdominal wound is closed, the ileostomy is created, and attention turned to the perineal dissection.

A pursestring suture is placed to close the anus at the level of the anal verge. A circular incision is made in the intersphincteric groove and carried through the subcutaneous tissue (Figure 50-17). The anococcygeal ligament is divided and the pelvic cavity is entered posteriorly. The incision is extended circumferentially mobilizing the entire distal rectum and anus. Care should be taken anteriorly to avoid injury to the vagina or prostate. The specimen is extracted through the perineal opening and the wound is then closed in layers (Figure 50-18).

Operative Details: Laparoscopic Proctectomy

As with the open approach, the rectal dissection begins with division of the terminal branch of the inferior mesenteric artery (the superior rectal artery). The rectal stump and distal sigmoid colon are retracted superiorly and anteriorly out of the pelvis exposing the inferior mesenteric artery (IMA). The peritoneum to the right of the superior rectal artery is

FIGURE 50-16. Distal transection at the level of the sacral promontory.



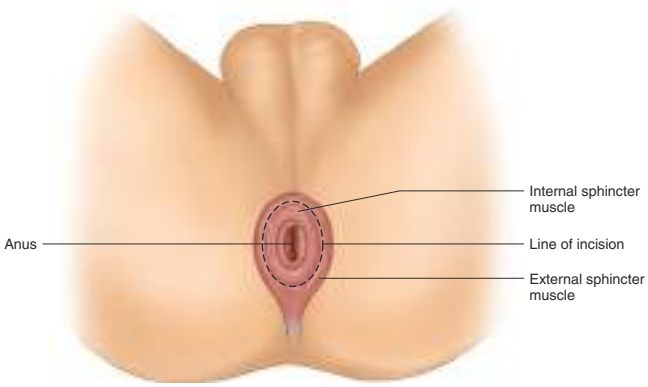


FIGURE 50-17. Perineal dissection—circular incision made along the intersphincteric groove.

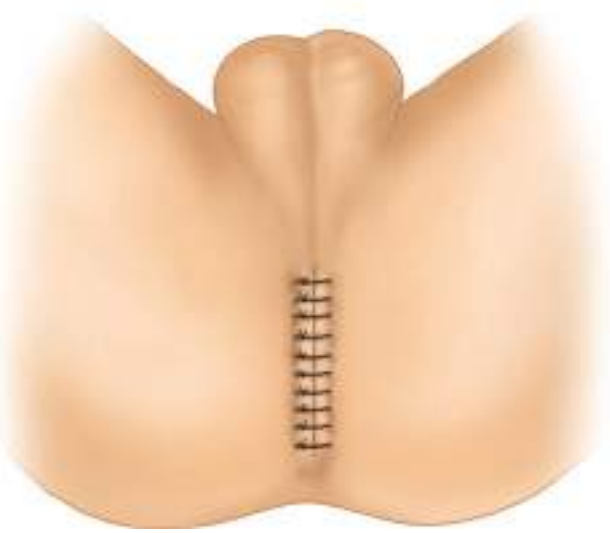

FIGURE 50-18. Closure of perineum.

incised starting at the sacral promontory and extending cephalad to the origin of the IMA. A mesenteric window is created allowing the visualization of the left ureter and gonadal vessels. The hypogastric nerves are swept posteriorly and the superior rectal artery is ligated and divided with a vessel-sealing device. The retrorectal space is entered and the rectum is completely mobilized circumferentially as above down to the pelvic floor. After ensuring no twisting of the bowel or mesentery, the cut edge of the ileum is brought out and the end ileostomy matured. The perineal dissection proceeds as above with the specimen brought out through the perineal incision.

Restorative Proctocolectomy with Ileal Pouch Anal Anastomosis

Before proceeding with an IPAA, fecal continence should be fully evaluated particularly in patients presenting preoperatively with impaired function. Multiparous women, particularly after multiple vaginal deliveries with episiotomies or lacerations, should be asked about their continence function. While it is important to note that continence significantly worsens in all patients during a flare, with multiple bloody and liquid bowel movements, the report of incontinence should be further discussed and investigated. A digital rectal examination performed by the operating surgeon often provides enough information to decide if evaluation by manometry and a rigid probe 3-D endoanal ultrasound should be entertained. Gearhart and colleagues [71] prospectively evaluated 42 women with anorectal manometry and endoanal ultrasound. All patients were continent at the time of evaluation. Endoanal ultrasound revealed significant sphincter defects in 19 patients, 4 of whom had involvement of both sphincters, as a result of an obstetric trauma. The findings of the endoanal ultrasound correlated with anal physiology studies which revealed significantly decreased resting pressures, squeeze pressures, and shorter anal canal length. All patients underwent an IPAA. The participants were surveyed postoperatively with the Cleveland Clinic Florida scale (Wexner score), Fecal Incontinence Severity Index (FISI), or Fecal Incontinence Quality of Life (FIQL) scale. The authors did not find a correlation between the size of the sphincter defect and postoperative incontinence. Almost all responders reported episodes of seepage. Three patients with sphincter defects (15.8 %) were dissatisfied with the functional outcome of the IPAA and said they would not undergo this procedure again. Finally 5 % of them underwent pouch excision. Given these outcomes among patients without reported preoperative incontinence, the existence of problems with defecation prior to surgery (incontinence, diabetic neuropathy, or other neurogenic disorders) should be considered a relative contraindication for IPAA.

Patients who present with very low rectal cancer requiring abdominoperineal resection for oncologic reasons obviously are not candidates for an IPAA. The standard oncologic principles for treatment of rectal cancer apply to rectal cancer in ulcerative colitis. Patients with stage II–III disease benefit from and should receive neoadjuvant chemoradiation therapy to decrease the risk of local recurrence and to increase the chances of achieving an R0 resection as previously shown by the Dutch and German rectal cancer trials [72, 73]. Neoadjuvant chemoradiation therapy does not represent an absolute contraindication to an IPAA for appropriate patients, but does clearly worsen long-term outcome. In a recent study from the Cleveland Clinic, pouch failure rate in rectal cancer patients was 42.9 % after radiation versus 17.6 % in patients who did not receive radiation [74]. A multidisciplinary approach to these patients is mandatory to balance oncologic principles, quality of life, and patient preference. Adjuvant radiation therapy should be avoided at all costs and it is typically not recommended or utilized [75, 76].

More than one-third (34.9 % or 78.6 million) of US adults are obese and the obesity epidemic has not spared the IBD population [77]. While studies from the Cleveland Clinic and other large volume centers have shown equivalent functional outcomes in obese patients undergoing IPAA [78], the authors consider morbid obesity a relative contraindication to immediate IPAA [79]. In a recent series from Washington University, obesity was associated with an increased risk of overall (80 % vs. 64 %, $p=0.03$) and pouch-related (61 % vs. 26 %, $p<0.01$) complications following IPAA [80]. In patients with an elective indication for surgery, performing an abdominal colectomy first as part of a staged approach has been proposed as a way for the patient to subsequently undergo weight reduction surgery before proceeding with the definitive restorative procedure. In the super obese (BMI>50) [81], this may never become an option given the time required for such a significant weight loss and therefore either permanent fecal diversion or abdominal colectomy with an ileorectal anastomosis should be considered. In order to avoid serious complications, increased hernia formation, and the need for multiple reoperations, with increased morbidity, mortality, and costs, meticulous preoperative evaluation using a strategic multidisciplinary team approach is mandatory. When safe to postpone surgery for a reasonable time, we have referred patients in our practice for weight reduction surgery in preparation for a procedure that could otherwise result in a permanent stoma. In these cases, laparoscopic gastric banding, or more recently a gastric sleeve procedure, has been performed given the need for these patients to maintain their entire intact small bowel for a successful IPAA. If the long-term use of corticosteroids is the primary reason for the increased BMI, they should undergo a staged procedure which allows them to discontinue corticosteroid therapy to facilitate weight loss. A goal of a BMI of ≤ 28 should be the target in mutual agreement with the patient

before proceeding for the IPAA in order to maximize the chances of a functional pouch and to avoid a permanent stoma.

Although advanced age was once considered a relative contraindication to IPAA, this has been reevaluated in the setting of optimized surgical and medical management and minimally invasive approaches [82, 83]. It is clear that IPAA can be safely offered to selected elderly UC patients who are strongly motivated and possess normal defecatory function. Their results seem to be stable over time and comparable to those of younger patients [83].

Operative Technique

If the patient is to undergo an RPC-IPAA, the resection of the colon and rectum is performed as described previously, but the rectum is divided with a TA stapler leaving a short rectal cuff. An ileal pouch can be created in the J, S, or W configuration (Figures 50-19 and 50-20), but the preference of the authors is the J-pouch construction.

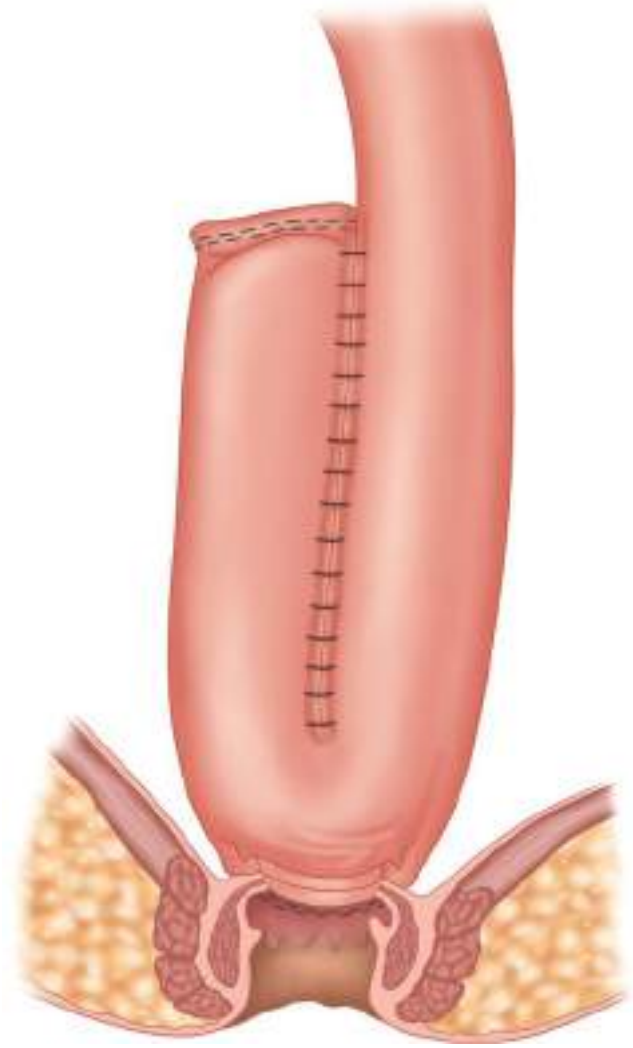

FIGURE 50-19. J-pouch configuration.

