- ***Patellar ballottement (maximal effusion).*** Ballottement of the patella is a useful technique for detecting an effusion. Using one hand, the clinician grasps the patient's thigh at the anterior aspect about 10 cm above the patella, placing the fingers medial and the thumb lateral. The patient's knee is extended. With the other hand, the clinician grasps the patient's lower leg about 5 cm distal to the patella, placing the fingers medial and the thumb lateral. The proximal hand exerts compression against the anterior, lateral, and medial aspects of the thigh and, while maintaining this pressure, slides distally. The distal hand exerts compression in a similar way and slides proximally (Fig. 20-8). Using the index finger of the distal hand, the clinician now taps the patella against the femur. In the normal knee joint with minimal free fluid, the patella moves directly into the femoral condyle and there is no tapping sensation underneath the clinician's fingertips. However, in the knee with excess fluid, the patella is "floating"; thus, ballottement causes the patella to tap directly against the femoral condyle. This sensation is transmitted to the clinician's fingertips. A positive test is indicative of a significant synovial effusion or hemarthrosis in the knee joint. However, sometimes, this test can produce false-positive results. When this is the case, the uninvolved side usually tests positive as well.

If there is no swelling but there is evidence of bruising or bleeding into the tibial area, disruption of the joint capsule may be present, or a SCFE, if the patient is an adolescent. Popliteal swelling, which can compress the tibial or common fibular (peroneal) nerves, or both, can produce complaints of paresthesia and anesthesia.

The formal observation of the patient is divided into three sections: standing and walking, seated, and lying examinations.

Patient Standing

The patient is asked to stand with the feet slightly apart and aligned straight ahead. This position can be used to assess overall limb alignment as well as to identify possible foot abnormalities. A careful physical examination of the hip, knee, and ankle is performed, observing for both static restraints, and, to a great degree, dynamic restraints.[127] Following this position, the patient is asked to stand with the feet shoulder-width apart. The entire trunk and lower extremities are observed. Areas of atrophy should be noted and correlated with other findings. Common areas include the medial aspect of the quadriceps following trauma, nerve injury, or knee surgery.

Degree of Femoral Retroversion or Anteversion

Femoral retroversion–anteversion is indicated by whether the feet are rotated outward or inward, respectively, in the relaxed standing position. The position of the patella is examined to see whether it looks inward (the so-called squinting patella), which could indicate femoral anteversion. Femoral anteversion results in internal rotation of the femoral sulcus, and an increase in the Q-angle. Femoral anteversion has been associated with abnormal patellofemoral mechanics.[147,275] Even if the patella looks straight in the presence of femoral anteversion, it may be held there by tight lateral structures.[266]

Leg-Length Discrepancy

Compensations for leg-length discrepancies include excessive foot pronation, toeing-out (forefoot abduction), and a flexed knee gait or stance.[276,277]

Degree of Genu Varum/Genu Valgum

Genu varus ("bow legs") can be the result of bowing of the tibia or varus at the knee joint. An increased varus moment can contribute to early degeneration of the knee and, when exaggerated, is most often an indication of advanced degenerative joint disease (DJD).[278] On the basis of the relationship between the proximal and distal aspects of the femur, a change in the orientation between the shaft and the neck will change the orientation of the tibiofemoral joint, thereby altering the weight-bearing forces through the knee joint. For example, an increase in the normal angle of inclination at the hip (coxa valga) will redirect the femoral shaft more laterally than normal, resulting in a decrease in the normal physiologic valgus angle of the knee (genu varus). This results in a shifting of the mechanical axis to the medial compartment of the knee, increasing the compression forces medially.[66]

Genu valgus ("knock knees") can result from a change of angulation of the femur caused by femoral anteversion, tibial torsion, or excessive foot pronation. A valgus knee increases the Q-angle by displacing the tibial tuberosity laterally and can be associated with patellofemoral pain.[279]

To observe genu varum and genu valgum, the patient is positioned in standing so that the patellae face anteriorly and the medial aspect of the knees and the medial malleoli of both lower extremities are as close together as possible. A distance of 9–10 cm (3.5–4 inches) between the malleoli of the ankles with the knees touching is considered excessive and indicates genu valgum, whereas a distance of 4 cm (1.6 inches) measured between the knees when the ankles are together, indicates genu varum.[280–282]

Degree of Knee Flexion

A flexed knee in the relaxed standing position is often indicative of arthritic changes of the knee.

Degree of Genu Recurvatum or Hyperextension

Knee recurvatum may be an expression of a generalized ligamentous laxity or may be associated with patella alta.[205] Hyperextension of knee produces stress on the posterior capsule, slackening of the ACL, and alterations in the compressive forces acting on the anterior articulating surface of the tibia.[278] The anterior compressive forces can cause the inferior pole of the patella to be driven posteriorly into the fat pad, producing an irritation.

Q-Angle Assessment

A properly measured Q-angle can contribute significantly to the evaluation of patellofemoral malalignment. However, relying solely on the Q-angle measurement to determine patellofemoral alignment is an oversimplification. As with other clinical signs, an abnormal value does not necessarily identify the source of pain. The Q-angle itself is not pathologic and is increased in only a small percentage of patients with patellar pain.[283]

The Q-angle should be assessed dynamically and statically. It is important that this angle be measured in a consistent fashion. The preferred position for this test is the one-legged standing position without shoes. Hyperpronation of the feet can be masked unless the foot and ankle are placed in a subtalar neutral position[284] (see Chap. 21). A measurement is then taken using an imaginary line drawn from the ASIS to the center of the patella, and a second line from the tibial tuberosity to the center of the patella (Fig. 20-6). The weight-bearing position can be simulated in a supine patient by dorsiflexing the ankles, extending the knees, and pointing the toes to the ceiling. With the knee flexed to 90 degrees, the tibial tubercle should lie less than 20 mm lateral to the midline of the femur at the upper edge of the femoral condyles; a distance of more than 20 mm indicates an abnormally lateral tubercle.[11] Both tight hamstrings and a decrease in ankle dorsiflexion can result in an increase in the dynamic Q angle.[188]

Degree of Tibial Torsion[285]

External tibial torsion increases the Q-angle, whereas internal torsion decreases it.[147] The vast majority of the studies focusing on anterior knee pain have examined the coronal relationships at the knee (Q-angle, patellar tilt, patellar subluxation). Few studies have addressed the rotational relationships, specifically the rotational orientation of the tibia to the femur.[286] This rotational relationship of the tibia to the femur in the transverse plane is referred to as *knee version*. Knee version often is recognized as a factor in the context of the osteoarthritic knee.[287–289] The significance of this rotational characteristic of the knee with anterior pain is that the patella is tethered to the tibia by the infrapatellar tendon and retinaculum, and if the tibia is rotated externally with respect to the femur, the patella will be pulled laterally by virtue of this attachment.[286] If the patella is not free to translate laterally, because of its soft tissue attachments and its conformity with the patellar groove, increased pressure may be placed on the lateral facet. This pressure may produce a condition called a *lateral patellar compression syndrome*.[286,290]

Tibia-to-Floor Angle

If the tibia-to-floor angle is 10 degrees or greater, the extremity requires an excessive amount of subtalar joint pronation to produce a plantigrade foot.[205]

Patella Tendon-to-Patella Height Ratio

This measurement is best performed radiographically. The patella tendon length should be equal, or slightly longer than the height of the patella.[291] If a ratio of greater than 15–20% exists, patella alta should be suspected. If the ratio is less than 15–20%, patella baja should be suspected.

Foot Alignment

An often-neglected feature, which directly impacts the patellofemoral joint, is that of foot alignment. The normal weight-bearing foot exhibits a mild amount of pronation. If the foot pronates excessively, a compensatory internal rotation of the tibia may occur. This produces an increased amount of rotatory stress and dynamic abduction movement at the knee that has to be absorbed through the peripatellar soft tissues at the knee joint.[205,226,275,292] These stresses can force the patella to displace laterally.[293,294] In addition, a change in the position of the talus can affect the functional leg length. Subtalar supination may cause the leg to lengthen, whereas subtalar pronation shortens the leg.

Gait

Abnormal foot mechanics are manifested during ambulation, and abnormal gait patterns may suggest an underlying condition (see Chap. 6). The gait assessment relative to the knee allows the clinician to identify deviations of the foot, ankle, knee, or hip joint, such as excessive subtalar and midtarsal joint pronation, limited ankle dorsiflexion, tibial or femoral torsion abnormalities, and excessive varus or valgus at the knee, all of which could place the knee structures at risk for further microtrauma.[167]

During normal gait, the knee should be observed to flex to approximately 15 degrees at initial contact before extending to the neutral position at terminal stance.[278] An increase in 5 degrees of pronation at midstance, a period where the foot should be in supination, holds more potential for producing pain than if the 5 degrees occurs during the contact phase.[229]

Since the joint reaction forces are reported to increase with the magnitude of quadriceps contraction and the knee-flexion angle,[295] patients with patellofemoral pain often adopt compensatory gait strategies to reduce the muscular demands at the knee. Evidence in support of this premise was reported by Dillon et al.,[296] who found that subjects with patellofemoral pain limited the amount of stance phase knee flexion during level and ramp walking.

An injury to the ACL produces distinct changes in lower extremity biomechanics during gait.[297] Although healthy individuals demonstrate an extensor torque at the knee for 10–45% of the stance phase,[298–300] gait analysis of individuals with recent ACL deficiency shows functional adaptations in a high proportion of patients, with an extensor torque that lasts for nearly the entire stance phase.[298] Other analysis has also shown a decrease in the flexion moment of the knee in the

range of 0–40 degrees of flexion in patients who have a chronic tear of the ACL.[301,302]

When the normal limb moves into the midstance phase, gravity and inertia generate a moment that tends to flex the knee. Since the quadriceps muscles balance this moment, a decrease in the flexion moment suggests a decrease in the quadriceps muscle moment.[303] Such a decrease has been noted in both limbs of patients who had only one knee with a torn ACL.[302]

Andriacchi[303] termed this finding the *quadriceps-avoidance gait,* although not all patients who have a torn ACL have such a gait, and its prevalence appears to be partly related to the time since the injury.[304] In activities that involve knee-flexion angles of less than 30 degrees (i.e., those involving normal gait), the quadriceps-avoidance gait is most effective in preventing anterior tibial translation.[303,305,306] In activities that involve knee-flexion angles of 40 degrees or more (e.g., jumping or sharp changes in running direction), increased contraction of the hamstrings is effective in preventing anterior tibial translation.[154,306–308]

Gait adaptations in individuals with ACL injury who have reconstruction surgery are less clear for two reasons[297]:

1. Very few comprehensive gait analyses have been conducted on this population.
2. The large variations in surgical and rehabilitation procedures and patient characteristics, and in patient compliance with rehabilitation, limit the generalization of these potential results.

Gait can also be affected by genu recurvatum, because during the loading response in gait, an individual with genu recurvatum transfers body weight directly from the femur to the tibia without the usual muscle energy absorption and cushioning of a flexed knee provided. This may lead to pain in the medial tibiofemoral joint (compression) and posterolateral ligamentous structures (tensile). In individuals with quadriceps weakness, compensation may occur by hyperextending the knee to provide greater knee stability.

Patient Sitting

Active Knee Extension

Although formally assessed as part of the active range of motion (AROM) with passive overpressure tests (see later), active knee extension may also be used during the observation phase of the examination. The patient should fully extend the knee from a flexed position. Normally, the patella follows a straight line, or a slight and smooth, gradual, lateral concave "C" curve as the knee extends. The presence of a "J sign," in which the patella slips off laterally as the knee approaches extension, or apprehension with motion involving lateral or medial stress, is necessary to confirm patellar instability.[11]

The patella may be compressed with the palm of the hand through the full ROM, as ulcerated lesions can be tender with this provocative test.[11] However, care should be taken with this maneuver, because it can provoke pain in otherwise asymptomatic patients.

Distal patellar lesions are often tender with this test in the early degrees of knee flexion, whereas proximal lesions are tender at approximately 90 degrees.[11] This information can help guide the clinician with the intervention. Crepitus at the knee is a nonspecific finding and can be associated with both cartilaginous and synovial lesions.[11] Although often a concern to patients because they believe it to be indicative of arthritis, crepitus is often a result of tight, deep, lateral retinacular structures and can be improved with retinacular stretching techniques.[266]

In addition to observing the patella during active knee extension, the clinician should also note any evidence of a quadriceps lag manifested by an inability to fully extend the knee. This lag can result from muscle atrophy, pain, effusion, reflex inhibition, or a loss of mechanical advantage. Quadriceps reflex inhibition has been well documented throughout the literature and is thought to result from pain or effusion, or both, although the exact etiology has yet to be determined.[262,309–314]

Some of the proposed causes for this reflex inhibition include

- the result of capsular stretching;[313]
- the result of increased intra-articular pressure.[310]

In the presence of various pain syndromes, such as CRPS,[309] additional muscle inhibition can occur. In most patients, limitations of motion resolve as the pain and effusion dissipate. However, this quadriceps inhibition may allow scar tissue to form while the knee is held in a flexed position. Atrophy of the quadriceps muscle and flexion contracture usually results, and activities of daily living become more difficult to perform. Joint immobilization can complicate all of these factors. Disuse may induce abnormal cross-links between collagen fibers at abnormal locations,[315,316] decreasing their extensibility[317] and promoting intra-articular and extra-articular scarring.

Patient Lying Supine

Malalignment can be observed on certain the supine, resting patients, whereas in other subjects a dynamic evaluation (walking, jumping, squatting, etc.) is required to detect an abnormal alignment. The lateral pull test can be performed to assess patellar tracking.[318] The patient lies supine with the knee extended and the clinician asks the patient to perform an isometric quadriceps contraction. The clinician observes patellar tracking during the contraction. The test is considered positive if the patella tracks more laterally than superiorly, and negative if superior displacement is equal to lateral displacement.[318] However, since the lateral pull test has been found to have only fair intrarater, and poor interrater reliability, care must be taken in placing too much emphasis on this test when making clinical decisions.

Hip Screening

With the patient supine and then prone, the hip is flexed and rotated as the clinician checks for a source of referred pain.[196]

Since patellar malalignment can be associated with adaptive shortening, the following structures (in decreasing order of frequency) are assessed[187,196]:

- ***Lateral retinaculum (see "Special Tests" section).*** A tight lateral retinaculum may pull the patella laterally.
- ***Hamstrings (see "Special Tests" section).*** When an individual with tight hamstrings runs, there is a decrease in

stride length and a potential for the quadriceps to fatigue in an effort to overcome the passive resistance of the hamstrings.[319] Tightness of the hamstrings also produces an increase in knee flexion at heel strike. Since the knee cannot straighten, an increased dorsiflexion is required to position the body over the planted foot.[266] If the range of full dorsiflexion has already occurred at the talocrural joint, further range is achieved by subtalar pronation. This has the effect of increasing the valgus vector force and the dynamic Q-angle.[266,320]

- ***Iliotibial band (see "Special Tests" section).*** The ITB is maximally taut at 20–30 degrees of flexion. Adaptive shortening of this band can cause a lateral tracking and tilting of the patella, and often a stretching of the medial retinaculum.[229]
- ***Tensor fascia latae and rectus femoris (see Chap. 19).*** Adaptive shortening of these structures can increase the amount of compression of the patella on the femur.[229]
- ***Hip rotators.*** The hip rotators can accentuate anteversion or retroversion (see Chap. 19).[229]
- ***Achilles–Soleus Length.*** A decrease in talocrural joint dorsiflexion ROM may result in a compensatory subtalar pronation during ambulation and weight-bearing.[321] Soft tissue tightness is particularly prevalent during the adolescent growth spurt, in which the long bones are growing faster than the surrounding soft tissues.[322]

Active Range of Motion

ROM testing for the tibiofemoral joint should include assessment of knee flexion and extension, tibial internal and external rotation. Normal knee motion (Table 20-7) has been described as 0 degrees of extension to 140 degrees of flexion, although hyperextension is frequently present to varying degrees.[323] In general, however, the best way to ascertain normal motion is to examine the contralateral knee, provided that it has no abnormal conditions.

The ROM testing can often be diagnostic and provides the clinician with some clues as to the cause of the problem. Examining the uninvolved knee first allays a patient's fears and helps to determine what the normal ROM is. In addition, observation of the uninvolved knee can afford the clinician information about the patellofemoral joint and the tracking of the patella.[324]

TABLE 20-7 Normal Ranges and End-Feels at the Knee

Motion	Range of Motion (degrees)	End-Feel
Flexion	0–140	Tissue approximation or tissue stretch
Extension	0–15	Tissue stretch
External rotation of tibia on femur	30–40	Tissue stretch
Internal rotation of tibia on femur	20–30	Tissue stretch

CLINICAL PEARL

Full active range of knee motion requires the following:

- Congruent articular surfaces
- Adequate muscle function
- An articular capsule with suitable capacity and flexibility
- Effective space in the medial and lateral articular recesses, intercondylar notch, and suprapatellar pouch
- Sufficient meniscal motion[325]

A number of studies have demonstrated that goniometric measurements of knee ROM performed in a clinical setting can be highly reliable.[326–330] Rothstein et al. showed that intratester and intratester reliability for flexion of the knee VIDEO was high ($r = 0.91–0.99$ and $r = 0.88–0.97$, respectively).[326] Watkins et al. showed that the intertester reliability for measurements of knee ROM obtained by visual estimation was 0.83 for flexion and 0.82 for extension.[330]

Flexion

The amount of knee flexion should be assessed to see if the motion is restricted by tight structures. If no restriction is suspected, tests are required for generalized ligament laxity and for abnormally loose patellar retinacula (see later discussion).

The primary flexors of the knee are the three hamstring muscles, assisted by the gracilis, sartorius, popliteus, and gastrocnemius muscles, and the TFL (in 45–145 degrees of flexion; see Table 20-2). The patient lies in the supine position. Using one hand, the clinician grasps the anterior aspect of the patient's lower leg, just proximal to the malleoli, while the other hand grasps the anterior aspect of the patient's thigh, just above the patella. The patient's hip is flexed to about 90 degrees and stabilized with one hand, while the clinician flexes the knee with the other hand (Fig. 20-9). At the end of the ROM, the clinician exerts slight overpressure. The normal end-feel is usually one of soft tissue approximation. A flexion limitation other than soft tissue approximation is usually the result of an articular lesion, such as arthritis or arthrosis (capsular pattern), a lesion of one of the menisci, or a loose body.[274]

Rotation of the tibia relative to the femur is possible when the knee is flexed and non–weight-bearing, with

FIGURE 20-9 Knee flexion.

FIGURE 20-10 Knee extension

rotational capability greatest at approximately 90 degrees of flexion.[97]

Extension

The primary extensors of the knee are the quadriceps muscles, consisting of the rectus femoris, VL, vastus medialis, and vastus intermedius (see Table 20-2). Also assisting with knee extension in the 0–30-degree flexion range is the ITB and TFL.

The patient extends the knee (see Fig. 20-10), and the clinician applies overpressure by stabilizing the thigh and pulling the ankle up to the ceiling, while allowing the conjunct external rotation of the tibia. Under normal conditions, the end-feel is usually hard.

A limitation of active knee motion can have a number of causes. The patient may have a neurologic deficit from a lumbar intervertebral disk (IVD) herniation, with loss of knee motion as the primary symptom. Any acute injury causing pain may limit active knee motion as a result of muscle inhibition.[310]

Passive Range of Motion

Passive movements, as elsewhere, can determine the amount of available motion, the presence or absence of a capsular pattern, and the end-feel. At the tibiofemoral joint, the end-feel of flexion should be tissue approximation, whereas the end-feel of extension and medial and lateral rotation of the tibia on the femur is tissue stretch. Passive hyperextension of the knee with overpressure is performed to assess (from the end-feel) whether the knee extension is limited as a result of an articular disorder. Such articular disorders include arthritis or arthrosis, a lesion of one of the menisci, or a loose-body involvement. Hayes et al.[331] found the intrarater reliability of end-feel and pain/resistance judgments at the knee to be generally good, especially after accounting for subject change and unbalanced distributions. Interrater reliability, however, was generally not acceptable, even after accounting for these factors.[331] In a separate study, Hayes et al.[332] explored the construct validity and test–retest reliability of the passive motion component of the Cyriax soft tissue diagnosis system and compared the hypothesized and actual patterns of restriction, end-feel, and pain/resistance sequence (P/RS) of 79 subjects with OA of the knee and examined associations among these indicators of dysfunction and related constructs of joint motion, pain intensity, and chronicity. The results of the study are discussed next.

Consistent with the hypotheses based on Cyriax's assertions about patients with OA, most subjects had capsular end-feels for extension; subjects with tissue approximation end-feels for flexion had more flexion ROM than did subjects with capsular end-feels, and the P/RS was significantly correlated with pain intensity ($\rho = 0.35$, extension; $\rho = 0.30$, flexion).[332]

Contrary to the hypotheses based on Cyriax's assertions, most subjects had noncapsular patterns, tissue approximation end-feels for flexion, and what Cyriax called pain synchronous with resistance for both motions.[332]

Pain intensity did not differ depending on end-feel. The P/RS was not correlated with chronicity ($\rho = 0.03$, extension; $\rho = 0.01$, flexion).[332]

Reliability, as analyzed by ICCs (ICC[3,1]) and Cohen's κ coefficients, was acceptable ($\geq$0.80) or nearly acceptable for ROM (ICC = 0.71–0.86, extension; ICC = 0.95–0.99, flexion) but not for end-feel ($\kappa = 0.17$, extension; $\kappa = 0.48$, flexion) and P/RS ($\kappa = 0.36$, extension; $\kappa = 0.34$, flexion).[332]

The study concluded that the use of a quantitative definition of the capsular pattern, end-feels, and P/RS as indicators of knee OA should be reexamined and the validity of the P/RS as representing chronicity and the reliability of end-feel and the P/RS are questionable.[332]

Others have found that a ratio of loss of extension to loss of flexion during passive range of motion (PROM) of between 0.03 and 0.50 was more likely than a noncapsular pattern in patients with an inflamed knee or osteoarthrosis (likelihood ratio = 3.2).[333]

According to the osteopathic theories of somatic dysfunction,[334] the following guidelines are used:

- If the restriction to movement is opposite to the direction that the bone seems to have traveled (e.g., the tibia has a reduced joint glide), a mobilization or a manipulation is the intervention of choice.
- If the restriction to movement is in the same direction that the bone seems to have moved and the opposite movement seems to be excessive (a change has occurred in the overall starting position), a muscle imbalance should be suspected, and a muscle energy technique used.
- If the patient demonstrates normal range but pain with movement, the joint cannot be at fault.
- If a muscle is very hypertonic, a spinal dysfunction may be present (unless trauma is involved), producing a hypermobility.

Even minor losses of knee motion may have adverse effects. It is common to lose both flexion and extension; however, loss of extension is usually more debilitating.[335] A loss of extension of more than 5 degrees may cause patellofemoral pain and a limp during walking,[336] whereas restricted flexion does not severely affect gait as long as the knee can be flexed to at least 60 degrees. [337] Diminished running speed is associated with loss of flexion of 10 degrees or more,[338] whereas an extension deficit of more than 10 degrees is poorly tolerated by active people.[339] A loss of more than 20 degrees of extension may cause a significant functional limb-length discrepancy.[338]

Patellar Motion Tests

Probably the most important part of the patellofemoral examination is the observation of the dynamics of patellar tracking in weight-bearing and non–weight-bearing.

A unilateral squat (Waldron test) can be used to assess patellofemoral function.[340] The patient stands on the involved leg, and the clinician sits or squats next to the patient. Using the entire surface of the palm, the clinician exerts slight pressure in an anteroposterior direction against the patient's patella (Fig. 20-11). From this position, the patient is asked to bend the knee slowly, if possible, to about 90 degrees, while the clinician palpates for crepitus and locking of the patella and assesses the course of movement of the patella. Crepitus or locking can indicate the presence of patellofemoral chondropathy or patellofemoral arthrosis. However, Nijs et al.[341] reported unimpressive positive and negative likelihood ratios for this test.

In patellar malalignment or pathologies of the corresponding femoral joint surface, movement of the patella can be disturbed. The patella is observed while the patient initiates flexion of the knee to see if it engages smoothly at the proximal end of the trochlea or more distally than normal. Lateralization of the patella can occur during flexion, particularly when the Q-angle is excessive.

The passive mobility tests for the patella are outlined in "Patellar Stability Tests" section.

Kinetic Chain Assessment

Ankle Motions

Ankle motions are tested because, as has been discussed, a number of structures share a common relationship with the foot, ankle, and knee joint complex (see Chap. 21) and can therefore have an impact on knee function. For example, adaptive shortening of the gastrocnemius, particularly in the presence of adaptively shortened hamstring muscles, may produce increased knee flexion at initial contact and during the stance phase of gait.[215]

Hip Motions

Several muscles cross both the hip and the knee. These include the rectus femoris, gracilis, sartorius, and hamstrings muscles. Adaptive shortening of any of these structures may cause alterations in postural mechanics and gait. The hip rotators can also influence other aspects of the lower kinetic chain. Sahrmann advocates the testing of length–strength relationship of the hip external rotators because of their CKC function of decelerating lower extremity internal rotation.[167,342]

Passive Accessory Motion Testing

The passive accessory motion tests, or joint glides, are performed at the end of the patient's available range to determine if the joint itself is responsible for the loss of motion.

Tibiofemoral Distraction

The patient lies in the prone position. The clinician is beside the patient. Using one hand to stabilize the thigh, the clinician uses the other hand to grip the distal tibia from the medial and lateral sides. The clinician then applies a force perpendicular to the tibial joint surface (Fig. 20-12).

Posterior Glide of the Tibia on the Femur

The patient lies in the supine position with the thigh supported by a towel. Standing to the side of the patient,

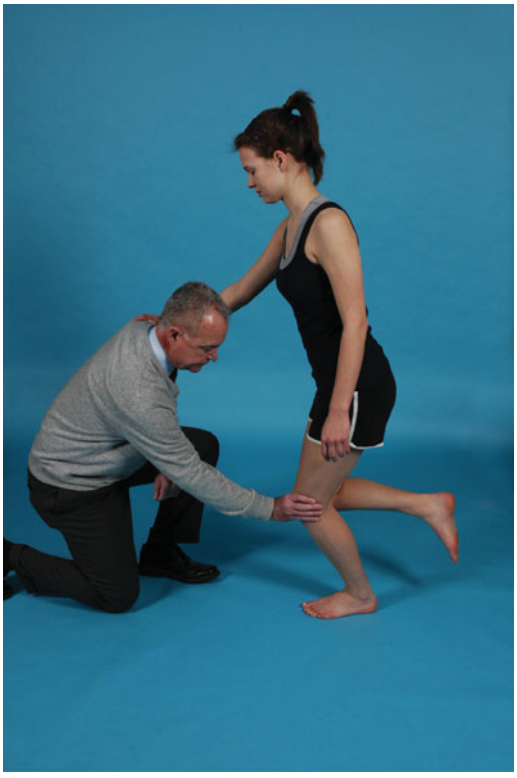

FIGURE 20-11 Waldron test.

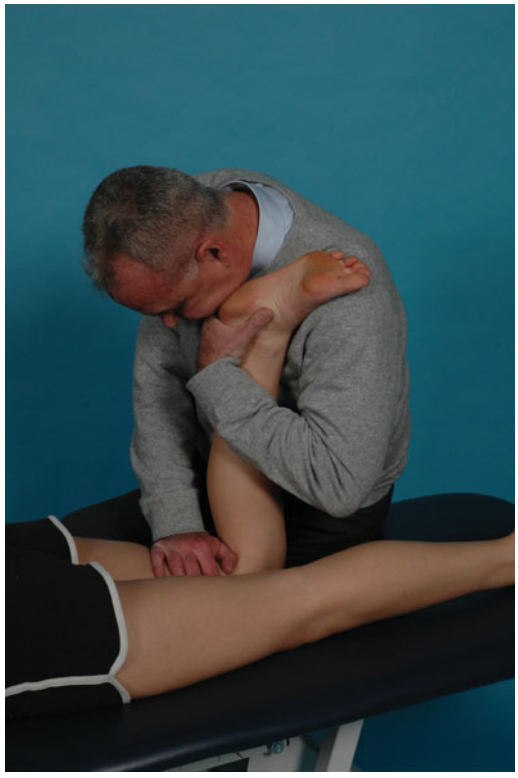

FIGURE 20-12 Tibiofemoral distraction.

FIGURE 20-13 Posterior glide of the tibia on the femur.

the clinician applies a posterior glide through the tibia (Fig. 20-13).

Anterior Glide of the Tibia on the Femur

The patient lies in the supine position with the knee flexed and the foot placed on the table. The clinician stands to the side of the patient. Using both hands, the clinician applies an anterior glide of the tibia (Fig. 20-14).

Proximal Tibiofibular Joint

The proximal tibiofibular joint can be assessed with the patient in the supine position and the knee flexed to approximately 90 degrees. The clinician stabilizes the tibia using one hand and uses the other hand to grasp the fibular head and to assess the anterolateral and posteromedial glides (Fig. 20-15).

FIGURE 20-14 Anterior glide of the tibia on the femur.

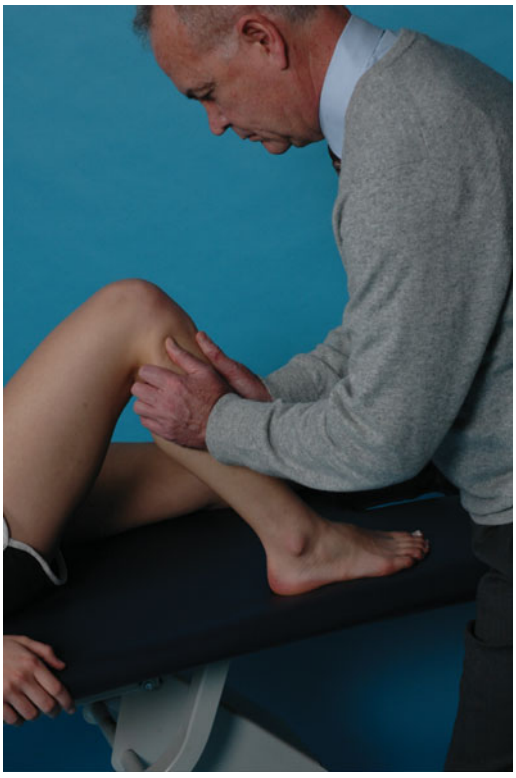

FIGURE 20-15 Mobility testing of the proximal tibiofibular joint.

Passive Tibial External Rotation

The patient lies in the supine position. Using one hand, the clinician grasps the patient's foot and brings the ankle into maximal plantar flexion. The other hand is positioned to monitor the joint space.[274] The patient's knee is flexed to 90 degrees and the hip to approximately 45 degrees. The distal hand performs an external rotation of the tibia while maintaining the ankle in maximum plantar flexion (see Fig. 20-16). At the end of the ROM, the clinician exerts slight overpressure. Under normal conditions, the end-feel is firm. The clinician notes whether the pain is provoked or whether there is a hypermobility or hypomobility[274]:

- Pain with passive external rotation of the tibia can be the result of a lesion of the medial meniscotibial ligament, medial meniscus, MCL, or the posteromedial capsuloligamentous complex.
- Hypermobility with this maneuver can be the result of a lesion of the posteromedial capsuloligamentous complex, often in combination with lesions of the MCL and the ACL. Hypermobility may also be seen in ballet dancers.
- Hypomobility of passive tibial external rotation is seen only in severe articular disorders with significant capsular limitations of motion.

Passive Tibial Internal Rotation

The patient lies in the supine position. Using one hand, the clinician grasps the patient's foot and brings the ankle into maximal plantar flexion. The other hand is positioned to monitor the joint space. The patient's knee is flexed to 90 degrees and the hip to about 45 degrees. The distal hand performs an internal rotation of the tibia while maintaining

FIGURE 20-16 Passive external rotation of tibia.

the ankle in maximum plantar flexion (see Fig. 20-17). At the end of the ROM, the clinician exerts slight overpressure. Under normal conditions, the end-feel is firm. The clinician notes whether pain is provoked or whether there is hypermobility or hypomobility[274]:

FIGURE 20-17 Passive tibial internal rotation.

FIGURE 20-18 Patellar mobility testing.

- Pain can be the result of a lesion of the lateral meniscotibial ligament, lateral meniscus or posterolateral capsuloligamentous complex.
- Hypermobility can be the result of a lesion of the posterolateral capsuloligamentous complex.
- Hypomobility is seen only in severe articular disorders with significant capsular limitations of motion.

Patellofemoral Joint Mobility Tests

The patient lies in the supine position with the involved knee supported in slight flexion. The clinician moves the patella superiorly, inferiorly, medially, and laterally (Fig. 20-18). Caution must be used with the lateral glide in case the joint is hypermobile, as this is the most common direction for patella dislocations. To assess the various tilts of the patella, both hands are wrapped around the patella and the thumbs are used to tilt the patella medially and laterally (Fig. 20-19). The findings are compared with the contralateral side.

Strength Testing

Gross muscle testing is useful in checking for deficits in the lower extremities. Strength testing involves the performance of resisted isometric tests. The joint is placed in its resting position to minimize any joint compression forces.

FIGURE 20-19 Patellar tilting test.

FIGURE 20-20 Strength testing the medial hamstrings.

Knee Flexion

The strength of the knee flexors (the hamstrings) can be assessed by positioning the patient prone with the knee flexed to approximately 80–90 degrees. By internally rotating the tibia (Fig. 20-20) and resisting knee flexion, the clinician can theoretically assess the integrity of the medial hamstrings (semimembranosus and semitendinosus). The biceps femoris is assessed similarly by externally rotating the tibia and resisting knee flexion (Fig. 20-21) **VIDEO**.

FIGURE 20-21 Strength testing the biceps femoris.

FIGURE 20-22 Strength testing of knee extensors at 60 degrees.

Knee Extension

Pain may be reproduced, and localized, with multiple angle isometric testing of the quadriceps, as described by McConnell.[189] Thus, the strength of the knee extensors (the quadriceps) is tested in 0, 30, 60 (Fig. 20-22), 90, and 120 degrees of knee flexion and held for 1 second with the femur externally rotated, to see if the pain can be reproduced or localized. The reproduction of pain with these tests suggests excessive pain from patellar compression. Any abnormal tibial movement with these tests may suggest ligamentous instability.[343] If pain is noted during this testing, McConnell suggests returning the knee to full extension, producing and maintaining a medial glide of the patella, and then returning the knee to the painful position to retest. This action should reduce the pain if it is of a patellofemoral origin.[189]

The final 15 degrees of knee extension require a 60% increase in muscle firing.[137] An extension lag (passive knee extension that is greater than active knee extension) indicates a slight loss of quadriceps muscle function.[167,266,344]

Siegel and Jacob[343] suggest testing the quadriceps muscle at 0, 30, 60, and 90 degrees while observing for any abnormal tibial movement. Any abnormal tibial movement would suggest ligament instability or excessive pain from patellar compression.

Plantar Flexion

The heel raise can be used to assess the strength of the gastrocnemius. The strength of the gastrocnemius muscle

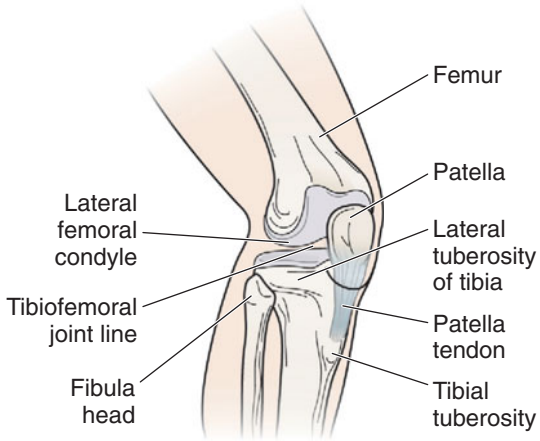

FIGURE 20-23 Palpable structures on the anterolateral surface of the knee.

is tested because of its intimate relationship to the knee and its importance in lower extremity function. The patient is positioned in standing, leaning against a wall, or supported by the clinician with the knees extended. One foot is tested at a time as the patient rises up on the toes for 10–20 repetitions (depending on age and physical ability) while standing.

- The patient everts the foot and raises up on the toes to test the lateral head.
- The patient inverts the foot and raises up on the toes to test the medial head.

The soleus muscle can be tested similarly by having the patient perform a unilateral heel raise while keeping the knee flexed.

Palpation

Palpation of the soft tissues about the knee is critical and often reveals more important information than any imaging tool. For palpation to be reliable, the clinician must have a sound knowledge of surface anatomy (Figs. 20-23 and 20-24), and the results from the palpation examination should be correlated with other findings. A logical sequence should be employed by the clinician. The skin, retinacula, quadriceps tendon, and patellar tendon are palpated to rule out any soft tissue sources of pain. Differences in temperature between the knees suggest inflammation in the warmer of the two. The following structures should be identified and palpated.

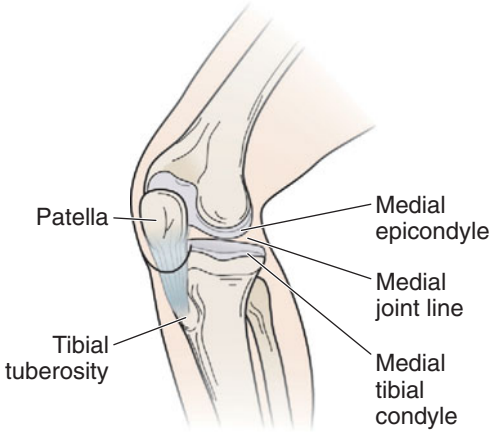

FIGURE 20-24 Palpable structures on the anteromedial surface of the knee.

Posterior Aspect

The patient lies in the prone position. The clinician locates the popliteal fossa. The semimembranosus and semitendinosus form the proximal medial border of the fossa. Deep inside this fossa, a Baker's cyst can be palpated if it is present. With the knee in a slightly flexed position, the thin round tendon of the semitendinosus should be easy to palpate. Medial and lateral to this tendon are the deeper parts of the semimembranosus. The popliteal pulse can be located just below the crease of the knee, more to the lateral side than to the medial side, and posterior to the tibial plateau. Medial to the pulse is the tendon of semimembranosus. At this point, if the thumb is pushed deeper, the attachment of the PCL can be located as it arises from the back of the tibia. Even under normal circumstances, this attachment will be tender. A little lateral to this is the attachment of the meniscofemoral ligament. The PCL and meniscofemoral ligament curve inward, to attach on the inner aspect of the medial condyle of the femur.

At the proximal lateral part the fossa, the biceps femoris tendon is found. This tendon is palpable together with the common fibular (peroneal) nerve. The tendon of the gracilis is medial and anterior to the medial part of the semimembranosus. Palpation performed medially and anteriorly to this point leads to the sartorius muscle. The tendons of the sartorius, gracilis, and semitendinosus form the pes anserinus. The sartorius and gracilis muscles can be differentiated as follows: the gracilis contracts during hip adduction, while the sartorius contracts during hip abduction. Palpation more anteriorly leads to the medial femoral condyle and the adductor tubercle. Tenderness at the anterior aspect of the medial femoral condyle, associated with a snapping sensation as the knee is flexed, can indicate a symptomatic plica.[345] The adductor tubercle serves as the attachment site for the patellar retinaculum and the medial patellofemoral ligament, and is a hallmark site of tenderness with lateral patellar dislocation.[274] The adductor tubercle is also the attachment site of the adductor magnus, and the origin of the MCL. The distal borders of the popliteal fossa are palpated by positioning the patient's knee in slight flexion. The medial head of the gastrocnemius can be palpated deep within and medial to the fossa, while the lateral head can be found deep within and medial to the tendon of the biceps femoris muscle.

Anterior Aspect

The patient lies supine with the hip and thigh positioned in extension. The clinician palpates the medial and lateral edges of the patella. The VMO normally inserts into the upper third or half of the medial patella and is readily palpable. In patients with patella malalignment, the VMO may be dysplastic and virtually invisible inserting proximal to the superior pole of the patella.[346] Palpation of the rectus femoris insertion on the superior aspect of the patella is only possible with the patella tipped slightly forward.[274] Complaints of pain distal to the patella during extension of the knee may indicate a patella tendon–ligament lesion at the inferior pole. In some individuals, the continuation of the tendon of the VL muscle, the lateral patellar retinaculum, can be palpated at the lateral side of the patella.[274]

Palpation of the joint space is made easier when the tibia is rotated internally and externally while in the flexed position. The anterior part of the medial meniscus is palpable in the medial joint space with the tibia externally rotated, between the patellar tendon–ligament and the anterior edge of the MCL. Under normal circumstances, the medial meniscus is not palpable beyond 30 degrees of flexion.[274] The medial meniscotibial or coronary ligament, which attaches the medial meniscus to the tibia, is palpable anteriorly with the knee positioned at 90 degrees of flexion and the tibia maximally externally rotated, proximal to the tibia (passive external rotation of the knee will provoke the patient's pain, if the ligament is damaged).[274]

CLINICAL PEARL

Joint line tenderness usually is associated with a tibiofemoral injury, such as a meniscal or collateral ligament tear, but it can also be associated with patellar pathology, although the reasons are probably multifactorial.[205,269,272] Numerous studies have shown that joint line tenderness, when used in isolation, is of little value in specifically diagnosing a meniscus tear.