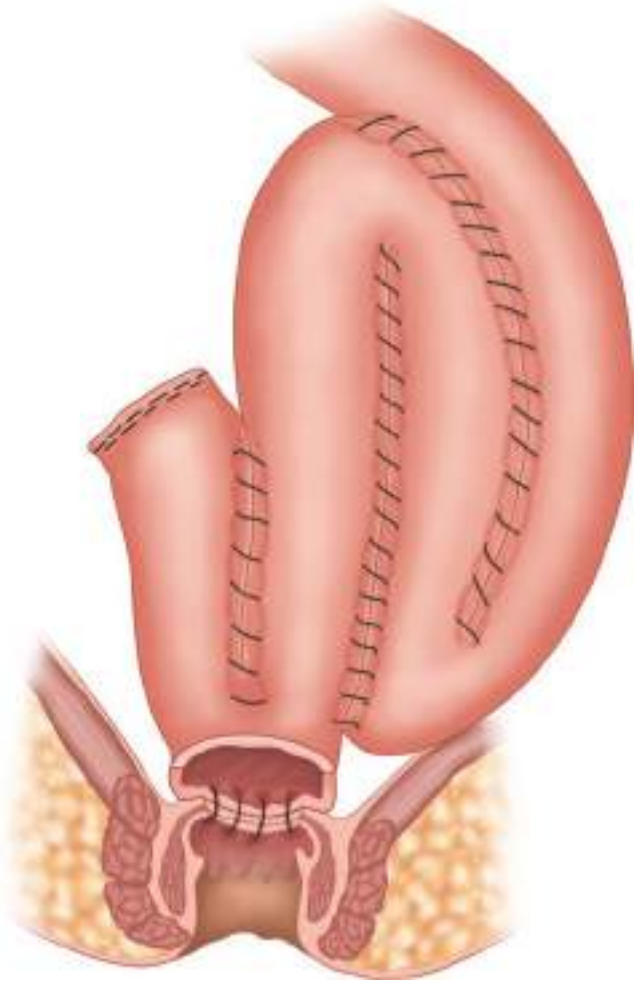

FIGURE 50-20. W-pouch configuration.

The length of the ileal J-pouch should be about 15–20 cm in length (Figure 50-21). The stapled end of the terminal ileum is oversewn with 4–0 silk Lembert sutures. After ensuring adequate blood supply to the terminal ileum, the apex of the pouch is chosen by bringing the ileum over the pubis and identifying the longest section of mesentery to enable a tension-free anastomosis. A stay suture is placed along the antimesenteric side of the apex. The two limbs are approximated and sutures are placed between the proximal and distal limbs at the ileomesenteric junction (Figure 50-22a, b). Corresponding longitudinal enterotomies are made on the proximal and distal limbs. Serial firings with a GIA stapler are used to create the pouch (Figure 50-23a, b) with care taken to ensure that the mesentery is not included in the staple line (Figure 50-24). The pouch is everted by gently applying Babcock clamps after each staple fire to aid in creating a common channel (Figure 50-25a, b). After the last firing (Figure 50-26a, b), the staple line is inspected for bleeding (Figure 50-27a, b) and the pouch reduced with gentle traction on the apical stay suture (Figure 50-28a, b, c). The anvil of an EEA stapler is brought out through the apex and secured in

FIGURE 50-21. J-pouch should be 15–20 cm in length.

place with a pursestring suture (Figure 50-29). The common enterotomy is closed in two layers (Figure 50-30). The EEA stapler is inserted transanally and after ensuring no twisting of the bowel or mesentery the ileoanal anastomosis is created. A flexible sigmoidoscope is then inserted to inspect the staple lines and perform an anastomotic leak test. It is our practice to divert patients with a temporary loop ileostomy for 3 months.

Special Considerations

Pouch Configuration

The introduction of restorative proctocolectomy and IPAA into clinical practice has improved quality of life in the majority of UC patients seeking surgical intervention for disease management. There have been several modifications of the technique since the original description by Parks and Nicholls [55] and Utsunomiya and Iwama [56]. Parks' initial ileal reservoir was a triple loop S-pouch, with a 5 cm long exit conduit, which created problems with emptying [55]. Subsequently the limb was shortened to less than 2 cm with significant functional improvement [84]. Currently, other pouch designs in use include the double loop J-pouch [56] and the quadruple loop W-pouch [85, 86]. The lateral isoperistaltic H-pouch is now of historical interest only [87]. Each pouch design has its own advantages, and while the J configuration is most commonly used currently due to relative technical ease and speed of performance [88, 89], there is a role for the other two in very selected situations. The S-pouch with the long exit limb allows for further reach in tall male patients with short mesentery [90], while the W-pouch has a large capacity and better compliance [85]. When comparing the W-pouch with either the S- [90] or the J-pouch [86, 91, 92] in the so-called "maturation period"(immediately following ileostomy closure), the W-pouch group patients have significantly less frequent bowel movements compared to either group. However, two randomized prospective trials comparing the J-pouch to the W-pouch did not confirm those findings and the two configurations had the same functional results at 1 year of follow-up [93, 94]. We prefer a J-pouch for the vast majority of our patients because of the lower complication rate and the excellent functional results in our hands [88, 89].

Anastomosis

The second topic of major controversy is the type of the anastomosis and the fate of the anal transition zone (ATZ), the so-called stapled ileal pouch distal rectal anastomosis versus a handsewn ileal pouch anal canal anastomosis with mucosectomy. The potential advantages of preserving the ATZ include preservation of the highly specialized anoderm, therefore better function; decreased trauma to the sphincter mechanism, therefore better continence; less tension on the anastomosis, therefore fewer septic complications; ease of construction, therefore shorter operative times. The disadvantages include the theoretical risk of malignant degeneration of the rectal cuff mucosa. We will discuss the functional results and the risk of neoplastic degeneration separately.

The initial descriptions of IPAA included a mucosectomy to the dentate line [55, 56, 95]. The dilatation necessary for complete mucosectomy [96] or the eversion of anorectum used at that time to facilitate mucosal removal [97, 98] caused significant decrease in the maximum resting pressure [96] and increase of the threshold sensation, which correlated with an increased number of episodes of incontinence [97, 98]. Avoidance of extensive manipulation of the anal sphincter complex limits the degree of trauma. Furthermore, the ATZ retains some of the anoderm sensory capacity, which together with the rectoanal inhibitory reflex allows for the sampling of rectal contents resulting in improved continence, whereas mucosectomy results in loss of this

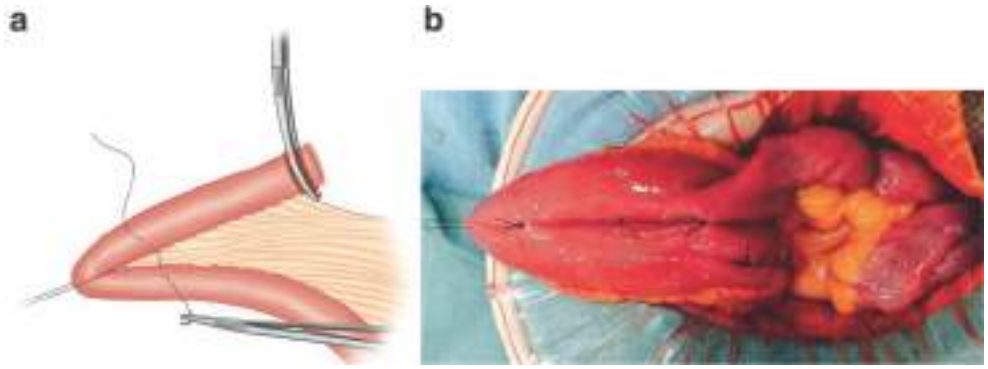

FIGURE 50-22. (**a** and **b**) A stay suture is placed along the antimesenteric aspect of the apex of the pouch. Additional sutures are placed between the two limbs of the J-pouch at the ileomesenteric junction.

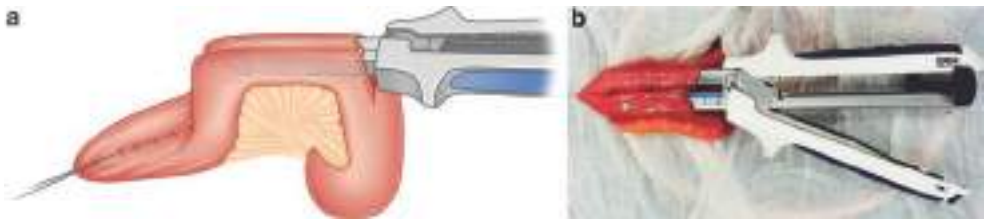

FIGURE 50-23. (**a** and **b**) Corresponding longitudinal enterotomies are created on the proximal and distal limbs of the pouch and the forks of a gastrointestinal stapler are gently inserted into each limb.

FIGURE 50-24. Care is taken to ensure that the mesentery of the ileum is not incorporated into the staple line.

sensation [99]. Several comparative long-term studied have reported better functional results for the stapled IPAA [100–104]. We compared patients with a mucosectomy with patients with intact ATZ and found that even in the presence of chronic inflammatory changes, patients with an intact ATZ have significantly better continence, defecatory function, satisfaction, and quality of life [57]. Gemlo et al. [100] evaluated 235 patients with a mean follow-up of 70 months and found that elimination of a mucosectomy dramatically reduced nocturnal major incontinence, nocturnal minor incontinence, daytime minor incontinence, and daytime pad use. Sagar et al. [104] studied anal physiological results in 20 patients up to 12 months after stapled IPAA. After an initial decrease, at 12 months, resting anal pressure was almost normal, the rectoanal inhibitory reflex was present in 19 patients, and sampling was observed in 17 patients. The compliance and capacity of the reservoir increased significantly. Ability to discriminate flatus from feces was associated with return of the rectoanal reflex and sampling. When the theoretical advantages of a stapled IPAA over a handsewn anastomosis with mucosectomy were evaluated in a prospective randomized fashion, no difference in functional results was noted [105–107]. However, these studies did not examine long-term function and conclusions are difficult to make based on this short follow-up and are limited by inadequate power to detect small differences. Surgeons in favor of stapled IPAA often point to a greater rate of anastomotic complications after mucosectomy and handsewn IPAA. Preserving a short rectal cuff lessens the tension on the anastomosis, supposedly reducing anastomotic complications. The Cleveland Clinic group evaluated 692 patients, 238 with handsewn IPAA and 454 with stapled IPAA. In the handsewn IPAA group, 25 patients (10.5 %) had 32 septic complications, and 24 required 89 reoperations. In seven patients, the pouch was excised. In the stapled IPAA group, 21 patients (4.6 %) had 23 septic complications, and 14 required 40 reparations. One patient needed pouch excision [108]. Again, when the complication rates were evaluated in a prospective randomized fashion, no difference was noted [105–107]. Beyond functional considerations, there are concerns regarding preservation of inflamed rectal mucosa

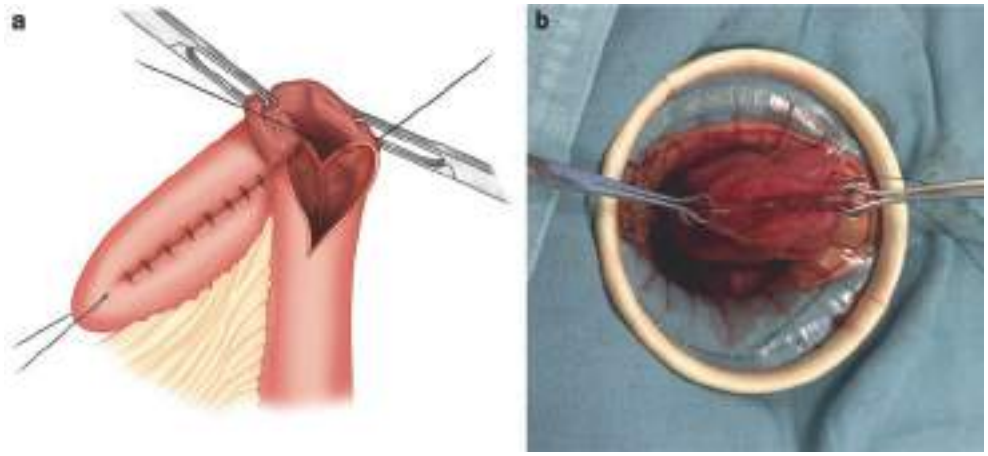

FIGURE 50-25. (**a** and **b**) The pouch is everted with the gentle application of Babcock clamps along the staple line until the intact apical septum is reached.

and associated persistent symptoms associated [109, 110]. The Cleveland Clinic group noticed that in their series symptomatic inflammation of the retained mucosa occurred in 14.7 % of patients; 4.1 % of patients had inflammation of the anal canal alone, and 10.6 % had pouchitis. Surgical intervention was required in 12.9 % of the total patients with isolated anal canal inflammation and 10.6 % of those with anal canal inflammation plus pouchitis [109, 110]. These patients are usually treated with topical steroids or 5-ASA. If medical management fails, a transanal mucosectomy with ileal pouch advancement is performed with excellent results [109]. When we looked at our stapled IPAA patients with chronic inflammatory changes, we found that their function was still superior to their mucosectomy counterparts, with minimal symptoms of cuffitis and no surgical interventions required at 36 months of follow-up [57, 58].

These outcomes may be explained by the shorter anal cuffs retained in patients undergoing laparoscopic operations.

Advocates of the mucosectomy argue that the entire diseased anorectal mucosa, including the ATZ, must be removed to eliminate the risk for future dysplasia and cancer. Anatomic studies have shown that actual microscopic extent of the ATZ is highly variable. Fenger [111], using Alcian blue staining, found that the mean span of the ATZ was 8.9 mm (range 0–20 mm), starting up to 6 mm below the dentate line. Thompson-Fawcett et al. [112] measured the ATZ by two techniques: whole-mount Alcian blue staining and a computer map of the histological findings based on longitudinal sections taken every 3 mm. They found that the Alcian blue technique overestimates the length of the ATZ, which usually commences just above the dentate line. The median length of the ATZ measured from computer maps of the histology was only 4.5 mm. Due to this variability, mucosectomy does not reliably remove the entire rectal mucosa [113]. Small islets of residual rectal mucosa have been identified in up to 14 % of patients and in 7 % it was located at the actual ileoanal anastomosis [113]. To determine the long-term risk of dysplasia and cancer in the retained mucosal cuff after stapled IPAA, the Cleveland Clinic group published their series of 210 patients with at least 5 years (median 77 months) of follow-up [114]. Dysplasia developed in seven patients (3.3 %) at a median of 11 months postoperatively. Patients with history of cancer or dysplasia in the colon or rectum were at a higher risk of developing dysplasia. Two patients, each with low-grade dysplasia detected on three separate occasions, underwent mucosectomy 29 and 38 months after detection of low-grade dysplasia, but no cancer was found. The five other patients with dysplasia on one or two occasions were treated expectantly and were dysplasia free for a median of 72 months. More importantly, preservation of ATZ did not lead to the development of cancer after 5–10 years of follow-up. The authors recommend long-term surveillance to monitor dysplasia, and if repeat biopsy confirms persistent dysplasia, mucosectomy with pouch advancement was advised [114]. When we looked at our experience with preservation of the ATZ in patients without dysplasia or cancer at the time of surgery, we found no evidence of subsequent dysplasia or cancer in 225 patients over a 36-month follow-up period. Our results suggest that in selected patients, i.e., without dysplasia or cancer, the preservation of the ATZ is safe [57, 58]. We have subsequently changed our surveillance protocol for patients with preserved ATZ from 1- to 3-year intervals [57, 58]. We believe that there is a role for both procedures in clinical practice. We preserve the ATZ in older patients with borderline sphincter function and in tall obese male patients to decrease tension on the anastomosis. Mucosectomy is otherwise advised in the presence of high-grade rectal dysplasia or cancer, in the pediatric population [115], and in patients with primary sclerosis cholangitis known to have a high risk of dysplasia and cancer [116].

Optimizing Reach

An anastomosis between the ileal pouch and anal canal performed under tension is associated with increased risk of dehiscence with severe short-term and long-term sequelae [117]. Described approaches for improving reach include leaving the pouch unattached in the pelvis, diverting the patient proximally, and returning at a later date for pouch anastomosis. Few studies have evaluated and compared the several reported techniques for lengthening the small bowel mesentery, including complete small bowel mobilization to the origin of its mesentery, ileocolic vessel ligation close to their origin from the superior mesenteric pedicle, and transverse mesenteric relaxing incisions [118]. These strategies facilitate a tension-free IPAA in most cases. In our practice, we have found that utilization of a staged approach is the best strategy to avoid finding ourselves in such a situation where the pouch does not reach the pelvic floor or the tension on the anastomosis is causing ischemia. By optimizing body weight, tissue characteristics, and general medical conditions, we have almost eliminated the need for mesenteric lengthening from our practice. For patients with an extremely short mesentery, an alternative strategy has been described by Goes et al. [119]. Multiple vascular ligations are performed between the right colon wall and the marginal vascular arcade, while the right branch of the middle colic artery is preserved and provides the blood supply to the ileal branch of the ileocolic artery. The right colic and ileocolic arteries at their origin and the superior mesenteric trunk at its distal third are divided. This technique is time-consuming and technically challenging and can lead to pouch ischemia, but it offers additional length in extreme situations.

Crohn's Disease

Ileal pouch surgery is contraindicated in patients with Crohn's colitis [120, 121]. Despite significant effort to correctly diagnose patients before surgery, some patients undergo surgery with a preoperative diagnosis of indeterminate colitis or ulcerative colitis and are found to have Crohn's disease on final pathological evaluation of the specimen. Sagar et al. [122] and Deustch et al. [123], in two separate unselected series, reported a pouch failure rate of 45 % at 10 years in patients with a preoperative diagnosis of mucosal ulcerative colitis who were subsequently proven to have Crohn's disease. In another series [124], only one of nine patients with preoperative clinical features suggestive of Crohn's disease had a functioning pouch, with complications consistently occurring within months of ileostomy closure. In contrast, 15 of 16 patients without preoperative features of Crohn's disease had maintained their pouch, generally with good results. These studies suggest that the pelvic pouch procedure should not be performed in patients with preoperative clinical features of Crohn's disease. However, it is possible that there is a subgroup of patients with Crohn's colitis who might be candidates for an ileal pouch procedure.

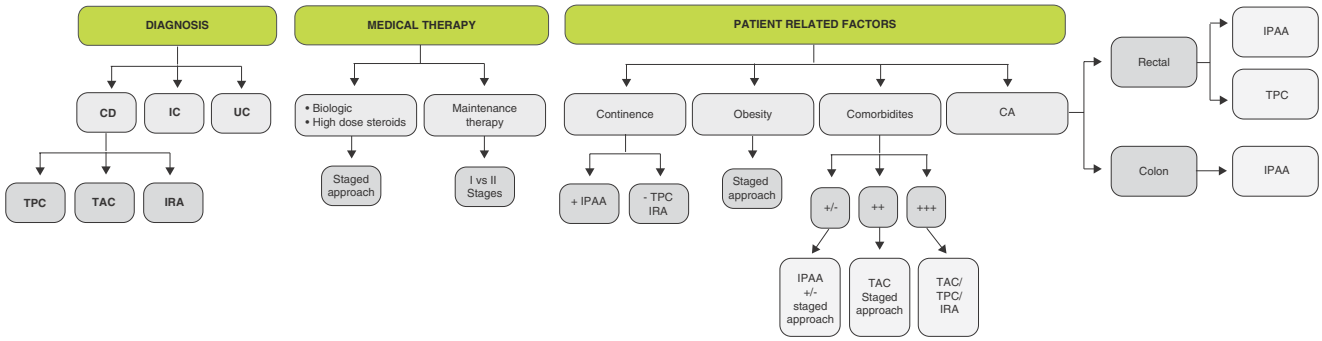

FIGURE 50-31. Algorithm showing the management of Ulcerative colitis. *CD* Crohn's disease, *IC* Indeterminate colitis, *UC* Ulcerative colitis, *TPC* Total proctocolectomy, *TAC* Total abdominal colectomy, *IRA* Ileo-rectal anastomosis, *IPAA* Ileal pouch anal anastomosis, *CA* Cancer.

Panis et al. [125] reported a series of 31 patients with Crohn's disease with no evidence of perineal or small bowel disease who were specifically selected for ileoanal pouch as an alternative to ileostomy. Of the 31 patients, only six (19 %) experienced specific complications 9 months to 6 years after surgery, and at the 5-year follow-up, there was no significant difference between patients with Crohn's disease and patients with ulcerative colitis in terms of stool frequency, continence, gas/stool discrimination, leak or need for protective pads, and sexual activity. In the future, more sophisticated diagnostic tests may allow selection of a subgroup of patients with Crohn's disease appropriate for ileal pouch procedures. At present, we do not offer IPAA in our practice to patients with preoperative clinical features of Crohn's disease.

The algorithm in Figure 50-31 shows the management of ulcerative colitis.

Complications of the Ileal Pouch

Daniel L. Feingold and P. Ravi Kiran

Key Concepts

- Pelvic sepsis after pouch surgery is associated with worse function and risks pouch failure. However, prompt management of early postoperative septic complications can preserve pouch function and increase pouch retention rates.
- Technical challenges during pouch surgery include ensuring tension-free reach, preserving adequate blood flow to the pouch, and creating an appropriate diverting ileostomy.
- A three-stage approach is recommended for patients who are malnourished, have severe active colitis, or are under treatment with larger doses of steroids or immunosuppressive medications in order to reduce pouch-related complications.
- The potential diagnosis of Crohn's disease should be considered in any patient presenting with fistulizing disease after pouch surgery as this affects management and prognosis.
- Repeat ileal pouch-anal anastomosis using a revised pouch or a new pouch is a reasonable option for selected patients with pouch failure.
- Mucosectomy at the time of a pouch-anal anastomosis does not prevent future dysplasia or cancer as islands of rectal mucosa may persist.
- Women with ulcerative colitis who undergo total proctocolectomy have a higher rate of infertility than women treated non-operatively, although a laparoscopic approach may reduce this risk.

Introduction

Ileal pouch-anal anastomosis (IPAA) is the preferred method for restoring gastrointestinal tract continuity after total proctocolectomy. While the majority of patients recover uneventfully from this operation, a proportion of patients develop complications that are unique to this procedure and deserve specific consideration. Complications after pouch surgery can be grouped into septic versus non-septic-related complications (including mechanical issues); alternatively, IPAA complications can be conceptualized as intraoperative, early postoperative, and late postoperative (Table 51-1).

Pouch-related complications can significantly affect functional outcomes and patients' quality of life, require multiple corrective procedures, and result, ultimately, in pouch failure [1]. Understanding the possible pouch-related complications and consideration of these complications in the operating room during pouch creation can reduce the incidence of these adverse events. In the postoperative setting, it is important to promptly address complications to better preserve pouch function and to reduce the risk of pouch failure which may be defined as the need for construction of a permanent stoma with or without excision of the pouch [2].