Other structures to palpate for tenderness on the anterior aspect of the knee include the following:

- ***Base (inferior pole) of patella.*** Tenderness at the inferior tip of the patella indicates patellar tendinitis.
- ***Infrapatellar fat pad (Hoffa's fat pad).*** This structure is located between the patella ligament (anteriorly) and the anterior joint capsule (posteriorly).
- ***Lateral retinaculum.***
- ***Apex of patella.***
- ***Accessory retinaculum from the ITB.***
- ***Medial retinaculum.***
- ***Medial and lateral patellar facets.*** These facets, which are readily palpated using the thumb and index finger, can be tested for tenderness and alignment, as can the overhang of the lateral facet over the patellar groove, by pushing the patella to one side and then the other (glide test), and then curling the fingers around and under the borders of the patella. Palpation of the facets should not elicit pain. The clinician should be able to palpate under one-third of the patella. A tilt of the patella (lateral side down) reflects a tight retinaculum, especially if the tilt cannot be passively corrected by the clinician.[346] When the patella is laterally displaced by the clinician and the patient reports sudden and considerable discomfort as the knee approaches extension, this is termed the apprehension sign (see "Special Tests" section).[346] The combination of tilt and lateral facet tenderness in the absence of any other positive findings on physical examination suggests clinically significant patella malalignment.[346]
- ***Dynamic restraints.*** The patient is asked to contract the quadriceps. In patients with malalignment, the VMO typically cannot be identified by sight or palpation; it inserts no farther distally than the proximal pole of the patella and it remains soft, even with maximal quadriceps contraction.[196] In the normal knee, the VMO should be felt to contract simultaneously with the VL.

Lateral Aspect

The fibular head can be palpated by following the tendon of the biceps femoris distally. It is often more distal and posterior than imagined. On the lateral side, the highest point on the lateral femoral condyle is the lateral epicondyle, which serves as the origin of the LCL. The LCL is best palpated when the hip is maximally externally rotated and the knee is flexed to 90 degrees in the "figure-four" cross-legged stance.[274] If the LCL is followed down to the fibular head, it will be felt to blend with the biceps femoris. On the posterolateral aspect of the condyle is the attachment for the lateral head of the gastrocnemius. Anterior to this, there is a small circular groove, which is where the tendon of the popliteus originates from the lateral condyle. Tenderness in this location, just behind the LCL, either anterior or posterior to it, would suggest damage to the popliteus muscle.[274] On the anterolateral aspect of the knee is Gerdy's tubercle, the largest bony prominence medial to the apex of the fibular head, which serves as the attachment site for the ITB.

The lateral joint space is palpated starting at a point just lateral to the patellar tendon–ligament. The anterior part of the lateral meniscus is best palpated with the knee in an extended position.

Medial Aspect

The highest point of the medial aspect of the femur is the medial epicondyle, which serves as the origin for the MCL. Superior to this point is the adductor tubercle, and superior to that is the supracondylar ridge, which is the attachment for the VMO. Very localized tenderness at the medial aspect of the knee, away from the joint line, may indicate a neuroma.[344]

Special Tests

Numerous special tests exist for the knee joint complex based on the intent and diagnostic purpose.

Stress Tests

The stress tests are used to determine the integrity of the joint, ligaments, and the menisci. A complete history and physical examination can diagnose approximately 90% of ligamentous injuries. The goal of the stress tests is to identify the degree of separation and the quality or end-feel of the separation when a stress is applied in a specific direction. Intact ligaments have an abrupt and firm end-feel, whereas sprained ligaments have a soft or indistinct end-feel depending on the degree of injury. A comparison should always be made with the uninvolved knee before a determination is made. It is important to remember that both pain and swelling can hamper the sensitivity of these tests.[347]

Serious functional instability of the knee appears to occur unpredictably. The reasons for such discrepancies are unknown, but they may be a result of[36]

- varying definitions of instability;
- varying degrees of damage to the ACL;[348,349]
- different combinations of injuries;[71]
- different mechanisms of compensation for the loss of the ACL;
- differences in rehabilitation;
- the diverse physical demands and expectations of different populations.

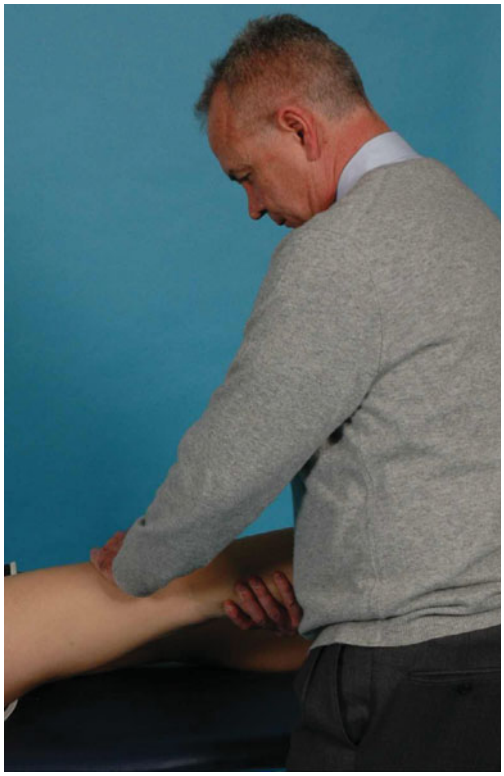

FIGURE 20-25 Valgus test.

Valgus Stress

The patient lies in the supine position, with the involved knee extended. The clinician applies a strong valgus force, with a counterforce applied at the lateral femoral condyle (Fig. 20-25). Normally, there is little or no valgus movement in the knee, and, if present, it should be less than the amount of varus motion. Under normal conditions, the end-feel is firm. With degeneration of the medial or lateral compartments, varus and valgus motions may be increased, while the end-feels will be normal.

With the knee tested in full extension, any demonstrable instability is usually very significant. Pain with this maneuver is caused by an increase in tension of the medial collateral structures or the connection of these structures with the medial meniscus. If pain or an excessive amount of motion is detected compared with the other extremity, a hypermobility or instability should be suspected. The following structures may be implicated:

- Superficial and deep fibers of the MCL
- Posterior oblique ligament
- Posteromedial capsule
- Medial capsular ligament
- ACL
- PCL

CLINICAL PEARL

A study by Garvin et al.[350] looked at 23 patients with a surgically proven tear of the MCL, where findings from magnetic resonance imaging (MRI) of the knee were evaluated retrospectively. MRI revealed the tear in all cases, although when the injury was severe, distinguishing high-grade partial tears from complete tears was difficult.[350] Physical examination had indicated a tear in 22 (96%) of the cases.[350] A high prevalence of associated cruciate and meniscal injuries was seen (in 23 [100%] and 12 [52%] of the cases, respectively). Tears of the LCL occurred in 13 (57%) of the patients and at least one bony infarction in 22 (96%); most of the infarctions were in the lateral compartment. Infarctions of the lateral femoral condyle were frequently geographic (in 14 [70%] of the 20 cases) or impacted (in 5 [25%]).[350]

To further assess the MCL, posterior oblique ligament, and PCL, the test is then repeated at 20–30 degrees of flexion. Hughston[55] concluded that a valgus stress test positive at 30 degrees and negative at 0 degree indicates a tear limited to the medial compartment ligaments (posterior oblique ligament) and posterior medial capsule, whereas a valgus stress test positive at 0 degree indicates a tear of both the PCL and the medial compartment ligaments.

The posterior fibers of the MCL can be isolated, by placing the knee in 90 degrees of flexion with full external rotation of the tibia.[274] The femur is prevented from rotating by the clinician's shoulder. The clinician places one hand on the posterior aspect of the foot and the other on the heel, and an external rotation force is applied using the foot as a lever.

These tests can be graded by the following:[63]

- Grade I: The joint space opening is within 2 mm of the contralateral side.
- Grade II: The joint space opens 3–5 mm more than the contralateral side in 20 degrees of knee flexion and less than 2 mm more than the normal knee in full extension.
- Grade III: The joint space opens 5–10 mm more than that of the normal knee in 20 degrees of flexion and full extension.

More research is needed to evaluate the diagnostic accuracy and reliability of this test.

Varus Stress

The patient lies in the supine position, with the involved knee in full extension. The clinician applies a strong varus force, thereby gapping the lateral aspect of the knee (see Fig. 20-26). To be able to assess the amount of varus movement, the clinician should repeat the maneuver several times, applying slight overpressure at the end of the ROM. Under normal conditions, the end-feel is firm, after slight movement. Unlike the valgus stress test, the varus test has been shown to be highly unreliable with many false-negative findings.[351]

FIGURE 20-26 Varus test.

Theoretically, if this test is positive for pain or excessive motion compared with the other extremity, the following structures may be implicated:

- LCL
- Lateral capsular ligament
- Arcuate-popliteus complex
- ACL
- PCL

If the instability is gross, one or both cruciate ligaments as well as, occasionally, the biceps femoris tendon and the ITB may be involved, leading to a rotary instability if not in the short term, certainly over a period of time.[159]

The test is then repeated at 10–30 degrees of flexion with the tibia in full external rotation to further assess the LCL, posterolateral capsule, and arcuate–popliteus complex.

Grading of these injuries is the same as for MCL injuries and is based on the degree of opening of the lateral joint line.[63]

More research is needed to evaluate the diagnostic accuracy and reliability of this test.

One-Plane Anterior Instability

Ensuring the integrity of the ACL is crucial for maintaining the normal biomechanical properties of the knee joint, protecting its periarticular structures, and preventing premature OA. Knee joints with ACL deficiencies have rotary instabilities that expose supporting ligaments and menisci adjacent to the ACL to further damage and degenerative joint disease.[28] Signs and symptoms of chronic rotary knee instabilities from ACL deficiencies include swelling, pain, a "giving way" of patients' knee joints, arthritis, and possible subsequent meniscal injuries.

Several tests have been advocated for testing the integrity of the ACL. Three of the more commonly used ones are the Lachman test, the anterior drawer test, and the pivot shift (see "Anterolateral Rotary Instability" section).

Lachman Test. Torg et al.[352] were the first to publish a description of the Lachman test, whereby the knee is held in 30 degrees of flexion while the tibia is anteriorly translated with respect to the femur (Fig. 20-27).

The accuracy and reliability of the Lachman appears to vary. Katz et al. found that in the hands of an experienced clinician, accuracy of this test was 81.8% sensitive and 96.8% specific,[353] increasing to 100% if the patient was anesthetized.[354,355] In contrast, Cooperman et al.[356] reported that the predictive value of a positive test was 47% for all examiners, whereas the predictive value of a negative test was 70%, results that would indicate that Lachman test judgments have limited reliability and may be more useful for predicting that a patient does not have an ACL injury than for predicting that the ACL is injured.[357]

These discrepancies likely occur as there are a number of factors that can influence the results. These include

- an inability of the patient to relax;
- the degree of knee flexion;
- the size of the clinician's hand;
- the stabilization (and thus relaxation) of the patient's thigh.

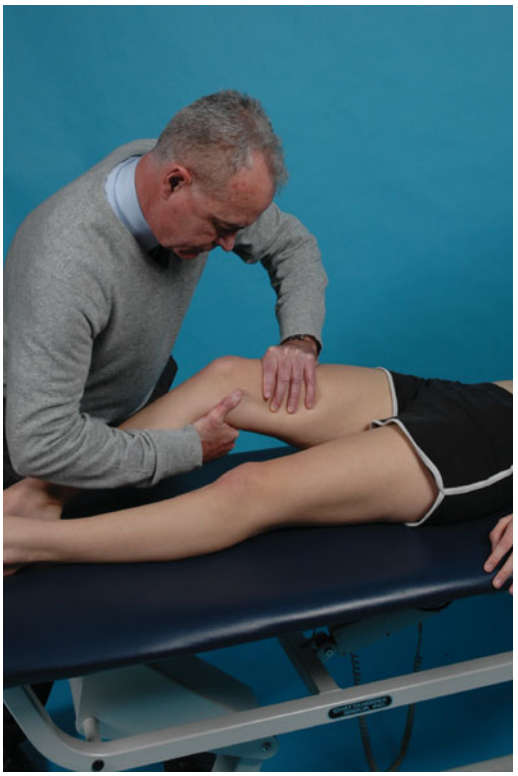

FIGURE 20-27 Lachman test.

According to Weiss et al., [358] these factors can be minimized by the use of the modified Lachman test. In this modification, the patient lies in the supine position, with the feet resting firmly on the end of the table and the knees flexed 10–15 degrees. The clinician stabilizes the distal end of patient's femur using the thigh rather than the hand, as in the Lachman test, and then attempts to displace patient's tibia anteriorly. If the tibia moves forward, and the concavity of the patellar tendon–ligament becomes convex, the test is considered positive.

The grading of knee instability is as follows[55,359,360]:

1 + (mild): 5 mm or less

2 + (moderate): 5–10 mm

3 + (serious): more than 10 mm

With this test, false-negatives can occur. False-negatives may be caused by a significant hemarthrosis, protective hamstring spasm, or tear of the posterior horn of the medial meniscus.[352]

Active Lachman Test. The patient lies in the supine position with a bolster under the distal femur so that the knee is flexed to 30–40 degrees. The patient is asked to actively extend the involved knee and then to relax back to the starting position. A positive test for a torn ACL is indicated by an anterior glide of the proximal tibia during the knee extension. The one study[361] that examined this test did not report reliability or diagnostic accuracy.

Anterior Drawer Test. The aforementioned Lachman test is a modification of the anterior drawer test.[274] The patient lies in the supine position with the clinician standing to the side of

FIGURE 20-28 The anterior drawer test.

the patient's involved knee. The clinician grasps the lower leg of the patient just distal to the joint space of the knee and the patient's knee is flexed to 90 degrees so that the foot is flat and the lower leg is not rotated. The clinician fixates the patient's leg by sitting on the foot. The clinician can place the thumbs either in the joint space or just distal to it to assess mobility. The clinician tests the tension in the musculature. It is important that all muscles around the knee be relaxed to allow any translatory movement to occur. With both hands, the clinician now abruptly pulls the lower leg forward (Fig. 20-28). This test is positive for an ACL tear when an abnormal anterior movement of the tibia occurs compared with the other extremity. Overall, there is wide variation in the reported sensitivities of the anterior drawer test. The anterior drawer test in 80 degrees of flexion without rotation has been found to be 40.9% sensitive and 96.8% specific.[353] This test appears to be a specific test helpful at ruling in a torn ACL when the test is positive.[352,362,363] False-negatives may occur with this test for the same reasons as those in the Lachman test. Given the low sensitivity of this test, the clinician should not rule out an acute ACL injury solely on the basis of a negative anterior drawer.

There are a number of variations to the anterior drawer test, all of which involve positioning the patient supine[274]:

- ***Anterior drawer test and maximal external rotation.***[274] The initial positions of the patient and clinician are the same as in the anterior drawer test in 80 degrees of flexion without rotation, except that the lower leg is positioned in maximum external rotation. For the performance, refer to the preceding description. The ACL and the medial and posteromedial capsuloligamentous structures are tested in this position. If this test is positive, there is likely to be an anteromedial rotatory instability. The specific medial and posteromedial structures that are affected can be further differentiated by the abduction (valgus) stress tests previously described. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.
- ***Anterior drawer test and maximal internal rotation.***[274] The initial positions of the patient and clinician are the same as in the anterior drawer test in 80 degrees of flexion without rotation, except that the lower leg is now maximally internally rotated. Performance of the test is the same as described earlier for that test. When in maximal internal rotation, the PCL can completely restrict anterior translation of the tibia. Thus, for this test to demonstrate excessive anterior translation, the PCL, ACL, and lateral or posterolateral capsuloligamentous structures have to be affected. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Comparison of the Lachman and Anterior Drawer Tests. The Lachman test has two advantages over the anterior drawer test in 90 degrees of knee flexion. First, all parts of the ACL are more or less equally taut. Second, in acute lesions it is often impossible to position the knee in 90 degrees of flexion because of a hemarthrosis. In a study of patients with an ACL rupture, the Lachman test was positive in 80% of nonanesthetized patients and 100% of anesthetized patients. In comparison, the anterior drawer sign was positive in 9% of nonanesthetized patients and 52% of anesthetized patients.[364]

Jonsson et al.[365] compared both the Lachman and anterior drawer tests in 45 patients with an acute ACL injury and 62 patients with a chronic knee injury. Patients were tested while nonanesthetized and anesthetized, and the diagnosis was verified by arthroscopy. The Lachman test results for the acute injury group was 87% (conscious) and 100% (anesthetized). The anterior drawer test results were 33% and 98%, respectively. The chronic injury group scored a positive Lachman test in 97% (conscious) and 99% (anesthetized). The anterior drawer test was positive in 92% and 100%, respectively.

According to Larson,[366] the Lachman test proved to be the most sensitive test for an ACL rupture. However, this article lacked statistical data to verify this assertion. Another study[355] that compared the two tests reported a sensitivity of 99% for the Lachman test and a sensitivity of 70% for the anterior drawer sign.

One-Plane Posterior Instability

The PCL is very strong and is rarely completely torn. It is typically injured in a dashboard injury or in knee flexion activities (falling on the patella). Several tests have been advocated to test the integrity of the PCL.[274]

Posterior Sag (Godfrey) Sign. The patient lies in the supine position with the knees flexed to approximately 90 degrees and the legs supported under the lower calf/heel by the clinician's arm. The clinician assesses the contour of the tibial tuberosities (Fig. 20-29). If there is a rupture (partial) of the PCL, the tibial tuberosity on the involved side will be less visible than that on the noninvolved side.[367] This discrepancy is caused by an abnormal posterior translation, resulting from a rupture of the PCL. In cases of doubt, the patient can be asked to contract the hamstrings slightly by pushing the heels into the clinician's arm. This maneuver usually results in an increase in the posterior translation of the tibia and is often performed as a quick test of the integrity of the PCL. This test may have

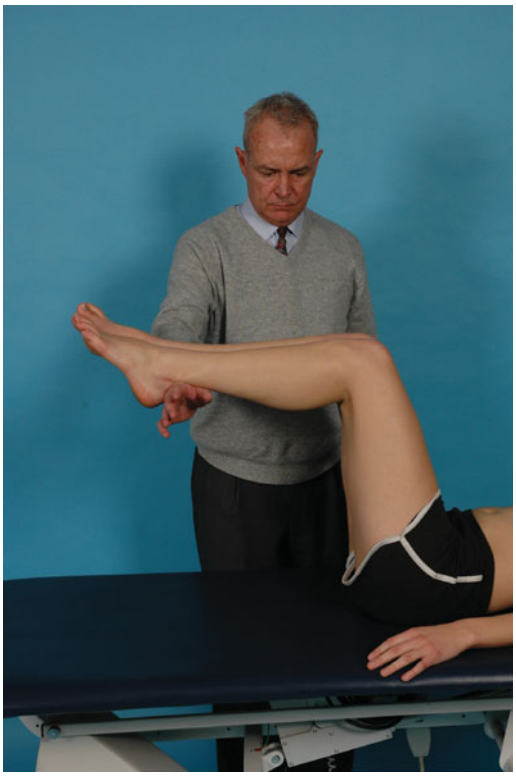

FIGURE 20-29 Godfrey sign.

FIGURE 20-30 Posterior drawer.

some value as a screening test when negative due to its high sensitivity.[368,369]

Posterior Drawer Test. The patient lies in the supine position, with the involved knee flexed to 90 degrees. The clinician attempts a posterior displacement of the tibia on the femur (Fig. 20-30). In a blinded, randomized, and controlled study involving 39 patients to assess the clinical examination skills of orthopaedic surgeons with fellowship training in sports medicine, Rubinstein et al.[370] reported that the accuracy for detecting a PCL tear was 96%, with a 90% sensitivity and a 99% specificity. The examination accuracy was higher for grades II and III posterior laxity than for grade I laxity.[370] Eighty-one percent of the time, the examiners agreed on the grade of the PCL tear for any given patient.[370]

Functional Posterior Drawer Test.[371] The patient lies in the prone position with the foot in neutral rotation and the knee flexed to 80–90 degrees. The patient is asked to isometrically contract the hamstrings while the clinician stabilizes the foot (Fig. 20-31). A positive result for a PCL tear is a posterior subluxation of the lateral tibial plateau.

Quadriceps Active Test. The patient lies in the supine position and the relaxed limb is supported with the knee flexed to 90 degrees in the drawer-test position. The patient is asked to execute a gentle quadriceps contraction to shift the tibia without extending the knee. If the PCL is ruptured, the tibia sags into posterior subluxation (~2 mm or more), and the patellar ligament is then directed anteriorly. Studies have shown significantly different sensitivities for this test. Rubinstein et al.[370] reported a sensitivity of 54% and a specificity of 97% whereas Daniel[372] reported a sensitivity of 98%.

Rotary Instabilities

Rotary or complex instabilities occur when the abnormal or pathologic movement is present in two or more planes. The ligamentous laxities present at the knee joint in these situations allow motion to take place around the sagittal, coronal, and horizontal axes.

Posterolateral Instability. This type of instability is relatively rare, because it requires complete posterior cruciate

FIGURE 20-31 Functional posterior drawer test.

FIGURE 20-32 Modified posterolateral drawer.

laxity. It occurs when the lateral tibial plateau subluxes posteriorly on the femur, with the axis shifting posteriorly and medially to the medial joint area. With a hyperextension test, this posterior displacement is obvious and has been labeled as the *external rotation recurvatum sign.*

Modified Posterolateral Drawer (Loomer's) Test.[55,360] The patient lies in the supine position with the hip and knee flexed to 90 degrees, and the lower leg in external rotation (Fig. 20-32).[373] If the tibia rotates posteriorly during the test, the test is positive for posterolateral instability, indicating that the following structures may have been injured:

- PCL
- Arcuate–popliteus complex
- LCL
- Posterolateral capsule

The one-plane medial and lateral stability tests, described earlier, can be used to further differentiate which lateral and posterolateral structures are affected.

Dial Test. This test is used to assess abnormal external tibial rotation to help differentiate between an isolated posterolateral corner injury and combined ACL/PCL injuries. The patient lies in the supine position with the knee flexed to 30 degrees over the edge of the table.[374] The clinician applies an external rotation force to the patient foot by placing the fingers and thumb alongside the talocalcaneal bone contours (Fig. 20-33). The foot–thigh angle is measured and compared with the uninjured knee. The test is then performed with 90 degrees of knee flexion and the foot–thigh angle is remeasured. When comparing the two angles, a difference of 10 degrees or more is significant. As the knee is flexed to 90 degrees, a reduction in increased rotation may occur although the amount of motion remains greater than the uninjured side if the PCL is still intact. This increased rotation occurs because the PCL is a secondary stabilizer to external rotation and gains mechanical advantage when the knee is flexed.[375]

Posteromedial Displacement with Valgus Stress Test. The patient lies in the supine position, with the involved leg slightly flexed.[373] The clinician pushes the lower leg posteriorly into hyperextension while applying a valgus stress (Fig. 20-34). If the tibia sags posteriorly during the test, the test is positive for posteromedial instability, indicating that the following structures may have been injured:

FIGURE 20-33 Dial test.

- PCL
- Posterior oblique ligament

FIGURE 20-34 Posteromedial displacement with valgus stress test.

- MCL
- Posteromedial capsule
- ACL

The one-plane medial and lateral stability tests, described earlier, can be used to further differentiate which medial and posteromedial structures are affected.

Anterolateral Rotary Instability. The pathology for this condition almost certainly involves the ACL and, clinically, the instability allows the medial tibial condyle to sublux posteriorly, because the axis of motion has moved to the lateral joint compartment.[159]

The diagnosis of anterolateral instability is based on the demonstration of a forward subluxation of the lateral tibial plateau as the knee approaches extension and the spontaneous reduction of the subluxation during flexion, in the lateral pivot-shift test.[159] This form of instability usually occurs when the individual is either decelerating or changing direction, and the sudden shift of the lateral compartment is experienced as a "giving way" phenomenon, often associated with pain.[159]

Pivot-Shift Test

This test was first described by Galway et al.[376] in 1972 and has been described since by a number of authors.[377–380]

The pivot shift is the anterior subluxation of the lateral tibial plateau that occurs when the lower leg is stabilized in (almost) full extension, whereby further flexion produces a palpable spring-like reduction.[381] The pivot shift is the most widely recognized dynamic instability of the knee, and it has been shown to correlate with reduced sports activity,[382] degeneration of the cartilage,[383,384] reinjury, meniscal damage,[385] joint arthritis,[385] and a history of instability symptoms.[357,386]

Since the majority of patients with an ACL rupture complain of a "giving way" sensation, the pivot-shift test is regarded in current literature as capable of identifying rotational instability.[377,378,380]

The patient lies in the supine position with the clinician standing to the side of the patient's involved knee. There are two main types of clinical tests to determine the presence of the pivot shift: the reduction test and the subluxation test.

- ***Reduction test.*** The clinician stabilizes the patient's lower leg and flexes the knee to 90 degrees with one hand while using the palm of the other hand to medially rotate the tibia, effectively subluxing the lateral tibial plateau (Fig. 20-35).[386] A sudden reduction of the anteriorly subluxed lateral tibial plateau is seen as the pivot shift.[376]
- ***Subluxation test.*** This test is effectively the reverse of the reduction test.[55] The test begins with patient's knees flexed. The clinician internally rotates the patient's tibias with one hand and applies a valgus stress to the knee joint with the other hand (Fig. 20-36). The clinician slowly extends the knee, maintaining rotation of the tibia. As the patient's knee reaches full extension, the tibial plateau will be felt to relocate. However, only 35–75% of patients whose knees pivot while the patient is under anesthesia will experience such a pivot when awake.[355,387–389]

FIGURE 20-35 Pivot-shift test—reduction.

Although the specificity of the pivot shift test is very high, namely 98% (95% CI, 25–38), there is little agreement in the literature with regard to the sensitivity of the test, which varies between 0% and 98%.[355,364,390] However, in a meta-analysis that looked at 28 studies to assess the accuracy of clinical tests for diagnosing ACL ruptures, Benjaminse et al.[391] found the pivot shift test to be very specific both in acute as well as in chronic conditions, and recommended that both the Lachman and pivot-shift tests be performed in all cases of suspected ACL injury.

It is worth noting that the pivot-shift test can be positive with an isolated ACL injury[355,392] or a tear or stretching of the lateral capsule,[379,393] although an injury to the MCL reduces the likelihood of a pivot shift even with ACL injury.[355,394]

Patellar Stability Tests

Patellar stability is assessed by gently pushing the patella medially and laterally while the knee is in a position of 90 degrees of flexion. This position is used because it places all of the retinacula on stretch. If this test is positive for laxity, further testing is performed by applying medial and lateral patellar glides, tilts, and rotations, with the knee in relaxed extension, and noting any limitations of motion or excessive excursion (Table 20-8).[266]

- ***Glide.*** The glide component determines the amount of lateral deviation of the patella in the frontal plane. A 5-mm

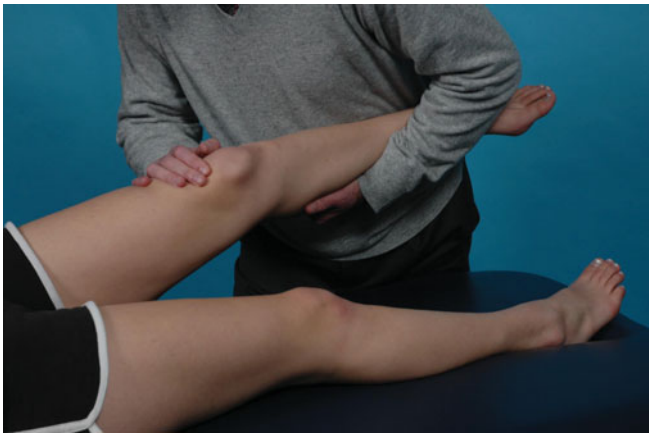

FIGURE 20-36 Pivot-shift test—subluxation.

TABLE 20-8 Assessing the Tilt, Orientation, and Glide of the Patella

Test and Measure	Procedure and Determination of Positive Finding	Population	Reliability Kappa Values
Superoinferior tilt[a]	Clinician visually estimates patellar alignment while palpating superior and inferior patellar poles Patellar orientation graded according to an ordinal scale extending from −2 to +2, with −2 representing inferior patellar pole below superior pole, and +2 representing inferior patellar pole above superior pole	27 asymptomatic subjects	Intraexaminer $\kappa = 0.50$ Interexaminer $\kappa = 0\ 30$
Anterior tilt[b]	Clinician palpates inferior patellar pole If the clinician can palpate inferior pole, no anterior tilt exists; if downward pressure on superior pole is required to palpate inferior pole, it is considered to have an anterior tilt	66 patients referred to physical therapy who would normally undergo evaluation of patellofemoral alignment	Interexaminer $\kappa = 0.24$
Anterior/posterior tilt component[c]	Clinician palpates inferior and superior patellar poles Scored 0, 1, or 2: 0 if inferior patellar pole is as easily palpable as superior pole; 1 if inferior patellar pole is not as easily palpable and superior pole; 2 if inferior pole is not clearly palpable compared with superior pole	56 subjects, 25 had symptomatic knees	Intraexaminer $\kappa = 0.03–0.23$ Interexaminer $\kappa = 0.04$
Rotation[a]	Clinician positions index fingers along longitudinal axes of patellar and estimates acute angle formed Graded according to ordinal scale extending from −2 to +2: −2 indicates that longitudinal axis of patella is more lateral than axis of femur; +2 indicates that patella is more medial than axis of femur	27 asymptomatic subjects	Intraexaminer $\kappa = 0.41$ Interexaminer $\kappa = –0.03$
Patellar rotation[b]	Clinician determines relationship between longitudinal axis of patella and femur Longitudinal axis of patellar should be in line with ASIS; if distal end of patella is medial, it is considered to be medially rotated; if distal end is lateral, it is considered to be laterally rotated	66 patients referred to physical therapy who would normally undergo evaluation of patellofemoral alignment	Interexaminer $\kappa = 0.36$
Patellar rotation component[c]	Clinician determines relationship between longitudinal axis of patella and femur Scored as −1, 0, or + 1: 0 when patellar long axis is parallel to long axis of femur; 1 when inferior patellar pole is lateral to axis of femur and classified as lateral patellar rotation; −1 when inferior pole is medial to axis of femur and classified as medial patellar rotation		Intraexaminer $\kappa = –0.06$ to 0.00 Interexaminer $\kappa = –0.03$
Mediolateral tilt[a]	Clinician estimates patellar alignment while palpating medial and lateral aspects of patella Patellar orientation graded according to an ordinal scale extending from –2 to +2 with –2 representing a lateral tilt, 0 no appreciable tilt, and +2 a medial tilt	27 asymptomatic subjects	Intraexaminer $\kappa = 0.57$ Interexaminer $\kappa = 0.18$
Medial/lateral tilt[b]	Clinician palpates medial and lateral borders of patella with thumb and index finger If digit palpating the medial border is higher than that palpating the lateral border, then the patella is considered laterally tilted; if digit palpating the lateral border is higher than that palpating the medial patella, then the patella is medially tilted	66 patients referred to physical therapy who would normally undergo an evaluation of patellofemoral alignment	Intraexaminer $\kappa = 0.28–0.33$ Interexaminer $\kappa = 0.21$

(Continued)

TABLE 20-8 Assessing the Tilt, Orientation, and Glide of the Patella *(Continued)*

Test and Measure	Procedure and Determination of Positive Finding	Population	Reliability Kappa Values
Medial/lateral tilt[c]	Clinician attempts to palpate posterior surface of medial and lateral patella borders Scored 0, 1, or 2: 0 if clinician palpates posterior border on both medial and lateral sides; 1 if >50% of lateral border can be palpated but posterior surface cannot; 2 if <50% of lateral border can be palpated	56 subjects, 25 had symptomatic knees	Intraexaminer $\kappa = 0.44–0.50$ Interexaminer $\kappa = 0.19$
Patellar tilt test[c]	Clinician lifts lateral edge of patella from lateral femoral epicondyle Graded as having positive, neutral, or negative angle with respect to horizontal plane	99 knees, of which 26 were symptomatic	Interexaminer $\kappa = 0.20–0.35$
Mediolateral position[a]	Clinician visually estimates patellar alignment while palpating sides of lateral epicondyles with index fingers, and patella midline with thumbs Patellar orientation graded according to an ordinal scale extending from −2 to +2 with −2 representing a lateral displacement, 0 no appreciable displacement, and +2 a medial displacement	27 asymptomatic subjects	Intraexaminer $\kappa = 0.40$ Interexaminer $\kappa = 0.03$
Mediolateral orientation[d]	With knee supported in 20 degrees of flexion, the clinician identifies medial and lateral epicondyles of femur and midline of patella. Clinician then marks medial and lateral epicondyles and patellar midline with tape Distances between patella midline and medial and lateral condyles are measured	20 healthy physiotherapy students	Interexaminer Medial distance: ICC = 0.91 Lateral distance: ICC = 0.94
Medial/lateral displacement[b]	Clinician palpates medial and lateral epicondyles with index fingers while simultaneously palpating midline of patella with thumbs Distance between index fingers and thumbs should be the same; when distance to index finger palpating lateral epicondyles is less, patella is laterally displaced; when distance to index finger palpating medial epicondyles is less, patella is medially displaced	66 patients referred to physical therapy who would normally undergo evaluation of patellofemoral alignment	Interexaminer $\kappa = 0.10$
Medial/lateral glide[c]	Clinician uses a tape measure to record distance from medial and lateral femoral condyles to mid-patella Scored 0 or 1: 0 if distance from medial epicondyle to mid-patella equals distance from lateral epicondyle to mid-patella; 1 if distance from medial epicondyle to mid-patella is 0.5 cm greater than that from lateral condyle to mid-patella	56 subjects, 25 had symptomatic knees	Intraexaminer $\kappa = 0.11–0.35$ Interexaminer $\kappa = 0.02$

lateral displacement of the patella causes a 50% decrease in VMO tension.[395] In the normal knee when fully extended and relaxed, the patella can be passively displaced medially and laterally approximately 1 cm in each direction, or approximately one-third of the width of the patella.[187] Displacement of more than half the patella over the medial or lateral aspect is considered abnormal.[9] If the patient is apprehensive as the glide maneuver is being performed, the

problem is likely to be one of poor patellar engagement. A decreased medial glide of the patella has been found to be related to ITB and/or lateral retinaculum tightness.[131]

- ***Tilt.*** The degree of patellar tilt is assessed by comparing the height of the medial patellar border with the height of the lateral border, which helps to determine the degree of tightness in the deep retinacular fibers. A slight lateral tilt of the patella is normal. An increased medial tilt results from a tight lateral retinaculum. If the passive lateral structures are too tight, the patella will tilt so that the medial border is higher than the lateral border (lateral tilt), making the posterior edge of the lateral border difficult to palpate.[266] A posterior tilt results in fat pad irritation.
- ***Rotation.*** The rotation component determines whether there is any deviation of the long axis of the patella from the long axis of the femur. If the inferior pole is sitting lateral to the long axis of the femur, the patient has an externally rotated patella, whereas if the inferior pole is sitting medial to the long axis, the patient has an internally rotated patella.

If the patient has one or more of these components present, the clinician needs to determine which of them, if any, is abnormal.

Meniscal Lesion Tests

McMurray's Test

The McMurray test was originally developed to diagnose posterior horn lesions of the medial meniscus. The patient lies in the supine position, and the clinician, standing on the same side as the involved knee, maximally flexes the hip and knee. This is accomplished by grasping the patient's foot in such a way that the thumb is lateral, the index and middle fingers are medial, and the ring and little fingers hold the medial edge of the foot (Fig. 20-37). The thumb of one hand is placed against the lateral aspect of the patient's knee (see Fig. 20-37). To test the medial meniscus, the clinician rotates the tibia into external rotation, then slowly extends the knee. To test the lateral meniscus, the clinician flexes the knee again but now internally rotates the patient's tibia and then slowly extends the knee. A positive test traditionally is indicated by an audible or palpable *thud* or *click*. In a study by Dervin et al.[396] to determine clinicians' accuracy and reliability for the clinical diagnosis of unstable meniscus tears in patients with symptomatic OA of the knee, a positive McMurray test was the only positive predictor of an unstable meniscal tear.[396]

Numerous variations exist for the McMurray test, including the addition of varus/valgus stresses. An examination of the variation seemed to indicate that the McMurray test has some value as a specific test where a positive test would rule in the disease.

Apley's Test[397]

The patient is placed in the prone position, with the knee flexed to 90 degrees. The patient's thigh is stabilized by the clinician's knee. The clinician grasps the patient's foot with one hand, distracts the tibia, and rotates the tibia internally and externally, noting whether or not pain is reproduced. A positive test is indicated by worse pain with rotation and is indicative of a *rotation sprain* of soft tissue. The clinician then applies internal and external rotation with compression to the lower leg, noting any pain and the quality of motion (Fig. 20-38). A positive test for a meniscus tear is indicated by more pain in compression than distraction. It would appear from a number of studies that the Apley test can be used as a specific test to rule in a meniscus tear when positive.

FIGURE 20-37 McMurray test.

Steinmann's Sign[274]

Steinmann's test can be used to diagnose meniscal lesions. The patient is placed in the supine position, while the clinician stands to the side. Using one hand, the clinician grasps the patient's lower leg just proximal to the malleolus. The other hand grasps the lateral side of the patient's lower leg as proximal to the knee as possible while also palpating the medial joint space with the fingers (Fig. 20-39). The knee is extended, and the joint line between the patellar tendon and the MCL is palpated. After the painful site is located with the fingers, pressure against this site is maintained while the knee is flexed. After several degrees of motion, the pain disappears, and the painful site can sometimes again be palpated more posteriorly in the joint space. If the most painful site is found in the joint space at the level of the MCL, the test is less reliable, because both the medial meniscus and the ligament move posteriorly during flexion.

Anderson Mediolateral Grind Test

The Anderson mediolateral grind test[398] can be used to detect meniscal lesions. The patient is placed in the supine position, and the clinician grasps the involved leg between the trunk and arm. The clinician places the index finger and thumb of the

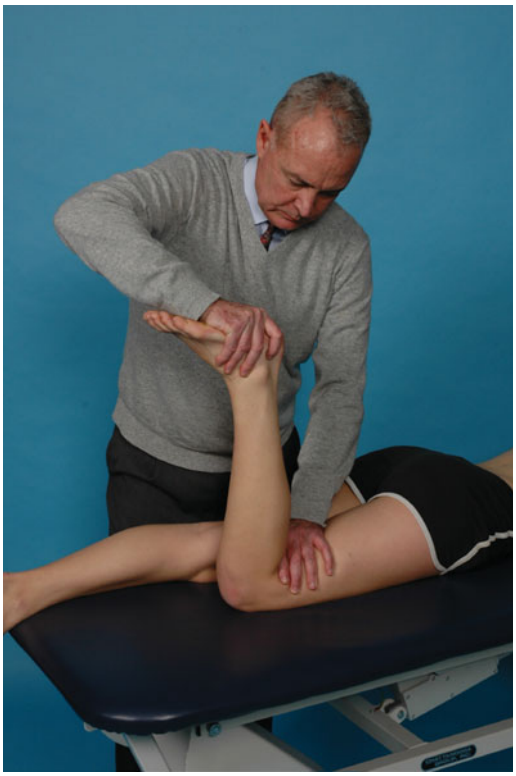

FIGURE 20-38 Apley's grind test.

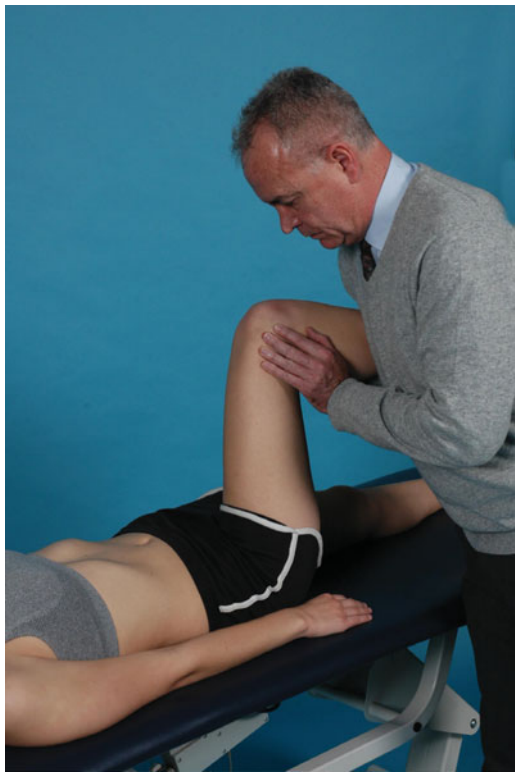

FIGURE 20-40 Anderson mediolateral grind test.

other hand over the anterior knee joint line. With the patient's knee flexed at 45 degrees, a valgus stress is applied as the knee is simultaneously slightly flexed (Fig. 20-40), followed by a varus component while the knee is extended, producing a circular motion of the knee. The maneuver is repeated, increasing the valgus and varus stresses with each rotation.