Modifying risk factors and focusing on preoperative planning details can potentially reduce the incidence of complications after pouch surgery and hence facilitate pouch function and preservation. Preoperative risk factors associated with pouch failure include type of resection (performing a completion proctectomy rather than total proctocolectomy), type of anastomosis (hand-sewn rather than stapled), diagnosis of Crohn's disease, and comorbidities [3]. Modifying risk factors to minimize risk of pouch failure should include appropriate medical management leading up to pouch surgery, expeditious surgical management to avoid needing urgent total abdominal colectomy with subsequent completion proctectomy, and medical optimization of comorbidities. Body mass index greater than 30 is also associated with septic complications after IPAA and obese patients should be counseled appropriately in advance of pouch surgery [4]. In fact, it may be reasonable to perform an initial abdominal colectomy to allow control of disease and achieve weight loss prior to proctectomy and IPAA.

In an effort to minimize the complications after a pouch procedure, it is important to individualize the operative plan to each patient. Deciding whether or not to operate in stages is one such

TABLE 51-1. Complications of the ileal pouch

Intraoperative	Problems with reach of the pouch
	Pouch ischemia
	Problems with stoma creation
	Problems with staplers and creating the anastomosis
Early postoperative	Anastomotic leak and pelvic sepsis
	Bleeding from the pouch
Late postoperative	Pouch-vaginal fistula
	Pouch-perineal fistula
	Pouch sinus
	Crohn's disease after pouch surgery
	Incontinence
	Outlet obstruction
	Pouchitis and cuffitis
	Pouch prolapse
	Leak from the tip of the "J"
	Dysplasia and cancer after pouch surgery
	Small bowel obstruction
	Sexual dysfunction
	Infertility

consideration that may impact the risk of complications. While well-nourished patients of average build with mild colitis who are not maintained on immunosuppressive medications may be candidates for single-stage procedures, this option is rarely utilized as a leak from an unprotected IPAA can have devastating complications including loss of the pouch. The vast majority of IPAA patients who do not undergo a three-stage procedure will undergo a two-stage procedure whereby the pouch is defunctionalized by a loop ileostomy (Figure 51-1). Patients who are malnourished, have severe active colitis, or are under treatment with larger doses of steroids or immunosuppressive agents are recommended to undergo a three-stage procedure in an effort to reduce the risk of complications. When the type of colitis based on colonoscopic biopsy is unclear preoperatively, an initial subtotal colectomy may help ascertain the diagnosis of Crohn's disease and determine the suitability of a pouch at the subsequent operation.

Another factor to consider when individualizing patient care in anticipation of an IPAA deals with the use of biologics. The findings of single-institution studies, confirmed by meta-analysis, demonstrate that patients with ulcerative colitis receiving infliximab, an antitumor necrosis factor-α antibody, are at particular risk for developing post-IPAA septic complications; a planned three-stage approach needs to be considered in this situation [5, 6]. This is especially true if the patient had experienced poor control of the disease despite aggressive medical management with these agents.

Another potential modifiable factor related to pouch complications deals with the use of radiotherapy prior to IPAA. Preoperative pelvic radiation in the setting of colitis-associated cancer is associated with an increased risk of subsequent pouch failure [7]. Oncologic benefits and anticipated pouch function should be carefully considered before proceeding with neoadjuvant radiotherapy in patients planning restorative proctocolectomy.

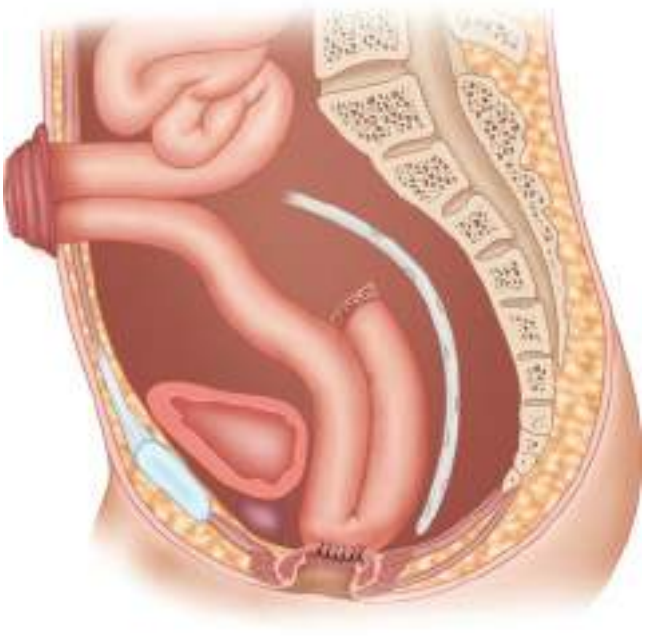

FIGURE 51-1. Ileal "J" pouch-anal anastomosis with defunctioning loop ileostomy.

Excessive weight gain (greater than 15 % increase) after ileostomy closure in patients with inflammatory bowel disease is also associated with pouch failure, though the underlying mechanism is not clear [8]. Counseling patients regarding appropriate weight control after restoring intestinal continuity may help improve pouch retention.

Intraoperative Complications

The two most common configurations currently used for IPAA are the "J" and "S" pouches which can be anastomosed via stapled or hand-sewn technique (Figure 51-2). While most primary ileoanal pouches are constructed in "J" fashion (20 cm long) and are stapled to the IPAA, the decisions to use one configuration over another and to staple or hand-sew are based on personal preference and unique patient factors [9]. The option of a planned mucosectomy with a hand-sewn IPAA is, in general, reserved for patients undergoing redo IPAA, with high-grade dysplasia or cancer involving the distal rectum, or those with familial adenomatous polyposis with polyps carpeting the distal rectum. In cases where a mucosectomy and hand-sewn IPAA are planned, an "S" configuration may fit through the pelvic floor anatomy better than a "J" pouch which can become distorted, especially in men with a long anal canal [10]. When creating the IPAA, it is critically important to avoid tension across the anastomosis, to maintain correct orientation of the pouch coming down to the low pelvis, to preserve the blood supply to the pouch and the residual anorectum, and to avoid incorporating nearby pelvic structures like the vagina, prostate, and seminal vesicles into the anastomosis.

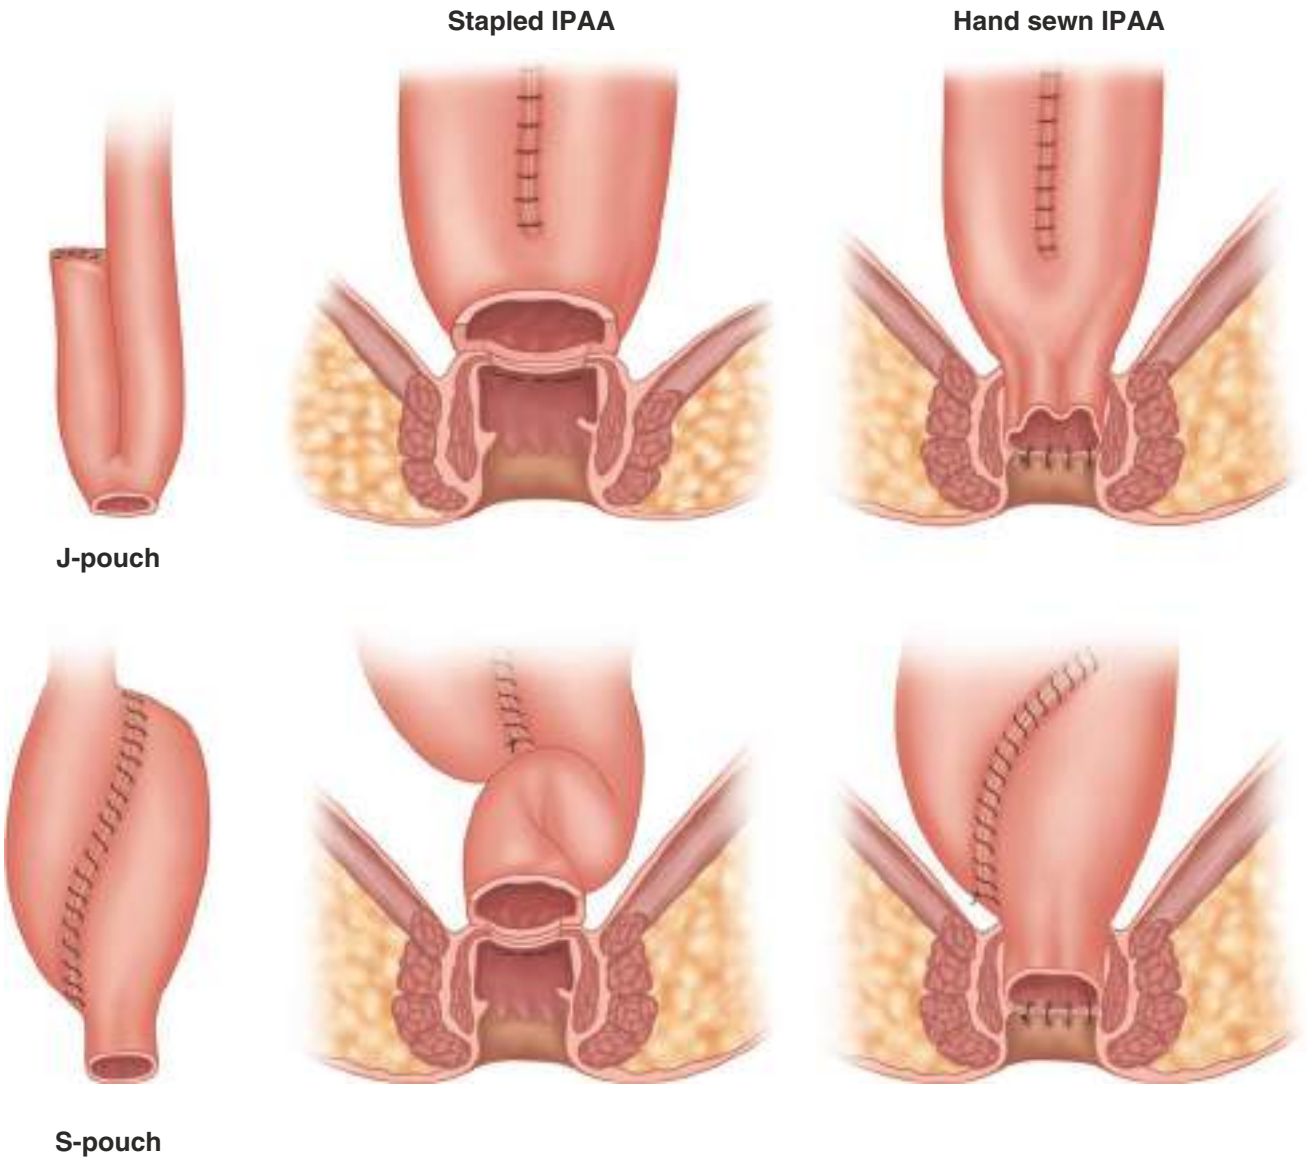

FIGURE 51-2. The "J" and "S" pouch configurations used in stapled and hand-sewn anal anastomoses.

Problems with Reach of the Pouch

Ensuring adequate reach of the pouch to the pelvic floor can be difficult and represents one of the more technically challenging aspects of a pouch procedure that can jeopardize the ability to create an IPAA and can directly impact the risk of postoperative complications. Tall patients, those with a high BMI, and patients with extensive previous abdominal or pelvic operations are particularly at risk for encountering a problem with reach. Weight loss in anticipation of surgery may be helpful. Maneuvers in the operating room that are routinely employed to facilitate reach include high ligation of the ileocolic vessels, complete release of the small bowel mesentery from the retroperitoneum, mobilization of the duodenum, and excision of the redundant mesenteric tissue lateral to the superior mesenteric vessels ("jib-sail"). Releasing incisions across the mesentery perpendicular to the small bowel mesenteric vessels supplying the pouch can also provide added reach (Figure 51-3). While sacrificing branches of the SMA or even the main trunk of the SMA may be required to improve reach, these maneuvers can compromise the blood flow to the pouch and are rarely required.