In one study[398] that examined 100 knees with the Anderson mediolateral grind test, as well as arthroscopy, the test was found to have a sensitivity of 70% and a specificity of 67%. However further research needs to be performed to corroborate the statistics reported in this study.

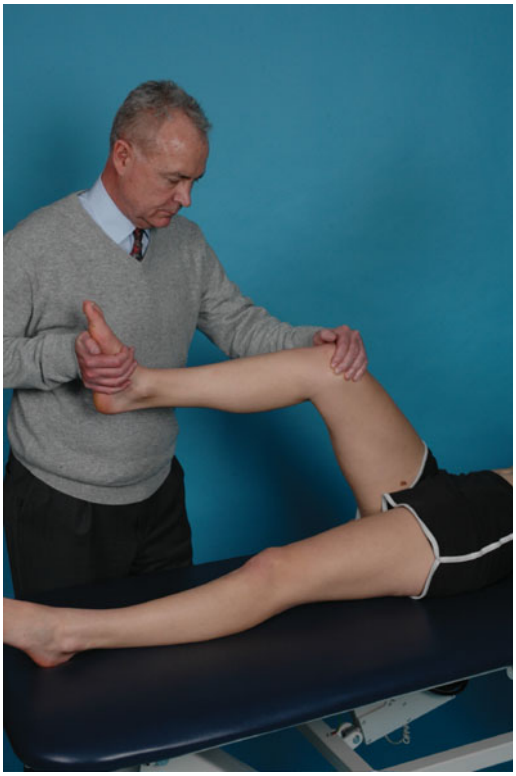

FIGURE 20-39 Steinmann's I sign.

Bounce Home Test

The patient is placed in the supine position and the clinician extends the involved knee to end range (Fig. 20-41). A positive test for meniscus tear is indicated by a block preventing full extension, or pain at end-range extension. A number of studies seem to indicate that neither pain at full extension nor an extension block seem to indicate a torn meniscus.[399–401]

FIGURE 20-41 Bounce home test.

FIGURE 20-42 Figure-4 test.

Figure-4 Test

This test was developed to detect popliteomeniscal fascicle tears, which create instability of the lateral meniscus. The patient lies in the supine position and is asked to place the foot of the involved knee by the contralateral knee, forming a figure 4 (Fig. 20-42). The clinician pushes the involved knee toward the bed. A positive test is indicated by pain over the lateral joint line at the popliteal hiatus. In a very small study[402] involving only six patients the test demonstrated a sensitivity of 100%. Further research is necessary before diagnostic conclusions can be made from this test.

Payr Sign

The patient is placed in the supine position or sits and places the foot of the involved knee on the medial aspect of the contralateral knee, forming a figure 4. The clinician pushes the involved knee toward the floor (Fig. 20-43). A positive test for a posterior horn lesion of the medial meniscus is indicated by reproduction of the patient's pain over the medial joint line. In a study by Jerosch and Riemer[403] this test was found to have a sensitivity of 54% and a specificity of 44%, demonstrating a diagnostic value similar to that of a coin toss.

FIGURE 20-43 Payr sign.

Other Special Tests

The remaining special tests for the knee joint complex are dependent on the clinician's needs, the structure of each joint, and the subjective complaints (Table 20-9). These tests are only performed if there is some indication that they would by helpful in arriving at a diagnosis. The special tests help confirm or implicate a particular structure and may also provide information as to the degree of tissue damage.

Plical Irritation

Plical irritation has a characteristic pattern of presentation. The anterior pain in the knee is episodic and associated with painful clicking, "giving way," and the feeling of something catching in the knee. Careful palpation of the patellar retinaculum and fat pad, with the knee extended and then flexed, can be used to detect tender plicae and to differentiate tenderness within the fat pad from tenderness over the anterior horn of the menisci.

- ***Medial plica test.*** This test can also be used to detect plical irritation. Using the heel of the cranial hand, the clinician pushes the patella medially and maintains it there (Fig. 20-44). While the patella is maintained in this position, the clinician flexes the patient's knee and internally rotates the tibia with the other hand. The knee is then extended from the flexed position while the clinician palpates for any clunks.
- ***Medial plica shelf test.*** The patient lies in the supine position on the bed, with the knee supported in about 30 degrees of flexion by either a bolster or the clinician's thigh. The clinician places both thumbs together at the lateral aspect of the patella and pushes the patella medially (Fig. 20-45). If a painful click is elicited during this test, there is likely to be a symptomatic mediopatellar synovial plica.

Suprapatellar or Infrapatellar Tendinitis

The patient is placed in the supine position, with the lower extremity extended.

- ***Infrapatellar test.*** The clinician pushes down on the suprapatellar aspect, palpates under the inferior pole of the patella, and checks for tenderness, which may indicate infrapatellar tendinitis.
- ***Suprapatellar test.*** The clinician pushes on the infrapatellar aspect of the patella, palpates under the superior pole of the patella, and checks for tenderness, which may indicate suprapatellar tendinitis.

Integrity of Patellofemoral Articulating Surfaces

These tests involve the application of manual compression to the patella in an attempt to elicit pain.

TABLE 20-9 Subjective Complaint, Potential Diagnosis, and Confirmatory Test

Subjective Complaint	Potential Diagnosis	Confirmatory Test(s)
My knee hurts when I get up from a chair or go up steps	Patellofemoral dysfunction	Patellofemoral grind test
My knee gives out when I step down from the curb	Subluxation/dislocation of the patella	Patella apprehension test
My knee locks	1. Torn medial meniscus 2. Loose body within the knee joint	McMurray test and Apley grinding and distraction tests
My knee feels swollen and tight	Fluid within the knee	Patellar effusion tests
My knee buckles; it gives out	1. Unstable knee joint (torn collateral or cruciate ligament) 2. Torn medial meniscus	Valgus and varus stress tests, anterior drawer, Lachman, Posterior sag, strength testing (neuro screen), meniscus tests
I cannot straighten my knee out	1. Fluid in the knee 2. Torn meniscus	Meniscus tests, patellar ballottement test, bounce home test
I have pain on the inside of my leg	1. Torn medial collateral ligament 2. Bursitis, pes anserinus bursa	Valgus stress test Palpation of the pes anserinus bursa
I made a quick turn while playing sports while my foot was planted, and my leg suddenly collapsed and the knee became swollen	Torn medial meniscus	Apley test and McMurray test
I have bow legs and they hurt	1. Osteoarthritis 2. Ligamentous instability	Range of motion (capsular) Patellofemoral grinding test Ligament stability tests
I have swelling in the back of my knee	Popliteal cyst	Palpation of popliteal fossa
I landed heavily on the front of my knee and it hurts	1. Patellar fracture 2. Chondromalacia 3. Fat pad syndrome 4. Prepatellar bursitis 5. Infrapatellar bursitis	Radiograph Palpation
I cannot move my knee in any direction without pain	Infected knee joint	Joint aspiration

Data from Hoppenfeld S: Physical examination of the knee joint by complaint. *Orthop Clin North Am* 10:3–20, 1979.

Zohler's Sign

The patient is placed in the supine position, with the knee extended and resting on the table. The clinician pulls the patient's patella in a distal direction. While continuing to exert pressure in a distal direction, the clinician instructs the patient to contract the quadriceps muscle (Fig. 20-46). If this test is painful, there is likely to be a symptomatic patellar chondromalacia, although this test may be positive in a large proportion of asymptomatic individuals. One study[367] to examine this test did not record reliability or diagnostic accuracy.

Clarke's Test

This test is similar to Zohler's test, except that the clinician applies an increasing compressive force to the base of the patella while the patient actively contracts the quadriceps. Like Zohler's test, this test may be positive in a large proportion of asymptomatic individuals.

Waldron Test

See "Patella Motion Tests" Section.

Patellar Mobility and Retinaculum Tests

Patellar glides can be used to examine retinacular mobility. The patella should be able to translate at least 33% of its width both medially and laterally. Inability to do this indicates tightness of the retinacula. Hypermobility of the patella is demonstrated if the patella can be translated 100% of its width medially or laterally.

The lateral retinaculum is assessed by way of a patellar tilt and a mediolateral displacement (glide).[189,404–406] A number of patient positions can be used to assess the flexibility of the retinacular tissue.

- ***Medial shift.***[274] The patient is supine, with the knee extended. The clinician places both thumbs together at the lateral aspect of the patella and pushes the patella medially. The amount of motion and the end-feel are assessed. Often the patella is found to have less ROM medially than laterally. Whether this condition is pathologic is best determined by comparison to the noninvolved side. This patellar movement often is limited after surgery and after immobilization.

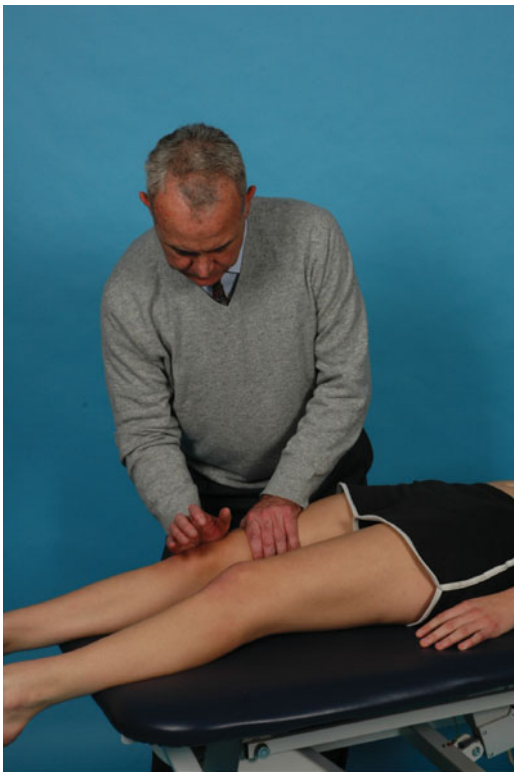

FIGURE 20-44 Medial plica test.

- ***Lateral shift.*** The patient is supine, with the knee extended. The clinician places the fingertips of both hands against the medial aspect of the patella and pushes the patella laterally. The amount of motion and the end-feel are assessed. Usually the patella has more ROM laterally than medially. When there are instabilities of the patella, the lateral mobility is usually abnormally increased. This patellar movement often is limited after surgery and after immobilization.
- ***Distal shift.*** The patient is supine, with the knee extended. With the thenar and hypothenar eminences placed against the base of the patient's patella, the clinician pushes the patella in a distal direction. As with the previous two shift tests, the amount of motion and end-feel are assessed. The motion usually is limited in instances of patella alta (a high position of the patella), after surgery, and after immobilization.

FIGURE 20-45 Medial plica shelf test.

FIGURE 20-46 Zohler's sign.

- ***Prone technique.*** The clinician passively flexes the patient's knee to 90 degrees and internally rotates the tibia. The lower extremity is then moved into hip adduction. The test is positive for tightness of the lateral structures if the hip cannot be fully adducted. This test also can be performed in the side-lying position, with the involved side uppermost.
- ***Lateral tilt of the patella.*** The patient lies in the supine position, with the knee extended and relaxed. The clinician attempts to lift the lateral border of the patella. An inability to lift the lateral border of the patella above the horizontal plane is an indication of tightness of the lateral retinaculum.
- ***Side-Lying technique.***[266] With the knee of the uppermost leg flexed to 20 degrees, the patella is moved in a medial direction toward the treatment table. The clinician should be able to expose the lateral femoral condyle, unless the tissues of the superficial lateral retinacula are tight. To test the deep fibers, the clinician places a hand on the middle of the patella, takes up the slack of the glide, and applies an anteroposterior pressure on the medial border of the patella. The lateral femoral condyle should move freely away from the femur. This test also can be used as an intervention technique.[266]

Fairbank's Apprehension Test for Patellar Instability

The Fairbank test[407] is best performed with the patient in the supine position and the patient's leg supported at approximately 30 degrees of knee flexion. The clinician places both thumbs on the medial aspect of the patella and applies a laterally directed force to the medial aspect of the patella, attempting to sublux it laterally while applying a small amount of passive flexion to the knee.[205] This test appears to be more specific than sensitive, meaning a positive test would help rule in patellofemoral instability.[341,408]

Wilson Test for Osteochondritis Dissecans

The following accessory test can be performed when osteochondritis dissecans of the knee is suspected. The patient is supine. The clinician flexes the patient's hip and knee to 90 degrees. Axial compression is exerted at the knee by pushing proximally, in line with the tibia, with the distal hand. The lower leg is held in internal rotation as the knee is slowly extended, maintaining the axial compression. In many cases of osteochondritis dissecans, the patient experiences pain because the pressure on the medial cartilaginous surfaces is increased significantly with this maneuver.

Hamstring Flexibility

The popliteal angle is the most popular method reported in the literature for assessing hamstring tightness, especially in the presence of a knee flexion contracture.[409] The patient is placed in the supine position and the opposite hip is extended. The popliteal angle is determined by measuring the angle that the tibia subtends with the extended line of the femur when the ipsilateral hip is flexed to 90 degrees and the knee of the limb under examination is maximally passively extended to initial tissue resistance.[410] The popliteal angle is at the maximum of 180 degrees from birth to age 2 years.[409] This angle then decreases to an average of 155 degrees by age 6 years and remains steady thereafter.[409] An angle less than 125 degrees suggests significant hamstring tightness.[409]

Hamstring flexibility can also be assessed with a passive straight leg raise, while ensuring that the lumbar spine is flattened on the treatment table and the pelvis is stabilized. However, this method may be used only if there is full extension at the knee of the leg being examined. Normal hamstring length should allow 80–85 degrees of hip flexion when the knee is extended and the lumbar spine is flattened.[266]

ITB Flexibility

The cardinal sign of iliotibial contracture is the presence in a supine patient of an abduction contracture when the hip and knee are extended, which is eliminated when the hip and knee are flexed.[411] Other tests include the following:

Retinacula Test. The patient is placed in the side-lying position and the knee is fully flexed. This position tightens the ITB. The clinician applies a medial and oblique force to the patella with the thumbs. Approximately 0.5–1 cm of patella motion should be available.

Ober's Test. The Ober test for ITB length is described in Chapter 19.

Quadriceps Flexibility. Quadriceps flexibility is examined by placing the patient in prone position and passively flexing the knee, bringing the heel toward the buttocks. The lumbar spine is monitored and stabilized if necessary to prevent motion. The heel should touch the buttocks. An adaptively shortened rectus femoris is usually the structure that prevents this motion (see later discussion).

Functional Tests

Functional outcome following knee injury must consider the patient's perspective and not just objective measurements of instability. Functional motion requirements of the knee vary according to the specific task. In normal level ground walking, 60–70 degrees of knee flexion is required. This requirement increases to 80–85 degrees for stair climbing and to 120–140 degrees for running.[3] Approximately 120 degrees of knee flexion are necessary for activities such as squatting to tie a shoelace or to don a sock.[412] Table 20-10 outlines the amounts of knee ROM that must be available for common activities of daily living.

TABLE 20-10 Approximate Range of Motion Required for Common Activities of Daily Living

Activity	Required Flexion Range of Motion (Degrees)
Running	120–140
Squatting	120
Tying shoelace	120
Donning a sock	120
Climbing downstairs	110
Sitting and rising	85
Climbing upstairs	80
Swing phase of gait	70
Stance phase of gait	20

Data from Laubenthal KN, Smidt GL, Kettelkamp DB: A quantitative analysis of knee motion for activities of daily living. *Phys Ther* 52:34–42, 1972.

Subjective Tests

Clinical research studies are placing an increased emphasis on the perspective of the patient with use of health-related quality-of-life instruments. Many patient-based knee-rating scales have been developed (Table 20-11). These include the following.

WOMAC Index. The Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) (Table 20-12) is a widely used measure of symptoms and physical disability, originally developed for people with OA of the hip or knee.[413] The measure was developed to evaluate clinically important, patient-relevant changes in health status as a result of intervention.[414] Evidence of the reliability (test–retest), validity, and responsiveness of the WOMAC has been provided in OA patients undergoing total knee or hip arthroplasty[413] and in OA patients receiving nonsteroidal anti-inflammatory drugs (NSAIDs).[415] The WOMAC evaluates three dimensions: pain, stiffness, and physical function with 5, 2, and 17 questions, respectively[416] (see Table 20-12). Each subscale is summated to a maximum score of 20, 8, and 68, respectively. There is also an index score or global score, which is most commonly calculated by summating the scores for the three subscales.[416]

International Knee Documentation Committee Questionnaire. The International Knee Documentation Committee (IKDC) questionnaire was formed to set standards for the evaluation of knee ligament injury.[417] The IKDC form uses four domains for the final rating: patient's self-reported

TABLE 20-11 Knee Questionnaire Indices

Indices	Indication	Reliability	Validity	Comment
Western Ontario and McMaster Universities Osteoarthritis Index Bellamy[a]	Osteoarthritis	Strong for osteoarthritis	Strong for osteoarthritis	Strong for pain, stiffness, and physical function in osteoarthritis
International Knee Documentation Committee Questionnaire[b]	Knee ligament injury	Good	Strong	Not sensitive for sports related function Not as responsive to changes over time
Lysholm Knee Score[c]	Ligament and meniscal injuries	Good	Unclear	Not useful for high functioning individuals Score is heavily weighted on pain and instability ratings Acceptable psychometric performances as outcome measures for patients with a meniscal injury of the knee
Cincinnati Knee Rating System[d]	Nonspecific knee injury	Unknown	Unclear	Allows assessment of outcome based on the patient's usual activities
Knee Outcome Survey[e]	Nonspecific knee injury	Strong for functional limitations	Strong for functional limitations	Responsive for functional limits for a variety of impairments
Lower extremity function scale[f]	All lower extremity conditions	Strong for hip and knee total arthroplasty	Strong for hip and knee total arthroplasty	Useful with patients following arthroplasty

function, self-reported symptoms, ROM, and ligament examination. The worst rating in any one of the four domains (normal, nearly normal, abnormal, or severely abnormal) determines the final rating of the knee.

Lysholm Knee Scoring Scale. The Lysholm Knee Scale[418] is commonly used as a subjective report scoring system designed to evaluate the intervention outcome and postsurgical result of knee patients. The scale consists of eight items related to limping; the need for an assistive device; ability to squat or climb stairs; and the presence of pain, swelling, locking, or "giving way," and leg atrophy.[419] Points are given for each level of ability or disability reported, with the perfect score being 100 (Table 20-13). The designers of this scale found that patients suffering from knee instability scored significantly lower than patients with minimal or no instability (average = 75.6 and 93.6, respectively).

Cincinnati Knee Rating System. The Cincinnati knee rating system self-report version uses a combination of functional level and symptom reporting to arrive at an overall disability rating for the knee.[420] The scale provides a point scoring system

TABLE 20-12 Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC)

Name: _____

Primary Care Physician: _____

This survey asks for your views about the amount of pain, stiffness, and disability you are experiencing. Please answer every question by filling in the appropriate response. If you are unsure about how to answer a question, please give the best answer you can. (Please mark your answers with an "X")

SECTION A: PAIN

The following questions concern the amount of pain you are currently experiencing due to arthritis in your hips and/or knees. For each situation, please enter the amount of pain recently experienced.

***Question:* How much pain do you have?**

	None	Mild	Moderate	Severe	Extreme
1. Walking on a flat surface.	☐	☐	☐	☐	☐
2. Going up or down stairs.	☐	☐	☐	☐	☐
3. At night while in bed.	☐	☐	☐	☐	☐
4. Sitting or lying.	☐	☐	☐	☐	☐
5. Standing upright.	☐	☐	☐	☐	☐

SECTION B: JOINT STIFFNESS

The following questions concern the amount of joint stiffness (not pain) you are currently experiencing in your hips and/or knees. Stiffness is a sensation of restriction or slowness in the ease with which you move your joints.

	None	Mild	Moderate	Severe	Extreme
1. How severe is your stiffness after first wakening in the morning?	☐	☐	☐	☐	☐
2. How severe is your stiffness after sitting, lying, or resting later in the day?	☐	☐	☐	☐	☐

SECTION C: PHYSICAL FUNCTION

The following questions concern your physical function. By this we mean your ability to move around and to look after yourself. For each of the following activities, please indicate the degree of difficulty you are currently experiencing due to arthritis in your hips and/or knees. (Please mark your answers with an "X")

***Question:* What degree of difficulty do you have with:**

	None	Mild	Moderate	Severe	Extreme
1. Descending stairs.	☐	☐	☐	☐	☐
2. Ascending stairs.	☐	☐	☐	☐	☐
3. Rising from sitting.	☐	☐	☐	☐	☐
4. Standing.	☐	☐	☐	☐	☐
5. Bending to floor.	☐	☐	☐	☐	☐
6. Walking on flat.	☐	☐	☐	☐	☐
7. Getting in/out of car.	☐	☐	☐	☐	☐
8. Going shopping.	☐	☐	☐	☐	☐
9. Putting on socks/stockings.	☐	☐	☐	☐	☐
10. Rising from bed.	☐	☐	☐	☐	☐
11. Taking off socks/stockings.	☐	☐	☐	☐	☐
12. Lying in bed.	☐	☐	☐	☐	☐
13. Getting in/out of bath.	☐	☐	☐	☐	☐
14. Sitting.	☐	☐	☐	☐	☐
15. Getting on/off toilet.	☐	☐	☐	☐	☐
16. Heavy domestic duties.	☐	☐	☐	☐	☐
17. Light domestic duties.	☐	☐	☐	☐	☐

for the type of sports-related activity and frequency of participation, which allows an assessment outcome that is based on the patient's usual activities.

Knee Outcome Survey. The Knee Outcome Survey (KOS) consists of two separate scales: the activities of daily living scale (ADLS) and the sports activity scale (SAS). The ADLS (Table 20-14)[421] assesses the full spectrum of symptoms and functional limitations that may occur due to knee disorders.[419] The test–retest reliability of this scale is 0.97.[422] The SAS scale includes factors commonly experienced during sports activities.

Lower Extremity Function Scale. The lower extremity function scale was designed to be applicable to all lower extremity conditions of musculoskeletal origin.[423]

TABLE 20-13 Lysholm Knee Scoring Scale

Category	Score
LIMP	
None	5
Slight or periodic	3
Serve and constant	0
SUPPORT	
None	5
Stick or crutch	3
Weight-bearing impossible	0
LOCKING	
No locking and no catching sensations	5
Catching, but no locking sensation	4
Locking	
Occasionally	2
Frequently	3
Locked joint on examination	0
INSTABILITY	
Never giving way	30
Rarely during athletics or other severe exertion	25
Frequently during athletics or other severe exertion (incapable of participation)	20
Occasionally in daily activities	10
Often in daily activities	5
With every step	0
PAIN	
None	30
Inconstant and slight during severe exertion	25
Marked on giving way	20
Marked during severe exertion	15
Marked on or after walking more than 2 km	10
Marked on or after walking less than 2 km	5
Constant	0
SWELLING	
None	10
With giving way	7
On severe exertion	5
On ordinary exertion	2
Constant	0
STAIR CLIMBING	
No problems	10
Slightly impaired	6
One step at a time	2
Impossible	0
SQUATTING	
No problems	5
Slightly impaired	4
Not beyond 90 degrees	2
Impossible	0

Data from Tegner Y, Lysholm J: Rating systems in the evaluation of knee ligament injuries. *Clin Orthop* 198:43–49, 1985.

Although these instruments have been commonly used to evaluate patients following knee surgery or trauma, relatively little work has been done to compare these knee instruments for the evaluation of athletic patients, and those that have been cross-sectional in design and therefore have not assessed reliability or how the instruments performed over time. Marx et al. performed a study to determine the reliability, validity, and responsiveness of the Lysholm scale, the American Academy of Orthopaedic Surgeons (AAOS) sports knee-rating scale (see "Advanced Functional Tests" section), the ADLS of the KOS, and the Cincinnati knee-rating system in athletic patients with a wide variety of disorders of the knee. According to the study, the reliability was high for all scales, with the ICC ranging from 0.88 to 0.95. As for construct validity, the correlations among the knee scales ranged from 0.70 to 0.85 and those between the knee scales and the physical component scale of the Short Form-36 (SF-36) and the patient and clinician severity ratings ranged from 0.59 to 0.77. Responsiveness, measured with the standardized response mean, ranged from 0.8 for the Cincinnati knee-rating system to 1.1 for the ADLS.

Patellar Joint Evaluation Scale. This scale assesses seven components of patellofemoral joint function (Table 20-15).

Objective Functional Tests

The functional tests for the knee are introduced once the patient is able to perform active and resisted motions without pain.

Aggregated Locomotor Function Score. The aggregated locomotor function (ALF) score was formed by summating the mean timed scores (seconds) from three locomotor functions (walking time, stair ascent, and stair descent) and time taken to transfer from sitting to standing.[424]

- ***Eight meter walk time.*** The patient is asked to walk 8 m at their own naturally preferred comfortable pace with or without walking aids as appropriate. Three repetitions of the walk are undertaken and the mean time is recorded.
- ***Stair ascent and descent time.*** The patient is asked to ascend and then descend seven steps (4 of 15 cm and 3 of 20 cm) at their naturally preferred comfortable pace. The method that the patient employs to negotiate the stairs is recorded, that is, whether they use alternate legs, use the banisters, or always lead with one leg. The patient is timed (in seconds) and asked to repeat the test four times. The mean time of the four repetitions is calculated.
- ***Transferring time.*** The patient is asked to walk, at their own natural pace, a distance of 2 m to a chair (with a seat height of 0.46 m, typical of a toilet seat) and sit down, then immediately stand up and walk back to the start. The patient is timed (in seconds) as they approach and retreat from the chair. The patient is asked to perform the test three times and the mean time is calculated.

The ALF score has demonstrated excellent intratester reliability with a high ICC statistic, narrow confidence

TABLE 20-14 Patient Reported Measure of Knee Function

ACTIVITIES OF DAILY LIVING SCALE

Instructions: The following questionnaire is designed to determine the symptoms and limitations that you experience because of your knee while you perform your usual daily activities. Please answer each question by checking the statement that best describes you over the last 1–2 days. For a given question, more than one of the statements may describe you, but please mark ONLY the statement that best describes you during your usual daily activities.

SYMPTOMS

1. To what degree does pain in your knee affect your daily activity level?
   - 5 I never have pain in my knee.
   - 4 I have pain in my knee, but it does not affect my daily activity.
   - 3 Pain affects my activity slightly.
   - 2 Pain affects my activity moderately.
   - 1 Pain affects my activity severely.
   - 0 Pain in my knee prevents me from performing all daily activities.
2. To what degree does grinding or grating of your knee affect your daily activity level?
   - 5 I never have grinding or grating in my knee.
   - 4 I have grinding or grating in my knee, but it does not affect my daily activity.
   - 3 Grinding or grating affects my activity slightly.
   - 2 Grinding or grating affects my activity moderately.
   - 1 Grinding or grating affects my knee slightly.
   - 0 Grinding or grating in my knee prevents me from performing daily activities.
3. To what degree does stiffness in your knee affect your daily activity level?
   - 5 I never have stiffness in my knee.
   - 4 I have stiffness in my knee, but it does not affect my daily activity.
   - 3 Stiffness affects my activity slightly.
   - 2 Stiffness affects my activity moderately.
   - 1 Stiffness affects my activity severely.
   - 0 Stiffness in my knee prevents me from performing all daily activities.
4. To what degree does swelling in your knee affect your daily activity level?
   - 5 I never have swelling in my knee.
   - 4 I have swelling in my knee, but it does not affect my daily activity.
   - 3 Swelling affects my activity slightly.
   - 2 Swelling affects my activity moderately.
   - 1 Swelling affects my activity severely.
   - 0 Swelling in my knee prevents me from performing all daily activities.
5. To what degree does slipping of your knee affect your daily activity level?
   - 5 I never have slipping of my knee.
   - 4 I have slipping of my knee, but it does not affect my daily activity.
   - 3 Slipping affects my activity slightly.
   - 2 Slipping affects my activity moderately.
   - 1 Slipping affects my activity severely.
   - 0 Slipping of my knee prevents me from performing all daily activities.
6. To what degree does buckling of your knee affect your daily activity level?
   - 5 I never have buckling of my knee.
   - 4 I have buckling of my knee, but it does not affect my daily activity level.
   - 3 Buckling affects my activity slightly.
   - 2 Buckling affects my activity moderately.
   - 1 Buckling affects my activity severely.
   - 0 Buckling of my knee prevents me from performing all daily activities.

(Continued)

TABLE 20-14 Patient Reported Measure of Knee Function *(Continued)*

SYMPTOMS

7. To what degree does weakness or lack of strength of your leg affect your daily activity level?
   - 5 My leg never feels weak.
   - 4 My leg feels weak, but it does not affect my daily activity.
   - 3 Weakness affects my activity slightly.
   - 2 Weakness affects my activity moderately.
   - 1 Weakness affects my activity severely.
   - 0 Weakness of my leg prevents me from performing all daily activities.

FUNCTIONAL DISABILITY WITH ACTIVITIES OF DAILY LIVING

8. How does your knee affect your ability to walk?
   - 5 My knee does not affect my ability to walk.
   - 4 I have pain in my knee when walking, but it does not affect my ability to walk.
   - 3 My knee prevents me from walking more than 1 mile.
   - 2 My knee prevents me from walking more than $^{1}/_{2}$ mile.
   - 1 My knee prevents me from walking more than 1 block.
   - 0 My knee prevents me from walking.
9. Because of your knee, do you walk with crutches or a cane?
   - 3 I can walk without crutches or a cane.
   - 2 My knee causes me to walk with 1 crutch or a cane.
   - 1 My knee causes me to walk with 2 crutches.
   - 0 Because of my knee, I cannot walk even with crutches.
10. Does your knee cause you to limp when you walk?
   - 2 I can walk without a limp.
   - 1 Sometimes my knee causes me to walk with a limp.
   - 0 Because of my knee, I cannot walk without a limp.
11. How does your knee affect your ability to go upstairs?
   - 5 My knee does not affect my ability to go upstairs.
   - 4 I have pain in my knee when going upstairs, but it does not limit my ability to go upstairs.
   - 3 I am able to go upstairs normally, but I need to rely on use of a railing.
   - 2 I am able to go upstairs one step at a time with use of a railing.
   - 1 I have to use crutches or a cane to go upstairs.
   - 0 I cannot go upstairs.
12. How does your knee affect your ability to go downstairs?
   - 5 My knee does not affect my ability to go downstairs.
   - 4 I have pain in my knee when going downstairs, but it does not limit my ability to go downstairs.
   - 3 I am able to go downstairs normally, but I need to rely on use of a railing.
   - 2 I am able to go downstairs one step at a time with use of railing.
   - 1 I have to use crutches or a cane to go downstairs.
   - 0 I cannot go downstairs.
13. How does your knee affect your ability to stand?
   - 5 My knee does not affect my ability to stand. I can stand for unlimited amounts of time.
   - 4 I have pain in my knee when standing, but it does not limit my ability to stand.
   - 3 Because of my knee, I cannot stand for more than 1 hour.
   - 2 Because of my knee, I cannot stand for more than half an hour.
   - 1 Because of my knee, I cannot stand for more than 10 minutes.
   - 0 I cannot stand because of my knee.

(Continued)

TABLE 20-14 Patient Reported Measure of Knee Function *(Continued)*

14. How does your knee affect your ability to kneel on the front of your knee?
    - 5 My knee does not affect my ability to kneel on the front of my knee. I can kneel for unlimited amounts of time.
    - 4 I have pain when kneeling on the front of my knee, but it does not limit my ability to kneel.
    - 3 I cannot kneel on the front of my knee for more than 1 hour.
    - 2 I cannot kneel on the front of my knee for more than half an hour.
    - 1 I cannot kneel on the front of my knee for more than 10 minutes.
    - 0 I cannot kneel on the front of my knee.
15. How does your knee affect your ability to squat?
    - 5 My knee does not affect my ability to squat. I can squat all the way down.
    - 4 I have pain when squatting, but I can still squat all the way down.
    - 3 I cannot squat more than $^{3}/_{4}$ of the way down.
    - 2 I cannot squat more than $^{1}/_{2}$ of the way down.
    - 1 I cannot squat more than $^{1}/_{4}$ of the way down.
    - 0 I cannot squat at all.
16. How does your knee affect your ability to sit with your knee bent?
    - 5 My knee does not affect my ability to sit with my knee bent. I can sit for unlimited amounts of time.
    - 4 I have pain when sitting with my knee bent, but it does not limit my ability to sit.
    - 3 I cannot sit with my knee bent for more than 1 hour.
    - 2 I cannot sit with my knee bent for more than half an hour.
    - 1 I cannot sit with my knee bent for more than 10 minutes.
    - 0 I cannot sit with my knee bent.
17. How does your knee affect your ability to rise from a chair?
    - 5 My knee does not affect my ability to rise from a chair.
    - 4 I have pain when rising from the seated position, but it does not affect my ability to rise from the seated position.
    - 3 Because of my knee, I can only rise from a chair if I use my hands and arms to assist.
    - 0 Because of my knee, I cannot rise from a chair.

intervals, low standard error of measurement (SEM), and low smallest detectable difference (SDD).[424] Importantly, the measure demonstrates moderately sized correlation with two validated self-report questionnaires of physical function (SF-36 and WOMAC) and appears to be more responsive to change induced by exercise intervention, than either.[424]

Simple Functional Weight-Bearing Tests

The simplest functional weight-bearing test for the knee is the squat position. The patient should be able to perform this maneuver without pain.

Duck Walk/Childress Sign. The patient squats with the toes pointing outward and walks forward. This maneuver is similar to the McMurray test for meniscal lesion (although more stressful). Pain, or crepitus, with this test supposedly indicates a lesion of the posterior horn of the meniscus or the MCL.[367] A positive test for meniscus tear is indicated by a block preventing full flexion or pain at end range flexion. However, studies have shown that pain neither with squatting nor with a duck walk seem to indicate a torn meniscus.[401,425]

Incidentally, a patient with a patellofemoral lesion can duck walk without difficulty, but experiences difficulty coming up out of the squat.[259]

Advanced Functional Tests

More advanced functional tests for the knee include the following AAOS sports knee-rating scale, vertical jump, functional hop, single-leg squat, and running tests.[419]

American Academy of Orthopaedic Surgeons Sports Knee-Rating Scale. The AAOS sports knee-rating scale was included in the Musculoskeletal Outcomes Data Evaluation and Management System (MODEMS) for athletic patients with disorders of the knee. This instrument has five parts with a total of 23 questions: a core section (seven questions) on stiffness, swelling, pain, and function, and four sections (four questions each) on locking or catching on activity, giving-way on activity, current activity limitations due to the knee, and pain on activity due to the knee.

Vertical Jump. Vertical jumping is an explosive movement, in which the vertical velocity of the trunk is of decisive importance for jump height. The vertical jump test is commonly used in sports medicine, and investigators have found it to be significantly related to athletic performance.[426–432] The vertical jump is performed in the following manner. A baseline measurement is made of the highest point that the patient can reach while remaining flat footed. The patient's fingertips are covered with chalk and he or she is then asked to jump as high

TABLE 20-15 Patellofemoral Joint Evaluation Scale

Function	Points
Limp	
None	5
Slight or episodic	3
Severe	0
Assistive devices	
None	5
Cane or brace	3
Unable to bear weight	0
Stair climbing	
No problem	20
Slight impairment	15
Very slowly	10
One step at a time, always same leg first	5
Unable	0
Crepitation	
None	5
Annoying	3
Limits activities	2
Severe	0
Instability (giving way)	
Never	20
Occasionally with vigorous activities	10
Frequently with vigorous activities	8

Occasionally with vigorous activities	30
Marked with vigorous activities	20
Marked after walking 1 mile or mild or moderate rest pain	15
Marked with walking <1 mile	10
Constant and severe	0

Scoring: 90–100 points, excellent; 80–90 points, good; 60–79 points, fair: <60 points, poor.
Data from Karlson J, Thomee R, Sward L: Eleven year follow-up of patellofemoral pain syndromes. *Clin J Sports Med* 6:23, 1996.

as possible, marking the wall with the chalk on the fingertips. The patient is allowed three jumps, after which the clinician subtracts the baseline reach from the maximum vertical jump to obtain the vertical jump distance.

Functional Hop Tests

- ***Hop for distance.*** This test has good test–retest reliability (0.79–0.99),[429,430,432–437] although its correlation with power and isokinetic strength testing is unclear.[336,428,430,437–440] The patient stands on the involved leg, with the toes as close to the starting position as possible. The hands are placed behind the back or on the hips. The patient then tries to hop as far as possible, landing on the same extremity. Three attempts are permitted. The distance is measured from the take-off toe to the landing heel and is compared with the hop distance of the uninvolved leg, and scored as a percentage. The distances hopped are influenced by age and sex.[436] Norms for this test in high school athletes are an average of 155 cm for boys and an average of 121 cm for girls.[441] The sensitivity of this test has been found to be 52% and the specificity to be 97%.[442] Barber et al.[430] found a significant relationship between the one-legged hop and the subjective limitations of sprinting, jumping, and landing.
- ***Triple hop.***[429,443] The triple-hop test is similar to the hop-for-distance test, except that the patient hops for three consecutive hops, and the score is the distance measured from the take-off toe to the landing heel of the third jump. One study reported a high correlation between concentric isokinetic strength of the quadriceps muscle and the triple hop for distance.[440]
- ***Timed 6-m hop.***[430,432,434] This test is reliable, with an ICC ranging from 0.66 to 0.77,[429,433] and is considered to be one of the best indicators of function.[438] The clinician marks off a distance of 6 m and the patient performs single-leg hops over the distance. The time taken is measured to the nearest 0.01 second and compared with the uninvolved leg. This functional test evaluates the strength, endurance, proprioception, balance, and power of the various knee structures. The test is recommended for use with athletes returning to sport. The sensitivity of this test has been found to be 49%, and the specificity to be 94%.[442]
- ***Crossover hop.*** The crossover hop has an ICC of 0.96 for test–retest reliability.[429] The results of this test have a relationship with the isokinetic parameter of acceleration range and are considered to be the best indicator of knee function.[438] The test is performed as follows: the patient places his or her feet behind the start line and a tape measure is laid perpendicular to that line. The patient is asked to stand on one leg to the right of the tape measure. The patient is then asked to jump, on one leg, to the left side of the tape, back to the right, and then back to the left, attempting to propel himself or herself forward as far as possible with each hop. The score is the distance measured from the take-off toe to the landing heel of the third jump. Three attempts are permitted, and two sides are compared as a percentage of each other.
- ***Stairs hop.*** The patient is timed as he or she hops up and down several steps (20–25 steps are recommended), first on the uninvolved leg and then on the involved leg.[443]
- ***Side-to-side hop.*** Steadman[444] advocates the use of the side-to-side Heiden hop. The Heiden hop involves the patient jumping from side to side, to a line placed approximately 5–6 feet (1.5–1.8 m) apart. The landing is

controlled with a soft flexion of the knee, balancing the body on the foot closest to the line. The patient then leaps sideways to the other line, landing on the opposite foot in a controlled fashion, gently assuming a semisquat position on the single leg.[445] This exercise is performed side to side for 5–10 minutes. Evidence of an ungraceful landing, loss of balance, or shaking muscles on the involved side indicates weakness of the quadriceps.[445]

Single-Leg Squat Test. The patient is asked to balance on one leg and then to squat down on that leg while keeping the trunk erect. The amount of flexion at the knee is measured with a goniometer and is compared with a similar measure of the uninvolved leg. If a hand or the opposite extremity touches the ground, the measurement is retaken. Although seemingly a static test, this is a test of the dynamic ability of the quadriceps, hamstring, gluteal, and gastrocnemius muscles to maintain eccentric control, and for the patient to maintain balance.

Running Tests

- ***Figure-of-eight running.*** Two cones are positioned 10 m apart. The patient is asked to run around the cones in a figure-of-eight pattern, for a certain number of rotations, rounding the turns rather than planting and cutting, while the clinician times the run. The time ratio of figure-of-eight running to straight running is one of the most definitive ways to compare patients with an ACL-deficient knee to those with normal knees.[446]
- ***Carioca test.*** The carioca test involves the patient running laterally with a crossover of the legs and a weaving of the feet, beginning with the trailing leg in front, then trailing the leg in back of the leading leg, for a distance of either 8 feet[447] or 24.4 m.[448]
- ***Shuttle run.***[439,449] The shuttle run involves having the patient run between cones or varying distances.

Imaging Studies

Radiographic imaging of the knee is described in Chapter 7. Arthrograms of the knee are used primarily to diagnose tears in the menisci and plica, although their use is gradually being replaced by arthroscopy, which allows the surgeon to diagnose and repair lesions simultaneously.

THE EVALUATION

Following the examination, and once the clinical findings have been recorded, the clinician must determine a specific diagnosis or a working hypothesis, based on a summary of all of the findings. This diagnosis can be structure related (medical diagnosis) (Table 20-16), or a diagnosis based on the preferred practice patterns as described in the *Guide to Physical Therapist Practice.*

Intervention Strategies

Acute knee injuries are a common occurrence. One study[450] demonstrated, perhaps not surprisingly, that the most common type of acute knee injuries were sports related, occurred in men younger than 35 years of age, and were of moderate severity. Studies[450–452] that compare the two sexes report higher rates of sports injuries in men. This finding could be a result of the greater numbers of men participating in sports activities or the greater frequency of injuries in men who do participate in sports.

Of particular interest are non–sports-related falls, which are experienced two to three times more frequently in women than in men, except in the group older than 55 years, for whom the incidence of falls is equal in both sexes.[450]

Most knee pain of nontraumatic origin improves with conservative intervention.[453] Different approaches have been emphasized over the years, including patient education,[454–456] activity modification ,[147,455,457,458] progressive muscle stretching and strengthening,[136,147,454,456–461] functional lower extremity training,[462] external patellar supports and braces,[147,454,456,463,464] foot orthotics (Table 20-17),[464,465] and taping to improve patella tracking.[454,457,460,466,467]

This wide range of interventions raises the question of whether any of them are efficacious, or whether a combination of some is to be recommended. What is clear is that the impairments and functional limitations found during the examination must guide the intervention. The successful intervention requires detailing the factors that influence these impairments and functional limitations, and determining the stage of healing.

Whatever the knee injury, the goal of the rehabilitation program is to return the patient to an optimum level of function. The emphasis during knee rehabilitation must focus on achieving a balance between allowing the damaged structures to heal, improving muscle control, and increasing the competence of the static restraints. Consideration must also be given to the various forces placed on the knee during CKC and OKC exercises. The techniques to increase joint mobility and soft tissue extensibility are described in "Therapeutic Techniques" section.

Acute Phase

Every attempt is made to protect the joint to promote and progress the healing. The goals during the acute phase are to

- reduce pain and swelling;
- control inflammation;
- regain ROM;
- minimize muscle atrophy and weakness;
- attain early neuromuscular control;
- maintain or improve the patient's general cardiovascular fitness.

The reduction of pain and the control of swelling are extremely important as both can inhibit normal muscle function and control. The principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication) are used to minimize pain, swelling, and inflammation.

TABLE 20-16 Differential Diagnosis of Common Causes of Knee Pain

Condition	Patient Age (years)	Mechanism of injury	Area of Symptoms	Aggravated by Symptoms	Observation
Patellofemoral syndrome	20–50	Gradual Macrotrauma Microtrauma	Anterior knee	Prolonged sitting Stairs Kneeling	Possible soft tissue thickening/swelling at anterior knee
Patellar tendinitis	15–50	Gradual (repeated eccentric overloading during deceleration activities)	Anterior knee	Squatting, jumping	Usually unremarkable
Quadriceps muscle tear	20–40	Sudden overload	Anterior thigh	Squatting	Possible bruising over anterior thigh/knee Possible swelling over anterior thigh/knee
Knee osteoarthritis	50+	Gradual due to microtrauma Macrotrauma	Generalized knee	Weight-bearing	Possible soft tissue thickening/swelling around knee
Anterior cruciate ligament sprain/tear	15–45	Trauma to knee (sudden deceleration, an abrupt change of direction, valgus force, rotary force) while foot is fixed	Varies according to number of associated structures involved Typically associated with immediate swelling of knee (acute hemarthrosis)	Weight-bearing	Knee swelling
Collateral ligament injury	Varies	Trauma to contralateral aspect of knee (valgus or varus)	Distal femur on medial or lateral aspect depending on whether MCL or LCL is involved	Varus stress (LCL) Valgus stress (MCL)	Swelling may be present depending on extent of trauma
Prepatellar bursitis	15–50	Direct trauma to anterior aspect of knee	Anterior knee	Kneeling	Local swelling, fluctuation
Patellar subluxation/dislocation	Varies	Twisting injury with the femur internally rotating on a fixed foot, although there may be no history of trauma	Varies according to tissues involved	Weight-bearing	Dependent on the degree of trauma
Lumbar disk pathology	20–50	Gradual Sudden overload of lumbar spine	L3 dermatome	Trunk flexion Bearing down	May have associated trunk deviation

(Continued)

TABLE 20-16 Differential Diagnosis of Common Causes of Knee Pain *(Continued)*

AROM	PROM	End-Feel	Resisted	Tenderness with Palpation
Usually no limited ranges	Pain at end range knee flexion	Usually unremarkable	Usually no pain with resisted tests	Anterior knee especially with patella compression
Usually unremarkable	Pain at end range knee flexion	Usually unremarkable	May have pain with resisted knee extension	Over the patellar tendon, inferior or superior to the patellar
Limited knee flexion	Pain with combined hip extension and knee flexion	Spasm/empty depending on extent of injury	Pain with resisted hip flexion;;; Pain with resisted knee extension	Anterior thigh
Loss of motion in a capsular pattern	Pain at end range knee flexion and extension	Unremarkable	Generalized weakness	Typically posterior knee if present at all
Loss of some knee flexion and extension (depending on extent of swelling)	Pain at end ranges	Loss of firm end-feel with Lachman/anterior drawer	Pain with resisted knee rotation	Depends on associated injuries
Depends on extent of trauma	Possible pain at end range of tibial rotation	Depends on extent of injury	Usually negative	Distal medial femur to medial joint line (MCL) Distal lateral femur to lateral joint line (LCL)
Unremarkable	Sometimes passive flexion is painful	Usually unremarkable	Usually unremarkable	Anterior aspect of knee
Dependent on extent of trauma	Dependent on extent of trauma, usually apprehension present	Spasm/empty	Usually unable to perform secondary to pain	Lateral femoral condyle, retinacular, patellar facet
Usually pain with trunk flexion	Unremarkable	May have painful SLR	Fatiguable weakness in associated myotome	May have tenderness over involved spinal segment

TABLE 20-17 Randomized Clinical Trials and Other Experimental Studies Related to Foot Orthotics and Patellofemoral Pain Syndrome

Investigators	Independent Variables	Dependent Variables	N	Statistical Significance	Clinical Importance	Study Design
Eng JJ and Pierrynowski MR[a]	Exercise group (isometric quadriceps set, straight leg raise, stretching) and soft orthotic group	Maximum pain (visual analog scale) with activities (walking, running, stair ascent, stairs descent, sitting one hour, squatting)	20 women with patellofemoral pain (comparison group, $n = 10$; experimental group, $n = 10$)	Statistically significant ($P < 0.05$) at weeks 4, 6, and 8.	Clinically important as compared with the compassion group	Randomized clinical trial
Eng JJ and Pierrynowski MR[b]	Walking and running with and without orthotics	Knee, talocrural, and subtalar joints range of motion for each plane of motion	10 women with patellofemoral pain syndrome and forefoot varus and calcaneal valgus >6 degrees	No significant difference at the knee except transverse and frontal plane range of motion	Could not determine	Repeated measures analysis
Hung Y and Gross MT[c]	Three foot positions (supinated, pronated, and neutral)	Vastus medialis obliquus–vastus lateralis EMG ratio (isometric quadriceps set; one leg squat, 0–50 degrees)	16 nonimpaired subjects (20 subjects started the study)	No significant difference	Not clinically important	Repeated measures analysis
Tomaro J and Burdett RG[d]	Walking with and without orthotics	EMG: tibialis anterior, fibularis (peroneus) longus, gastrocnemius	10 subjects with a history of like pathology (three men and seven women)	Average muscle electromyogram, no significant difference; duration and tibialis anterior/stance × 100% $P < 0.05$	Not clinically important	Repeated measures with randomization
Nawoczenski DA et al.[e]	Running with orthotics	Tibial internal rotation	20 recreational runners with lower limb pain	A decrease of 2.1 degrees in tibial rotation	Clinically important	Repeated measures analysis

Therapeutic Exercises

Numerous clinical trials have used therapeutic exercise as part of a comprehensive intervention program for both the tibiofemoral and patellofemoral joints.[235,243,250,468–470,471]

Once the pain, swelling, and inflammation are under control, early controlled ROM exercises are initiated. In the acute phase of healing, the interventions focus on decreased loading of the joint complex, which might include postural correction, activity modification, or the use of an assistive device. Bracing may be needed to provide adequate protection (see the discussion in "Functional Phase" section). Exercises prescribed for the knee joint complex must include those that promote neuromuscular control, timing, balance, and proprioception.

Exercises recommended for this phase include isometric muscle setting (quadriceps sets **VIDEO**, hamstring sets, gluteal sets), active knee flexion (heel slides **VIDEO**), straight leg raises (if appropriate) (Fig. 20-47), hip swings **VIDEO** and patellar mobilizations. Proprioceptive neuromuscular facilitation (PNF) activities may be initiated with slow-speed, low-force, controlled exercises. Electrical stimulation can be used to facilitate muscle activity and to promote muscle reeducation.[472] The training of the VMO should be regarded as a motor skill acquisition rather than a strengthening procedure,[150,473] with the goal of the training to produce a modification of the length–tension relationship between the VMO and its antagonist, the VL. This may result in a change of the equilibrium point, which will enable the appropriate alignment of the patella.[474] If the muscle control of the VMO is poor, biofeedback can be used to augment the hip adductor training.[475] Taping can be used as an adjunct (see later discussion).

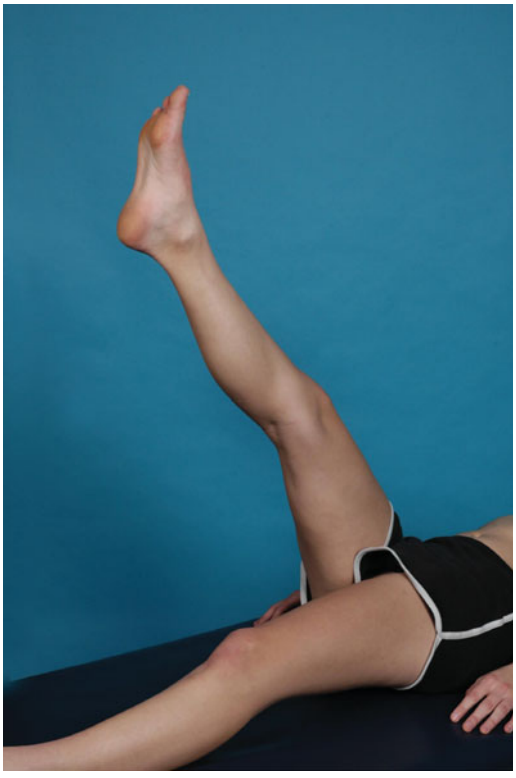

FIGURE 20-47 Straight leg raise.

Once the muscle control is achieved, gentle CKC exercises are initiated. CKC exercises initially include small-range wall slides and heel raises. Contractions of the quadriceps should be encouraged in the functional knee positions that provoke pain, such as sitting, and stair negotiation. The benefit of CKCEs is that they decrease shear forces and emphasize cocontractions.[476,477] General recommendations for CKC exercise at the knee are from 0 to 20 degrees,[471] or 0–40 degrees of flexion.[234] All the exercises performed in the clinic should be performed by the patient at home whenever possible.

Tibiofemoral Joint

The CKC exercises previously mentioned are progressed to include the supine leg press, the hip sled with minimal resistance.[478231] These exercises are performed bilaterally initially and then unilaterally once there is evidence of good dynamic stability.

Cocontraction exercises for the hamstrings and quadriceps, which further reduce tibiofemoral shear forces,[243,244,308,479,480] can be achieved by having the patient perform single-leg bridges by leaning back on a Swiss ball (Fig. 20-48) and raising the uninvolved leg off the floor, while the involved leg is used to maintain balance. Cocontraction also can be accomplished by "single-leg" wall slides using the Swiss ball (Fig. 20-49), with the uninvolved leg supporting most of the body weight.

Stationary bicycling has long been recognized as a useful therapeutic exercise for knee rehabilitation to control the ROM and impact forces at the knee.

- The ROM at the knee can be controlled by adjusting the seat height.
- The impact forces can be adjusted on most exercise bicycles by varying the resistance at the pedal–foot interface.

The amount of strain on the ACL during stationary bicycling is relatively low compared with other rehabilitation activities[481] (see Table 20-1).

Patellofemoral Joint

Rehabilitation that includes a combination of painless muscle strengthening, stretching, and patellofemoral taping often is beneficial in creating an internal biomechanical environment that encourages maximal tissue healing.[482] A number of

FIGURE 20-48 Single-leg bridges on Swissball.

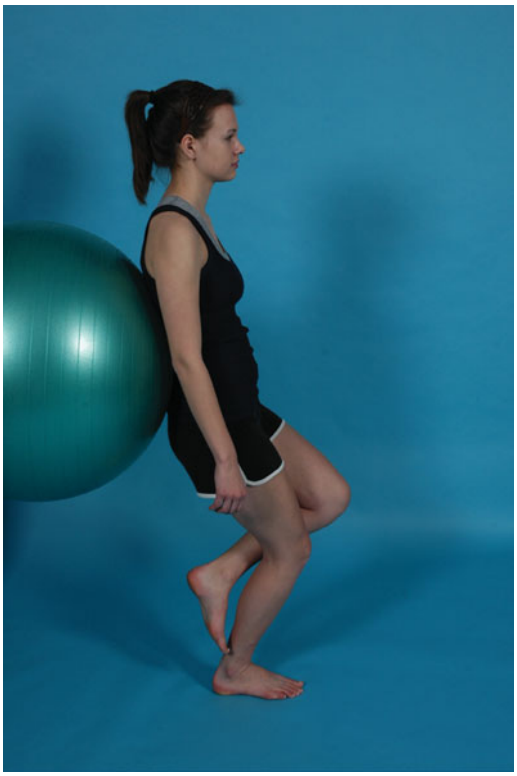

FIGURE 20-49 Wall slide with Swissball.

classification systems have been used to categorize individuals with patellofemoral disorders (Table 20-18). As with any disorder, although the use of a classification system may help, the clinician must formulate effective treatment interventions based on the findings from the history, subjective examination, physical examination, functional assessment, and the patient's response to the prescribed exercises.

A number of activities have been identified that increase patellofemoral compression. These include jumping, stair climbing, squatting, prolonged sitting with the knee flexed beyond 40 degrees, prolonged kneeling, arising from chairs, prone lying, or standing in genu recurvatum.[9,147] During the early stages of healing, the patient must try to avoid these activities or at least minimize exposure. In the presence of biomechanical dysfunctions of the foot, including pronation, correct footwear must be worn. If the malalignment of the lower extremity is severe, a foot orthosis can be prescribed.[463,474] The type of orthosis used is dependent on the diagnosis. Most commonly, an orthosis is used to correct a flat foot so that the patella no longer squints. Foot pronation imparts internal torsion to the tibia and a valgus moment at the knee. Klingman et al.[483] have shown that medial rearfoot-posted orthoses result in a more medial position of the patella during static weight-bearing radiographs. In the presence of genu recurvatum, a heel raise can be issued for use during

TABLE 20-18 Classification Systems for Nonoperative Patellofemoral Syndrome

Lohman[a]	Wilk et al.[b]	Holmes et al.[c]
1. Overconstrained—tight lateral or inferior structures (tilt, glide, anteroposterior tilt)	1. Patellar compression syndrome—excessive lateral pressure syndrome; global pressure syndrome	1. Patellofemoral instability—subluxation or dislocation, single episode; lateral or medial subluxation or dislocation, recurrent; chronic dislocation of patella, congenital or acquired; associated fractures, osteochondral or avulsion
2. Combination—tight lateral structures and loose medial structures	2. Patellar instability—chronic patellar subluxation; recurrent patellar dislocation	2. Patellofemoral pain with malalignment—increased functional quadriceps angle (femoral anteversion, external tibial torsion, genu valgum, foot hyperpronation); tight lateral retinaculum; grossly inadequate medial stabilizers; electrical dissociation; patella alta; patella baja; dysplastic femoral trochlea
3. Underconstrained—loose lateral and medial structures (excessive joint play) resulting in instability (subluxation or dislocation)	3. Biomechanical dysfunction	3. Patellofemoral pain without malalignment—tight medial and lateral retinaculum; plica (medial, lateral, suprapatellar); osteochondritis dissecans; traumatic patellar chondromalacia; fat pad syndrome; patellofemoral osteoarthritis; patella tendinitis; quadriceps tendinitis; prepatellar bursitis; apophysitis; symptomatic bipartite patella; other trauma (quadriceps tendon rupture, patella tendon rupture, patella fracture, proximal tibial epiphysis fracture, contusion, turf knee or wrestler's knee, cruciate ligament instability)
4. Normal—normal alignment but painful (e.g., tendinitis, apophysitis, or bursitis)	4. Direct patella trauma—articular cartilage lesion (isolated); fracture and dislocation; articular cartilage lesion with associated malalignment	
5. Unable or not specified—the underlying cause of patellofemoral pain syndrome cannot be determined	5. Soft tissue lesions—suprapatellar plica, fat pad syndrome; medial patellofemoral ligament pain; iliotibial band friction syndrome	
6. Other causation—osteochondrosis dissecans, chondromalacia patellae, sympathetically maintained pain, fractures, synovial plicae	6. Overuse syndromes—tendinitis; apophysitis	
	7. Osteochondritis dissecans	
	8. Neurologic disorders—complex regional pain syndrome; sympathetically maintained pain

exercise. It is therefore reasonable, for selected patients, to prescribe an orthotic device for the shoe.[188,484]

It remains unclear to what extent there are specific exercises to strengthen the VMO.[11,146,485] A study by Mirzabeigi et al.[486] attempted to isolate the VMO from the VL, vastus intermedius, and VML, using nine sets of strengthening exercises. These exercises included isometric knee extension with the hip in neutral, 30 degrees of external rotation, and 30 degrees of internal rotation; isokinetic knee extension through full range; isokinetic knee extension in the terminal 30-degree arc; side-lying ipsilateral and contralateral full knee extension; and stand and jump from a full squat. Although the study concluded that isometric exercises in neutral and external rotation of the hip challenged both the VMO and VL, none of the exercises demonstrated isolation of the VMO.[486] Indeed, a thorough review of the existing literature shows that isolated contraction of the VMO, independent of the VL has never been documented.[487] The VMO does not extend the knee and is not, therefore, activated by the traditional straight leg raise,[488] even with the addition of adduction.[489] However, because of the relationship of the VMO to the adductor magnus, and its separate nerve supply in most cases,[137] the clinician should still emphasize adduction of the thigh, while minimizing internal rotation of the hip, to facilitate a VMO contraction.[475] According to Hodges and Richardson,[490] activation of the adductor magnus significantly improves the VMO contraction in weight-bearing, but maximum contraction of the adductor magnus in non–weight-bearing is required before facilitating VMO activity.

The hip external rotators and abductors affect lower limb control, and a strengthening program that addresses these muscle groups should be integrated into the overall progression. For example, weakness of the hip external rotators may allow uncontrolled and excessive pronation of the foot to occur along with excessive femoral internal rotation, both contributing to an increase in the valgus alignment of the knee, thereby increasing the Q-angle.[167] Strengthening of the hip rotators may need to be initiated in the OKC, but should be advanced to strengthening in the CKC as soon as functional muscular control is present.[167]

Exercises during this phase include the following:

- Isometric quadriceps sets at 20 degrees of flexion, progressing to multiple angle isometrics.
- Heel slides with the tibia positioned in internal and then external rotation.
- Straight leg raises performed with the thigh externally rotated and the knee flexed to 20 degrees. Performing the exercise in this fashion is reported to allow the least amount of patellofemoral contact force while maximally stressing the vastus medialis component of the quadriceps muscle.[207,232,491] The resistance is progressed from 0 to 5 lb.
- Straight leg raises performed into abduction with the thigh externally rotated to enhance strengthening of the gluteus medius.
- Low-resistance knee extension (short-arc quadriceps) exercises, performed with the leg externally rotated, from 50 to 20 degrees (avoiding terminal knee extension) (Fig. 20-50). During non–weight-bearing knee extension, the amount of quadriceps muscle force required to extend the knee steadily increases as in the moves from 90 degrees to full knee extension. The resistance is progressed from 0 to 5 lb.

FIGURE 20-50 Short arc quad in external rotation.

- Hip adduction exercises performed in the side-lying position on the involved side (Fig. 20-51). The exercise can also be performed with the hip internally rotated and the knee flexed to 20 degrees.[140,492] This position of knee flexion places the patella midway between the two femoral condyles.

Functional exercises that incorporate the entire lower kinetic chain are implemented as soon as tolerated. Kibler[493] advocates the following protocol:

- Active hip extension and quadriceps activation with the foot flat on the floor or stepping on or off a flat step (Fig. 20-52). This reactivates the normal sequencing pattern for the entire leg.
- Isolation and maximal activation of the quadriceps in a CKC position by working with the foot on a slant board (Fig. 20-53), effectively removing the hip and ankle from full activation, but placing maximal load on the slightly flexed knee. Care must be taken not to exercise through pain as this may indicate that muscle control is insufficient.[150] During weight-bearing exercises, the quadriceps muscle force is relatively minimal when the knee is extended and steadily increases as the knee flexes.
- Unilateral stance with hip extension, slight knee flexion, and hip and trunk rotation.

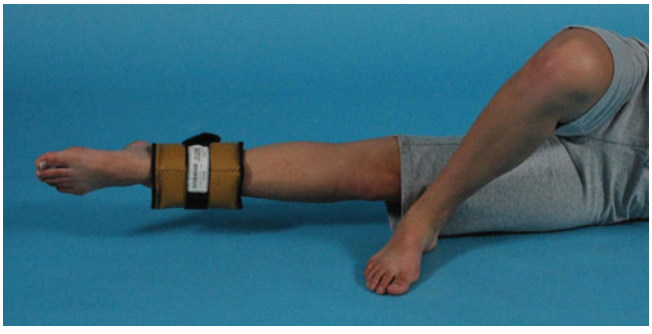

FIGURE 20-51 SLR into adduction.

FIGURE 20-52 Step downs.

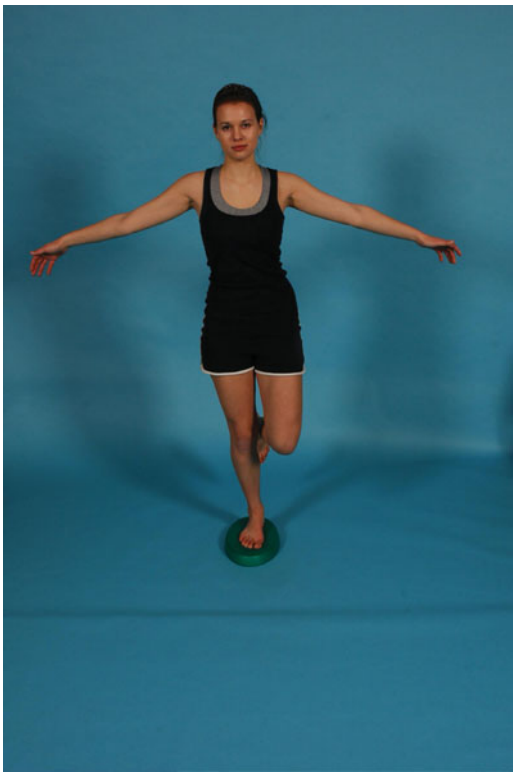

FIGURE 20-54 Unilateral stance on soft surface.

The correction of muscle inflexibilities is very important in the rehabilitative process. This activity can be made more challenging using softer surfaces (Fig. 20-54).

Stretching of the quadriceps **VIDEO** hip flexors, ITB, lateral retinaculum, hamstrings, and gastrocnemius are usually initiated during this phase. The rationale for stretching the ITB and lateral retinaculum is well recognized.[129,454,494] Adaptive shortening in the hamstrings and gastrocnemii has been associated with a compensatory pronation.[320] In addition, adaptively shortened hamstrings may cause increased flexion of the knee and increased patellofemoral compression forces, especially during the stance phase of gait.[300] Correction of muscle imbalances is based on a full analysis as to the effect that these interventions will have on the pathologic process, or on other structures within the kinetic chain. For example, stretching the hamstrings of an elderly patient to relieve the stresses at the knee may exacerbate the symptoms of lateral recess stenosis, because the adaptively shortened hamstrings may be helping to maintain the pelvis in a posterior pelvic tilt.[495]

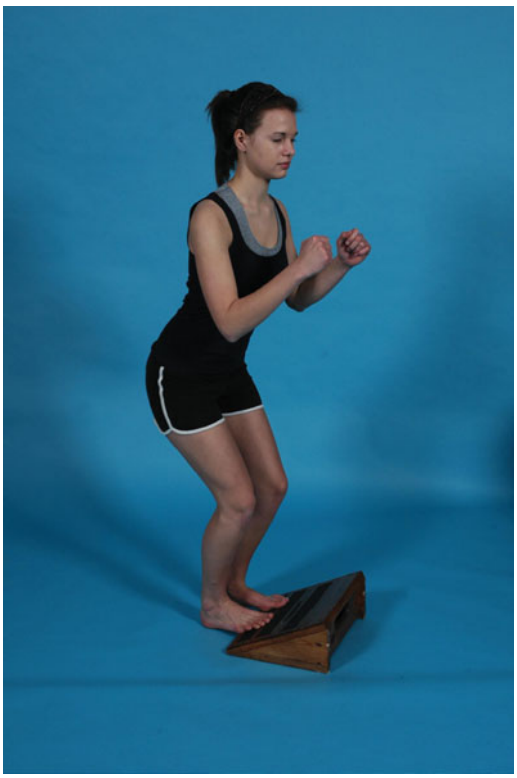

FIGURE 20-53 Squat on slant board.

Functional Phase

The functional phase of the knee rehabilitation program should be designed to addresses any tissue overload problems and functional biomechanical deficits once the painful symptoms have improved. During this phase, the patient gradually and incrementally increases joint-loading activities. As an approximation, patients typically progress to this phase when terminal knee extension exercises can be done with 25–30-lb weights.[9] Among the goals for this phase are to

- attain full range of pain-free motion;
- restore normal joint kinematics;
- improve muscle strength;
- improve neuromuscular control;
- restore normal muscle force–couple relationships.

ROM exercises during this phase include flexion and extension exercises; stationary cycling progressing to moderate resistance; and standing wall slides **VIDEO**. The stationary bike exercises are initially performed with a high seat (providing about 15 degrees of knee flexion in the extended leg).

There is controversy about whether knee exercises should be performed in an OKC or CKC manner.[234] CKCEs, such as the squat, leg press, dead lift, and power clean, have long been used as core exercises by athletes to enhance performance in sport.[496,497] These multijoint exercises have biomechanical and neuromuscular similarities to many athletic movements.[235] OKCEs appear to be less functional in terms of many athletic movements and primarily serve a supportive role in strength and conditioning programs. However, it is advised that a combination of the OKC and CKC exercises be used.

Closed-Chain Exercises

CKCEs during this phase include a continued progression of those exercises introduced during the acute phase. Other exercises are introduced including sideways step-ups (Fig. 20-55) and step-downs **VIDEO**, single knee toe raises **VIDEO** (Fig. 20-56) and dips, partial (Fig. 20-57) to full squats with added resistance,[454] the seated leg press, front and side lunges **VIDEO** (Fig. 20-58), jumping and landing exercises **VIDEO** (Fig. 20-59 and Fig. 20-60), Fitter-board exercises (Fig. 20-61), resisted walking in all four planes **VIDEO** (flexion, extension, abduction, and adduction) using elastic tubing (Fig. 20-62), balance activities **VIDEO** and obstacle jumping[498] **VIDEO** (Fig. 20-63).

In the presence of knee version, an adjunct to the usual exercise regimen may be strengthening of the internal tibial rotators (semimembranosus, gracilis, semitendinosus, sartorius), with greater emphasis placed on hamstring stretching, particularly the biceps femoris, while adding stretching of the ITB.[286] CKCEs to strengthen the hamstrings, gastrocnemii, and quadriceps in a functional manner include a variety of exercises on a stair climber. The patient stands on the machine backward for the quadriceps and forward for the hamstrings.

FIGURE 20-56 Single leg heel raises.

FIGURE 20-55 One quarter step up to the side.

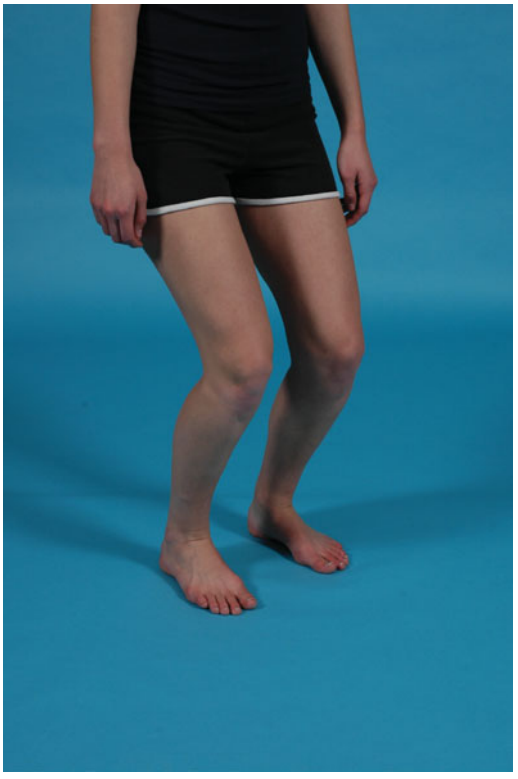

FIGURE 20-57 Partial squat.

FIGURE 20-58 Resisted side lunges.

FIGURE 20-59 Jumping and landing.

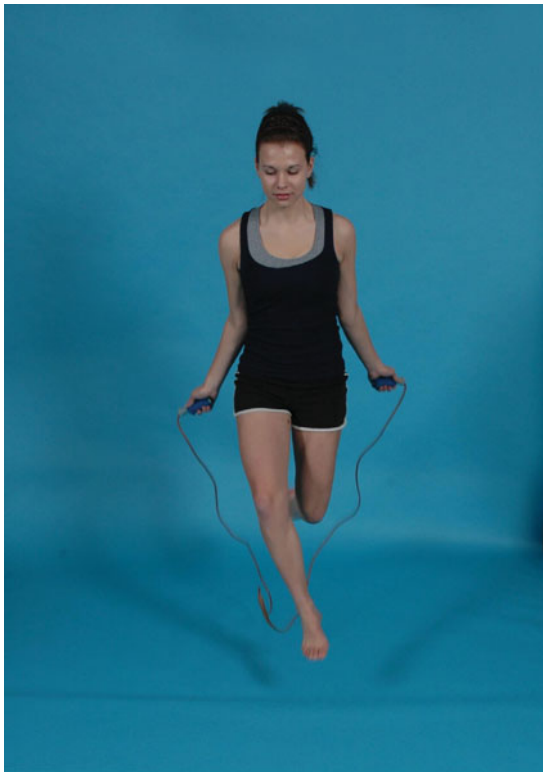

FIGURE 20-60 Jump roping as a plyometric exercise.

FIGURE 20-61 Fitter board exercises.

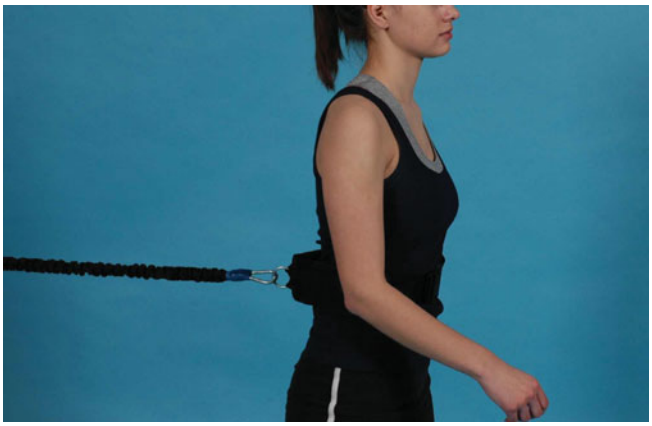

FIGURE 20-62 Resisted walking exercise.

The use of an inclined treadmill can also be used to selectively exercise the hamstrings, gastrocnemii, and quadriceps as follows:

- Walking or running downhill works the quadriceps eccentrically.
- Walking or running uphill works the gastrocnemii and hamstrings concentrically.
- Walking or running downhill backward works the gastrocnemii and hamstrings eccentrically.
- Walking backward uphill uses the quadriceps concentrically.

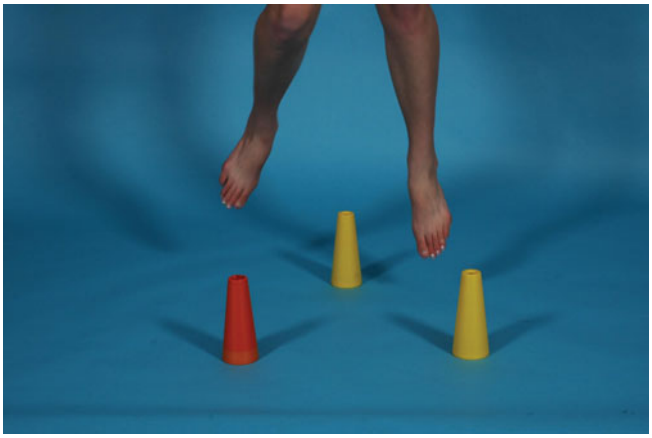

FIGURE 20-63 Obstacle jumping.

Uphill and retrotreadmill walking have been found to produce less patellofemoral joint restrictive forces than forward walking.[499]

For those patients with patellofemoral pain, or weak hip abductors, hip abductor action can be facilitated during a lunge task by creating an adduction force using elastic tubing that the patient is instructed to counteract.

Open-Chain Exercises

OKCEs during this phase can include a wide variety of exercises including seated knee extension and knee flexion exercises that are viewed as single-joint, single-muscle-group exercises.[235] Using the knowledge of the compressive forces at the joint, OKCEs (e.g., short-arc quadriceps **VIDEO**, multiple-angle isometrics) should be performed in the 50–90-degree or 90–50-degree range of knee flexion.[234,488] Other exercises include

- straight leg raises in all four planes (flexion, extension, abduction, and adduction), progressing to about 10% of body weight in resistance;
- supine leg lowering;
- seated leg lowering;
- short-arc quadriceps progression to about 10% of body weight in resistance;
- Side-lying (clam) exercise to strengthen the gluteus medius (see Chap. 19). The patient is positioned in side lying with the hips and knees flexed to about 45 degrees. A piece of Theraband is wrapped around both sides and the patient is asked to abduct and externally rotate the uppermost leg against the resistance of the Theraband.

Swenson et al.[500] recommend the use of the 4-minute OKC exercise for patellofemoral pain. The exercise protocol was developed by Glen Porter, ATC, a basketball trainer at Michigan State University, MI, and Alan Glock, MD, an orthopaedic surgeon in Richmond, IN. The exercise is performed as follows.

The patient sits on the edge of a chair, with the upper leg supported. The patient is asked to contract the quadriceps muscle with the knee in full extension. The contraction is held for 1 minute, after which the leg is flexed to 45 degrees for 30 seconds. Four cycles of extension and flexion constitute the 4-minute VMO program. Initially, the exercise is performed four to six times a day. Ankle weights are added after 1–2 weeks and the number of sets is decreased.[500]

The functional rehabilitation strategy should be to progressively improve three-dimensional dynamic lower extremity postural stability. This can be achieved using a multiplanar task progression integrating both non–weight-bearing and weight-bearing lower extremity function.[160] An example of a non–weight-bearing exercise is standing in unilateral knee flexion in conjunction with tibial internal rotation and hip external rotation, performed either actively or with a resistive band.[160] To make efficient use of elastic resistance, quick concentric activation should be followed by a slower eccentric activation.[160] For weight-bearing exercises, both forward and side lunges on varying surfaces can be used. Task speed can be progressively increased and spontaneous responses can be achieved by having the patient respond to random cues to provide the direction of movement. Simultaneous use of different size and weight balls for catching and tossing may increase specificity and serve as a distractor to better assess the patient's true ability to maintain appropriate, well-controlled, three-dimensional, dynamic, lower extremity postural stability.[160]

For some patients, a return to sports may be a goal. Since strenuous activities may exert five times more force than is imparted with the various ligament stress tests,[501] the clinician cannot rely on the results from the ligament stress tests as a means to assess a patient's readiness to return to sport. Once strength and endurance have reached at least 70% of the uninvolved extremity with isokinetic testing, the more advanced (PNF) exercises involving high-speed, high-force, uncontrolled movements are initiated, stopping short of cutting, jumping, and twisting maneuvers if symptoms of instability develop.[502,503] Running, jumping, and twisting activities must be included in the clinical examinations of such patients to enable true assessment.[443] Criteria for progression into the return to sport phase include the following:

- Full AROM and PROM compared with the uninvolved knee. It has been suggested that the patient should have 8–118 degrees of knee motion, demonstrate a normal gait pattern, ascend and descend stairs, and demonstrate no gait deviation when running, before participating in athletic activity.[445,504]
- A quadriceps-to-hamstring ratio of 2:3 and equal to or greater than 75% of the uninvolved leg.
- Ability to perform a one-leg squat for 15–20 repetitions.
- Normal joint kinematics.

A return to cutting sports at the competition level is permitted when the quadriceps strength index is 85–90% of the uninvolved leg at 60 degrees per second with isokinetic testing. Sport-specific drills are added late in the functional phase as the athlete approaches return to play. Activity-specific progressions must be completed to test all of the working parts involved in the activity before full return to function is advised.

Bracing

Patellofemoral Bracing

External patellar supports are commonly employed in the management of patellofemoral pain as an adjunct to other intervention methods. Although they relieve symptoms in many patients, their mode of action remains theoretical and their usefulness is unpredictable.[267]

Theoretically, the brace is designed to centralize the patella within the patellar groove, thereby reducing symptoms and improving function.[463,505] The various commercially available patellofemoral braces use a number of methods to improve patellar tracking, including patellar cut-outs, lateral buttresses, air bladders, and positioning straps.

Despite the wide use of patellofemoral bracing, only a few studies have attempted to document their effectiveness in correcting patellar alignment. Using MRI, Koskinen and

Kujala[506] reported a quantitative decrease in lateral patellar displacement using the safety brace (Axini, Boliden, Sweden), while Worrell et al.[507] found that the Palumbo brace (Dynorthotics LP, Vienna, VA) reduced lateral patellar displacement and increased patellofemoral congruence at 10 degrees of flexion. These studies, however, used static imaging techniques and, therefore, actual patellar tracking was not assessed. This is an important limitation because patellar tracking is considered to be a dynamic entity. Studies comparing active and passive procedures have shown that patellar motion is significantly influenced by the degree of quadriceps contraction.[217,267,508,509] Finestone et al.[510] found that some braces were less effective and more harmful to the skin than conservative therapy (i.e., maintaining activity and avoiding pain-causing activity, or no therapy, or simple muscle stretching and strengthening).[511]

Although it is debatable whether bracing can influence patellar tracking, it appears that external supports must, in some way, interact mechanically with the patellofemoral joint because many patients report significant clinical improvements.

Tibiofemoral Bracing

Functional knee braces are commonly prescribed following an ACL injury or reconstruction to promote healing, by reducing anterior translation of the tibia with respect to the femur and thereby restoring normal joint kinematics.[22,512,513]

The efficacy of knee bracing with regard to providing adequate protection is controversial, because the compliance of the soft tissues around the thigh decreases the ability of the brace to function correctly, particularly at high loads.[513,514]

A study by Fleming et al.[513] using the Legend brace (dj Orthopaedics LLC, Vista, CA) indicated that a functional knee brace can protect the ACL during anteroposterior shear loading in the non–weight-bearing and weight-bearing knee and during internal torques in the non–weight-bearing knee. However, this study used only one brace and one knee flexion angle (20 degrees).

Risberg et al.,[515] who used randomized, prospective clinical trials of bracing after ACL injury or reconstruction, found no difference in joint laxity, pain, muscle strength, and functional knee tests between patients who wore a functional knee brace and those who did not wear a functional brace during postsurgical rehabilitation.