Difficulty with reach of the pouch can be anticipated before rectal transection by using a long Babcock forceps to simulate the reach of the most dependent part of the bowel to be used in the creation of the pouch and delivering this bowel down into the pelvis (Figure 51-4). Manual palpation through the anal canal helps determine the anticipated reach of the mobilized bowel. This exercise, best done prior to completing the proctectomy, can alert the surgeon that there may be a reach issue and the operation can be modified to increase the chance of a successful IPAA. In cases where reach remains a problem despite implementing the maneuvers described above, it may be helpful to orient the pouch coming down to the IPAA with

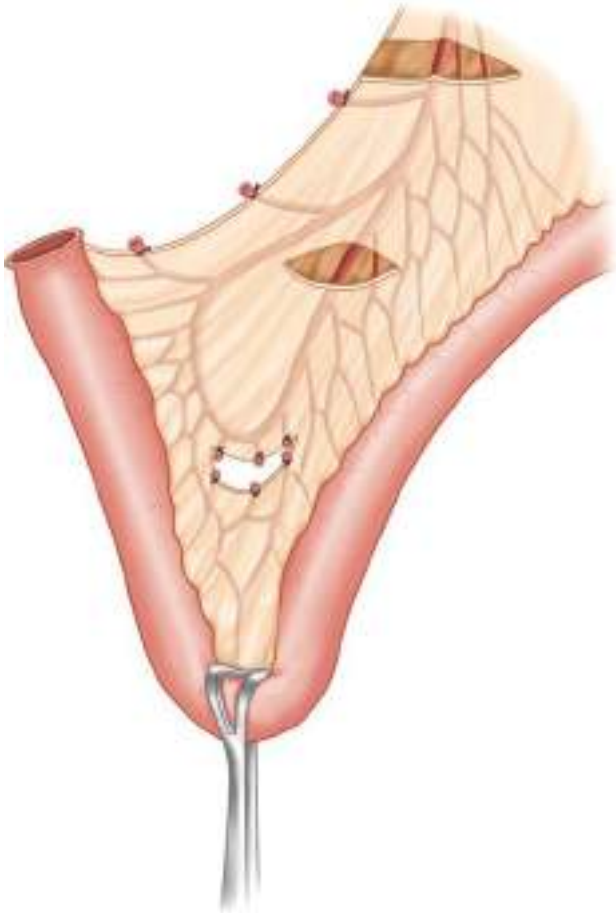

FIGURE 51-3. Lengthening of the ileal mesentery in anticipation of "J" pouch construction. The peritoneum is scored to provide additional reach. Selective ligation of the mesenteric arcade can also reduce tension; transillumination of the mesenteric fat can be helpful.

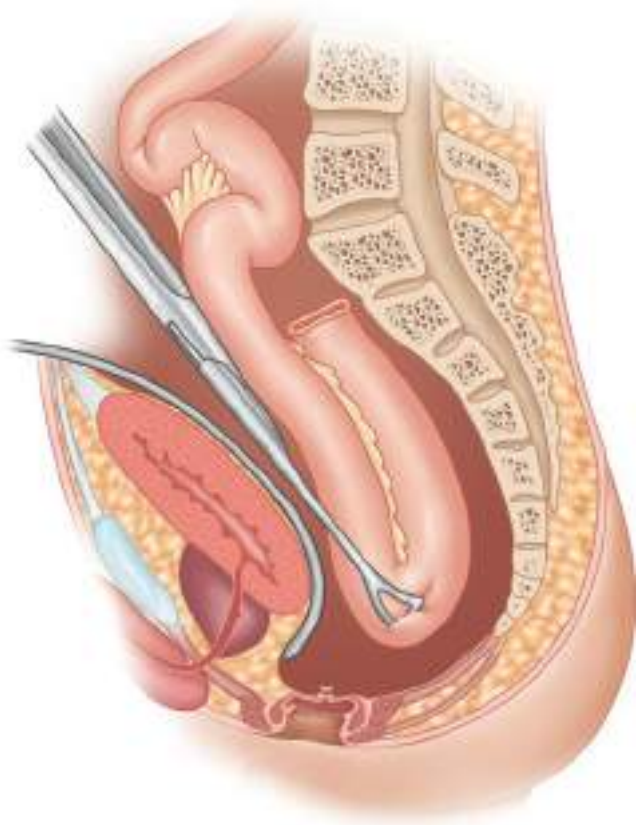

FIGURE 51-4. Simulating the reach of the "J" pouch to the level of the anastomosis.

its mesentery oriented anteriorly as this can release tension across the tissues. In certain circumstances, and where the pathology permits, the rectal stump may intentionally be left slightly longer in order to minimize tension at the IPAA. If a "J" pouch cannot reach appropriately, changing to an "S" configuration may be advisable as this adds approximately 2 cm of extra reach to the IPAA. In rare cases where a pouch is created and insufficient reach cannot be remedied, it is recommended to secure the closed pouch to the pelvis and create a defunctioning ileostomy; this maneuver may allow the pouch to lengthen over time in anticipation of repeat attempt at IPAA.

Pouch Ischemia

In an effort to provide reach, care should be taken to avoid overzealous skeletonization of vessels within the small bowel mesentery which can result in ischemia. The pouch blood supply can also be injured by direct trauma while scoring the mesentery or by creating a traction injury across the mesentery by creating an IPAA with excessive tension. Twisting the pouch around its mesentery as it is brought down to the IPAA can affect arterial inflow and venous outflow causing ischemia or bowel obstruction and should be avoided. Confirming correct orientation of the pouch by following the cut edge of the ileal mesentery from the mobilized duodenum to the IPAA can help prevent twisting of the pouch. Pouch ischemia requires pouch excision and an attempt at creating another pouch.

Problems with Stoma Creation

Creating a defunctioning loop ileostomy for an IPAA patient can be challenging especially in patients with difficult reach or a high BMI because the ileal mesentery is fixed at the root of the SMA and at the low pelvis and this can restrict the surgeon's ability to exteriorize the bowel. One possible option available to facilitate stoma creation and minimize tension across the IPAA is to defunctionalize using a more proximal segment of the bowel. Patients diverted in this fashion need to be monitored for high ostomy output. Anticipating diversion difficulties and discussing potential strategies to address these with the patient allows for setting more realistic expectations and highlights the importance of individualized operative planning requisite for pouch surgery. These strategies may include

mandating weight loss prior to surgery, trading off the ideal stoma location for one that is functionally better, and instituting a medical regimen early on to preempt high output stoma issues.

Problems with Staplers and Creating the Anastomosis

Once the pouch has been created and prior to bringing the pouch down to the pelvis, insufflating the opened, distal end of the pouch with an air-filled bulb syringe as a leak test will alert the surgeon to any structural issues that need to be addressed. Prior to firing the circular stapler, it is important to exclude nearby pelvic structures from being incorporated into the stapler mechanism. This requires a combination of careful assessment of the field through the abdomen and also a digital exam from below confirming the vagina is free. When performing a stapled IPAA, like any low pelvic anastomosis, mechanical circular staplers are prone to misfire; an on-table pouchoscopy after creating the IPAA is needed to check the integrity of the anastomosis and the health of the pouch [11]. Although a misfiring is disheartening, the situation is usually salvageable.

When a defect in the anastomosis is detected, adequate assistance to facilitate the necessary retraction and exposure allowing access to the field from the abdomen and the perineum is needed. The specific management in this situation depends on the location, size, and cause of the staple line defect. For a small dehiscence, a defunctioning stoma may be sufficient to allow healing. In this situation, attempt at suture closure through an abdominal or trans-anal approach should be considered. In the case of a major dehiscence due to stapler misfiring or possibly from a breach in the cuff staple line from inserting the circular stapler too far, the IPAA may have to be taken down and redone. In this situation, once the pouch is brought up from the pelvis, an assessment of the structure and reach of the pouch as well as of the length and condition of the anal canal is performed. In some situations it may be possible to place a purse string to close the remaining rectal cuff to allow repeat stapling, but typically a mucosectomy with hand-sewn IPAA will be required.

Early Postoperative Complications

Complications related to the anastomosis and pelvic sepsis can affect the long-term function of the pouch. Prompt diagnosis and management of these complications is required to preserve pouch function.

Anastomotic Leak and Pelvic Sepsis

Pelvic sepsis related to pouch surgery is loosely defined as an abdominopelvic or perianal infectious process detected by clinical, radiologic, or operative means within 3 months of IPAA creation or within 3 months of stoma reversal. Depending on the manifestations and severity of the infection, this can be a significant complication associated with worse functional outcomes, diminished quality of life, and, potentially, pouch failure [1].

An anastomotic disruption may be an isolated finding discovered incidentally on pre-stoma reversal evaluation or can present clinically with pelvic sepsis. While patients with a pelvic abscess usually exhibit the expected signs and symptoms of infection, some IPAA patients have a more indolent presentation with persistent ileus or fail to meet expected recovery milestones after the surgery. Patients with hemodynamic instability and peritonitis require operative exploration to evaluate the anatomy, washout the field, and effect drainage (Figure 51-5). Patients with less impressive clinical

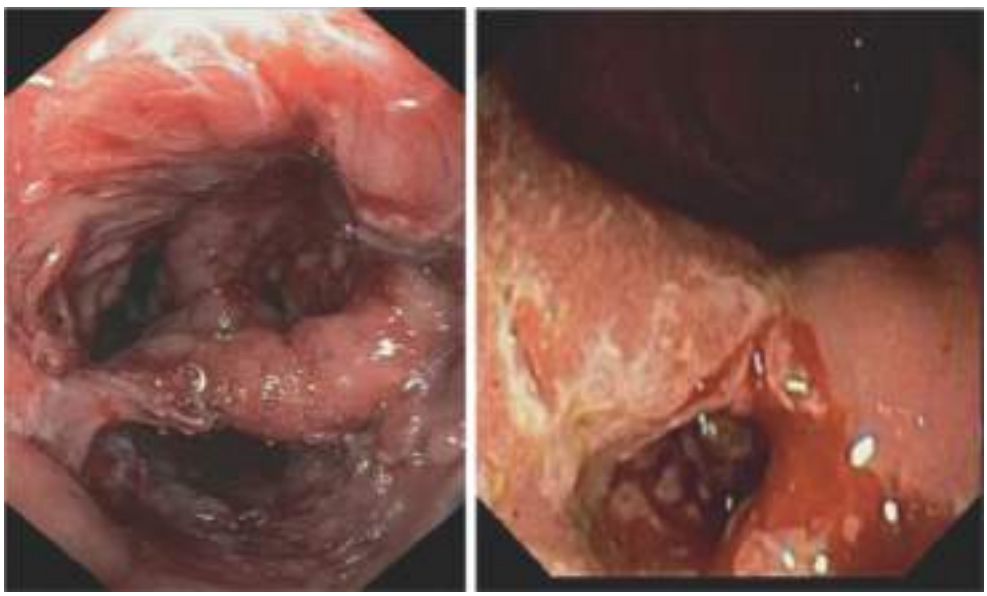

FIGURE 51-5. Pouchoscopy demonstrating IPAA dehiscences with posterior defects.

findings can undergo cross-sectional imaging to guide management. CT scan of the abdomen and pelvis with intravenous and water-soluble oral and trans-anal contrast is helpful to diagnose an abscess and an associated leak. In patients with an abscess amenable to percutaneous drainage, prompt drainage and broad-spectrum IV antibiotic administration may allow for control of the sepsis and may minimize the long-term consequences to the pouch.