Several studies have indicated that subjects with chronic ACL-deficient knees have impaired proprioception.[516–518] Whether functional knee braces enhance proprioception in ACL-deficient knees remains unclear. Although a few studies have addressed the relationship between proprioception and functional outcome measures,[516,517] the studies that have compared the effect of functional braces on proprioception between ACL-reconstructed knees and the contralateral uninvolved knee have as yet demonstrated no improvement in proprioception with the wearing of such braces,[519] and no effect on long-term outcome.[22]

Interestingly, bandaging of the knee, or the use of a neoprene brace, has been shown to improve proprioception in both normal individuals and those with different types of knee disorders, including knee OA and an ACL tear.[22,520]

Taping

The primary goal of taping[189,521] is to pull the patella away from a painful area, thereby unloading it and reducing pain, rather than as a adjustment for patellofemoral malalignment.[454,522,523] The extent to which this is possible and the amount of displacement required to provide pain relief varies from patient to patient and from study to study (Table 20-19).[11] Indeed, the displacement does not need to be perceptible to effect improvement. Bockrath et al.[522] found that taping did affect perceived pain but was not associated with patellar position changes. A recent computed tomography (CT) study,[524] involving 16 female patients (aged 16–25 years) who had anterior knee pain related to patellofemoral incongruence, evaluated the effect of patellar taping on patellofemoral incongruence. The subjects underwent CT examination with their quadriceps muscles relaxed and contracted, both before and after patellar taping. The study found that patellar taping did not significantly affect patellofemoral lateralization, or tilt, and concluded that although patellar taping may well be effective in controlling anterior knee pain, it does not do so by medializing the patella.[524] Another study found that McConnell taping was effective in moving the patella medially but ineffective in maintaining this difference after exercise.[525]

A secondary function of taping is to increase the beneficial proprioceptive characteristics of the patellofemoral joint.[526,527] Grabiner et al.[528] have postulated that the VMO needs time to develop force, relative to the VL, to optimally track the patella. This lag time can cause the patella to track laterally. By applying tape across an overly powerful VL, the clinician may be able to change the relative excitation of the VMO and VL, diminishing the pull of the VL,[11,189,521] although the mechanisms by which this works are unknown.

One other function of taping for malalignment of the patella is to position the patella optimally so that the area of contact between the patella and femur is maximized.[266] This position places the patella parallel to the femur in the frontal and sagittal planes, and the patella is midway between the two condyles when the knee is flexed to 20 degrees.[266]

Once the tape is applied, the clinician assesses the following:

- The overall limb alignment. This includes an assessment when walking normally, on the heels, and with the feet in the inverted and everted positions; stair climbing; and squatting.
- The effect on functional painful and pain-free ranges.

From this information, the patellar position is adjusted by taping. The most obvious deviation is always corrected first. The glide component can be corrected by firmly gliding the patella medially and taping the lateral patellar border (Fig. 20-64). The tilt component can be corrected by firm taping from the middle of the patella medially, which lifts the lateral border and provides a passive stretch to the lateral structures (Fig. 20-65). To correct external rotation of the patella, firm taping from the middle inferior pole upward and medially is required. For correction of internal rotation, firm taping from the middle superior pole downward and medially is needed.

In addition to the taping, biofeedback, stretching of the lateral structures, and a home exercise program are recommended. For a more detailed description of the application of

TABLE 20-19 The Effects of Patellofemoral Taping on Patellofemoral Pain

Investigators	Study Design	Number of Interventions	Percentage Improvement and Clinical Importance
Eburne and Bannister[a]	Single-blind randomized control trial	3 months or until pain-free	Both groups 50%—no clinical importance
McConnell[b]	Experimental	Eight sessions	92%, no control—could not determine
Gerrard[c]	Experimental	Five sessions	96%, no control—could not determine
Powers et al.[d]	Experimental	One session	78%, no control—clinical importance
Salsich et al.[e]	Experimental	One session	92.6%, no control—clinical importance
Bockrath et al.[f]	Experimental	One session	54%, no control—clinical importance
Kowall et al.[g]	Randomized control trial	Eight sessions over 1 month	44%, no control—no statistical difference between groups but clinical importance
Clark et al.[h]	Single-blind randomized control trial	Six sessions (five taping sessions)	No statistical difference between groups or clinical importance

the tape, the reader is referred to an excellent book, *The Patella: A Team Approach*.[188]

Lesher et al.[529] attempted to determine the predictive validity and interrater reliability of selected clinical examination items and to develop a clinical prediction rule (CPR) to determine which patients would respond successfully to a medial glide patellar taping technique. A CPR is, by definition, an optimum number of clinical examination items use for predicting a diagnosis or prognosis. Two examination items (positive patella tilt test or tibial varum >5 degrees, +LR = 4.4 [95% CI = 1.3–12.3] and a −LR of 0.53 [0.38–0.86]) comprised the CPR. Application of the CPR improved the probability of a successful outcome from 52% to 83%. As the CPR in this study represented a level IV CPR, it requires validation in a separate sample before it can be implemented on a broad basis.[530]

Taping can also be used with patients who have patellar OA. A controlled clinical trial[531] found that patients achieved significant reduction in pain after medial knee taping to realign the patella.

Walking Poles

Results from a number of studies[532–534] have demonstrated that walking poles reduce the forces on the lower extremity

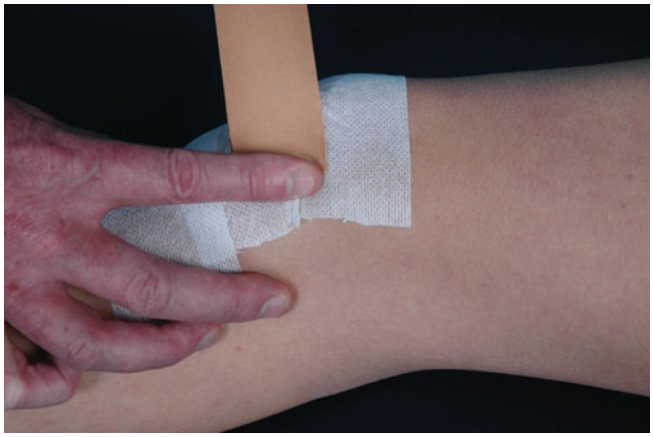

FIGURE 20-64 Patellar taping for correction of tilt.

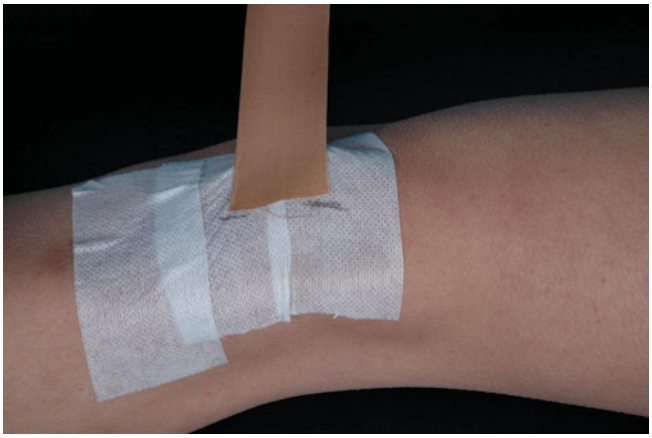

FIGURE 20-65 Patellar taping for correction of glide.

during level walking when walking velocity is controlled. Schwameder et al.[535] reported 12–25% reduction in peak and average ground reaction force, knee joint moments, and tibiofemoral compressive and shear forces walking down a 25-degree gradient.

A study by Willson et al.[532] found that the use of the poles tended to reduce the vertical joint reaction forces at the knee over the no-poles condition. Differences of 4.4% were found in vertical joint reaction forces at the knee between the no-poles, pole-back, and pole-front conditions.[532] However, knee extensor angular impulse was greater with all pole conditions compared with no-poles. Thus, walking with poles caused a more flexed knee position through stance, reducing the vertical bone-on-bone forces and increasing the internal (muscular) knee extensor kinetics.[532] This reduction of lower extremity stress during a faster walking velocity may symbolize a less harmful mode of exercise for healthy and pathologic populations alike. Thus, the use of walking poles may lead to an increased training stimulus as a result of the greater walking velocity and reduced lower extremity loading conditions compared with a self-selected walking velocity.[532]

PREFERRED PRACTICE PATTERN 4C: IMPAIRED MUSCLE PERFORMANCE

Patellofemoral Pain

Patellofemoral-related problems are characterized by pain in the vicinity of the patella that is worsened by sitting and climbing stairs,[147,536] inclined walking and squatting.[491] It is a common reason for referral to physical therapy.[457] A British sports injury clinic study showed that 5.4% of the total injuries seen and 25% of all knee problems treated for a 5-year period were attributed to patellofemoral pain.[537]

Although patellofemoral pain can occur in anyone, particularly athletes, women who are not athletic appear to be more prone to this problem (2:1 ratio) than men who are not athletic.[538] However, among athletes, the incidence is higher in males (4:1).[461]

Numerous authors have proposed classification systems for patellofemoral pain using various clinical, radiographic, etiologic, and pathologic criteria to categorize patients.[134,285,538–543] The purpose of a physical therapy classification system is to aid in proper diagnosis and intervention based on impairment. To help in the determination of the classification, the clinician must answer the following questions:

- Is the problem truly related to the patellofemoral joint or its related structures?
- Is a muscle imbalance present?
- Is inflammation present?
- Is instability present?

Determining the classification gives significant guidance to intervention options. Patellofemoral instability, especially recurrent, usually requires surgical intervention, whereas patellofemoral pain resulting from inflammation or a muscle imbalance usually responds well to conservative intervention.[284]

The term *malalignment* implies that the static or dynamic restraints of the patellofemoral joint are insufficient to allow normal patellar tracking. Malalignment appears to be a necessary but not sufficient condition for the onset of patellofemoral pain. Symptoms seem to be set off by a trigger, or combination of structural and dynamic factors, the nature of which varies from patient to patient.[284]

Anatomic Variance

A number of anatomic features can have an impact on the function of the patellofemoral joint and subsequent dysfunction:

- Femoral trochlear dysplasia.[182]
- Patellar morphology and the amount of congruence of the patellofemoral joint
- The natural positioning of the patella (alta or baja)[194,291,544–546]

Gender[216]

A commonly cited reason as to why women have more anterior knee pain than men is the difference in the orientation and alignment of the lower extremity. The broader pelvis of the female moves the hip joints farther lateral relative to the mid-line. This produces an increased valgus angle from the hip to the knee and then to the ground. Females also have a higher prevalence of increased femoral anteversion, which also increases the valgus angle.[547] Although the increased valgus thrust on the patella is not necessarily a problem, it increases the tendency for excessive lateral pressure on the patella, which then can lead to retinacular stress around the patella and, in some people, concavity of the lateral facet and anterior knee pain.

Tibial Rotation

The Q angle can be influenced distally through motions of the tibia. For example, external rotation of the tibia moves the tibial tuberosity laterally, thereby increasing the Q angle, whereas tibial internal rotation decreases the Q angle by moving the tibial tuberosity medially.

Subtalar Joint Position

Tibial rotation is influenced by subtalar joint motion. For example, subtalar joint pronation causes internal rotation of the tibia, whereas subtalar joint supination causes the tibia to rotate laterally.

Femoral Rotation

As with tibial rotation, the Q angle can be influenced through motions of the femur. For example increased femoral internal rotation results in a larger Q angle, whereas femoral external rotation minimizes the Q angle.

The impairments resulting from patellofemoral dysfunction have been related to problems that cannot be improved by physical therapy and those that can. EMG evidence of poorly coordinated muscle activation has been documented in other

joints, such as the shoulder and low back.[548] At the knee, the VMO may be proximally positioned and abnormally oriented, and the timing of its contractions may be poorly synchronized with those of the surrounding muscles.[146,196,454,489,492,549] Since coordinated firing of the dynamic stabilizing muscles is important for the normal functioning of the patellofemoral joint it would be reasonable to assume that physical therapy would be of benefit to enhance the dynamic stabilizers. Thus, the intervention for a maltracking patella must seek to restore the balance of force production of the medial and lateral stabilizers of the patellofemoral joint and to attempt the reestablishment of functional control of the VMO (see "Intervention Strategies" section).[188,189,284,454,457,466,467,521]

Patellar Compression Syndromes

Patellar compression syndromes result from an overconstrained patella whose motion is severely restricted by surrounding soft tissues.

Lateral Patellar Compression Syndrome[131,146,187,550]

A tight lateral retinaculum may be responsible for patellar tilt and excessive pressure on the lateral patellar facet, producing the excessive lateral pressure syndrome as described by Ficat and Hungerford.[265] The patient typically complains of pain over the lateral retinaculum.[187,551,552] The diagnosis is confirmed clinically by a decreased medial patellar glide and evidence of a lateral patellar tilt.

The medial stabilizers play a role in the lateral pressure syndrome, and the VMO frequently becomes atrophied, probably as a result of the new patellar position, the associated pain, and the resultant inflammation.[319] The presence of nerve-fiber changes in the lateral retinaculum[129,187] raises the possibility that these changes might be a catalyst for pain, although it is not clear whether the malalignment precedes the nerve changes or vice versa. The major long-term problem with excessive lateral pressure syndrome is a chronic imbalance of facet loading and the subsequent effect on the articular cartilage and surrounding soft tissue.

Fortunately, this condition seems to respond well to a conservative approach consisting of[319]

- stretching of the lateral retinacular structures;
- patellar taping to correct the excessive lateral tilt and to apply a long duration, low-load stretch of the lateral retinaculum;
- stretching of the hamstrings, quadriceps, and ITB;
- strengthening of the VMO;
- anti-inflammatory measures;
- activity modification through minimization of stair ambulation and deep knee squats.

Infrapatellar Contracture Syndrome[553]

The term *infrapatellar contracture syndrome* (IPCS) was first coined by Paulos et al. in 1987.[339] This condition is characterized by a restriction of patellar movement because both the medial and lateral retinaculum are excessively tight. This restriction may result in a decrease in knee flexion and extension. Another term for this condition, *global patellar pressure syndrome,* was proposed by Wilk et al.[319]

The development of this condition appears to be related to direct trauma and subsequent pathologic fibrous hyperplasia in the peripatellar tissues or secondary to prolonged immobilization after surgery.[339]

IPCS has been described as having three progressive stages: a prodromal stage, an active stage, and a residual stage.[554]

Prodromal Stage. The prodromal stage begins between 2 and 8 weeks after trauma to the knee. Knee ROM is painful, there is a decrease in patellar mobility, and an extensor lag is present. This scenario is usually noted with patients who fail routine postoperative rehabilitation. Without recognition, patients can progress to the second stage within 6–20 weeks. Early detection of IPCS is important because only the prodromal stage is amenable to nonsurgical intervention. Rehabilitation should be initiated with early patellar mobilization, stretching of the hamstrings, hip flexors, quadriceps, gastrocnemius, and ITB, with the emphasis on restoring full knee extension. Other components in the prodromal stage should include active ROM, multiangle isometric strengthening of the quadriceps, neuromuscular stimulation, transcutaneous electrical nerve stimulation (TENS), and NSAIDs. When performing the patella mobilizations, the glides should be held for a long duration (1–12 minutes) to enhance the remodeling of the soft tissue.[319,555] Activities such as bicycling, resisted knee extensions, deep knee bends, or deep squats (beyond 60 degrees) should not be initiated until patellar mobility is restored to prevent excessive patellar compression and patellofemoral joint contact pressures.[319]

Active Stage. In the second stage, there is loss of the extensor lag because of the restriction of passive and active knee ROM. There are also tissue texture changes in the patella tendon. This creates a positive shelf sign: an abrupt step-off or "shelf" from the patellar tendon to the tibial tubercle.[339] Patients who progress to this stage require surgery, with open intra-articular and extra-articular debridement. Immediate daily rehabilitation with continuous passive motion (CPM), full AROM, and extension splints at night also can be used.

Residual Stage. The third stage is notable for significant patellofemoral arthrosis and a residual low-riding patella at 8 months or even years after the onset of IPCS. Additional classifications distinguish whether the patellar entrapment is primary, caused by infrapatellar contracture (see separate section), or secondary, as a result of surgical intervention or postoperative immobilization. The patient history typically includes complaints of knee pain and stiffness, swelling, and crepitus, and "giving way" may also be reported. On physical examination, the diagnosis may be made by a 10-degree or greater loss of extension, a 25-degree or greater loss of flexion, and significantly reduced patellar mobility as demonstrated by decreased patellar glide. Additional findings include atrophy of the quadriceps femoris, palpable patellofemoral crepitus, diffuse synovitis, and an antalgic or flexed knee gait.

PREFERRED PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Articular Cartilage Defects

Articular cartilage defects of the knee are a common cause of pain and functional disability. Since nonoperative rehabilitation and palliative care for this condition are frequently unsuccessful, many patients opt for surgical procedures designed to facilitate the repair or transplantation of autogenous cartilage tissue.[556] Reparative techniques include the following:

- ***Arthroscopic lavage and debridement.*** This procedure is performed to reduce the inflammation and mechanical irritation within a given joint. Debridement can include smoothing of the fibrillated articular or meniscal surfaces, shaving of motion-limiting osteophytes, and removal of inflamed synovium.[557]
- ***Microfracture.*** The surgical objective of microfracture is the controlled perforation of the subchondral bone plate to permit an efflux of pluripotent marrow elements into a chondral defect.[557]
- ***Autologous osteochondral mosaicplasty grafting.*** This is a method to transplant bone and hyaline cartilage, using small osteochondral plugs, to a region of chondral or osteochondral defect.
- ***Autologous chondrocyte implantation (ACI).*** This is a cartilage restorative procedure in which a concentrated solution of autologous chondrocytes is implanted into a defect with the goal of restoring hyaline cartilage to the injured area.[557]
- ***Osteochondral autograft transfer (OAT).*** Osteochondral autograft is most clearly indicated for a symptomatic, unipolar lesion of the distal femoral condyle in a nondegenerative joint that has proper limb alignment, as well as ligamentous stability and meniscal competence.[557]
- ***Osteochondral allograft transplantation.*** In contrast to OAT, osteochondral allograft transplantation relies upon tissue taken from cadaveric donors rather than from the patient's own knee. The benefits of allografting include elimination of donor site morbidity and the ability to provide fully formed articular cartilage without specific limitation with respect to defect size. The drawbacks to the procedure are graft availability, cell viability, immunogenicity, and risk of disease transmission.[557]

The postsurgical rehabilitation progression is designed based on the four biologic phases of cartilage maturation: proliferation, transitional, remodeling, and maturation. The duration of each phase that follows varies depending on the lesion, patient, and the specifics of the surgery.[556]

- ***Proliferation phase.*** This phase generally lasts 4–6 weeks following surgery. The goals during this phase are to protect the repair, decrease swelling, gradually restore PROM and weight-bearing and to enhance volitional control of the quadriceps.
- ***Transition phase.*** This phase typically consists of weeks 4 through 12 postsurgery. During this phase, the patient progresses from partial to full weight-bearing while full ROM and soft tissue flexibility is achieved.[556] It is during this phase in which patients typically resume most normal activities of daily living.
- ***Remodeling phase.*** This phase generally takes place from 3 to 6 months postoperatively. At this point, the patient typically notes improvement of symptoms and has normal ROM. During this phase, low-to-moderate impact activities, such as bicycle riding, golfing, and recreational walking, are gradually incorporated.
- ***Maturation phase.*** This phase begins in a range of 4–6 months and can last up to 15–18 months postsurgery. The duration of this phase varies based on lesion size and location, and the specific surgical procedure performed.

Tibiofemoral Osteoarthritis

OA has been acknowledged as the most common cause of disability in the United States.[558,559] Thirty-three percent of persons aged 63–94 years are affected by OA of the knee, which often limits the ability to rise from a chair, stand comfortably, walk, and use stairs.[560,561]

OA may affect one or more of the three compartments of the knee: medial tibiofemoral, lateral tibiofemoral, and patellofemoral.

OA has long been regarded as a "wear-and-tear" or "degenerative" condition, a view supported by epidemiologic surveys that demonstrated associations with certain occupations and life choices and its increased prevalence with advancing age.[562] Recognized risk factors include physically demanding occupations, particularly jobs that involve kneeling or squatting,[335,563–566] certain sports,[567,568] older age, female sex, evidence of OA in other joints, obesity,[569] and previous injury or surgery of the knee.[570]

The clinical findings of OA at the knee include swelling, which can vary from minimal to severe, depending on the clinical stage and severity. The joint can also be warm to touch, although that again depends on the stage and severity. Usually, the patient reports pain with weight-bearing activities and, at times, pain at rest. The loss of motion, if present, is typically in a capsular pattern. Muscle weakness is probably the longest documented and best established correlate of functional limitation in individuals with OA, particularly with knee OA.[563,571–573]

Regular partaking in physical activity has been recognized for several years as being of benefit in the management of knee OA,[574–580] and exercises to strengthen the quadriceps are becoming established as a useful adjunct in the treatment for OA of the knee.[581] Although there is agreement that strengthening exercises can be helpful, the effect of exercise therapy on pain, quadriceps strength, and physical function appears to be small to moderate in most clinical trials.

Puett and Griffin[574] reviewed 15 controlled trials of conservative intervention for hip and knee OA from 1966 through 1993 and concluded that exercise reduces pain and improves

function in patients with OA of the knee, but that the optimal exercise regimen has yet to be determined.[574] In addition to strengthening exercises, fitness walking and aerobic exercise have both been reported to result in functional improvement in patients with OA of the knee.[574–580] However, unweighted treadmill walking has not been shown to decrease pain associated with OA of the knee.[582]

Deyle et al.[469] conducted a randomized trial comparing the use of manual therapy techniques to the knee, hip, foot and ankle, and lumbar spine combined with exercises for lower extremity strengthening, ROM and endurance to a group of patients with knee OA that received a placebo ultrasound treatment. The study concluded that patients with OA of the knee who were treated with manual physical therapy and exercise experienced clinically and statistically significant improvements in self-perceptions of pain, stiffness, and functional ability, and the distance walked in 6 minutes. The beneficial effects of intervention, which were achieved in eight clinic visits, persisted at 4 weeks and 1 year after the conclusion of clinical treatment.[469] An important aspect of the treatment described by Deyle et al. was that the impairments that were present at other joints in addition to the knee were addressed. This emphasizes the need to evaluate and address a variety of problems that a patient with knee OA may have to optimize the response to treatment.[583]

In addition to the exercises that recover lower extremity strength, ROM, and cardiovascular endurance, it is now being recommended that therapy programs also include techniques to improve balance and coordination and provide patients with an opportunity to practice various skills that they will likely encounter during normal day activities.[584]

Other conservative interventions for OA of the knee include NSAIDs, cortisone injections, patient education, weight loss, and thermal modalities.[469,581] The use of shoes with a well-cushioned sole is recommended, as are frequent rest periods during the day. Wedged insoles with an angle of 5–10 degrees on a frontal section have been shown to be helpful for OA of the medial compartment knee OA.[585,586] The patient is instructed in principles of joint protection, and advised to seek alternatives to prolonged standing, kneeling, and squatting.[581]

CLINICAL PEARL

Isokinetic and concentric/eccentric exercises must be prescribed carefully to avoid excessive compressive forces or shear forces at the knee.

Total Knee Arthroplasty

Total knee arthroplasty (TKA) has been shown to be an effective long-term intervention for the elderly population to relieve knee pain, improve function, increase social mobility and interaction, and contribute to psychologic well-being.[587–589]

Although pain and loss of function are the primary reasons for a TKA, the procedure can also be used to correct knee instability and lower extremity alignment and for the treatment of isolated but severe patellofemoral disease.[66,590] Since TKA is generally contraindicated in younger and more active patients, those with unicompartmental osteoarthritis of the knee may be considered candidates for a high tibial osteotomy or a distal femoral osteotomy. The high tibial osteotomy is used with isolated medial compartment arthritis. The distal femoral osteotomy is used in lateral compartment arthritis. The short-term results for these procedures have been very successful,[591,592] even to the point where the need for TKA is eliminated.[593] However, permanent pain relief with high tibial osteotomy is as yet unlikely.

Absolute and relative contraindications for a TKA include, but are not limited to

- active infection of the knee;
- significant genu recurvatum;
- severe obesity;
- return to high-impact sports or occupations;
- arterial insufficiency;
- neuropathic joint;
- mental illness.

Several techniques are at the surgeon's disposal. The choice of approach is determined by surgeon's familiarity and comfort. Three approaches are commonly described: anterior, subvastus, and lateral.[594]

- ***Anterior approach.*** The anterior approach is generally through an anterior midline longitudinal skin incision and median parapatellar arthrotomy. The advantages of this approach include its extensile potential and its wide exposure medially and laterally. The disadvantages include its violation of the quadriceps mechanism, and the potential for patellar devascularization.[594]
- ***Subvastus approach.*** The subvastus approach uses the same midline anterior skin incision as the anterior approach. The advantages of this approach include maintenance of the quadriceps mechanism with decreased postoperative pain and earlier functional recovery.[594] The disadvantage is its somewhat limited exposure.
- ***Lateral approach.*** The lateral approach occurs lateral to the patella and through the medial edge of Gerdy's tubercle. Proponents of this technique feel that it is a superior method in the correction of valgus deformity.[594]

Most primary arthroplasties rely upon the patient's anatomy to confer stability to the articulation. Anatomic structures that can confer stability include the PCL and a balancing of the soft tissues around the knee. The fate of the PCL in primary TKA remains controversial. If the PCL is sacrificed, a posterior stabilizer (see later) is used. However, the long-term results of PCL-retaining and posterior-stabilized TKAs are similar.[595,596] PCL substitution may be indicated in patients requiring TKA who present with end-stage DJD with varus or valgus malalignment and an associated flexion contracture, with a combined deformity greater than 15 degrees.[597,598]

Many of the earlier designs of TKA replaced only the tibiofemoral joint and did not address the patellofemoral articulation. The posterior stabilizer was developed to increase the arc of motion of these earlier models and thereby improve the functional results of TKA. Although the ROM improved

substantially with these components, patellofemoral complications emerged as a key problem after knee replacement. Errors in sizing, alignment, and rotation of the tibial and femoral components were eventually highlighted as contributing factors to many of these patellofemoral problems. In addition, many of these complications appear to be secondary to patellar resurfacing which may be a part of the procedure. Whether to resurface the patella remains among the most controversial topics in TKA.

Following a knee replacement, there is a decrease in the contact area and consequent increase in the contract stress at the patellofemoral joint.[599] A study by Matsuda et al.[599] showed that resurfacing the patella reduced the contact area to a larger degree compared with not resurfacing the patella. In addition, kinematic studies of motion of the patellofemoral joint after knee replacement have consistently shown some degree of altered kinematics.[600]

Preoperative instruction is believed to be invaluable in the early postoperative setting. Preoperative instruction should include education regarding the ice–compression–elevation program, ROM exercises, isometric quadriceps strengthening, patellofemoral mobilization, and gait training with the appropriate postoperative assistive devices.[601]

Complications associated with TKA include the following[602]:

- Thromboembolic disease
- Fat embolism
- Poor wound healing
- Infection
- Periprosthetic fractures
- Neurologic problems, including fibular nerve palsy
- Vascular injuries
- Arthrofibrosis
- Disruption of the extensor mechanism

Postoperative rehabilitation for the TKA continues to be studied in an effort to decrease the cost while still providing the quality of clinical results expected by the surgeon and the patient.[603]

A review of the literature divulges conflicting practice patterns in the physical therapy management of TKA patients.[604–607]

The success of the rehabilitation program for this patient population is dependent on knowledge of the surgical procedure, communication with the surgeon and the patient, and above all, the ability of the rehabilitation team to educate the patient to participate actively in the treatment program.[601]

Patellofemoral Osteoarthritis

Patellofemoral OA is diagnosed by correlating patellofemoral pain with radiographic changes consistent with joint degeneration. Differentiation of idiopathic and posttraumatic subtypes is based on the history. Intervention for patellofemoral OA is usually conservative unless it coexists with severe tibiofemoral degenerative joint disease, in which case a total knee replacement may be warranted.

The term *chondromalacia patella* has long been a catch-all category of anterior and, specifically, retropatellar knee pain. The term *chondromalacia* was first used by Aleman in 1928.[608] He used the term "chondromalacia posttraumatica patellae" to describe lesions of the patella found at surgery and thought to be caused by prior trauma. With time, "chondromalacia" became an all-inclusive term with no agreed-on classification system or definitions of terms.[284]

True chondromalacia refers to a softening of the cartilage on the posterior aspect of the patella and is estimated to occur in fewer than 20% of persons who present with anterior knee pain.[204] The syndrome is most common in the 12–35-year-old age group, and most studies show a predominance in females.[125,203,204,461,500,609]

Two types of chondromalacia have been described. One type involves surface degeneration of the patella that is age dependent and most often asymptomatic. The other type involves basal degeneration. This type results from trauma and abnormal tracking of the patella and is symptomatic.[213]

Chondromalacia is classified into four grades, according to the degree of degeneration noted arthroscopically[610]:

- ***Grade 1.*** Closed disease. This grade is characterized by an intact joint surface that is spongy. The softening is reversible. A blister or raised portion of the articular surface is seen.
- ***Grade 2.*** Open disease. This grade is characterized by fissures that may or may not be obvious initially.
- ***Grade 3.*** Severe exuberant fibrillation or "crabmeat" appearance.
- ***Grade 4.*** The fibrillation is full-thickness and the erosive changes extend down to bone, which may be exposed. This is, in effect, OA and its extent depends on the size of the lesion.

Since cartilage has no nerve supply, chondral lesions themselves are usually asymptomatic,[611] although cartilage that is worn down to bone remains a potential source of pain due to irritation of, or abnormal pressure on, the richly innervated subchondral bone.[500]

The conservative intervention for patellofemoral OA includes the removal of any muscle imbalances of flexibility or strength. Occasionally, surgical realignment may prove beneficial when the articular degeneration is isolated to the lateral patellofemoral joint.

Arthrofibrosis

The term *arthrofibrosis* has been used to describe a spectrum of knee conditions in which loss of motion is the major finding.[497,612–616] It is perhaps best defined as a condition of restricted knee motion characterized by dense proliferative scar formation, in which intra-articular and extra-articular adhesions can progressively spread to limit joint motion.[617] This dense scar tissue can obliterate the parapatellar recesses, suprapatellar pouch, intercondylar notch, and eventually the articular surfaces.[338] Patella infera and chronic patellar entrapment also may develop as a consequence of this process.[338]

Arthrofibrosis may occur as the result of the inflammatory cascade after injury or operative treatment. Although

inflammation is undoubtedly present in a large number of individuals, it is not clear why an aggressive form of this condition may develop in some patients.

To diagnose arthrofibrosis accurately, other causes of restricted active and passive motion of the knee must first be eliminated. Mechanical causes include loss of articular congruency (e.g., as a result of fracture, meniscal tear, or loose body), interruption of the extensor or flexor mechanism, substantial effusion,[618,619] or nonisometric placement of a graft during reconstruction of the ACL.[315,339,614] Some investigators believe that an ACL reconstruction performed within 3 weeks after an injury may increase the likelihood of arthrofibrosis[620,621] although others disagree.[622] Poor or unsupervised rehabilitation[315] preoperatively or postoperatively, with delayed motion protocols, may further increase the risk.[623]

Symptoms vary and often do not correlate with the severity of the condition. Since arthrofibrosis usually occurs after trauma or an operative procedure, pain and stiffness may be the initial symptoms.

- The presence of pain may complicate preexisting knee stiffness.[338,624] Although pain can be present early, it often becomes more prominent when joint degeneration and arthritis occur because of long-standing arthrofibrosis. Pain may also be constant, especially when it is associated with CRPS.[338,624]
- Stiffness is usually the primary symptom and is often worse in the morning hours.[617] Patients may complain of a warm, swollen knee that is painful with attempted motion.

Global arthrofibrosis of the knee manifests as marked limitation of flexion, extension, and patellar glide associated with widespread joint inflammation as well as intra-articular formation of fibrous tissue. This can progress to chondrification and ossification of soft tissues.[617]

Quadriceps function can be decreased or absent because of pain.[624] As function of the quadriceps muscle decreases, the ability of the muscle to act as a shock absorber is lessened, which may lead to additional articular degeneration. Often, the knee is held in a flexed position, which encourages tightening of the posterior part of the capsule and the hamstrings.

Crepitus and weakness are frequently present with swelling following prolonged standing or walking. Even when the patient does not have pain, loss of motion and quadriceps weakness can be substantial impediments to the performance of activities of daily living. An antalgic, flexed-knee gait is often seen.[339] Although effusion may be present, swelling is more often a result of inflamed, thickened capsular and pericapsular tissues.

Active and passive knee flexion and extension often are restricted in a capsular pattern, and the mediolateral and superoinferior patellar glides are reduced. This restriction of passive motion often has a spring-like end-feel, reflecting the density and stiffness of the thickened, inflamed, or scarred peripatellar tissue.

Intervention includes ROM exercises and the stretching of specific structures. When a plateau has been reached during rehabilitative efforts to restore motion or when there is progressive loss of motion, additional intervention of a gentle manipulation of the knee under anesthesia may result in improvement. Closed manipulation or vigorous attempts to gain passive motion may cause indiscriminate tearing of intra-articular tissue,[613] excessive tibiofemoral and patellofemoral compression with the risk of chondral damage or fracture,[325,613,625] rupture of the patellar ligament,[613,625] and even femoral fracture.[613] Manipulation has also been noted to initiate CRPS.[625]

Anteroposterior Slide Dysfunction: Tibia on Femur

In this condition, the tibia demonstrates a restricted anterior or posterior joint glide. This motion is coupled to knee flexion–extension.[334] Movement of the tibia on the femur into extension is coupled with an anterior glide. Movement of the tibia on the femur into flexion is coupled with a posterior glide. The initial complaints or findings are restrictions of flexion or extension movements.

The technique used to treat this dysfunction is a modification of the anterior drawer test. The patient is placed in the supine position, with the involved knee flexed and the foot flat on table, while the clinician sits on the patient's foot, anchoring it to the table. The clinician wraps both hands around the proximal tibia, placing the thumbs in front of the medial and lateral condyles and pressing on them. The clinician's hand encircles the leg and grasps it firmly below the popliteal space. The clinician creates a direct anteroposterior translatory glide of the tibia on the femur by first pulling the tibia forward with both hands, before pushing it backward with both thumbs.

Tibiofemoral Instability

Both intrinsic and extrinsic trauma to the knee occurs frequently. Several factors can predispose an individual to knee joint laxity:

- Repetitive microtrauma
- Severe macrotrauma
- Genetics[626]
- Gender[626]
- Ethnic factors[626]

Knee laxity may contribute to the development and progression of knee OA. It may also be a consequence of moderate to severe OA, although some knees become more stable with time because of the formation of osteophytes. Laxity is associated with more abrupt joint motion, large displacements, and suboptimal distribution of larger forces over the articular cartilage.[627,628] Since significant instability or damage to the internal structures of the knee joint can damage the articular surfaces and lead to degenerative changes, it is imperative that these injuries be treated as soon as possible.

There is no typical clinical presentation for knee instability in terms of the history. However, a history of "giving way" should always be taken seriously, as well as any evidence of locking or "catching" within the joint.[159]

The examination may reveal laxity. The direction of the laxity will determine the intervention. The intervention usually consists of muscle strengthening, correcting muscle imbalances, and the use of passive restraints, such as orthotics.

Anterior Cruciate Ligament Tear

More than 250,000 athletes are diagnosed with ACL injuries each year, making the management of sports-related ACL injuries the most widely discussed subject in the field of sports medicine.[629] This emphasis could be a result of the increasing frequency of the problem and the controversy surrounding its management. ACL injury factors have been divided into intrinsic and extrinsic factors.[630] Intrinsic factors include a narrow intercondylar notch, weak ACL, generalized overall joint laxity, and lower extremity malalignment; extrinsic factors include quadriceps and hamstring imbalances, altered neuromuscular control, shoe-to-surface interface, playing surface, and athlete's playing style.

Gender has also been implicated, with women being two to eight times more likely to sustain an ACL injury than men participating in the same sports.[630,631] Theories about the higher rates of ACL injury in women have centered on:[632]

- ***Anatomic alignment and structural differences.*** These include the differences in pelvic width and tibiofemoral angle between males and females, which can affect the entire lower extremity.[633] The magnitude of the quadriceps femoris angle (Q-angle) and the width of the femoral notch are thought to be anatomic factors that have contributed to the disparity of ACL injury rates between males and females.[632] Hypothetically, a larger Q-angle increases the lateral pull of the quadriceps femoris muscle on the patella placing medial stress on the knee,[633] and decreasing the effectiveness of the quadriceps as a knee extensor and diminishing the hamstrings' ability to exert its protective influence on the ACL.
- ***Femoral notch.*** A narrow intercondylar notch appears to increase the potential for ACL ruptures.[634] In a cadaver study, Norwood and Cross[635] showed that the ACL impinges on the anterior intercondylar notch with the knee in full extension.[632] The shape of the femoral notch varies with gender and may contribute to the incidence of ACL injury.[636] A small, A-shaped notch may be a sign of a congenitally smaller ACL.[636]
- ***Joint laxity.*** Joint laxity tends to be greater in women than in men,[637–639] although the correlation between ligamentous laxity and injury is not clear.
- ***Hormonal influence.*** Hormones, especially estrogen, estradiol, and relaxin, may be involved indirectly in increased ACL injury in females.[640,641]
- ***ACL size.*** Females typically have a smaller ACL than males, which would tend to enhance the risk of tissue failure.[642]
- ***Muscular strength and muscular activation patterns.*** Several studies have demonstrated that women have significantly less muscle strength in the quadriceps and hamstrings compared with men, even when muscle strength is normalized for body weight.[639,643–646] Approximately 30% of all ACL injuries are classified as contact injuries and the remaining 70% are not related to direct contact and are therefore classified as noncontact.[647,648] The most common noncontact of ACL injury in females are as follows[647,648]:
  - Planting and cutting
  - Straight knee landings
  - One-step stop with the knee hyperextended
  - Sudden deceleration

While landing injuries to the ACL are common in both males and females, male athletes appear to employ different mechanisms to compensate for high landing forces than females, resulting in a decrease in both varus and valgus laxity of the knee during the landing.[649–652]

The observation about the varying orientation and tensions of the ACL has clinical importance in a number of ways, and can help to define the following[36]:

- ***Mechanism of injury.*** Since the posterolateral portion of the ligament is taut when the knee is in extension, it is the most commonly injured portion.[36]
- ***How diagnostic tests are performed.*** When the ACL is tested for torn fibers, the knee joint should be assessed for stability in various positions, especially in slight flexion.
- ***Operative reconstruction.*** Reconstruction should be aimed at replacing the damaged portions of the ACL at the relevant angles of the joint.

All ACL tears (i.e., sprains) are categorized as grade I, II, or III injuries. Ligament tears are classified according to the degree of injury, which ranges from overstretched ligament fibers (i.e., partial or moderate tears) to ligament ruptures (i.e., complete tears or disruptions). The term *midsubstance tear* refers to the site of the ACL injury and indicates a central ligament tear as opposed to a tear at one of the ligament's bony attachment sites. Almost all ACL tears are complete midsubstance tears.[40,41] Young athletes may sustain growth plate injuries (e.g., avulsion fractures) rather than midsubstance tears because the epiphyseal cartilage in their growth plates is structurally weaker than their ligaments, collagen, or bones. In the past, research has shown that tears in ACL complexes of young athletes usually resulted in avulsion fractures not midsubstance tears. Recent studies, however, now suggest that young athletes may sustain midsubstance tears similar to those in adult athletes.[2,653]

Symptomatic ACL deficiencies in young athletes' knee joints are subject to the same long-term detrimental effects that occur in adult athletes.[654] Young athletes also may be more predisposed to more long-term degenerative knee conditions as the result of more years of chronic rotary knee instabilities from ACL deficiencies.[655]

Associated Knee Injuries

ACL injuries rarely occur in isolation, because the ACL functions in conjunction with other structures of the knee. For example, when the outer aspect of the knee sustains a direct blow that produces a valgus stress, the MCL is often torn first, followed by the ACL.[28] Debate continues regarding clinical intervention for the patient with combined ACL and MCL injury. For example, the following protocol is used at the University of Cincinnati Sports Medicine:[656]

- Grade 1 MCL: injury with or without meniscus damage. ACL surgery performed within 1 week; no presurgery motion restriction.
- Grade 2 MCL: injury with or without meniscus damage. ACL surgery performed within 2 weeks; a 7-day period of

motion limitation (brace locked at 30 degrees of full motion performed in rehabilitation on a daily basis, and after 7 days the brace is unlocked to full motion).

- Grade 3 MCL: injury with or without meniscus damage. ACL surgery performed after 3 weeks with a 10-day motion restriction (brace locked at 30 degrees and full motion is performed in rehabilitation starting day 7 after injury, and brace unlocked after 14 days).

Meniscal injuries can also occur, with the medial meniscus being more commonly involved. Approximately 49% of patients with sports-related ACL injuries have meniscal tears.[657]

Transection of the ACL leads to slight degenerative changes in the cartilage, but additional deafferentation of the knee joint produces severe degenerative changes.[658,659] This suggests that sensory input from the joint may play a role in adapting movement strategies so that potentially harmful positions and loads are prevented.