Whether abscess drainage should be performed transanally or percutaneously is a matter of debate due to concerns over the development of an extra-sphincteric fistula related to percutaneous drainage. When a break in anastomotic integrity is demonstrated coexistent with an abscess, trans-anal drainage through the anastomosis is preferable; however, when the anastomosis is intact, percutaneous CT-guided drainage is preferable. This strategy allows prompt drainage of abscesses while minimizing the risk of an extra-sphincteric fistula.

Bleeding from the Pouch

This low-frequency complication can be further minimized by performing a dedicated inspection of the back row of staples along the mesentery of the small intestine after pouch construction and before IPAA creation and over-sewing any bleeding sites. Postoperative pouch bleeding may manifest as bleeding through the anus or up through the loop ileostomy. Pouchoscopy with cauterization, clip application, or epinephrine injection usually controls the bleeding. In patients with generalized oozing, instilling ice-cold saline with dilute epinephrine into the pouch facilitates hemostasis [12].

Late Postoperative Complications

Due to the defunctioning nature of the loop ileostomy, some pouch-related complications do not manifest clinically until after stoma reversal. Pre-stomal reversal pouch imaging with water-soluble contrast (done by fluoroscopy or CT scan) and flexible pouchoscopy are routinely performed but do not eliminate the occurrence of late complications.

Pouch-Vaginal Fistula

Pouch-vaginal fistula (PVF) is a potentially disabling complication that can cause significantly diminished quality of life. The overall risk of PVF ranges from 4 to 16 % with pouch failure occurring in as many of 30 % of these patients [13]. Common symptoms include discomfort, irritation, incontinence, and recurrent vaginal and urinary tract infection. In order to tailor the most effective treatment to each patient, the size, nature, and location of the fistula, the state of the perineum and sphincter mechanism, and the configuration, size, and health of the pouch need to be assessed. While exam under anesthesia is considered the gold standard study to evaluate PVF, imaging studies are relied on to provide additional information and include water-soluble pouchogram, vaginogram, and pelvic MRI (Figure 51-6). CT or MR enterography can be useful as well to delineate the anatomy above the pouch.

The potential diagnosis of underlying Crohn's disease should be considered in any patient presenting with fistulizing disease after IPAA ostensibly performed for ulcerative colitis as this affects PVF management and prognosis. In practice, differentiating septic complications from Crohn's disease is difficult especially when pathognomonic clinical and histopathological features of Crohn's disease are absent. In general, PVF occurring in a colitis patient within 1 year of stoma reversal is likely due to a septic complication of the IPAA while fistulas presenting beyond the first year should raise the specter of Crohn's disease [14]. A thorough review of the history and medical records pertaining to the IPAA surgery and the postoperative course may provide insight into the potential etiology of the PVF and review of the pathology from the pouch surgery and even from preoperative biopsies may prove helpful.

The recommended treatment for a patient with PVF depends on the severity of the symptoms and their effect on the patient's quality of life and on the specific anatomic and pathologic details that are elucidated on a case-by-case basis. Examination under anesthesia allows for assessment of the fistula tract and the associated tissues. Active inflammation with induration of the tract and surrounding tissues may respond to drainage and

FIGURE 51-6. Gastrografin enema demonstrating a pouch-vaginal fistula with contrast filling both structures.

seton placement which may restore the elasticity and tensile strength of the tissues to be used in future definitive repair of the PVF. Medical treatment with antibiotics, anti-inflammatories, and Crohn's disease medications may be required to reduce inflammation in anticipation of a repair procedure. Although there is a risk of ultimate pouch failure for patients with PVF, up to 85 % of these fistulas can heal using a variety of surgical approaches in combination with medical optimization [13].

Treatment Options for PVF

Advancement Flap Repair

This is a local repair that may be considered in patients with a low, simple PVF without excessive inflammation. Prone jackknife positioning with general anesthesia provides the best exposure to the field. Placing four quadrant effacement sutures or using a Lone Star™ retractor (Cooper Surgical Inc., Trumbull, CT) further improves exposure. Using appropriately sized Hill-Ferguson retractors in both the vagina and anal canal allows for visualization of the fistula so that a fistula probe can be passed to identify the actual tract. In the absence of smoldering infection and if the tissues are supple and healthy, consideration may be given to creating a flap for repair.

The fistula opening in the pouch is circumscribed and, after the infiltration of 0.25 % Bupivacaine with epinephrine, a U-shaped broad-based flap is raised, mobilizing mucosa and submucosa with the fistula opening at the apex of the flap. The fistula tract is dissected within the pouch-vaginal septum and is excised and the resulting defect is approximated using #2-0 Vicryl suture. The flap is secured to the pouch-anal mucosa with sutures incorporating the adjoined sphincter mechanism ensuring a tension-free repair. If the defect on the vaginal aspect is small, it may be left alone. However, when large, the edges of the defect are freshened and the defect is approximated with interrupted absorbable sutures. Patients are kept on strict bedrest for 24 h and the bladder catheter is removed after 48 h.

The success of an advancement flap in the setting of PVF is influenced by the underlying etiology of the fistula, the quality of the tissues involving the fistula, and technical considerations at the time of the repair. Flap ischemia, bleeding under the flap, and tension across the flap risk failure of this procedure are to be avoided. Patients with a failed advancement flap may be candidates for a redo flap procedure provided any residual local sepsis or ongoing inflammation is addressed and the tissues allow for a redo flap [15, 16].

Trans-vaginal Repair

This can occasionally be attempted when poor access, as with a mild stenosis of the IPAA, impedes repair via the pouch. A vaginal advancement flap repair is performed using similar principles as described above.

Fibrin Glue, Fistula Plug, Biologic Mesh Repair, and Gracilis Muscle Interposition

These perineal procedures have been described for the management of PVF and, given the variable success rates associated with these procedures, will not be reviewed in further detail [17–19].

Perineal Pouch Advancement

This can be performed through a perineal approach. The anterior half of the IPAA is disconnected from the anal canal and the pouch is mobilized down from the vagina and is reapproximated to the anal canal after freshening and repairing the tissue surrounding the defect in the rectovaginal septum. If the defect on the vaginal aspect is large, the edges are freshened and the tissue is approximated with interrupted absorbable sutures. The degree of mobilization obtainable through this technique is often limited given the constraints of operating trans-anally.

Redo IPAA

Redo IPAA is the definitive treatment option for patients with PVF who have failed prior attempts at repair and desire restoration of the continuity of the intestine. Patients with an otherwise healthy perineum, adequate sphincter mechanism, and a low suspicion of having Crohn's disease may be considered for a redo IPAA.

Redo IPAA is performed via a combined abdominoperineal approach so that the pouch can be disconnected from the prior anastomosis. These operations are usually technically challenging and preoperative planning should consider the placement of ureteral stents to avoid ureteric injury. After pouch-anal disconnection, the fistula is excised and debrided to prepare the pouch for repeat IPAA if the existing pouch is salvageable. The pouch may be augmented or refashioned, as required, based on intraoperative evaluation of the health and capacity of the pouch. The length of remaining small intestine and anticipated challenges with reach influence whether or not the pouch is revised or excised and created anew. If the status of the pouch is not sufficient, a neoileal pouch may be required. Once the pouch is prepared and the vaginal defect is repaired, mucosectomy and repeat IPAA are completed in hand-sewn fashion followed by a protecting loop ileostomy. If the greater omentum is available and can be mobilized to reach the low pelvis, an omental pedicle flap is used as an interposition between the pouch and the vagina to potentially reduce recurrent fistulization.

Redo pouch surgery is a reasonable option for selected patients with pouch failure due to a variety of conditions besides PVF including anastomotic leak, pelvic abscess, fistula, stricture, and pouch dysfunction from other causes [20–26]. While these salvage procedures are associated with acceptable

functional outcomes and quality of life, these outcomes are typically inferior to the results experienced with successful primary IPAA [27, 28]. Sphincter injury due to repeat operative trauma, mucosectomy with hand-sewn anastomosis, shortened length of remaining small intestine, and decreased compliance of a revised pouch may each contribute to worse functional outcomes after redo pouch surgery. The decision to proceed with redo IPAA requires consideration of anticipated function as well as the individual patient's conviction regarding the importance of long-term stoma avoidance.

Proximal Diversion

A defunctioning ileostomy is often considered as a temporizing measure to control symptoms and improve the quality of the tissues in anticipation of a local PVF repair or may be performed concomitantly with the repair. In certain cases pouch excision with permanent, conventional end ileostomy creation may be recommended; alternatively, conversion of the pouch to a continent ileostomy may be considered in select, highly motivated patients. The "K" pouch procedure is complex and risks additional complications due to the technical challenges inherent in creating the nipple valve mechanism and the continent ileostomy reservoir. Patients who undergo the procedure are, however, extremely satisfied with the operation [29]. Patients with pouch failure who are not candidates for another restorative procedure are generally recommended to undergo pouch excision as leaving the pouch in situ can cause long-term problems with seepage, anal pain, and overall decreased quality of life [30].

Pouch-Perineal Fistula

This is another potential septic complication after pouch surgery that may arise due to tracking of infection or may be due to undiagnosed Crohn's disease. The evaluation, management, and surgical options for pouch-perineal fistula are similar to those for pouch-vaginal fistula. Figure 51-7 illustrates the steps for an advancement flap repair for this kind of fistula.