Mechanism of Injury

Most published studies of the ACL are directed toward the basic mechanics of the ligament, method of surgical repair, and rehabilitation.[247,603,660–662] Unfortunately, little is known about the actual mechanism of injury during sport activity, although one sport that has been studied in some detail is alpine (downhill) skiing,[663,664] in which three common causes of ACL injury have been discussed:

- The first is referred to as the "phantomfoot" mechanism.[664] This mechanism occurs when a skier falls backward with the knee flexed and the tibia internally rotated. The combination of a strong quadriceps contraction (to maintain balance) with a rigid boot that fails to release may lead to an ACL disruption.[665] As a result, the ligament disruption occurs during a hard landing when the skier is off balance.
- In the second mechanism, when the skier lands on the ski's tail, the stiff posterior shell of the boot combined with a strong quadriceps contraction to maintain balance slides the tibia anteriorly, leading to an anterior drawer maneuver.
- The third mechanism, valgus rotation, seems to be more common in men who participate in downhill or cross-country skiing. It occurs when the inside (medial) edge of the front of the ski becomes caught in the snow. The leg is abducted and externally rotated while the skier is driven forward by momentum. High-speed skiing and poorly groomed ski slopes also are factors that contribute to this type of injury.

Regrettably, little attention has been directed to the mechanism of ACL injuries in other sports, although sudden deceleration, an abrupt change of direction, and a fixed foot have all been cited as key elements of an ACL injury.[665] For example, a common mechanism of injury to the ACL occurs when excessive lateral force (i.e., valgus stress) is applied to the outer aspect of the knee joint. This type of injury often is seen in contact sports activities (e.g., football, soccer, and rugby), resulting from tackles or blows to the lateral side of the knee. A twisting injury to the ACL occurs when the knee is in full extension and the femur is rotated externally on a fixed tibia. This mechanism of injury usually occurs because of abrupt changes in speed, direction, or velocity that torque the knee. Maneuvers often seen in sports activities, such as football, basketball, and soccer, can cause twisting injuries to the ACL. Snowboarders also may experience the same mechanism of injury when their feet and ankles are locked in ski boots and their knees are torqued. A less common mechanism of injury to the ACL occurs with extreme hyperflexion or hyperextension of the knee joint.[28]

Examination

Diagnoses of sports-related ACL injuries can be difficult, and clinicians must consider many factors when determining the best treatment options for patients with ACL injuries. A thorough patient history and physical examination are essential for accurate diagnoses of ACL injuries. Patients commonly describe the sensation of their knee "popping" or "giving out" as the tibia subluxes anteriorly. Other signs and symptoms of ACL injuries include pain, immediate dysfunction, instability in the involved knee, and the inability to walk without assistance. In rare instances, when patients have isolated ACL injuries that do not involve related collateral or meniscal tears, local tenderness around the knee joint may be absent.[655]

The classic sign of ACL injuries is acute hemarthrosis (i.e., extravasation of blood into a joint or synovial cavity).[666] The signs and symptoms of hemarthrosis (i.e., pain, edema, and joint stiffness) make clinical examinations more difficult for clinicians and very uncomfortable for patients.

Atrophy of the quadriceps is a regular finding with patients who have a torn ACL.[667–671] Several authors found a decrease in extensor torque that was larger than would be expected on the basis of the decrease in the volume of the quadriceps as measured with CT,[668,669,672–674] whereas the hamstring muscles do not have a comparable force deficit. It would appear that even specific conservative intervention can only partially correct the deficit.[675] The difference in torque has been reported to persist after reconstruction of the ACL with use of autogenous grafts or allografts from the patellar ligament[675,676] or with use of semitendinosus grafts.[677,678]

During the examination, it is important for the clinician to examine the patient's contralateral knee for baseline comparisons. This especially is true in children who have inherent or congenital laxities, such as knock-knee (genu valgum) or saber legs (genu recurvatum). It is also important to remember that the pain the patient experiences during the examination may affect the accuracy of the test results. Common manual tests to assess the ACL include the anterior drawer and the Lachman test (see "Stress Testing" section).

Arthrometer

An arthrometer, such as a KT1000, is a noninvasive mechanical testing device for measuring anteroposterior knee motion. This device assesses the amount of displacement between the femur and the tibia at a given force in millimeters. Intratester reliability and intertester reliability for the KT1000 have been reported to be high, both within and between days.[359] In addition, based on a number of studies, the KT1000 appears to be a clinically applicable instrument that can be used to assess

anterior laxity in patients with an ACL deficient knee.[63] Before using the KT1000 to assess anteroposterior laxity of the knee, the clinician must screen for PCL injury.

Although most patients who have a complete tear of the ACL have increased tibial translation on instrumented testing,[679] it is not known exactly how many of these patients will have "giving way" of the knee or how many knees will have overt or latent damage of the cartilage within a few years.[36,680,681]

Imaging Studies

Radiographs can identify arthritic changes that may be associated with chronic rotary instability from ACL deficiencies. They can also demonstrate avulsion fractures of the tibial spine, or hypoplastic intracondylar notches with diminished tibial spines, which indicate a congenital absence of the cruciate ligaments.[27]

MRI scans are useful for diagnosing ACL injuries, although their use in discriminating between complete and partial ACL tears is limited. Diagnostic MRI scans, however, can detect associated meniscal tears that routine radiographs cannot show.[2] Both MRI scans and radiographs are necessary to assess whether young athletes' growth plates are closed or open, a factor that may affect treatment decisions.

The primary healing potential of the ACL has been reported to be extremely poor in both clinical and experimental studies.[385,682–685] This is probably due to its minimal blood supply and the presence of joint fluid, both of which contribute to a reduced healing potential.[685–687] One study[687] did report two rare cases of spontaneous healing of an acute tear of the ACL, although the injuries were either near the origin or near the insertion of the ACL.

Patients with either partial (grades I and II) ACL tears (negative pivot shifts) or "isolated" ACL tears, who lead a less active lifestyle and participate in linear, nondeceleration activities are considered to be candidates for conservative intervention.[502] However, to return to normal preinjury activity levels, patients must be thoroughly rehabilitated and protective measures (e.g., knee bracing and activity restrictions) must be taken to prevent further knee injuries. Conservative intervention for these patients does not mean "nonintervention," because these patients require aggressive treatment to decrease pain and swelling, protect the joint from further injury, regain motion, increase strength and endurance, and return to function.[502] Numerous lower extremity rehabilitation protocols following injury or surgery have been reported in the literature.[233,268,444,623,688–698] For the middle-aged and older athlete, physical therapy often is the treatment of choice, unless the patient plans to participate in sports activities that expose the knees to vigorous twisting forces. Certain sports activities, however, must be avoided, especially those involving jumping, quick starts and stops, and abrupt lateral movements (e.g., soccer, basketball).

ROM exercises, which are initiated as early as possible, must be performed carefully so as not to further aggravate soft tissue injury and prolong pain and effusion. Failure of the pain and effusion to resolve, and ROM to improve, should arouse suspicion of a displaced torn meniscus.[502]

Most authors stress the importance of strengthening the quadriceps, gastrocnemius-soleus, and hamstrings muscles to prevent, or minimize, atrophy and maintain or improve strength.[233,268,623,688–692,694,696,697,699] The strengthening exercises should be performed through a limited ROM, determined by patient tolerance and response to the exercises.[231,233,444,689,690,696,697] Others recommend CKC exercises[243,623,689,696] to promote cocontraction of the thigh musculature and limit anterior tibial translation. A comprehensive knee rehabilitation protocol should include all of these factors.

Surgical treatment of the torn ACL includes direct repair, repair with augmentation, and reconstruction with autographs or allografts. Currently, arthroscopic reconstruction remains the treatment of choice. Numerous surgical approaches and postsurgical rehabilitation protocols exist that are beyond the scope of this text. Generally speaking, the rehabilitation progression following ACL reconstruction can either be accelerated, when used for young, athletic patients, or slower when used for older patients whose needs are more recreational. Normal return to sports activities occur at about 6 months for the accelerated patient and 6–9 months for the general orthopaedic patient.

Genu Recurvatum ("Saber Legs")

Genu recurvatum is a position of the knee joint complex in which the ROM occurs beyond neutral or 0 degrees of extension.[157] Genu recurvatum appears to be more common in females than in males and may exist due to postural habit, increased joint laxity, or knee injury.[700]

Traditionally, rehabilitation has only been used to address this condition when poor muscle control of the knee exists, such as occurs following trauma or a neurologic insult such as a cerebral vascular accident (CVA). However, one might question whether genu recurvatum predisposes an individual to knee injury. Certainly, the posterior structures of the knee (the capsular and noncapsular soft tissue structures, including the arcuate complex, posterior capsule, lateral meniscus, fabellofibular ligament, and biceps femoris muscle) are likely to be stressed with genu recurvatum. The posterior capsule forms two pouches that extend over the articular surface of the femoral condyle and tibial plateaus.[156] The capsule is thin over the posterior aspect of the femoral condyles but is supported by the two heads of the gastrocnemius and reinforced by the oblique popliteal ligament. The arcuate ligament also reinforces the capsule laterally. Stability is further enhanced internally by the lateral meniscus, which forms a concave articular surface for articulation with the convex lateral femoral condyle.[5]

A thorough history will guide the clinician to suspect genu recurvatum as a contributing factor in knee or another lower-leg injury. Individuals with genu recurvatum may present with one of a variety of lower extremity diagnoses as it is doubtful that their primary diagnosis will be genu recurvatum. Patients may have a history of an injury that forced them into hyperextension. Examples include landing from a jump on an extended knee; a blow to the anteromedial aspect of the proximal tibia, forcing the knee into hyperextension; and a noncontact external rotation hyperextension injury. From the anatomic and biomechanical review, it appears that the possible consequence of genu recurvatum in the active individual may be an increase in stress placed on the ACL, the anterior

joint, or the posterolateral corner of the knee. Symptoms attributable to genu recurvatum include the following:

- ***Anteromedial joint pain.*** This pain results from the compressive forces at the medial tibiofemoral compartment. This pain may be accentuated if a varus alignment is present.
- ***Posterolateral knee pain.*** This pain results from the tension placed on the posterior structures and is aggravated by stepping or forceful knee extension in weight-bearing.[101]

The patient may also complain of knee instability during activities of daily living. Noyes et al. have described the posterolateral syndrome as an injury to the posterolateral structures in conjunction with a torn ACL.[701] This syndrome is usually characterized by no history of injury and a gradual onset of knee pain. Loudon et al.[702] found a positive correlation between genu recurvatum and ACL injury in female athletes. Hutchison and Ireland[638] attributed the recurvatum posture and laxity in the posterior capsule to habitual posture.

Patients with genu recurvatum are easily identified during static standing, with the sagittal view best demonstrating this posture. Individuals also may present with excessive femoral internal rotation, genu varum or valgum, tibial varum, or excessive subtalar joint pronation, which is more noticeable in the frontal plane.

When performing activities such as step-ups, patients will use momentum to straighten the lower extremity, and they will be unable to control weight-bearing terminal knee extension. Kendall et al.[153] report that the hyperextension posture of the knee is caused from weakness in the gastrocnemius.

Proprioception in individuals with genu recurvatum may be deficient, especially near the end range of extension. One study[702] demonstrated that individuals who stood in hyperextension and without knee injury were unable to reproduce knee joint angles in the last 15 degrees of extension compared with other knee angles of 45 and 60 degrees on a leg-press machine. Individuals may perceive the hyperextended knee position as "normal" and, when they are introduced to a more vigorous activity, they may have a tendency to stay in hyperextension, putting the knee at risk for injury.[702,638]

If genu recurvatum is suspected as contributing to the patient's symptoms, special attention is needed to identify posterolateral instability. This can be achieved using the posterolateral drawer test and the varus stress test at 30 degrees. If the recurvatum is unilateral, the clinician should assess the lumbar spine and pelvis for obliquity or muscle imbalance. In addition, the hip should be evaluated for excessive internal rotation, which contributes to genu recurvatum, and the subtalar and midfoot joints should be checked for excessive pronation, which allows excessive internal rotation of the tibia (see Chap. 19).

Patients with genu recurvatum need to learn that 0 degree of knee extension is the normal knee position, and hyperextension is to be avoided.[703] The patient is taught to keep the knee in the same plane as the foot. Verbal cueing is helpful, but other strategies, such as the temporary use of posterior knee taping, can give the patient direct sensory feedback. This neutral position should then be carried over to dynamic strengthening exercises.

Muscle sequencing is the key, with the hamstrings and gastrocnemius firing in conjunction with the quadriceps to guide the knee into extension rather than using the passive force of gravity.[639] Patients should progress through weight-bearing exercises that require sequential use of eccentric and concentric control of the lower extremity, such as resistive terminal extension, single leg balance, mini-dips, squats, forward and backward step-ups, lunges, and jump landings.

Knee control during gait can be taught in conjunction with the previously mentioned exercises. Noyes et al. recommend that the patient maintain knee flexion of 5 degrees throughout the stance phase of gait. A 1–2-inch elevated heel may be used in the initial training to create a flexion moment at the knee, and the trunk should be maintained in an upright position versus a forward lean or flexed hip during midstance to avoid an anterior shift of body weight.[701] Excessive internal femoral rotation also should be controlled during this phase of gait.[701]

Continued training of the patient with genu recurvatum should focus on functional tasks. These include stair climbing and sit-to-stand transfers, such as stair climbing. During the pull-up phase of stair climbing, patients should be trained to refrain from thrusting into knee extension. Individuals may have a tendency to hyperextend their knees with other daily activities, such as bending forward to brush their teeth or prolonged standing.

The final phase of rehabilitation focuses on more complex activities and sports-specific skills. It is important that athletes involved in jumping and cutting sports master a flexed knee position. Henning et al.[231] have suggested that extreme loads are placed on the ACL when the knee is straight or near-straight during planting and cutting, landing from jumps, and sudden stops while running. Emphasis should thus be placed on flexing the knee during these sports activities to prevent injuries to the ACL. Hamstrings that are adaptively shortened offer protection to these joints and should not be stretched.

Meniscal Tears

Because of the interrelationship of the menisci with other structures of the knee, a torn meniscus is the most common cause of mechanical symptoms in the knee. Knee injuries may result in isolated or combined meniscal lesions. Collagen and proteoglycan damage can be caused by mechanical factors (tears or surgical resection), enzymatic degradation, or synthesis of new, poorly functioning molecules.[80] Meniscal lesions usually occur when the patient attempts to turn, twist, or change direction when weight-bearing, but they can also occur from contact to the lateral or medial aspect of the knee while the lower extremity is planted.[66] Collagen damage leads to abnormal hydration and an irreversible cascade of tissue alteration.[80] When proteoglycans are damaged (and the collagen remains intact), these tissue changes are reversible. For example, immobilization leads to proteoglycan loss, which is reversed after return of motion stimulates fibrochondrocytes to synthesize new proteoglycan molecules.[80] With aging, the meniscal tissue degenerates and can delaminate, thus making it more susceptible to splitting from shear stress, resulting in horizontal cleavage tears.[704] Without the menisci, the loads on the articular surfaces are increased significantly, leading to a greater potential for articular cartilage injuries and degenerative arthritis. Since the menisci are without pain fibers, it is the tearing and bleeding into the peripheral attachments as

well as traction on the capsule that most likely produce a patient's symptoms.[257] In fact, 16% of asymptomatic patients have meniscal tears demonstrated on MRI, with the incidence increasing to 36% for patients older than 45 years.[705]

Patients with meniscal injuries typically present with a history of swelling, popping, or clicking, and pain along the joint line. With posterior horn tears, the meniscus may return to its anatomic position with extension. If the tear extends anteriorly beyond the MCL, creating a bucket-handle tear, then the unstable meniscus fragment cannot always move back into an anatomic position.[257] Such a meniscal tear can result in locking of the knee in a flexed position. The lateral meniscus, being more mobile, is less likely to be associated with locking when torn. The patient may also note a "clicking" sensation while walking as a result of traction against a torn medial or lateral meniscus.[705] Locking of the knee is more common in younger patients with meniscal tears, because older patients are more likely to have degenerative meniscal tears with less mechanical symptoms and an insidious onset.[257]

The joint line pain is thought to result from capsular irritation. Meniscal tears are symptomatic as they render a portion of the meniscus abnormally mobile.[706] The shape and location of the meniscal tear determines the symptoms and clinical findings.

At the time of writing, four conservative approaches exist for the intervention of meniscal injuries: rehabilitation, meniscectomy, meniscus repair, and allograft transplantation.[66] The choice of intervention depends on several factors, including age, activity demands, size and location of the tear, and collateral tissue damage.[707]

Meniscal lesions that can be treated conservatively (~one-third) include the diffusely degenerative meniscus. Unless a tear is acute, peripheral, and stable, the relative avascularity of the middle third and the inner third of both menisci indicates a poor healing potential in these areas.

The conservative intervention for meniscal tears focuses on the resolution of impairments such as swelling, restricted ROM, and strength by using exercises, bracing, and oral medications.[708]

If the knee is locked or cannot be fully extended, the torn meniscal fragment is displaced and must be treated surgically. Although most peripheral tears are successfully repaired because of the healing capabilities of the meniscus, tears of the inner third of the meniscus are usually treated by meniscectomies.[66]

A number of surgical techniques exist for meniscal repair:

- Open repair. Open meniscal repair currently is most useful with multiple-ligament injuries in which the collateral ligament injuries may require open repair or tibial plateau fractures require open reduction and internal fixation.
- Arthroscopic. This technique allows evaluation and treatment of meniscal tears that are not possible with open techniques.

Rehabilitation after meniscal repair depends on whether ACL reconstruction was performed at the same time. For example, if ACL reconstruction is performed concurrently with the meniscal repair, more aggressive ROM exercises should be performed although flexion should be limited to 90 degrees for the first 4–6 weeks. Although many protocols exist, the principles of rehabilitation include an initial period of non–weight-bearing and limitation of flexion. Arnoczky et al.[78] have demonstrated that the meniscus is subject only to small amounts of motion and stress between 15 and 60 degrees of knee flexion.

An example of a rehabilitation protocol for a postsurgical lateral meniscal repair is outlined in Box 20-1.

Allograft Meniscal Transplantation[239]

Studies demonstrating the ability of meniscal tissue to heal if attached to a well-vascularized periphery led to the hypothesis that transplanted allographic meniscal tissue would have the potential to revascularize and function within the recipient's knee.[240–244]

Meniscal transplantation was first performed in humans in 1984 by Milachowski et al..[245] Since that time, preliminary reports and case studies have appeared in the literature. These reports have shown good or satisfactory results in 85–95% of patients.[241,245–248]

The topic of postoperative rehabilitation for the meniscal transplant is not fully developed within the current literature. Most reports advocate the use of a brace on the involved knee, 5–6 weeks of partial or non–weight-bearing status on the involved extremity and immediate ROM of the knee joint.[241,246,248,249] Restoring full extension immediately after surgery is emphasized, particularly in medial transplants, because this often involves removal and reattachment of the posterior oblique ligament and deep portion of the MCL. Loss of motion after ACL reconstruction has been correlated with repairs of these structures.[250] As rehabilitation progresses, CKC activities are limited from 0 to 60 degrees of flexion, because the load borne by the menisci increases as the knee approaches 90 degrees.[216] Proprioceptive training is emphasized, because the menisci contain mechanoreceptors and likely have a proprioceptive role.[251] On the basis of the findings from a variety of studies,[241–245,247] the initiation of functional activities can occur at approximately 9 months, with a full return to functional activities at approximately 1 year after surgery. The functional progression initially includes jogging, and progresses to running straight ahead. Cutting activities, which are added slowly, are monitored carefully. Returning to hard cutting and pivoting activities following meniscal transplant surgery is not recommended because of the high stresses these activities place on the menisci and the increased risk of reinjury they present.

Posterior Cruciate Ligament Tear

Injury to the PCL is thought to account for 3–20% of all knee injuries depending on the source, which suggests that many go undiagnosed.[709,710] Because of its inherent strength, damage to the PCL usually only occurs with significant trauma such as a dashboard injury associated with a motor vehicle accident,[711] or by a fall on a hyperflexed knee with the foot positioned in plantarflexion.[712] Isolated injuries of the PCL are less frequent as compared with combined injuries. For example, Fanelli[713,714] reported that 96.5% of traumatic knee injuries that involved the PCL were combined injuries. High energy mechanisms are

Box 20-1 Rehabilitation Protocol for Postsurgical Lateral Meniscus Repair

Week 1

- Continuous passive motion (CPM): PROM 10–70 degrees (knee extension/flexion), 3 × 60 min/d
- No AROM exercises
- Partial weight-bearing with crutches (20% of body weight)
- Knee brace locked in extension (for 4 weeks); wear brace day and night; remove brace for exercising and CPM
- Modalities to decrease swelling and pain: ice 6 × 10 min/d, transcutaneous electrical nerve stimulation (TENS) 2 × 20 min/d
- Patella mobilizations, low grade, 5 min/d
- Soft tissue massage (posterolateral, suprapatellar), 15 min/d
- Isometric quadriceps contractions (in 20 degrees of flexion), 10 × 30 s/d
- Electrical muscle stimulation (EMS) for quadriceps (in 20 degrees of flexion): 30 contractions per day (4-s duration [85 Hz], 20-s rest time per day)
- Upper body ergometer aerobic program, 10 min/d
- Upper extremity and trunk strengthening program, 30 min/d

Week 2

- Continue with the above program
- Partial weight-bearing with crutches (20% of body weight)
- PROM goal: 0–90 degrees
- AROM exercises for extension (in available range)
- No AROM for flexion
- Seated concentric quadriceps contractions, 60–0 degrees of flexion (against manual resistance, Theraband), 6 × 20 reps/d
- EMS for quadriceps (60 degrees of flexion), 30 contractions per day (4-s duration [85 Hz], 20-s rest time)
- Pool exercises (gait, balance, coordination), 20 min/d

Week 3

- Continue with the above program
- Partial weight-bearing with crutches (50% of body weight)
- ROM goal: 0 degree, 120 degrees, discontinue CPM when goal reached
- Flexibility exercises for quadriceps (Thomas position), 6 × 30 s/d
- Bilateral proprioceptive exercises (knee flexion, 10–20 degrees), on different unstable surfaces, 6 × 1 min/d
- Bilateral balance exercises (Biodex Stability System), 6 × 30 s/d
- Isokinetics (speeds 30 degrees/s and 60 degrees/s) in limited ROM (40–90 degrees of flexion) for quadriceps, 3 × 20 reps/d
- Stationary bike for gentle ROM exercise (low resistance), 3 × 15 min/d

Week 4

- Continue with the above program
- Partial weight-bearing with crutches (70% of body weight)
- ROM goal: 0–130 degrees
- Begin gentle AROM exercises for flexion
- Bilateral mini-squats (0–40 degrees), 6 × 20 reps/d
- Unilateral proprioceptive and balance training (knee flexion, 10–20 degrees), 6 × 20 s/d
- Isometric hamstring exercises (in 0, 20, 40, 60, and 80 degrees of flexion), 6 × 30 reps/d
- Simulated leg press on the CKC attachment (Biodex Systems), range 0–60 degrees, speed 90 degrees/s, 3 × 30 reps/d
- Deep-water running program (with wet vest), 20 min/d

Week 5

- Continue with the above program
- Full weight-bearing for *level* gait (avoid stairs), discontinue the use of crutches
- ROM goal: ensure 0–130 degrees with active and passive exercises
- Discontinue knee brace, use of knee neoprene sleeve

Box 20-1 Rehabilitation Protocol for Postsurgical Lateral Meniscus Repair *(Continued)*

- Flexibility exercises: add stretching for hamstrings, gastrocnemius/soleus, iliotibial hand, hip flexors, adductors, 3 × 30 s for each muscle group
- Unilateral proprioceptive and balance training (knee flexion, 10–20 degrees), 6 × 30 s/d
- Isokinetics quadriceps (speeds, 30, 60, 90, 120, 150, and 180 degrees/s; range, 110–0 degrees), 6 × 10 reps (each speed)/d
- Hamstring exercises (0–90 degrees of flexion) with Theraband, 5 × 20 reps/d
- Stationary bike (increase resistance), 3 × 20 min/d

Week 6

- Continue with the above program
- Exercise passive flexion end of ROM (unloaded flexion), 6 × 10 min/d
- Bilateral semi-squats (0–60 degrees), 6 × 20 reps/d
- Bilateral reactive/quickness training, 10 × 30 s/d
- Agility training (lateral movements with Sport Cord), 3 × 15 min/d

Week 7

- Continue with the above program
- "Sit back on heels" exercise (loaded flexion), 12 × 1 min/d
- Stairs allowed
- Unilateral mini-squats (0–40 degrees), 6 × 20 reps/d
- Isokinetics quadriceps AND hamstring (speeds 180, 210, 240, 270, and 300 degrees/s; range, 110–0 degrees), 6 × 10 reps (each speed)/d
- Strengthening program on weight machines (leg press, leg curls), 1 × 30 min/d
- Endurance program on bike, 1 × 45 min/d

Week 8

- Continue with the above program
- PROM goal: symmetrical
- Progress unilateral mini-squats to semisquats
- Lunges program (front, lateral, diagonal), 3 × 25 each
- Stairmaster, 1 × 30 min/d

Week 9

- Continue with the above program
- Intensify strengthening (2 × 45 min/d) and endurance program (1 × 60 min/d)

Week 10

- Continue with the above program
- "Sit back on heels" goal: symmetrical
- Plyometrics program (bilateral vertical and horizontal jumping), 1 × 20 min/d
- Controlled return to sports

Week 11 to 14

- Continue with the above program
- If no problems, discontinue rehabilitation by end of week 12
- Intensify sport-specific ice training until complete integration in the team training

Data from Bizzini M, Gorelick M, Drobny T: Lateral meniscus repair in a professional ice hockey goaltender: A case report with a 5-year follow-up. *J Orthop Sports Phys Ther* 36:89–100, 2006.

thought to result in a higher portion of combined injuries, whereas lower energy mechanisms are thought to result in a high proportion of isolated injuries.[715]

Clinical findings for a PCL tear include the following:

- Reports of hearing a "pop."
- Pain in the posterior aspect of the knee joint that may be aggravated with kneeling. Minimal pain typically occurs with extension, but is typically increased past 90 degrees of flexion and the patient may lack 10–20 degrees of flexion.[716]
- Minimal swelling.

- Possible abrasion or contusion on the superior, anterior aspect of the tibia, suggesting the occurrence of a posteriorly directed force of the tibia on the femur.
- Instability may or may not be present, depending on the severity of the tear. If present, the patient may complain of "giving way."
- Positive special tests, such as the posterior drawer, posterior sag, and quadriceps active test (see "Special Tests" section).
- Variable neurovascular findings based on severity. Structures to be assessed include the posterior tibial artery and vein (palpation of the distal posterior tibialis and dorsal pedis pulses and the fibular (peroneal) nerve (motor and sensory distributions of the nerve).

It is important for the clinician to delineate between isolated and combined lesions as intervention recommendations between these groups is different.[716] Specifically, isolated injuries (grades I and II, where the posterior translation is <10 mm) are generally treated conservatively, whereas combined injuries frequently necessitate a more aggressive intervention.[368]

Diagnostic studies may include radiographs, MRI, instrumented testing and stress radiographs. In acute cases, routine radiographs are essential to determine the absence or presence of associated fracture or an avulsion.

CLINICAL PEARL

MRI has been heralded as the gold standard for assessing PCL injuries.[717] Sensitivity and specificity for detection of PCL tears with MRI has been reported at 99%.[718]

Although it is not possible to predict which patients will obtain a favorable clinical results from conservative intervention and which will worsen over time, it would appear that the prognosis for an injury that occurs at high velocities and force levels is less favorable when compared with injury that occurred at low velocities and lower force levels.[719,720]

The focus of conservative intervention for isolated PCL injuries is to restore ROM and to strengthen the quadriceps and gastrocnemius, while delaying hamstring strengthening (for approximately 6–8 weeks) and protecting the articular surfaces.

- Quadriceps strengthening is performed to help reduce posterior tibial translation.[721] Theoretically, with the distal end fixed, a concentric contraction of the gastrocnemius can glide the femoral condyles posteriorly thereby reducing posterior subluxation of the tibia on the femur.
- Hamstring strengthening is delayed following the injury to decrease the potential for PCL stress. Resisted OKC knee flexion exercises should be avoided. Instead the hamstrings should be strengthened in a CKC environment to minimize any posterior shear stresses due to joint compression as well as substantially decreasing the angle of pull of the hamstrings on the posterior tibia.

A combination of OKCEs and CKCEs are initiated to promote dynamic stability of the knee.

CLINICAL PEARL

Many isolated PCL injuries heal with conservative intervention, especially in light of the fact that many PCL-deficient patients do not experience functional instability.[716] However, the long-term follow-up studies of PCL injuries reveal a progressive development of pain and degeneration of the medial compartment of the tibiofemoral joint.[722]

Important exercises include squats, lunges, and CKC knee extensions. Heavy resistance OKC knee extension exercises through a range of 45–20 degrees of flexion are avoided to protect the patellofemoral joint.[232,254] Balance and proprioceptive exercises also are performed. For the symptomatic patient, the use of a PCL brace may be advantageous. In addition, for patients with medial compartment pain, a trial of a lateral heel wedge may be beneficial.

Plyometrics are introduced for appropriate patients such as athletes. Return to sport may occur in as little as 6–8 weeks, but on average takes 12–16 weeks, providing that there are no complicating factors. These complicating factors include significant varus or valgus alignment, or damage to additional tissues.

Surgical intervention of isolated PCL injuries is an area of continued controversy and there is yet no clear consensus as to which techniques or graft designs are best. Complicating matters is that outcomes between the various surgical treatments are difficult to compare due to the wide range of injury patterns, differences in surgical and rehabilitation protocols. As the outcomes of conservative management are good or excellent in 50–80% of patients with isolated grade I or grade II PCL injuries, a trial period of rehabilitation as described above is typically recommended initially.[719,723]

The surgical management of patients who have PCL injuries combined with other ligament or capsular injuries is somewhat clearer and is recommended in the presence of pain and/or significant instability. As with postsurgical ACL protocols, a wide variety exists, a summary of which follows:

- Day 1–1 month: the goals during this phase are to control inflammation and promote healing, achieve full knee extension, knee flexion range of motion to 90 degrees, and quadriceps strength $\geq$3/5. Exercises during this phase include quad sets, ankle pumps, supine straight leg raise, and hip abduction/adduction. Any added resistance is applied proximal to the knee.
- 1–3 months: the goals during this phase are to achieve knee flexion ROM equal to 125 degrees, and quadriceps strength $\geq$4/5. At approximately 8 weeks postoperatively, exercises can include stationary bike without toe clips, leg press from 0 to 90 degrees, CKC terminal knee extension, and balance and proprioceptive exercises.
- 3–9 months: the goals during this phase are to have no limitation with activities of daily living and a limited resumption of low impact recreational activities. The CKCEs are progressed.
- 9–12 months: During this phase steps should be taken to return to previous levels of physical function and athletic pursuits.

Patellofemoral Instability

Patella instability can be produced by the following:

- ***A small patella.*** A smaller patella decreases the stability of the patella during its tracking.[11,724,725]
- ***A shallow patellar groove.*** The term *dysplastic femoral trochlea* implies a shallow intercondylar sulcus, especially at the lateral ridge, which often contributes to instability.[11,724,725]

There is strong evidence that implicates the depth of the trochlear groove of the femur for abnormal patella malalignment relative to the femur.[726] Powers[726] compared the trochlear groove or sulcus angle, using pneumatic MRI, of 23 women with patellofemoral disorders, 12 of whom had no history of patellofemoral disorders, at various degrees of knee flexion (45, 56, 27, 18, 9, and 0 degrees). The study indicated that the trochlear groove depth correlated with patella kinetics. Trochlear groove shallowness was found to be predictive of lateral tilt at the angles studied between 27 and 0 degrees and lateral patella displacement at 9 and 0 degrees.[726] These findings suggest that the depth of the trochlear sulcus affects the orientation of the patella in the first 30 degrees of knee flexion for lateral tilt and the first 10 degrees for lateral glide.[727]

- ***An abnormal patellar position.*** The patella may lie too far proximally or distally relative to the trochlea, conditions called *patella alta* and *patella baja* (or patella infera), respectively.[227,728,729] Patella alta, as a separate entity, does not necessarily contribute to knee pain, but it can certainly contribute to lateral maltracking by causing the patella to enter into the patellar groove late in knee flexion. Patella baja occurs rarely in otherwise normal individuals. It is seen in achondroplastic dwarfs, who seldom have anterior knee pain, and as a postoperative complication of knee surgery.[339,730,554] Several radiographic methods for diagnosis of patella alta and baja have been reported in the literature.[729,731–733]
- ***A muscle imbalance between the VMO and VL.***[133,146,460] These imbalances are discussed in the "Biomechanics" Section.
- ***Generalized ligamentous laxity or complex malalignments of the entire extremity (genu recurvatum).***[187,285,734]

Instability is usually identified through the history, with the patient reporting either dislocation or subluxation episodes. A subluxation needs to be differentiated from "giving way," as this can be simply a reflex inhibition of the quadriceps secondary to pain. The direction of instability is usually lateral, with medial instability almost always secondary to iatrogenic causes.[284] On palpation, medial retinacular and distal patellar pole tenderness or distal quadriceps tenderness may be elicited.[319]

The number of episodes is important because patients who are first-time dislocators and infrequent subluxators should have a trial of conservative intervention or limited arthroscopic evaluation for documented osteochondral lesions,[187] whereas, recurrent instability is an indication for surgical intervention.[284] Once the instability and its direction have been established, the anatomic cause of the instability is determined.

Cruciate ligament instabilities can lead to secondary patellofemoral pain through increased patellofemoral contact pressures and abnormal joint loading patterns.

Symptomatic Plica

The plica syndrome has been associated with anterior pain as well as clicking, catching, locking, or pseudolocking of the knee, and it may even mimic acute internal derangement of the knee.[119,345,735–740]

There is some controversy regarding the prevalence of the plica syndrome, with some reports suggesting that it does not exist.[741–743] Jackson et al.,[119,743] Dandy,[742] and others[115,116,227,345,744–747] have stated that although plicae may indeed cause symptoms, the syndrome is overdiagnosed and many normal synovial plicae are removed. Conversely, other authors consider the plica syndrome to be a common cause of anterior pain in the knee that is often misdiagnosed, and believe that a suprapatellar membrane is virtually never asymptomatic.[124,748,749]

Sherman and Jackson[750] have proposed a set of criteria for the diagnosis of symptomatic synovial plica:

- History of the appropriate clinical symptoms.
- Failure of nonoperative intervention.
- Arthroscopic finding of a plica with an avascular fibrotic edge that impinges on the medial femoral condyle during flexion of the knee. This is often a diagnosis of exclusion and can only be confirmed at arthroscopy.
- No other abnormality in the knee that would explain the symptoms. It has also been suggested that a localized area of chondromalacia at the site of impingement by a plica on the femoral condyle is evidence that a plica is the cause of the symptoms.

Clinical Findings

The mediopatellar plica (also termed *Lino's shelf*), although the least common, this variety is often the cause of problems if it becomes thickened, resulting in pain with palpation over the medial parapatellar area. The severity of symptoms is not proportional to the size or breadth of the synovial plica.[119] There also appears to be no correlation between the duration of symptoms and the presence of pathologic changes in the plica.[751]

A palpable band or snapping, especially over the medial femoral condyle, should be sought. In one study of plicae in the knee, clicking was reported in 64%, "giving way" in 59%, and pseudolocking in 45% of the patients.[345] A number of special tests exists for the detection of plical irritation (see "Special Tests" section).

Plicae are not visualized well on plain radiographs, but a double-contrast arthrogram may demonstrate a suprapatellar plica or an anterior plica.[746,752–756] A skyline radiograph may demonstrate a synovial shelf.[736,757,758]

The conservative intervention for plica syndrome involves stretching of the quadriceps, hamstrings, and gastrocnemius as well as isometric strengthening, cryotherapy, ultrasound, patellar bracing, anti-inflammatory medication, and an altered sports-training schedule.[116,735,759–762] In an uncontrolled

study,[763] this type of intervention resulted in an improvement in 40% of patients over a 1-year period.

Injection of the synovial plicae with corticosteroids and a local anesthetic in another uncontrolled study[764] was reported to have an excellent result in 73% of patients.

When patients are truly symptomatic, or when conservative measures have failed, surgical excision is usually curative.

PREFERRED PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION ASSOCIATED WITH LOCALIZED INFLAMMATION

Tendinitis

Patellar tendinitis (jumper's knee) and quadriceps tendinitis are overuse conditions that are frequently associated with eccentric overloading during deceleration activities (e.g., repeated jumping and landing, downhill running). The association of patellar tendinitis with jumping was first described by Maurizio,[765] but the term *jumper's knee* originated from Blazina et al.. [766] Some authors feel that the term *patellar tendinitis* is a misnomer because the patellar "tendon," which connects two bones, is in fact a ligament.[767,768]

The high stresses placed on these areas during CKC functioning place them at high risk for overuse injuries. Overuse is simply a mismatch between stress on a given structure and the ability of that structure to dissipate the forces, resulting in inflammatory changes.[769]

The diagnosis of tendinitis is based on a detailed history and careful palpation of the tendon in both flexion and extension. Pain on palpation near the patellar insertion is present in both patellar and quadriceps tendinitis. These are usually self-limiting conditions that respond to rest, stretching, eccentric strengthening,[470,770,771] bracing, and other conservative techniques. When treating overuse injuries, it is essential that the clinician limit both the chronic inflammation and degeneration by working on both sides of the problem: tissue strength should be maximized through proper training, and adequate healing time must be allowed before returning to full participation.[769]

Several protocols have been advocated for the conservative intervention of patellar tendinitis. Stanish et al.[771] proposed the following strengthening program of eccentric exercise for chronic patellar tendinitis.

A 5-minute warm-up period consisting of a series of three to five static stretches held for 15–30 seconds each is performed. Next, the patient, from a standing position, flexes the knees, abruptly drops to a squatting position, and then recoils to the standing position. The velocity of the drop is increased until the patient is able to perform it as quickly as possible without pain. At this point, sandbags are added to the patient's shoulders to increase the load on the tendon. Apart from some minor discomfort during the exercises and some post-exercise muscle soreness, the procedures should be performed without pain.[771]

Reid[772] proposes a protocol based on the severity of the lesion. Grade I lesions, which are characterized by no undue functional impairment and pain only after the activity, are addressed with adequate warm-up before training and ice massage after training. With grade II to III strains, activity modification, localized heating of the area, a detailed flexibility assessment, and an evaluation of athletic techniques are recommended. In addition, a concentric–eccentric program for the anterior tibialis muscle group is prescribed, which progresses into a purely eccentric program as the pain decreases.[773]

The patient is positioned in supine with the foot in full plantar flexion. The clinician applies overpressure on the posterior aspect of the foot, placing the foot into further plantar flexion and stretching the anterior tibialis. The patient is asked to perform a concentric contraction into full dorsiflexion, which is resisted by the clinician. An eccentric contraction is then performed by the patient by returning the foot into its plantar flexed position as the clinician resists the motion from full dorsiflexion to full plantar flexion. This maneuver is repeated to the point of fatigue of the anterior tibialis.[773] As soon as possible, the eccentric loading program is added.

It is not clear why a program initially directed at the anterior tibialis muscle group should be therapeutic for the infrapatellar tendon and ligament, but it is theorized that the program may stretch the infrapatellar ligament, change the quadriceps-to-foreleg strength ratio or alter the biomechanics of take-off and landing.[772]

Surgical intervention is usually required only if significant tendonosis develops and is successful in the majority of patients.[774]

Iliotibial Band Friction Syndrome

As its name suggests, ITBFS is a repetitive stress injury that results from friction of the ITB as it slides over the prominent lateral femoral condyle at approximately 30 degrees of knee flexion.[775] The friction has been found to occur at the posterior edge of the band, which is felt to be tighter against the lateral femoral condyle than the anterior fibers.[775,776] The friction causes a gradual development of a reddish-brown bursal thickening at the lateral femoral condyle.

ITBFS is the most common overuse syndrome of the knee, being particularly common in long-distance runners (20–40 miles/week). In addition, long-distance runners who train on hilly terrain, graded slopes, or road cambers are also at risk, especially if their runs include downhill running,[776,777] which positions the knee in significantly less flexion than normal at initial contact. Finally, running on canted surfaces can result in a leg-length inequality and a change in the Q-angle, which can increase the stress on the ITB.

Although most cases of ITBFS have been reported in distance runners, anyone engaging in activity that requires repetitive knee flexion and extension, such as downhill skiing, circuit training, weight lifting, and jumping sports, is prone to developing this pathology.[494] ITBFS is also common in cyclists.[778–780] This is thought to be due to the pedaling stroke, which causes the ITB to be pulled anteriorly on the down-stroke and posteriorly on the upstroke. Extrinsic factors

include excessive bike seat height or cleat position on the pedal. If the cleats are excessively internally rotated on the pedal, the tibia also internally rotates, resulting in a valgus force on the knee and increased tension of the ITB.