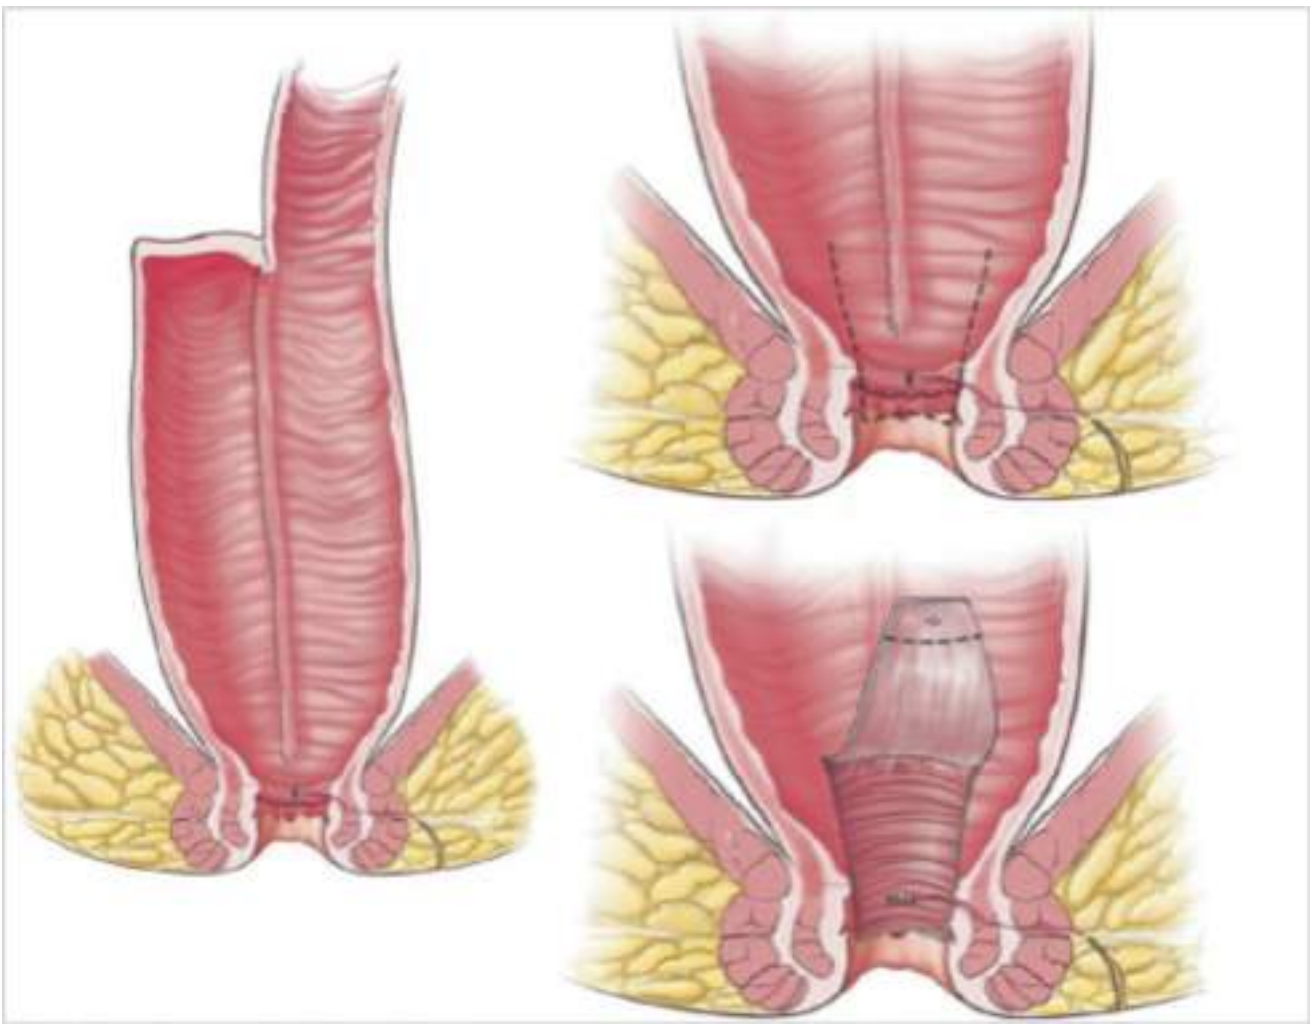

FIGURE 51-7. Technique for advancement flap repair of a pouch-perineal fistula.

Pouch Sinus

A pouch sinus, generally considered an anastomotic leak confined to a blind-ending tract, occurs in 2–8 % of patients after IPAA [31–34]. While these tracts may be asymptomatic and incidentally discovered, some patients present with symptoms ranging from minor inflammation to pelvic sepsis, pain, pouch dysfunction, and pouch failure. In terms of treatment, debridement, unroofing, fibrin glue injection, pouch revision, and redo pouch have all been described with variable rates of healing. Symptomatic presentation is a significant predictor for low healing rates and is associated with a high risk of pouch failure. Management is individualized to each patient and depends on the presenting symptoms, size, and location of the sinus as well as other factors such as whether or not the patient is diverted. Observation is recommended over intervention, when permitted by clinical circumstances, as these sinuses can resolve spontaneously.

Sinuses detected incidentally in patients without an ostomy are usually best left alone. Patients with a sinus detected incidentally on routine evaluation before stoma reversal are usually recommended to delay reversal for a few months until repeat evaluation demonstrates the sinus has healed (Figure 51-8). Patients with a symptomatic sinus or a non-resolving tract may be managed by trans-anal debridement with drainage, unroofing of the sinus, or glue injection. Proceeding with ileostomy reversal may be considered in selected asymptomatic patients with a persistent small tract who have failed attempts at resolving the sinus. Symptomatic patients who fail local attempts to resolve their sinus may go on to require diversion, pouch revision, or redo pouch surgery.

FIGURE 51-8. Gastrografin pouchogram demonstrating a posterior sinus (at *arrows*).

Crohn's Disease After Pouch Surgery

In general, patients with Crohn's disease are not considered good candidates for IPAA because of the high rates of pouch complications, including failure, in this group of patients [35–37]. However, even with a histologic diagnosis of Crohn's colitis, a highly select subset of patients with disease entirely confined to the colon and rectum and in whom the small intestine and anoperineum are spared may be candidates for an IPAA provided patients are thoroughly counseled regarding the higher risks of long-term pouch loss [36].

Pouch patients with presumptive ulcerative colitis or indeterminate colitis may, after developing complications, ultimately be diagnosed with Crohn's disease. The diagnosis of Crohn's disease after pouch surgery is usually based on the presence of perianal fistulas unrelated to the surgery, non-necrotizing granulomas on histopathology, or inflammation and ulceration in the afferent limb or in the small intestine on endoscopy in the absence of nonsteroidal anti-inflammatory use [38]. Confirming the diagnosis of Crohn's disease after pouch surgery can be challenging. In the early postoperative period after restorative proctocolectomy, septic complications related to the pouch may manifest with findings similar to Crohn's disease as reviewed earlier in this chapter. In terms of long-term effects after pouch surgery, Crohn's disease may interfere with pouch function by affecting the body, afferent limb, or anastomosis of the pouch, the perineum, or the proximal small intestine.

Management depends on the disease manifestations (inflammatory, fibrostenosing, fistulizing) and the resulting symptoms. Pouch-related complications in the setting of Crohn's disease are more difficult to resolve compared with complications in patients without Crohn's disease and have a higher rate, ultimately, of pouch failure [3, 39]. Treatment relies on a combination of conventional medical therapy for Crohn's disease and surgical intervention tailored to the specific complication at hand. Endoscopic balloon dilation may be used for isolated short-segment strictures reserving surgery for stricturing disease not amenable or responsive to through-the-scope interventions. Bowel-preserving stricturoplasty, a cornerstone of Crohn's disease management, if appropriate, is preferred over bowel resection in these cases. In the presence of localized disease at these sites, stricturoplasty of the pouch-anal anastomosis, pouch body, and small bowel proximal to the pouch with or without a defunctioning

ileostomy may help control symptoms and salvage the pouch. Perianal disease may be managed with drainage and medical therapy in anticipation of future surgical intervention. Extensive or refractory Crohn's disease may require diversion and possible pouch excision.

Incontinence

Functional issues after undergoing IPAA can significantly impact quality of life. Patients may present with varying degrees of urgency, seepage, pad dependence, nocturnal leakage, and incontinence [9, 40]. Patients over 50 years of age at the time of IPAA have higher rates of postoperative incontinence and this dysfunction can become more pronounced with longer post-IPAA follow-up [41]. Control issues may be due to pouch abnormalities like pouchitis, cuffitis, presacral sinus, or a chronic presacral cavity related to an anastomotic leak. Another contributing factor can be weakness of the sphincter mechanism that may have preexisted the IPAA or may be postsurgical in nature from mucosectomy or other operative trauma [42]. Evaluation of the pouch, anal canal, and sphincter mechanism can usually elucidate the etiology of these symptoms and treatment is tailored to the underlying problem.

Outlet Obstruction

Problems with pouch evacuation may be due to a mechanical or anatomic cause like IPAA stricture, pouch prolapse, or kinking of the outflow of the pouch which can occur in patients with an "S" pouch with a long efferent limb (Figure 51-9). A functional pouch evacuation disorder can be due to paradoxical, non-relaxation of the puborectalis muscle which can present similar to chronic post-IPAA bowel obstruction [43]. Treatment of IPAA outlet dysfunction depends on the underlying cause of the symptoms. Biofeedback with pelvic floor retraining may be helpful for some patients without a mechanical cause of the symptoms. Enemas and intermittent self-intubation to vent or to irrigate the pouch may be useful for patients with obstruction from either anatomic or functional causes.

FIGURE 51-9. CT scan of a patient with outlet obstruction of an "S" pouch due to kinking of the outflow tract. The pouch is distended with fecalized material.

Pouchitis and Cuffitis

Pouchitis and cuffitis are distinct post-IPAA entities that have similar presentations and treatment options. These conditions relate to poorly understood, nonspecific inflammation of the pouch or of the retained rectal columnar mucosa above the anal transition zone that causes bleeding, cramping abdominal pain, anal discharge, tenesmus, urgency, and increased frequency. Pouchitis is the most common complication requiring medical treatment after IPAA and occurs much more commonly in pouch patients with ulcerative colitis as compared with pouch patients with polyposis [35]. An estimated 40 % of ulcerative colitis patients develop pouchitis after IPAA and some patients develop a chronic pouchitis condition [2, 44]. Patients are diagnosed by pouchoscopy and biopsy (Figures 51-10 and 51-11).

Treatment for pouchitis and cuffitis is primary medical and often includes antibiotics, probiotics, anti-inflammatories, and steroids that can be administered orally or trans-anally. Patients who exhaust medical therapy and remain symptomatic may benefit from a diverting ileostomy, pouch excision, and possible redo pouch surgery. Small focal areas of cuff inflammation may be addressed with ablation. Recalcitrant cuffitis may be treated with mucosectomy and pouch advancement or may require redo IPAA if the cuffitis is due to a longer segment of retained rectum at the time of the original IPAA.

Pouch Prolapse

This is a rare complication occurring in less than 1 % of patients after IPAA [45]. Patients have been reported to present with mucosal prolapse or full-thickness prolapse. Diagnosis is usually based on symptoms and physical examination and initial treatment relies on dietary manipulation, bulking agents, and avoidance of straining. Biofeedback may be useful, as well. Patients with symptomatic mucosal prolapse may undergo definitive treatment with excision of the redundant mucosa. Patients with full-thickness prolapse may require an abdominal approach with fixation of the pouch to the sacrum [46]. Volvulus of the pouch is extremely rare and will not be discussed in detail.

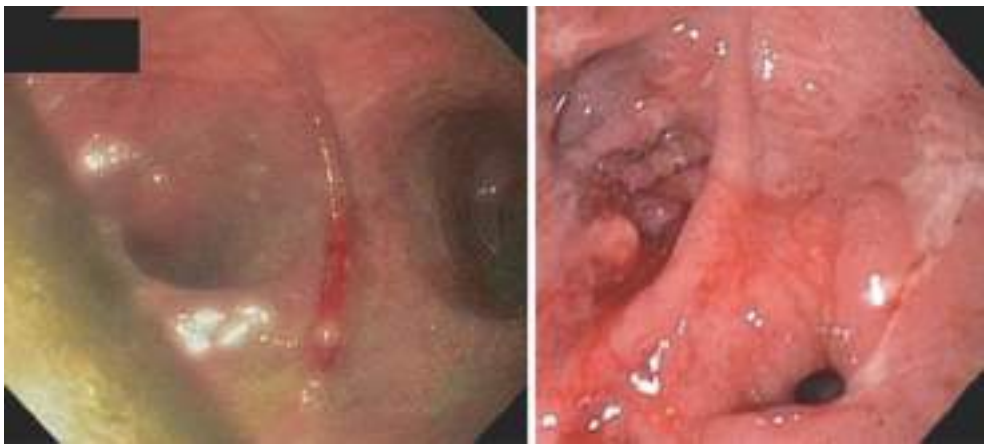

FIGURE 51-10. Pouchitis on flexible pouchoscopy. On the *left*, notice the erythematous mucosa and the watery consistency of the pouch contents. Patients can also have friable, ulcerated, or edematous mucosa as seen on the *right*. These findings can mimic and may be difficult to differentiate from Crohn's disease of the pouch.

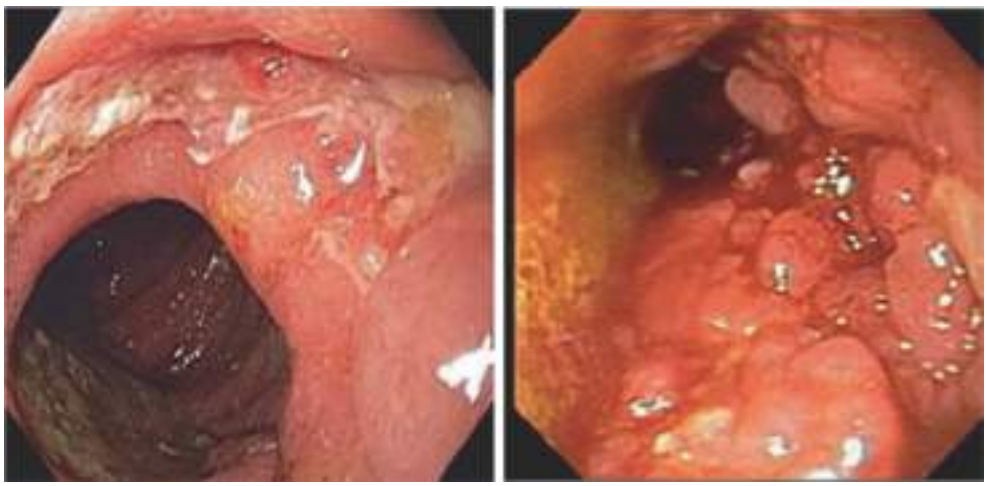

FIGURE 51-11. Cuffitis on flexible pouchoscopy. The inflammatory changes are limited to the rectal mucosal remnant and can be severe.

Leak from the Tip of the "J"

Leak from the tip of the "J" is less common than anastomotic leak after IPAA and occurs in less than 1 % of pouch patients [47] (Figure 51-12). Since the tip of the "J" is formed by the terminal portion of the small intestine, care must be taken to ensure adequacy of blood supply to the segment when this is stapled. Over-sewing of the staple line is also prudent. Patients present with variable and often nonspecific symptoms of abdominal pain, fever, and changes in pouch output and some patients develop an abscess or fistula. These leaks can be difficult to discover on routine pre-stoma reversal evaluation and may not become symptomatic until after the ileostomy is taken down. The indolent course associated with this particular pouch complication may explain why some patients are not diagnosed until the time of reoperation. Salvage surgery may involve suture repair of the pouch or excision of the tip of the "J" (Figure 51-13).

Dysplasia and Cancer After Pouch Surgery

Dysplasia and cancer can develop in the ileal pouch, in retained rectal mucosa, or in the anal transition zone after IPAA and has been reported to occur in patients with ulcerative colitis and familial adenomatous polyposis. Mucosectomy at the time of IPAA does not prevent future dysplasia as islands of rectal mucosa may persist even after "complete" mucosectomy at the time of IPAA [48]. The development of dysplasia or neoplasia within the pouch of ulcerative colitis patients is extremely rare such that routine surveillance of the pouch is not warranted [49]. Ulcerative colitis patients, whether stapled or hand-sewn after mucosectomy, should be counseled about the future risk of malignant degeneration in or near the anal transition zone and can be offered periodic surveillance. Prior colorectal dysplasia or cancer and chronic pouchitis are risk factors for developing

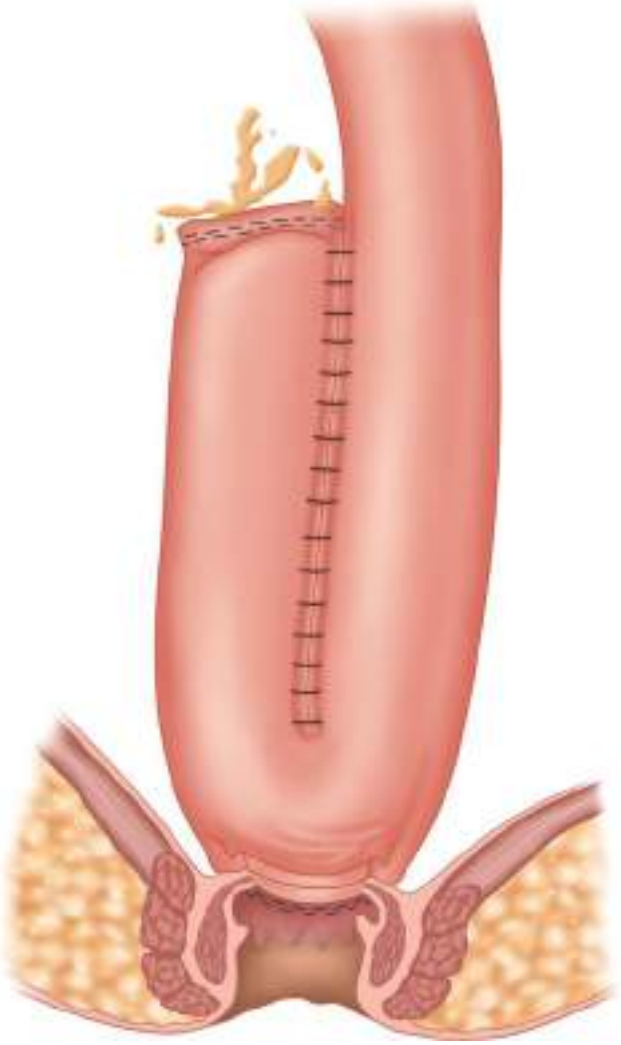

FIGURE 51-12. Leak from the tip of the "J".

pouch neoplasia; these patients may benefit from a more targeted pouch surveillance program [50]. Pouch patients with familial adenomatous polyposis are at risk for developing future polyps or cancer and should undergo annual surveillance with pouchoscopy and biopsies [51]. Pouch patients with focal dysplasia are recommended to undergo ablation or excision and surveillance. Patients with cancer will most likely require radical surgery with pouch excision.

Small Bowel Obstruction

SBO is one of the most common long-term complications after IPAA occurring in as many as 25 % of patients [2, 52]. Obstruction above the level of the pouch, most commonly due to adhesions, may also be due to volvulus, internal hernia, or stenosis at the site of stoma reversal. Laparoscopy, generally thought to reduce the formation of adhesions as compared with open surgery, has not been shown to reduce the long-term incidence of SBO in pouch patients [53, 54]. Adhesion barriers have been studied in the setting of pouch surgery but are not used routinely in practice [55]. Adhesive SBO in pouch patients is treated in the same fashion as SBO after other abdominal operations with bowel rest, decompression, and exploration with adhesiolysis, if necessary. The rate of requiring adhesiolysis appears to be higher in patients with SBO after pouch surgery compared with patients who have had other types of abdominal surgery.

Sexual Dysfunction

Historically underappreciated and underreported, sexual dysfunction after total proctocolectomy with IPAA may affect up to 20 % or more of patients [56, 57]. Men may

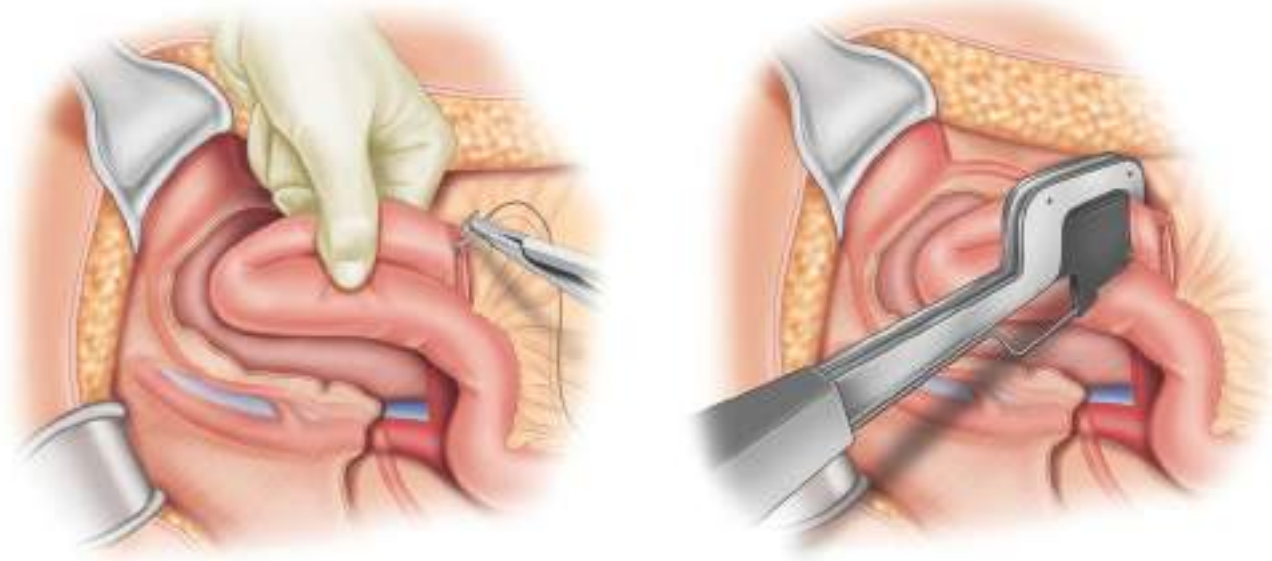

FIGURE 51-13. Leak from the tip of the "J" treated with suture repair or excision.

develop erectile dysfunction and retrograde ejaculation and women can experience alterations in sexual desire, arousal, and satisfaction and can suffer from dyspareunia [58]. The etiology of sexual dysfunction after IPAA is multifactorial and may involve nerve injury, altered pelvic anatomy, issues related to body image, presence of an ileostomy, and pouch dysfunction. In a large retrospective review of sexual function after IPAA, including 762 men and 692 women, 56 % of patients reported no change in function, 25 % reported having improved function, and 19 % had worse function postoperatively [41]. The seemingly paradoxical improvement in function may be attributed to improved quality of life experienced by patients after pouch surgery.

Hypogastric nerve injury during pelvic dissection should be avoided in order to reduce the incidence of sexual dysfunction. Performing close rectal dissection rather than total mesorectal excision has been studied and does not appear to improve preservation of sexual function [59]. Similarly, laparoscopic pouch surgery, as compared with open surgery, does not influence the risk of sexual dysfunction [60, 61].

Infertility

Women with ulcerative colitis have decreased fertility rates after total proctocolectomy compared with women who are managed non-operatively. A meta-analysis estimated that these patients have a threefold increased risk of infertility [62]. The differences in fecundity are thought to be due to adhesions and occlusive scarring of the fallopian tubes resulting from the pelvic dissection [58]. The higher rate of fertility described after laparoscopic pouch surgery compared with open procedures is thought to be due to decreased pelvic adhesions in this setting [63, 64]. Women contemplating pouch surgery should be counseled appropriately regarding the risk of future infertility and the possible impact of the laparoscopic approach.

Conclusion

While the ileal pouch remains a common operation, unfortunately pouch-related complications may occur and can impact quality of life, require multiple repeat interventions, and result in poor function or even loss of the pouch. Modifying patients' risk factors and considering the range of pouch-specific complications before, during, and after pouch surgery can potentially reduce the risk of these adverse events. Any healthcare provider managing these patients should have a thorough understanding of the potential complications and things to watch for in order to maximize quality outcomes for these patients.