A study of six cadavers by Muhle et al.[781] found that in four of six individuals, some fibers of the ITB remained in contact with the lateral femoral condyle during extension. With further flexion, the ITB moves posteriorly and contacts the lateral femoral epicondyle and LCL, indicating a phase during knee flexion during which an impingement of the band occurs. In runners, this impingement phase occurs predominantly during the early stance phase, very soon after initial contact.[494] In general, the faster the speed of running, the less the time spent in the impingement zone, because the knee flexion angle at initial contact increases with speed of running.[782–784]

Subjectively, the patient reports pain with the repetitive motions of the knee. There is rarely a history of trauma. Although walking on level surfaces does not generally reproduce symptoms, especially if a stiff-legged gait is used,[165,776] climbing or descending stairs often aggravates the pain.[785] Patients do not usually complain of pain during sprinting, squatting, or during such stop-and-go activities as tennis, racquetball, or squash.[776] The progression of symptoms is often associated with changes in training surfaces, increased mileage, or training on crowned roads. The lateral knee pain is described as diffuse and hard to localize.

Objectively, there is localized tenderness to palpation at the lateral femoral condyle or Gerdy's tubercle on the anterolateral portion of the proximal tibia. The resisted tests are likely to be negative for pain. The special tests for the ITB (Ober's test, Noble compression test, and creak test) should be positive for pain, or crepitus, or both, especially at 30 degrees of weight-bearing knee flexion. There may also be associated biomechanical changes. In addition to an adaptively shortened ITB, the following findings have all been associated with ITB friction problems, although they have yet to be substantiated: cavus foot (calcaneal varus) structure,[786] leg-length difference (with the syndrome developing on the shorter side),[787,788] fatigue,[789] internal tibial torsion (increased lateral retinaculum tension), anatomically prominent lateral femoral epicondyle, and genu varum.[790]

A study by Fredericson et al.[791] found that long-distance runners with ITBFS have weaker hip abduction strength in the involved leg compared with the uninvolved leg and symptoms improved with a successful return of hip abductor strength. To control coronal plane movement during stance phase, the gluteus medius and TFL must exert a continuous hip abductor movement. Fatigued runners or those with weak gluteus medius muscles are prone to increased thigh adduction and internal rotation at midstance. This, in turn, leads to an increased valgus vector at the knee and increased tension on the ITB, making it more prone to impingement.[791]

Conservative intervention for ITBFS consists of activity modification to reduce the irritating stress (decreasing mileage, changing the bike seat position, and changing the training surfaces), using new running shoes,[792] heat or ice applications, strengthening of the hip abductors, and stretching of the ITB.[203] Surgical intervention, consisting of a resection of the posterior half of the ITB at the level that passes over the lateral femoral condyle, is reserved for the more recalcitrant cases.[780]

Bursitis

Several types of bursitis are differentiated:

- ***Superficial and deep infrapatellar bursitis.*** Inflammation of these bursae usually results from a mechanical irritation during such activities as kneeling ("nun's knee") or direct trauma.
- ***Prepatellar bursitis ("housemaid's knee").*** Inflammation of this bursa is seen in patients who experience recurrent minor trauma of the anterior knee. Those whose occupations require long periods of kneeling are particularly at risk. Diagnosis is straightforward, with pain and possibly swelling present on palpation of the prepatellar bursa.
- ***Superficial pes anserinus bursitis.*** This condition can involve any of the bursae lying between the various tendons of the superficial pes anserinus or a bursa between the MCL and the superficial pes anserinus. Inflammation of these bursae is common in novice swimmers and long-distance runners. Clinical findings may include medial knee pain just distal to the joint line, and an externally rotated tibia, compared with the uninvolved side.
- ***MCL bursitis.***[553] MCL bursitis was first described by Brantigan and Voshell[793] as inflammation of the bursae deep to the MCL.[793–795] Because of the proximity of this bursa to the medial meniscus or medial meniscotibial ligament, this condition is often misdiagnosed. Patients describe pain along the medial joint line, confirmed on physical examination by a tender palpable mass that can be exacerbated by placing the knee under a valgus load. Because of the proximity of the semimembranosus tendon to the bursa, internal and external rotation can also impinge on the bursa and cause pain.[793] Imaging is not essential, but an MRI scan may show the inflamed bursa.[261]

The intervention for bursitis includes the removal of the irritation. This may involve the stretching of adaptively shortened structures or joint mobilizations to help correct alignment.

Sindig–Larson–Johansson Syndrome and Osgood–Schlatter Disease

This condition is an apophysitis of the tibial tubercle (Osgood–Schlatter disease) and inferior pole of the patella (Sinding–Larsen–Johanssen syndrome) that occurs in skeletally immature individuals, especially those involved in sports requiring repetitive-loaded knee flexion.

Osgood–Schlatter disease presents between the ages of 8 and 13 years in females and 10 and 15 years in males, who are affected about three times as often.[772] In 25–33% of the cases, there is bilateral involvement.[796] The condition is the result of a retrograde ossification of the tibial tubercle, which produces

an apophysitis. Although usually self-limiting, it can progress to an osteonecrosis.

Sinding–Larsen–Johanssen syndrome usually occurs prior to the growth spurt. Fragmentation of the tibial tubercle or irregular calcification of the inferior patellar pole may be seen on radiographs. Pain is usually reported with use of the knee in activities such as athletics, cycling, or resisted knee extension. The involved area is tender and usually prominent on physical examination.

The intervention for these conditions is usually symptomatic, including short courses of anti-inflammatory medications, a focus on hamstring flexibility, and moderate-intensity quadriceps strengthening. The traditional approach of activity limitations is no longer considered necessary. Rarely, individuals will require excision of symptomatic ossicles or degenerated tendons for persistent symptoms at skeletal maturity. More persistent cases may require immobilization for 6–8 weeks.[772]

Quadriceps Contusion

Quadriceps contusions, resulting from a direct blow, can be very disabling.[797] Contusions of the anterior portion of the muscle are usually more serious than those involving the lateral portion of the muscle because of the differences in muscle mass present in the two areas.

As elsewhere in the body, contusions are graded according to severity. A grade I contusion produces only mild discomfort, with no swelling and no detrimental effect on gait. The patient with a grade II contusion may or may not have a normal gait cycle. Grade III contusions in this muscle are very rare due to the lack of muscle belly tissue.

These are frustrating injuries for the clinician and the patient, because there are often few clinical and radiographic findings to establish the diagnosis, resulting in a diagnosis made by way of exclusion. MRI may be helpful in the acute phase, but this remains a diagnosis that is largely based on the history.

If the intervention for these contusions occurs too early, or is too aggressive, myositis ossificans can develop. Myositis ossificans is a pathologic bone formation resulting from muscle tissue damage, bleeding, and damage to the periosteum of the femur, and producing ectopic bone formation.[798,799]

The intervention includes ice and 24-hour compression applied immediately, which should be continued until all of the signs and symptoms are absent. Gentle pain-free quadriceps-stretching exercises are begun on the first day, progressing to resistive exercises as tolerated, usually on the second day. If an abnormal gait is present, the patient may be issued crutches until the normal gait returns.

Patients with a grade I contusion can continue with normal activities as tolerated. A patient with a grade II contusion may require 3–21 days for rehabilitation. Grade III contusions may require 3 weeks to 3 months to fully heal.

Turf Knee or Wrestler's Knee

Turf knee, or wrestler's knee, is an injury to the soft tissue overlying the knee. It is caused by a shearing mechanism within the subcutaneous tissues. Swelling and tenderness are present, but the swelling is present in the extra-articular tissues and should be differentiated from a true joint effusion. A joint effusion is characterized by a ballotable patella, and the intra-articular fluid is mobile and can be pushed to and from the suprapatellar pouch. With turf knee, these signs are absent, but there is boggy swelling in the soft tissue and a sense of subcutaneous fluid is present on palpation. This injury usually responds well to rest and avoidance of the aggravating trauma.

Hoffa's (Fat Pad) Syndrome

The infrapatellar fat pad may be a cause of anterior knee pain. This syndrome was first described by Hoffa[800] in 1904. It is thought to represent hypertrophy and inflammation of the infra-patellar fat pad secondary to impingement between the femoral condyles and tibial plateau during knee extension. Direct trauma and overuse have also been attributed as causes. Irritation also can be produced by a posterior tilt of the inferior pole of patella.

Symptoms include anterior knee pain that is inferior to the pole of the patella. Pain is exacerbated by knee extension, particularly hyperextension, but not by knee flexion.[319] Inspection may reveal inferior patellar edema and associated tenderness of the fat pad when palpated through the tendon. Direct palpation of the fat pad on either side of the patellar tendon as the knee is brought from flexion into full extension is painful if the fat pad is inflamed. A diagnostic test, termed the *bounce test* (eliciting pain with passive knee hyperextension), is sometimes useful.[261] One must be careful to look for other causes of inflammation, such as OA, before concluding that the fat pad is the primary source of pain.[284] Plain radiographs are invariably negative, but abnormalities of the fat pad can be noted on MRI.[801]

Conservative intervention includes rest, ice, anti-inflammatory medications, and iontophoresis or phonophoresis. Local corticosteroid injections into the fat pad are preferred by some physicians because they can be both diagnostic and therapeutic.

Biomechanical interventions include addressing the causes of hyperextension through orthotic interventions, such as heel lifts or taping the superior pole posteriorly and holding the patella in a superior glide with tape.

In recalcitrant cases, surgical resection of portions of the fat pad is indicated.

Medial Retinaculitis

Medial retinaculitis is a rare condition seen almost exclusively in runners. It probably represents a fatigue tear in the medial capsular insertion into the patella. A positive bone scan in the medial edge of the patella confirms this diagnosis.

Baker's Cyst

Usually a Baker's cyst is asymptomatic, but in the presence of a synovial effusion, the cyst can swell up with fluid and become painful. On occasion, the cyst can become so large that it protrudes through the soft tissues, just proximal to the

popliteal fossa, between the heads of the gastrocnemius. Ruptures of the cyst can occur, and these can mimic the symptoms of a tear of the gastrocnemius.

Clinical findings with the larger cysts include pain with active and passive knee flexion and extension, with weight-bearing, and pain and an increased prominence of the swelling with resisted knee flexion.

The conservative intervention for this condition normally involves treating the articular disorder that caused the cyst to swell. The medical management includes aspiration or surgical resection.

Popliteus Tendinitis

Popliteus tendinitis is common in runners who used canted surfaces, which produce oblique lateral rotary stresses to the knee, or who run downhill frequently. The condition typically manifests as point tenderness in the lateral aspect of the knee corresponding to the popliteus insertion site, which is exacerbated with eccentric loading.

Popliteus tendinitis can be diagnosed by having the patient sit so that the leg is in the figure-4 position, with the lateral aspect of the ankle resting on the contralateral knee.

Intervention involves a modification in the training regimen, ultrasound, and transverse friction massage.

Breaststroker's Knee

This condition of pain and tenderness localized on the medial aspect of the knee is often associated with performance of the whip-kick, the kick used with breaststroke.[97] The forceful whipping together of the lower legs often forces the lower leg into slight abduction at the knee, with subsequent irritation and inflammation to the MCL of the knee.

In a study of breaststroke kinematics,[802] it was found that angles of hip abduction of less than 37 degrees, or greater than 42 degrees at the initiation of the kick, resulted in a dramatic increase in the incidence of knee pain.[97]

PREFERRED PRACTICE PATTERN 4G: IMPAIRED JOINT MOBILITY, MUSCLE PERFORMANCE, RANGE OF MOTION ASSOCIATED WITH FRACTURE

Tendon Ruptures or Fractures

Quadriceps and patellar tendon ruptures, and patellar fractures, usually result from eccentric overload of the extensor mechanism or direct trauma. These are usually easy to diagnose, because the patient is unable to actively extend the knee, and there is a palpable defect at the site of injury. Radiographs will confirm fractures or avulsions. In skeletally immature individuals, fractures involving the proximal tibial epiphysis can occur. These are usually evident on radiographs and often require surgical intervention.

INTEGRATION OF PREFERRED PATTERNS 4 F AND 5 F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION SECONDARY TO COMPLEX REGIONAL PAIN SYNDROME (REFLEX SYMPATHETIC DYSTROPHY), MYOFASCIAL PAIN SYNDROMES (REFERRED PAIN SYNDROMES), PERIPHERAL NERVE ENTRAPMENT

Peripheral Nerve Entrapment

Compression Neuropathy of the Saphenous Nerve[553]

Saphenous nerve palsy is an impingement of the large cutaneous branch of the femoral nerve by the fascia of its three bordering muscles (anterolaterally by the vastus medialis, posterolaterally by the adductor longus, and medially by the sartorius) as it exits the adductor canal.[794,803–805] Occasionally, branches of the femoral vessels also may impinge on the nerve. The onset can be insidious or secondary to trauma or surgery about the knee.

Entrapment of the saphenous nerve often results in marked pain at the medial aspect of the knee. Patients describe a burning sensation in the nerve's sensory distribution, which typically worsens at night and is exacerbated by lower limb activity. The pain can be confused with an internal derangement of the knee or an anserine bursitis.

Physical examination reveals a Tinel's sign at the adductor canal. Often there is associated local tenderness. Sensory changes may be seen within the sensory distribution of the nerve. There is no motor weakness. Confirmation of a saphenous lesion can be made using resisted flexion of the knee or resisted adduction of the thigh, which should increase the pain, or pressure over the saphenous opening, in the subsartorial fascia, producing a radiation of the pain. Active flexion of the knee beyond 60 degrees can also reproduce the pain.

EMG and nerve conduction studies can help eliminate L-3 and L-4 radiculopathies and aid in the diagnosis.[803] Diagnostic peripheral nerve blocks with lidocaine also may be performed. Mild-to-moderate cases can be treated with rest, anti-inflammatory medications, ice, ultrasound, and TENS.[794,805,806] Second-line interventions include therapeutic nerve blocks with phenol.[804] Cases refractory to these interventions can be managed with surgical release of fascial bands and neurectomy.[805]

Compression Neuropathy of Superficial Fibular (Peroneal) Nerve

This nerve can be entrapped as a result of fibrosis following a direct blow,[807,808] or surgery. Symptoms typically include pain over the lateral distal aspect of the leg and ankle, mimicking symptoms of a disk herniation, with irritation of the L5 nerve

root. However, differentiation can be made with percussion or pressure over the nerve at its point of exit, which will cause reproduction of the symptoms in this syndrome.[809]

Myofascial Pain Dysfunction: Vastus Medialis

This muscle refers pain deep to the patella, and patients typically complain of knee joint stiffness and loud cracking noises as the patella suddenly releases during knee flexion.[810] Dysfunction of the vastus medialis, which counters the lateral pull of the other three quadriceps muscles and ensures proper patellar tracking, can lead to patellofemoral dysfunction and pain. Structural deformities, such as valgus deviation of the knee or overpronation of the foot, put additional strain on this muscle and perpetuate trigger point activity.[810]

Complex Regional Pain Syndrome (Reflex Sympathetic Dystrophy)

This condition is characterized by intractable knee pain of considerable duration. The patient may appear severely disabled, often using crutches, and may appear anxious and depressed. The presence of cyanosis or mottling indicates autonomic dysfunction. There also may be a noticeable difference in temperature between the involved area and the contralateral limb. In late cases, trophic changes of the skin occur. In addition, wasting of the quadriceps and stiffness of the joint may be evident.

Early diagnosis is the key to a successful intervention. The intervention should include a comprehensive team approach involving the physician and physical therapist. The most important rule is to avoid excessive pain.[811] Complete rest to the involved region, particularly immobilization in a cast, is harmful.[812,813]

It is important to not reinjure the region or aggravate the problem with aggressive physical rehabilitation.[813] Thus, the progression should occur slowly and gently.

- Exercises are prescribed for strengthening, active assistive ROM, and AROM. Weight-bearing exercises and active stress loading exercises also should be incorporated.
- Sensory threshold techniques, including fluidotherapy, vibration desensitization, TENS, contrast baths, and desensitization using light and heavy pressure of various textures over the sensitive area, should be used.
- Affected joints should be rested and elevated to counteract the vascular stasis, but the joint also should be mobilized gently several times per day.[812]

THERAPEUTIC TECHNIQUES

Techniques to Increase Joint Mobility

A number of techniques can be used to increase joint mobility.

Joint Mobilizations

The mobilizations described in this section should always be complimented with exercises or automobilization techniques performed at home by the patient.

Patellofemoral Mobilizations

Numerous studies in the literature recommend using patellar mobilizations as one of the components of a physical therapy intervention for patellofemoral disorders.[191,814] These mobilizations are advocated to be performed in a variety of directions to increase the mobility of the patella, presumably to improve tracking. These include superior mobilizations, inferior mobilizations, and medial and lateral glides. However, from an evidence-based perspective, there is not one randomized study supporting the efficacy of patellofemoral mobilizations in the treatment of patellofemoral disorders at present.

The mobilizations for the tibiofemoral joint are identical to the techniques used to assess the joint, which are described in the passive physiologic articular mobility tests of the examination.

Distraction of the Tibiofemoral Joint

A variety of techniques can be used to apply a long-axis traction force to the tibiofemoral joint. Joint distraction is used for pain control and general mobility. Distraction at this joint tends to occur when moving into flexion. Using the resting position of the joint as a starting point, and the tibia rotated into either neutral, external rotation, or internal rotation, different ranges of flexion can be used.

Posterior Glide of the Tibia on the Femur

This technique is used to increase the joint glide associated with flexion of the tibiofemoral joint, with the emphasis of the mobilization technique varying according to the ROM being treated. For example, in the midranges of flexion, the posterior glide of the tibia is applied along the plane of the joint, whereas in the last few degrees of flexion, the posterior glide is applied with the congruent rotation of internal rotation of the tibia. Active mobilization can also be employed by positioning the patient's foot and leg into internal rotation, and asking the patient to pull isometrically with the hamstrings.

Anterior Glide of the Tibia on the Femur

This technique is used to increase the joint glide associated with extension of the tibiofemoral joint. If the clinician is attempting to regain the last 10–30 degrees of extension, the emphasis is placed on positioning the tibia in external rotation.

Proximal Tibiofibular Joint

The mobilizations for this joint are identical to the techniques used to assess the joint, which are described in the passive physiologic articular mobility tests of the examination. Myofascial restrictions of this joint present with the fibular head in an anterior or posterior position, and in the absence of adaptive shortening, the passive mobility tests will be normal. The intervention should be aimed at the cause of the muscle imbalance, but if direct treatment is attempted, active mobilization (muscle energy) techniques are used.

- To increase the posterior movement, the patient is asked to contract the hamstrings. The biceps femoris is attached to the fibular head and will help draw the fibular posteriorly.

- To increase the anterior glide, the patient is asked to contract the anterior tibialis, whose attachment will pull the fibula anteriorly.

Pericapsular hypomobility restrictions also present with the fibular head positioned anteriorly or posteriorly. The passive mobility test demonstrates reduced motion with a capsular end-feel. Treatment is by anterolateral (foot in plantar flexion) or posteromedial (foot in dorsiflexion) capsular stretches.

High-Velocity Correction for a Posterior Fibular Head

The patient is placed in the supine position, with the clinician standing beside the table, opposite the dysfunction. The clinician grasps the patient's foot and ankle on the side of the dysfunction with the nonthrusting hand and flexes the patient's hip and knee to 90 degrees. The clinician first places the index finger of his or her thrusting hand into the patient's popliteal crease, monitoring the dysfunctional fibular head. Next, the clinician locks the patient's foot on the side of the dysfunction in his or her armpit. The clinician then exerts a rapid downward thrust on the distal tibia and fibula while simultaneously pulling the fibular head anteriorly with his or her index finger.

AUTOMOBILIZATIONS

To Increase Extension

- Towel hyperextensions. A towel of sufficient height to elevate the calf and thigh off the table is placed under the heel (Fig. 20-66). A weight can be added to the tibia or femur to assist in regaining hyperextension at the knee (Fig. 20-67).
- Prone hangs (Fig. 20-68) **VIDEO**.
- Quadriceps setting. These exercises are done repeatedly during the day and can also be performed during the towel extension exercise.
- Standing extension (Fig. 20-69) with foot placed on a stool or chair.

FIGURE 20-66 Towel hyperextensions.

FIGURE 20-67 Towel hyperextensions with weight.

FIGURE 20-68 Prone hangs.

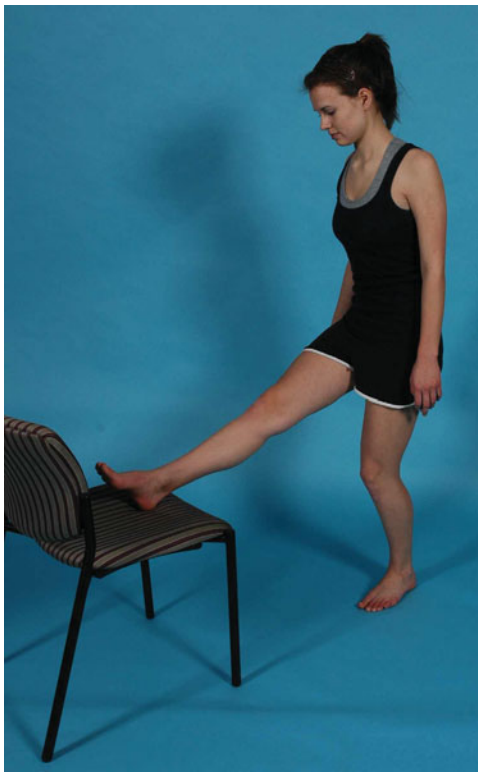

FIGURE 20-69 Standing extension.

FIGURE 20-70 Seated heel slides with passive overpressure.

FIGURE 20-71 Passive knee flexion with towel roll behind knee.

To Increase Flexion

- Wall slides in supine with the sole of the foot on the wall are performed until 90 degrees of flexion is obtained, and then seated heel slides with passive overpressure are initiated (Fig. 20-70).
- The patient is placed in the supine or sitting position. A rolled-up towel/pillow of sufficient size is placed behind the knee so that with the knee actively flexed, the towel/pillow can be held in place and act as a fulcrum. Using one or both hands, the patient grasps the anterior aspect of the lower leg (Fig. 20-71). By gently pushing the lower leg posteriorly, flexion of the knee can be increased.

Techniques to Increase Soft Tissue Extensibility

Increasing soft tissue extensibility is the hallmark of the functional knee rehabilitation protocol and includes stretching of the ITB, hamstring muscles, quadriceps, hip flexors, and Achilles tendon[189,319] (Table 20-20). The stretching techniques for the ITB, hamstring muscles, quadriceps, and hip flexors are described in Chapter 19. The technique for the Achilles tendon is described in Chapter 21.

Patients with marked internal rotation of the hip may require stretching of the anterior hip structures to increase the available external rotation and to help the gluteal muscles work in the inner range.[475]

TABLE 20-20 Muscle Stretching: Positions of Maximal Elongation and Stretch

Muscle	Maximal Elongation	Stretch
Gastrocnemius	Subtalar joint neutral, knee extension	Ankle dorsiflexion
Soleus	Subtalar joint neutral, knee flexion	Ankle dorsiflexion
Medial hamstrings	Hip external rotation, abduction, and flexion	Knee extension
Lateral hamstrings	Hip internal rotation and flexion	Knee extension
Rectus femoris	Hip extension	Knee flexion
Tensor fascia lata	Knee flexion, hip extension and external rotation	Hip adduction
Iliotibial band	Hip extension, neutral hip rotation, slight knee flexion	Hip adduction

CASE-STUDY

LEFT ANTERIOR KNEE PAIN

HISTORY

History of Current Condition

A 30-year-old woman presented with a 2-month history of progressive anterior left-knee pain. [553] The pain had started insidiously 3 months after she began playing field hockey. She denied any traumatic inciting mechanism. The pain was increased with hyperflexion and weight-bearing activities, abated with rest, but seemed aggravated with prolonged sitting. The patient also noted difficulty achieving full knee extension and had intermittent swelling and stiffness. Previous trials of oral anti-inflammatories had only mildly improved her pain.

History of Current Condition

No previous history of knee surgery or injury.

Past Medical/Surgical History

Unremarkable.

Medications

None.

Other Tests and Measures

Radiographs were negative for loose bodies, tumors, and fracture.

Social Habits (Past and Present)

Nonsmoker and drinker; active lifestyle.

Social History

Single; living alone.

Family History

No relevant history of knee problems in family.

Growth and Development

Normal development; right-handed.

Living Environment

Two-storey house.

Occupational/Employment/School

Full-time laborer; high-school education.

Functional Status/Activity Level

The patient denied any locking of her left knee, although there had been occasions when she felt the knee gave way because of pain. Pain increases with stair negotiation, particularly ascending stairs, and with prolonged sitting.

Health Status (Self-report)

The patient reported being in generally good health, but pain interferes with tasks at home and at work.

Questions

1. What structure(s) do you suspect to be at fault in this patient and require a specific examination?
2. What might the history of pain with prolonged sitting and stair negotiation tell the clinician?
3. What other activities do you suspect would increase the patient's symptoms? Why?
4. To help rule out the various causes of anterior knee pain, what other questions can you ask?
5. What is your working hypothesis at this stage? List the various diagnoses that could present with these signs and symptoms, and the tests you would use to rule out each one.
6. Does this presentation/history warrant a scan? Why or why not?

CASE-STUDY

LATERAL KNEE PAIN WITH RUNNING

HISTORY

History of Current Condition

A 22-year-old male runner complained of lateral right-knee pain that radiated from the lateral aspect of the knee, up the lateral thigh, and down to the proximal aspect of the lateral tibia. The pain was aggravated with running, especially on hills, and had begun about 6 weeks ago when he began training for a triathlon. The patient reported no pain with walking. The patient saw his physician, who prescribed a course of NSAIDs and recommended physical therapy.

History of Current Condition

No previous history of lower extremity pain.

Medical/Surgical History

Unremarkable.

Medications

Ibuprofen, 800 mg daily.

Functional Status/Activity Level

Pain was interfering with training for a triathlon. The patient also experienced pain with stair climbing.

Health Status (Self-report)

The patient reported being in generally good health.

Questions

1. What structure(s) could be at fault with complaints of lateral knee pain aggravated with running?
2. What might the history of a gradual onset of pain related to a change in training tell the clinician?
3. Why do you think the patient's symptoms are worsened with running on hills but not affected with walking?
4. What additional questions would you ask to help rule out referred pain from the lumbar spine?
5. What is your working hypothesis at this stage? List the various diagnoses that could present with these signs and symptoms, and the tests you would use to rule out each one.
6. Does this presentation/history warrant a scan? Why or why not?

REVIEW QUESTIONS*

1. Name a structure of the knee joint that is extra-articular and extrasynovial.
2. List three functions of the menisci.
3. Which peripheral nerve is primarily responsible for knee extension?
4. Anteversion of the hip may result in which knee deformity?
5. Which facet of the patella is likely to be involved if pain is reproduced at 20–30 degrees of knee flexion?

*Additional questions to test your understanding of this chapter can be found in the Online Learning Center for *Orthopaedic Assessment, Evaluation, and Intervention* at www.duttononline.net.

CHAPTER 21 The Ankle and Foot

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joints, ligaments, muscles, and blood and nerve supply that comprise the ankle and foot complex.
2. Describe the biomechanics of the ankle and foot complex, including the open- and close-packed positions, normal and abnormal joint end-feels, kinesiology, and the effects of open- and closed-chain activities.
3. Outline the purpose and components of the tests and measures of the ankle and foot complex.
4. Perform a detailed examination of the ankle and foot complex, including palpation of the articular and soft tissue structures, range-of-motion (ROM) testing, passive articular mobility tests, and stability tests for the ankle and foot complex.
5. Discuss the significance of the key findings from the tests and measures.
6. Evaluate the total examination data to establish a physical therapy diagnosis.
7. Describe the significance of muscle imbalance in terms of functional muscle performance and the deleterious effects on the lower kinetic chain.
8. Develop self-reliant examination and intervention strategies.
9. Describe the intervention strategies based on clinical findings and established goals.
10. Apply manual techniques to the ankle and foot complex, using the correct grade, direction, and duration.
11. Incorporate appropriate therapeutic exercises into the intervention progression.
12. Evaluate intervention effectiveness in order to progress or modify the intervention.
13. Plan an effective home program and instruct the patient in same.

OVERVIEW

The ankle and foot is a complex structure of 28 bones (including two sesamoid bones) and 55 articulations (including 30 synovial joints), interconnected by ligaments and muscles.

The foot has undergone a number of evolutionary adaptations, which make it very effective for bipedal locomotion.[1] First, the foot has become plantigrade, which allows most of the sole to be a weight-bearing surface. Second, the great toe has come to lie in a position with the other toes and, because of the relative immobility of the first metatarsal at the metatarsophalangeal (MTP) joint, is now relatively nonprehensile. Third, the metatarsals and phalanges have progressively shrunk and become small in comparison to the hypertrophied tarsus. Last, the medial side of the foot has become larger and stronger than that of any other primate.

The ankle joint sustains the greatest load per surface area of any joint of the body.[2] Peak vertical forces reach 120% of body weight during walking and they approach 275% during running.[3] The joints and ligaments of the ankle and foot complex act as stabilizers against these forces and constantly adapt during weight-bearing activities, especially on uneven surfaces. It is estimated that an average 180-lb man absorbs 76.2 tons on each foot while walking 1 mile and that the same man absorbs 121.5 tons per foot while running 1 mile.[4] Approximately 60% of this weight-bearing load is carried out by the rearfoot, and 28% by the metatarsal heads.[56] Although the ankle and foot complex normally adapts well to the stresses of everyday life, sudden or unanticipated stresses to this region have the potential to produce dysfunction.

ANATOMY

The ankle and foot complex is a sophisticated musculoskeletal arrangement designed to facilitate numerous and various weight-bearing and non–weight-bearing functions.[7] Anatomically and biomechanically, the foot can be subdivided into the

TABLE 21-1 The Joints of the Foot and Ankle: Their Open- and Close-Packed Positions and Capsular Patterns

Joints of the Hind Foot	Open-Packed Position	Close-Packed Position	Capsular Pattern
Tibiofibular joint	Plantar flexion	Maximum dorsiflexion	Pain on stress
Talocrural joint	10 degrees of plantar flexion and midway between inversion and eversion	Maximum dorsiflexion	Plantar flexion and dorsiflexion
Subtalar joint	Midway between the extremes of ROM	Supination	Varus and valgus
Joints of the Midfoot			
Midtarsal joints	Midway between the extremes of ROM	Supination	Dorsiflexion, plantar flexion, adduction, and internal rotation
Joints of the Forefoot			
Tarsometatarsal joints	Midway between the extremes of ROM	Supination	None
Metatarsophalangeal joints	10 degrees of extension	Full extension	Great toe: extension and flexion of second to fifth toes: variable
Interphalangeal joints	Slight flexion	Full extension	Flexion and extension

rearfoot or hindfoot (tibia, fibula, talus and calcaneus), the midfoot (the navicular, cuboid, and the three cuneiforms), and the forefoot (the 14 bones of the toes, the five metatarsals, and the medial and lateral sesamoids) (Table 21-1 and Fig. 21-1). The seven tarsal bones occupy the proximal half of the foot (see Fig. 21-1). Although described separately, the joints of the lower leg, ankle, and foot act as functional units and not in isolation. The joints of the foot and ankle, their open- and close-packed positions, and capsular patterns are outlined in Table 21-1. The shapes of the articulating surfaces of the leg and foot are outlined in Table 21-2. An appreciation of the shapes of the articulating surfaces is important when examining the joint glides and when performing joint mobilizations. Most of the stability of the foot and ankle is provided by a vast array of ligaments (Table 21-3).

REARFOOT

The joints of the rearfoot are the tibiofibular joint, talocrural (ankle) joint, and the subtalar (talocalcaneal) joint. The proximal row of tarsals comprises the talus (astragalus) (see Fig. 21-1), and calcaneus (or calcis). The function of the rearfoot is as follows:

- to influence the function and movement of the midfoot and forefoot;
- to convert the transverse rotations of the lower extremity into sagittal, transverse, and frontal plane movements.[8]

MIDFOOT

The joints of the midfoot include the talocalcaneonavicular joint, cuneonavicular joint, cuboideonavicular joint, intercuneiform joints, cuneocuboid joint, and the calcaneocuboid joint. The distal tarsal row contains, medial to lateral, the medial, intermediate, and lateral cuneiforms and the cuboid, which is roughly in parallel with the proximal row and which forms a transverse arch, posteriorly (dorsally) convex. Medially, the navicular is positioned between the talus and the cuneiforms (see Fig. 21-1). Laterally, the cuboid is positioned between the calcaneus and the lateral cuneiform and the fourth and fifth metatarsals (see Fig. 21-1). The function of the midfoot is to transmit motions from the rearfoot to the forefoot and to promote stability.[8]

CLINICAL PEARL

The midtarsal, or Chopart's joint, consists of the calcaneocuboid joint and talonavicular joint and connects the rearfoot to the midfoot. The midtarsal joint facilitates adduction and abduction of the forefoot.[7] The tarsometatarsal, or Lisfranc's joint, connects the midfoot and the forefoot.[7]

FOREFOOT

The joints of the forefoot include the tarsometatarsal joints, the intermetatarsal joints, the MTP joints, and the interphalangeal (IP) joints. The function of the forefoot is to adapt to the terrain, adjusting to uneven surfaces. The first metatarsal is the shortest and the strongest (see Fig. 21-1), whereas the second is the longest and the least mobile, serving as the anatomic touchstone for abduction and adduction of the foot.[9] The phalanges of the foot, although similar in number and distribution to those in the hand, are shorter and broader than their counterparts.

DISTAL TIBIOFIBULAR JOINT

The distal tibiofibular joint (Fig. 21-1) is classified as a syndesmosis, except for approximately 1 mm of the inferior portion, which is covered in hyaline cartilage. The joint consists of a concave tibial surface and a convex or plane surface on the medial distal end of the fibula. There is an

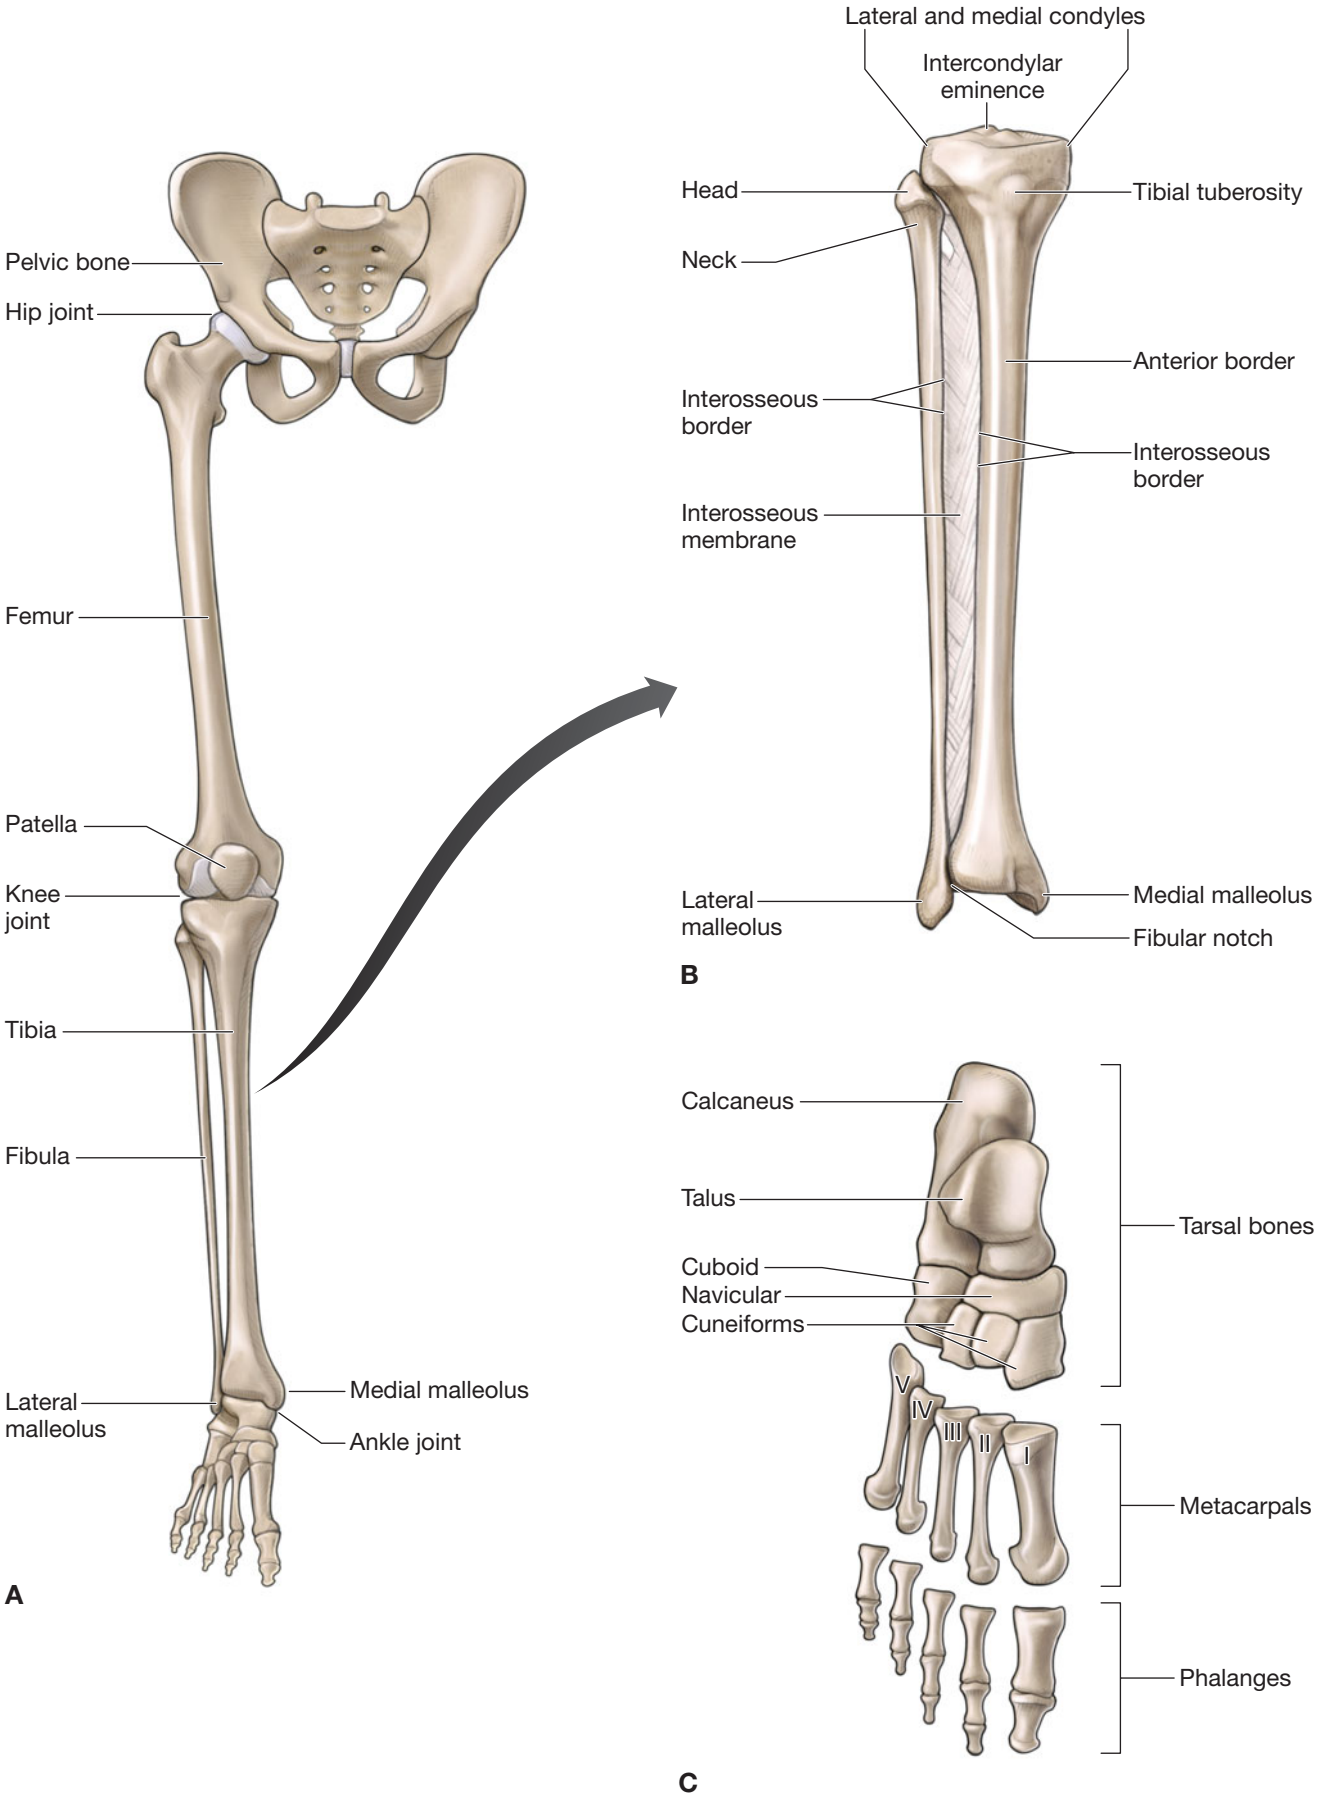

FIGURE 21-1 Bones of the lower extremity and foot. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

TABLE 21-2 Shapes of the Articulating Surfaces of the Leg and Foot

Joint	Proximal Bone and Shape of Its Joint Surface	Distal Bone and Shape of Its Joint Surface
Inferior tibiofibular	Tibia—concave	Fibula—convex
Talocrural	Tibia—concave in anterior–posterior direction and concave–convex–concave in mediolateral direction	Fibula—convex in anterior–posterior direction and convex–concave–convex in mediolateral direction
Talocalcaneal	Talus—posterior facet biconcave, middle facet biconvex, and anterior facet convex	Calcaneus—posterior facet biconvex, middle facet biconcave, and anterior facet concave
Talonavicular	Talus—biconvex	Navicular—biconcave
Calcaneocuboid	Calcaneus—convex in mediolateral direction and concave in superior–inferior direction (saddle shaped)	Cuboid—concave in mediolateral direction and convex in superior–inferior direction (saddle shaped)
Cuboideonavicular	Navicular—planar	Cuboid—planar
Cuneonavicular	Navicular—slightly convex	Cuneiforms—slight concave
Intercuneiform	Cuneiforms (medial and middle)—planar	Cuneiforms (middle and lateral)—planar
Cuneocuboid	Lateral cuneiform—planar	Cuboid—planar
Tarsometatarsal	Cuneiforms and cuboid—planar to slightly convex	Bases of metatarsals—planar to slightly concave
Metatarsophalangeal	Metatarsals—biconvex	Proximal phalanges—biconcave
Interphalangeal	Proximal phalanges—convex in superior–inferior and concave in medial–lateral direction	Middle phalanges—concave in superior–inferior and convex in medial–lateral direction

elongation into the joint by the synovium of the talocrural joint, the fibers of which are oriented inferiorly and laterally. The fibula serves as a site for muscular and ligamentous attachment, providing stability for the talus at the talocrural joint. The tibia is the second longest bone of the skeleton and is a major weight-bearing bone.

As at the proximal tibiofibular joint (see Chap. 20), support for this joint is provided primarily by ligaments. The joint is stabilized by four ligaments, collectively known as the syndesmotic ligaments. These include the inferior interosseous ligament, the anterior inferior tibiofibular ligament, the posterior inferior tibiofibular ligament, and the inferior transverse ligament. Of these ligaments, the inferior interosseous ligament is the primary stabilizer.

THE TALOCRURAL (ANKLE) JOINT

The talocrural (tibiotalar) joint is the articulation between the talus and the distal tibia. The talus serves as the link between the foot and the leg through the ankle joint and functions to distribute the body weight posteriorly toward the heel and anteriorly to the midfoot. The talus is divided into an anterior head and a posterior neck and body:

- ***Body.*** The superior dome-shaped surface of the body articulates with the tibia. The body is convex in the anteroposterior (A-P) direction and slightly concave in the mediolateral (M-L) and superior directions. The shape of this articulating surface can be compared with that of a cone, with the base of the cone facing laterally and the apex medially. Since the superior aspect of the body of the talus is wedge shaped with the wider portion anterior, no varus/valgus movement is possible when the ankle is positioned in maximum dorsiflexion, unless the mortise or the tibiofibular ligaments are compromised.
- ***Neck.*** The neck of the talus is a narrow region between the head and the body of the talus, and it is medially inclined. Its rough surfaces serve as attachments for ligaments. Inferior to the neck of the talus is the sulcus tali, which, when the talus and the calcaneus are articulated, roofs the sinus tarsi and is occupied by the talocalcaneal interosseous and cervical ligaments.
- ***Head.*** The plantar surface of the head has three articular areas separated by smooth ridges. The most posterior and largest of the articular areas is oval, slightly convex, and rests on a shelf-like medial calcanean projection called the *sustentaculum tali*. The other two articulating facets connect the talus with the navicular and the plantarcalcaneonavicular ligament.

The medial malleolus extends distally to approximately one-third of the height of the talus, whereas the lateral malleolus extends distally to approximately two-thirds the height of the talus.

The fibrous capsule of the ankle joint is relatively thin on its anterior and posterior aspects. It is lined with synovial membrane and reinforced by the collateral ligaments (see later).

CLINICAL PEARL

No tendons, with the exception of a small slip from the posterior tibialis, attach to the talus. However, the talus serves as the attachment for many ligaments.

TABLE 21-3 Ankle and Foot Joints and Associated Ligaments

Joint	Associated Ligament	Fiber Direction	Motions Limited
Distal tibiofibular	Anterior tibiofibular	Distolateral	Distal and posterior glide of fibula
	Posterior tibiofibular	Distolateral	Distal and anterior glide of fibula
	Interosseous	Distolateral	Separation of tibia and fibula
Ankle	Deltoid (medial collateral)		
	Superficial		
	Tibionavicular	Plantar–anterior	Lateral translation and external rotation of the talus
	Calcaneotibial	Plantar, plantar–posterior	Eversion (abduction of talus, calcaneus and navicular)
	Posterior talotibial	Plantar–posterior	Dorsiflexion, lateral translation and external rotation of the talus
	Deep		
	Anterior talotibial	Anterior	Abduction of the talus when in plantar flexion or eversion
	Lateral or fibular collateral		
	Anterior talofibular	Anterior–medial	Inversion and plantar flexion
			Anterior displacement of the talus
			Internal rotation of the talus
	Calcaneofibular	Posterior distal and medial	Inversion and dorsiflexion
	Posterior talofibular	Horizontal	Dorsiflexion
			Posterior displacement of foot
			Inversion
Subtalar	Lateral (anterior) talocalcaneal	Distal anterolateral	Joint separation during inversion and dorsiflexion
	Medial (posterior) talocalcaneal	Distal	Anterior translation of talus and inversion
	Cervical ligament	Distal–posterior–lateral	Inversion
	Interosseous	Distal and lateral	Joint separation
Main ligamentous support of longitudinal arches	Long plantar	Anterior, slightly medial	Eversion
	Short plantar	Anterior	Eversion
	Plantar calcaneonavicular	Dorsal–anterior–medial	Eversion
	Plantar aponeurosis	Anterior	Eversion
Midtarsal or transverse	Bifurcated		Joint separation
	Medial band	Longitudinal	Plantar flexion
	Lateral band	Horizontal	Inversion
	Dorsal talonavicular	Longitudinal	Plantar flexion of talus on navicular
	Dorsal calcaneocuboid	Longitudinal	Inversion, plantar flexion
Intertarsal	Dorsal and plantar ligaments		Joint motion in direction causing
	Interosseous ligaments connecting cuneiforms, cuboid, and navicular		ligament tautness
			Flattening of the transverse or longitudinal arch
Tarsometatarsal	Dorsal, plantar, and interosseous		Joint separation
Intermetatarsal	Dorsal, plantar, and interosseous		Joint separation
			Joint separation
	Deep transverse metatarsal		Flattening of the transverse arch
Metatarsophalangeal	Fibrous capsule		
	Dorsal, thin—separated from extensor tendons by bursae		Flexion
	Plantar— inseparable from deep surface of plantar and collateral ligaments		Extension
	Collateral		Flexion, abduction, or adduction in flexion
Interphalangeal	Collateral		Flexion, abduction, or adduction in flexion
	Plantar		Extension

The talus receives its blood supply from the branches of the anterior and posterior tibial arteries and is very susceptible to aseptic necrosis, particularly with proximal fractures.[10]

Talocrural Ligaments

The most important ligaments of the talocrural joint can be divided into two main groups: lateral collaterals and medial (deltoid) collaterals.

Lateral Collaterals

The lateral collateral ligament complex consists of three separate bands, which function together as the static stabilizers of the lateral ankle. Each of the lateral ligaments has a role in stabilizing the ankle and/or subtalar joint, depending on the position of the foot. As such, these ligaments are commonly involved in ankle sprains.[11–15]

Anterior Talofibular Ligament. This thickening of the anterior capsule extends from the anterior surface of the fibular malleolus, just lateral to the articular cartilage of the lateral malleolus, to just anterior to the lateral facet of the talus and to the lateral surface of the talar neck (Fig. 21-2).

The anterior talofibular ligament (ATFL) is an intracapsular structure and is approximately 2–5-mm thick and 10–12-mm long.[16] The ATFL functions to resist ankle inversion in plantarflexion. Regardless of ankle position, the ATFL is usually the first ankle ligament to be torn in an inversion injury.[16] The accessory functions of the ATFL include providing resistance against anterior talar displacement from the mortise and resistance against internal rotation of the talus within the mortise.[17]

CLINICAL PEARL

The ATFL requires the lowest maximal load to produce failure of the lateral ligaments, although it has the highest strain of failure in that group.

Calcaneofibular Ligament. The calcaneofibular ligament (CFL) (see Fig. 21-2), an extra-articular structure covered by the fibular (peroneal) tendons, is larger and stronger than the ATFL. It fans out at 10–40 degrees from the tip of the fibular malleolus to the lateral side of the calcaneus, paralleling the horizontal axis of the subtalar joint. This ligament effectively spans the ankle and subtalar joints, which have markedly different axes of rotation.[18–21] Thus, its attachment is designed so that it does not restrict motion in either joint, whether they move independently or simultaneously.[20,22,23] As the ankle joint passes from dorsiflexion to plantarflexion, the CFL is less able to resist talar tilt to inversion, although the ATFL is more able to resist this tilt.[22]

Posterior Talofibular Ligament. The posterior talofibular ligament (PTFL) (see Fig. 21-2) is the strongest of the lateral ligament complex,[16] and serves to indirectly aid talofibular stability during dorsiflexion due to its anatomic location, where it can act as a true collateral ligament and prevent talar tilt into inversion.[22,24] The PTFL is rarely injured except in severe ankle sprains. The ligament is coalescent with the joint capsule, and its orientation is relatively horizontal. Its attachment on the talus involves nearly the entire nonarticular portion of the posterior talus to the groove for the flexor hallucis longus (FHL)

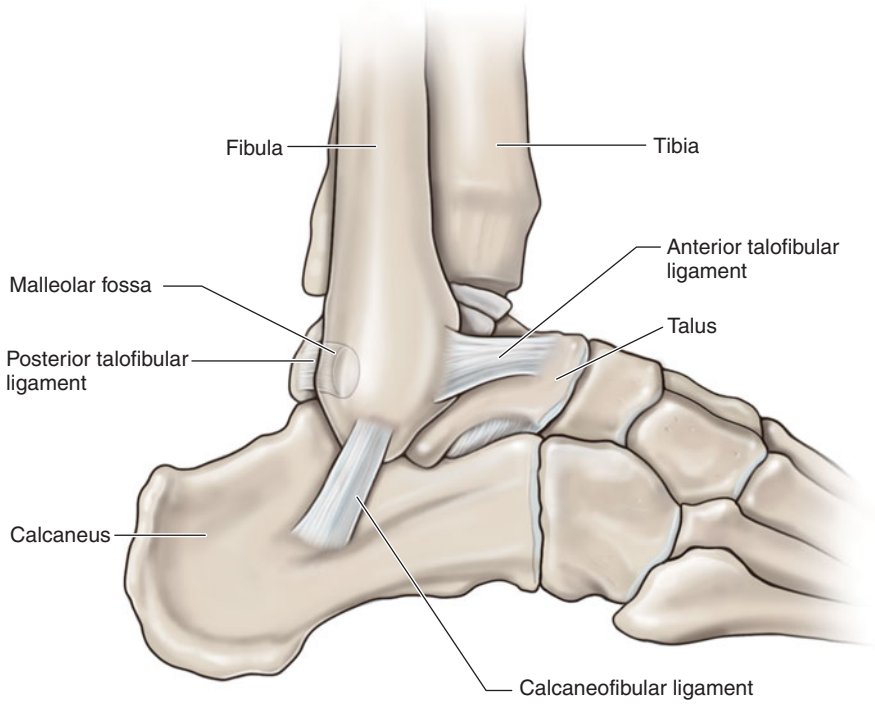

FIGURE 21-2 Lateral ligaments. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

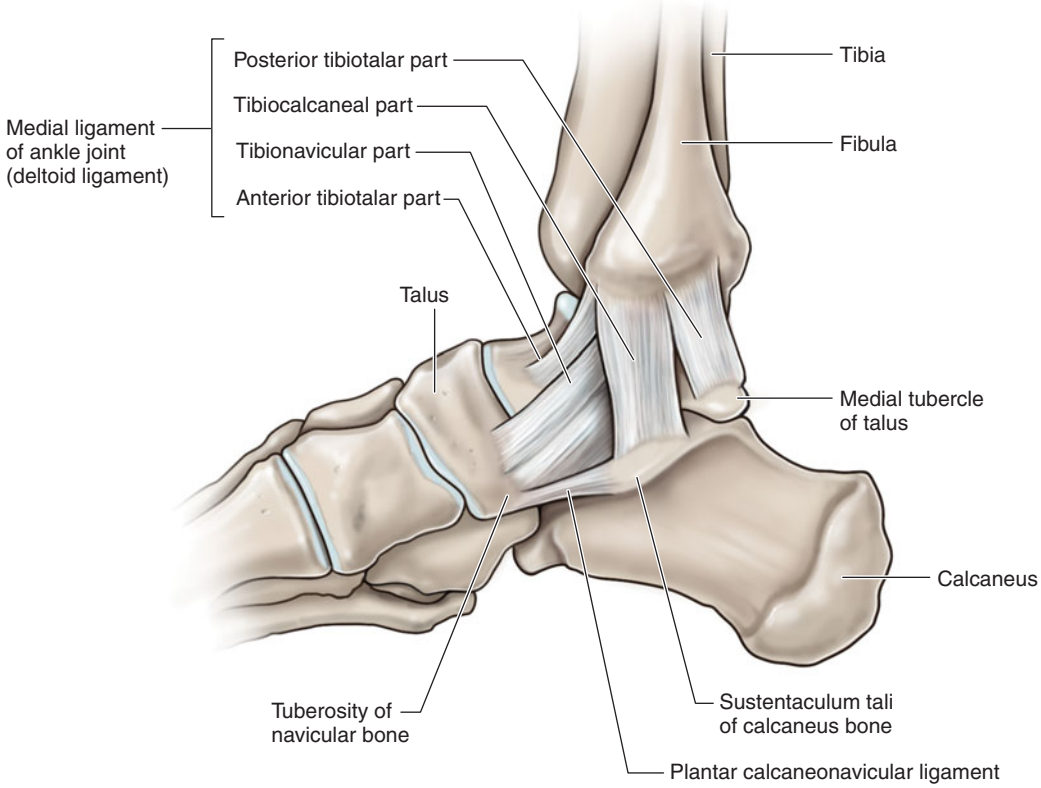

FIGURE 21-3 Medial ligaments. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

tendon, and anteriorly to the digital fossa of the fibula, which transmits the vessels that supply the talus and the fibula.[25,26]

Lateral Talocalcaneal Interosseous. The lateral talocalcaneal interosseous (LTCIL) ligament is sometimes included in this group as it does play a role in lateral ankle and subtalar stability (see Talocalcaneal Ligaments).[16,27]

CLINICAL PEARL

In dorsiflexion, the PTFL is maximally stressed, and the CFL is taut, whereas the ATFL is loose. Conversely, in plantarflexion, the ATFL is taut, and the CFL and PTFL become loose.[26,28–30]

Besides maintaining lateral ankle stability, the lateral ankle ligaments play a significant role in maintaining rotational ankle stability.[22] Significant compromise to the ATFL and/or CFL leads to a measurable increase in inversion without any tilting of the talus or subtalar gapping.[22] A loss of ATFL function permits an increase in external rotation of the leg and unlocks the subtalar joint, allowing further inversion, which may lead to symptomatic instability.[22]

Medial Collaterals. Collectively, the medial collateral ligaments form a triangular-shaped ligamentous structure known as the deltoid ligament of the ankle (Fig. 21-3). Wide variations have been noted in the anatomic description of the deltoid ligament of the ankle but is generally agreed that it consists of both superficial and deep fibers. The superficial fibers consist of the following:

- ***Tibionavicular fibers (see Fig. 21-3).*** These fibers extend from the medial malleolus to the tuberosity of the navicular and serve to resist lateral translation and external rotation of the talus.
- ***Posterior talotibial fibers (see Fig. 21-3).*** These fibers travel in a posterolateral direction from the medial malleolus to the medial side of the talus and medial tuberosity of the talus. These fibers resist ankle dorsiflexion and lateral translation and external rotation of the talus.
- ***Calcaneotibial fibers (see Fig. 21-3).*** These thin fibers extend from the medial malleolus to the sustentaculum tali. The fibers are oriented in such a way that they resist abduction of the talus, calcaneus, and navicular, when the foot and ankle are positioned in plantar flexion and eversion.[19]

The deep fibers consist of the following:

- ***Anterior talotibial fibers (see Fig. 21-3).*** The fibers of this strong ligament extend from the tip of the medial malleolus to the anterior aspect of the medial surface of the talus. These fibers are oriented in such a way that they resist abduction of the talus, when it is in plantar flexion and eversion. Such is the strength of these fibers that an injury to this ligament is often associated with an avulsion fracture.

Although the calcaneotibial ligament is very thin and supports only negligible forces before failing, the talotibial

ligaments are very strong.[31,32] Rasmussen et al.[33,34] found that the superficial fibers of the deltoid ligament of the ankle specifically limited talar abduction or negative talar tilt and that the deep layers of the deltoid ligament of the ankle ruptured with external rotation of the leg, without the superficial portion being involved.

CLINICAL PEARL

The strength of the ankle ligaments from weakest to strongest is the ATFL, PTFL, CFL, and deltoid complex.[35]

SUBTALAR (TALOCALCANEAL) JOINT

The subtalar joint consists of two separate, modified ovoid surfaces with their own joint cavities. The two anterior and posterior articulations are connected by an interosseous membrane.

- The anterior joint consists of a concave facet on the calcaneus and a convex facet on the talus. The anterior component is situated more medial than the posterior, giving the plane of the joint an average 42 degrees (±9 degrees) superior from the transverse foot plane and 23 degrees (±11 degrees) medial from the sagittal foot plane.[36]
- The posterior joint consists of a convex facet on the calcaneus and a concave facet on the talus.

This relationship ensures that the anterior and posterior aspects can move in opposite directions to each other during functional movements (while the anterior aspect is moving medially, the posterior aspect is moving laterally).

The calcaneus, the largest tarsal bone and the most frequently fractured, projects further posteriorly than the tibia and fibula. It serves as a weight-bearing bone and as a short lever for muscles of the calf, which are attached to its posterior surface. The skin and fat over the distal-inferior area of the calcaneus are specialized for friction and shock absorption.[37]

CLINICAL PEARL

The skin on the sole of the foot is thicker than anywhere else in the body. Located beneath the skin in the heel area is a fat pad, which is designed to handle compressive loads beyond what other fat pads in the body will tolerate. This fat pad comprises a honeycombed pattern of subcutaneous fat globules in fibroelastic septae 13–21 mm thick, which abuts the calcaneus.[38] The septae closest to the calcaneus are aligned concentrically, in a pattern that opposes a concentrically aligned reversed pattern closest to the skin. These opposing patterns create a torsion effect that resists compression, thereby providing a cushion for initial contact by the heel and allowing the skin to resist forces up to five times the body weight during running.[38] However, after the age of 40, the thickness of the subcutaneous fat decreases, with a resultant loss of shock absorbency.[3940] This can be counteracted by using a heel cup/counter, which confines the overall volume of the fat pad around the calcaneus.

The retrocalcaneal bursa lies anterior to the posterosuperior calcaneal tuberosity of the calcaneus. It lubricates the Achilles tendon anteriorly, as well as the superior aspect of the calcaneus.[39] The superior or proximal surface of the calcaneus is divisible into thirds.

- ***The posterior third.*** This is a roughened surface that is concavoconvex in extension, the convexity transverse. It supports fibroadipose tissue between the calcaneal tendon and the ankle joint. Distal to the posterior articular facet is a rough depression that narrows into a groove on the medial side—the sulcus calcanei—which completes the sinus tarsi with the talus.
- ***The middle third.*** This surface carries the posterior talar facet and is oval and convex anteroposteriorly.
- ***The anterior third.*** This surface is only partly articular.

Talocalcaneal Ligaments

A number of ligaments provide support to this joint, although some confusion exists in the descriptions and nomenclature of these ligaments. In relation to the sinus tarsi, the most medial ligament is the talocalcaneal interosseous ligament, which branches superiorly into medial and lateral bands.[22] The cervical ligament and portions of the retinaculum are located more laterally. The talocalcaneal interosseous and cervical ligaments are often collectively referred to as the interosseous ligaments.[41]

Medial (Posterior) Talocalcaneal Interosseous

The medial talocalcaneal interosseous ligament extends from the medial tubercle of the talus to the posterior aspect of the sustentaculum tali and the area of the calcaneus just posterior to the sustentaculum tali. It functions to stabilize against anterior translation of the talus (especially at the initial contact phase of the gait cycle) by producing passive eversion of the talus. This results in a close packing of the lateral foot and fibula. Damage to this ligament, which typically occurs with inversion sprains and rotational compression fractures of the calcaneus, can permit excessive anterior motion of the talus. This excessive motion may result in posterior tibialis tendinitis[42] and on occasion, Achilles' tendinitis.[43]

Lateral (Anterior) Talocalcaneal Interosseous

The lateral (anterior) talocalcaneal interosseous ligament (LTCIL) originates from the roof of the sinus tarsi and extends in a posteroinferior direction from the lateral process of the talus to the lateral surface of the calcaneus, just anterior to the CFL. This ligament functions to prevent the talus and the calcaneus from separating during inversion movements. This highly innervated structure is typically injured with a dorsiflexion and inversion mechanism.[44]

MIDTARSAL (TRANSVERSE TARSAL) JOINT COMPLEX

The midtarsal joint complex consists of the talonavicular and calcaneocuboid articulations.

Talonavicular

The talonavicular joint is classified as a synovial, compound, modified ovoid joint.

The joint is actually formed by components of the talus, navicular, calcaneus, and plantar calcaneonavicular (spring) ligament. The rounded convex anterior head of the talus fits into the concavity of the posterior navicular and the anterior component of the subtalar joint and rests on the posterior (dorsal) surface of the spring ligament. The joint capsule is only well developed posteriorly, where it forms the anterior part of the interosseus ligament.

Calcaneocuboid

The calcaneocuboid joint is classified as a simple, synovial, modified sellar joint.

The anterior surface of the calcaneus, which articulates with the reciprocally shaped posterior surface of the cuboid, is relatively convex in an oblique horizontal direction and relatively concave in an oblique vertical direction.[45] The cuboid, most lateral in the distal tarsal row, is located between the calcaneus proximally and the fourth and fifth metatarsals distally. To the posterior (dorsal) surface are attached posterior (dorsal) calcaneocuboid, cubonavicular, cuneocuboid, and cubometatarsal ligaments, and to the proximal edge of the plantar ridge, deep fibers of the long plantar ligament. To the projecting proximal–medial part of the plantar surface are attached a slip of the tendon of tibialis posterior and flexor hallucis brevis (FHB). To the rough part of the medial cuboidal surface are attached the interosseous, cuneocuboid, and cubonavicular ligaments, and proximally the medial calcaneocuboid ligament, which is the lateral limb of the bifurcated ligament.[46] The capsule is thickened posteriorly (dorsally) to form the posterior (dorsal) calcaneocuboid ligament. The joint has a large plantar phalanx to provide additional support during weight-bearing.

A number of ligaments help provide support to this region. The spring ligament (plantar calcaneonavicular Fig. 21-3) connects the navicular bone to the sustentaculum tali on the calcaneus. The ligaments of the calcaneocuboid joint include the long plantar ligament and a portion of the bifurcate ligament posterior (dorsally).

- The long and strong plantar ligament attaches to the plantar surface of the calcaneus, the tuberosity on the plantar surface of the cuboid bone, and to the bases of the second, third, and fourth (and possibly fifth) metatarsals.[46] The plantar ligament functions to provide indirect plantar support to the joint, by limiting the amount of flattening of the lateral longitudinal arch of the foot.[47] Together with the groove in the cuboid bone, it forms a tunnel for the passage of the fibularis (peroneus) longus tendon across the plantar surface of the foot.[46]
- The bifurcate ligament functions to support the medial and lateral aspects of the foot when weight-bearing in a plantar flexed position (twisted).

The plantar calcaneocuboid ligament, sometimes referred to as the short plantar ligament, is a relatively broad and strong strap-like structure that extends from the area of the anterior tubercle of the calcaneus to the adjacent plantar surface of the cuboid bone. It provides plantar support to the joint and possibly helps to limit flattening of the lateral longitudinal arch.

CUNEONAVICULAR

The cuneonavicular joint is classified as a compound, synovial, modified ovoid joint. The navicular presents a convex surface to the concave surface of the combined cuneiforms. The wedge-like cuneiform bones articulate with the navicular proximally and with the bases of the first to third metatarsals distally (see Fig. 21-1). The medial cuneiform is the largest and the intermediate, the smallest. In the intermediate and lateral cuneiforms, the posterior (dorsal) surface is the base of the wedge, but in the medial, the wedge is reversed, a prime factor in shaping the transverse arch. The wedge shape of these bones also provides a cavity for the neurovascular and musculotendinous structures of the foot.

The cuneiforms, together with articulations with the metatarsal bones, form Lisfranc's joint.[9] The proximal surface of all three cuneiforms form a concavity for the convex surface of the navicular. In the intermediate and lateral cuneiforms, the posterior (dorsal) surface is the base of the wedge, but in the medial, the wedge is reversed, which assists in the formation of the transverse arch. The medial cuneiform is the largest, the intermediate the smallest. The ligament of Lisfranc runs between the medial cuneiform and second metatarsal base. Disruption of this ligament can lead to a dislocation of the medial aspect of the foot, as the first metatarsal and medial cuneiform separate from the second metatarsal and intermediate cuneiform.

The joint cavity and capsule of the cuneonavicular joint is continuous with that of the intercuneiform and cuneocuboid joints, and the synovium is continuous with that of these joints, the second and third cuneometatarsal joints, and the intermetatarsal joints of each base except the fifth.

INTERCUNEIFORM AND CUNEOCUBOID JOINTS

These joints (see Fig. 21-1) are classified as compound, synovial, modified ovoid joints. The joint capsule and synovium is contiguous between all of these joints and with that of the cuneonavicular joint.

Dysfunctions in the cuneocuboid joint result from a collapse of the plantar supporting structures or from direct trauma. Such dysfunctions may result in the cuboid subluxing in a plantar direction (medial border of cuboid moves inferiorly). At the intercuneiform joints, the third cuneiform may sublux on the second cuneiform.

CUBOMETATARSAL

Laterally, the cuboid bone articulates with the fourth and fifth metatarsals distally, and with the calcaneus proximally. When considered alone, the cubometatarsal joint is classified as a compound, modified ovoid, synovial joint. When

the cubometatarsal joints are considered together, they form a modified sellar joint. The joint capsule and synovium of the fourth and fifth cubometatarsal joints are separated from the other tarsometatarsal joints by an interosseous ligament.

CUBONAVICULAR

The cubonavicular joint (see Fig. 21-1) is classified as a syndesmosis or a plane surfaced joint. If the joint is synovial, the capsule and synovium is continuous with the cuneonavicular joint.

INTERMETATARSAL

The first intermetatarsal joint (see Fig. 21-1) is classified as a simple, synovial, modified ovoid joint, whereas the second, third, and fourth are classified as compound joints. If the joint is synovial, the capsule and synovium is continuous with the cuneonavicular joint. Motion at these joints is confined to posterior (dorsal)/anterior (plantar) gliding, producing a fanning and folding motion of the foot. Proximally, the five metatarsals articulate with the tarsals and with themselves through broad concavities.[9]

METATARSOPHALANGEAL

The MTP joints (see Fig. 21-1) are classified as simple, synovial, modified ovoid joints. The capsule and synovium in each of these joints is confined to its own joint and posteriorly (dorsally) is thin, whereas plantarly (anteriorly), it is blended with the plantar and collateral ligaments. Rotation occurring in the early stages of development of the limbs results in the thumb being the most lateral digit in the hand, whereas the hallux (great toe) is the most medial digit in the foot.[48]The concave bases of the proximal phalanges (see Fig. 21-1) articulate with the convex heads of the metatarsals. The first MTP joint, with its more extensive articular surface on the anterior (plantar) aspect of the metatarsal than on the posterior (dorsal), allows for a greater freedom of motion,[48] and its anterior (plantar) surface forms two grooves for articulation with the hallucal sesamoids (see next section). The fifth metatarsal has a lateral styloid process at its base, which serves as the insertion site for the tendon of the fibularis (peroneus) brevis. The styloid area is often avulsed during acute inversion injuries of the foot.[9] Three types of forefoot are recognized based on the length of the metatarsal bones, although it is unclear whether these various types affect foot function in any way[48]:

- ***Index plus.*** This type is characterized by the first metatarsal being longer than the second, with the other three of progressively decreasing lengths, so that $1 > 2 > 3 > 4 > 5$.
- ***Index plus–minus.*** In this type, the first metatarsal is of the same length as the second, with the others progressively diminishing in length, so that $1 = 2 > 3 > 4 > 5$.
- ***Index minus.*** With this type, the second metatarsal is longer than the first and third metatarsals. The fourth and fifth metatarsals are progressively shorter than the third, so that $1 < 2 > 3 > 4 > 5$.

Stability of the MTP joints is primarily provided by a musculocapsular ligamentous complex anteriorly (plantarly), and medially and laterally by the medial and lateral collateral ligaments, respectively.

First MTP Joint

The first MTP joint is the articulation between the head of the first metatarsal and the proximal phalanx. Although there is some anatomic variation from patient to patient, the first MTP joint is typically a cam-shaped, condylar-hinged joint.[49] The MCP joint has little inherent stability because the proximal phalanx has a fairly shallow cavity in which the metatarsal head articulates. The joint is stabilized posteriorly (dorsally) by the capsule and expansion of the extensor hallucis tendon. Fan-shaped medial and lateral collateral ligaments provide valgus and varus stability, respectively. The plantar surface of the capsule is reinforced by a fibrocartilaginous plate, called the plantar accessory ligament. In addition, the MTP joints are dynamically stabilized by the short flexor complex (FHB and the two sesamoids embedded in the FHB tendons), the adductor hallucis, and the abductor hallucis tendons.

CLINICAL PEARL

The sesamoids are contained within the tendon of the FHB and serve to increase the lever arm for flexion of the MTP joint, analogous to the function of the patella at the knee.[50]

The sesamoids are connected distally to the base of the proximal phalanx by extensions of the FHB called the plantar plate. Typically, the sesamoids are anterior (plantar) to the medial and lateral condyles of the metatarsal pad. The sesamoids are separated on the anterior (plantar) aspect of the first metatarsal head by a cresta, which helps to stabilize the sesamoids, and are connected to one another by the intersesamoidal ligament. The abductor hallucis inserts into the medial sesamoid, and the adductor hallucis inserts into the lateral sesamoid. The FHL (Fig. 21-4) pierces the two heads of the FHB muscle to run just anterior (plantar) to the intersesamoidal ligament. In normal gait, the capsuloligamentous complex of the first MTP joint must withstand 40–60% of body weight, but in athletic activity, this can reach as much as eight times body weight.[47,51–56]

INTERPHALANGEAL

The hallux has two phalanges, whereas each of the remaining toes have three (see Fig. 21-1). The IP joints are classified as simple, synovial, modified sellar joints. The saddle-shaped articular fossa of the head of the proximal phalanx articulates with the base of the intermediate phalanx. This in turn receives the smaller and flatter distal phalanx.

ACCESSORY OSSICLE

An accessory ossicle (accessory bone) is an anomalous bone that fails to unite during developmental ossification. Common locations include the fibular malleolus, tibiar malleolus, navicular, and talus.

The accessory navicular is the most common accessory bone in the foot.[57] It occurs on the medial, anterior (plantar) border of the navicular, at the site of the tibialis posterior tendon insertion.[58] The incidence in the general population has been reported to be 4–14%[58,59] The posterior aspect of the talus often exhibits a separate ossification center, appearing at 8–10 years of age in girls and 11–13 years of age in boys. Fusion usually occurs 1 year after its appearance.[60,61] When fusion does not occur, an *os trigonum* is formed (see "Pathologies" section).

CLINICAL PEARL

An accessory bone can be differentiated from a fracture radiographically, because an accessory bone will have rounded edges, where a fracture will have sharp edges.[62]

PLANTAR FASCIA/PLANTAR APONEUROSIS

The terms *plantar fascia* and *plantar aponeurosis* (Fig. 21-4) are often used interchangeably, although strictly speaking only the central part of the plantar fascia is extensively aponeurotic.[63] The plantar fascia is the investing fascial layer of the anterior (plantar) aspect of the foot that originates from the os calcis and inserts through a complex network to the anterior (plantar) forefoot. It is a tough, fibrous layer, composed histologically of both collagen and elastic fibers. The plantar fascia is often regarded as being analogous to the palmar fascia of the hand. However, unlike the fascial layer of the palm, which is generally thin, the plantar fascia is a thick structure, and not only serves a supportive and protective role, but is also intricately involved with the weight-bearing function of the foot.[63] The plantar fascia is divided into three major areas: a central portion and medial and lateral sections, each oriented longitudinally on the anterior (plantar) surface of the foot.[26]

- ***Central portion.*** The central portion is the major portion of the plantar fascia both anatomically and functionally.[63] This

portion is the thickest and the strongest and is narrowest proximally where it attaches to the medial process of the calcaneal tuberosity, proximal to the flexor digitorum brevis (FDB). This attachment site is often involved in a condition called plantar heel pain (see "Intervention Strategies" section); however, pain can occur anywhere along the structure. From its insertion, the central portion of the fascia fans out and becomes thinner distally. Its fibers are longitudinally oriented and adhere to the underlying FDB muscle.[63] The central portion envelops the FDB muscle on both sides, forming the medial and lateral intermuscular septums, which anchor the plantar fascia to the deep plantar pedis.[63] At the midshaft of the second to fifth MTP joints, the body of the central portion branches into five superficial longitudinal tracts.[63] All five superficial longitudinal tracts terminate by inserting into, and blending with, the overlying subcutaneous tissues and skin. Due to the anatomical connections of the central portion, dorsiflexion of the toe slides the plantar pads distally, placing tension on the plantar aponeurosis. The central portion of the fascia primarily functions as a dynamic stabilizer of the medial longitudinal arch during weight-bearing activities.

- ***Lateral and medial portions.*** The smaller and thinner lateral and medial portions are thin and cover the under surface of the abductor digiti minimi and abductor hallucis muscles, respectively.

With standing and weight-bearing, the plantar fascia plays a major role in the support of the weight of the body, by virtue of its attachments across the longitudinal arch. During the different phases of gait, the plantar fascia assumes different biomechanical functions. For example, during the toe-off portion of the gait cycle, the windlass effect on the plantar fascia helps to reconstitute the arch and generates a more rigid foot for propulsion.*[62] During heel strike, and during the first half of the stance phase of the gait cycle with the toes in neutral, the plantar fascia relaxes, flattening the arch. This allows the foot to accommodate to irregularities in the walking surface and to absorb shock.[62] As the foot proceeds from midstance to terminal stance, the toes dorsiflex and, through its attachments to the toes via the plantar plate, the plantar fascia tightens. The plantar fascia is pulled over the metatarsal heads, causing the metatarsal heads to be depressed and the longitudinal arch to rise.[63] During the swing phase of gait, the plantar fascia is under little tension and appears to serve no important functional role.

RETINACULA

There are four important ankle retinacula, which function to tether the leg tendons as they cross the ankle to enter the foot (Fig. 21-4).[64]

- ***Extensor retinaculum.*** The extensor retinaculum consists of two parts: superior and inferior. The superior part functions to contain the tendons of the extensor digitorum longus, extensor hallucis longus, tibialis anterior, and fibularis (peroneus) tertius. The Y-shaped inferior part consists of an upper and a lower band, which prevent "bow-stringing" of the posterior (dorsal) tendons.
- ***Superiofibular (peroneal) retinacula.*** This firmly tethers the fibularis (peroneus) longus and brevis tendons behind the fibular malleolus.
- ***Flexor retinaculum.*** The flexor retinaculum provides a firm support structure for the flexor digitorum longus, FHL, tibialis posterior, and the neurovascular bundle.

EXTRINSIC MUSCLES OF THE LEG AND FOOT

The extrinsic muscles of the foot (Table 21-4) can be divided into anterior, posterior superficial, posterior deep, and lateral compartments.

Anterior Compartment

This compartment contains the dorsiflexors (extensors) of the foot. These include the tibialis anterior, extensor digitorum longus, and extensor hallucis longus (see Fig. 21-5).

Posterior Superficial Compartment

This compartment, located posterior to the interosseous membrane, contains the calf muscles that plantar flex the foot. These include the gastrocnemius, soleus (see Fig. 21-5), and the plantaris muscle (Fig. 21-6).

Triceps Surae

The triceps surae comprises the two heads of the gastrocnemius, which arise from the posterior aspects of the distal femur, and the soleus, which arises from the tibia and fibula, which combine to form the Achilles tendon.[65] The medial head of the gastrocnemius is by far the largest component and, according to electromyographic (EMG) studies, is the most active of the two during running.[66,67] The soleus (Fig. 21-5), because it does not cross the knee joint, is subject to early disuse atrophy with undertraining and/or immobilization.[66] The Achilles tendon is formed from the conjoint tendons of the gastrocnemius and soleus muscles. The fibers from the gastrocnemius and soleus interweave and twist as they descend, producing an area of high stress 2–6 cm above the distal tendon insertion.[68] A region of relative avascularity exists in the same area,[69] which correlates well with the site of some Achilles tendon injuries, including complete spontaneous rupture.[66,70,71] The plantaris muscle has its own tendon and contributes no fibers to the Achilles tendon.[72]

Achilles Tendon. The Achilles tendon is the thickest, strongest tendon in the body.[65] As the Achilles tendon comes off the posterior calf muscles, it courses distally to attach approximately three-quarters of an inch below the superior portion of the os calcis, on the medial aspect of the calcaneus. Two bursae occur at the point of insertion of the Achilles tendon into the calcaneus. The retrocalcaneal bursa lies deep into the tendon, adjacent to the calcaneus. The superficial bursa of the tendo

*The orientation of the aponeurosis promotes inversion of the calcaneus and supination of the subtalar joint when it is under tension, which raises the longitudinal arch and provides a rigid lever for propulsion.

TABLE 21-4 Extrinsic Muscle Attachments and Innervation

Muscle	Proximal	Distal	Innervation
Gastrocnemius	Medial and lateral condyle of femur	Posterior surface of calcaneus through Achilles tendon	Tibial S2 (S1)
Plantaris	Lateral supracondylar line of femur	Posterior surface of calcaneus through Achilles tendon	Tibial S2 (S1)
Soleus	Head of fibula, proximal third of shaft, soleal line and midshaft of posterior tibia	Posterior surface of calcaneus through Achilles tendon	Tibial S2 (S1)
Tibialis anterior	Distal to lateral tibial condyle, proximal half of lateral tibial shaft, and interosseous membrane	First cuneiform bone, medial and plantar surfaces, and base of first metatarsal	Deep fibular (peroneal) L4 (L5)
Tibialis posterior	Posterior surface of tibia, proximal two-thirds posterior of fibula, and interosseous membrane	Tuberosity of navicular bone and tendinous expansion to other tarsals and metatarsals	Tibial L4 and L5
Fibularis (peroneus) longus	Lateral condyle of tibia, head, and proximal two-thirds of fibula	Base of first metatarsal and first cuneiform, lateral side	Superficial fibular (peroneal) L5 and S1 (S2)
Fibularis (peroneus) brevis	Distal two-thirds of lateral fibular shaft	Tuberosity of fifth metatarsal	Superficial fibular (peroneal) L5 and S1 (S2)
Fibularis (peroneus) tertius	Lateral slip from extensor digitorum longus	Tuberosity of fifth metatarsal	Deep fibular (peroneal) L5 and S1
Flexor hallucis longus	Posterior distal two-thirds fibula	Base of distal phalanx of great toe	Tibial S2 (S3)
Flexor digitorum longus	Middle three-fifths of posterior tibia	Base of distal phalanx of lateral four toes	Tibial S2 (S3)
Extensor hallucis longus	Middle half of anterior shaft of fibula	Base of distal phalanx of great toe	Deep fibular (peroneal) L5 and S1
Extensor digitorum longus	Lateral condyle of tibia proximal anterior surface of shaft of fibula	One tendon to each lateral four toes, to middle phalanx, and extending to distal phalanges	Deep fibular (peroneal) L5 and S1

achillis lies superficial to the distal portion of the tendon, between the tendon itself and the subcutaneous tissues, but is not visible unless it is pathologically inflamed. Deeper to the Achilles tendon is the pre-Achilles fat pad, a triangular area of adipose tissue, also known as Kager's triangle. Further anterior to this fat pad are the deep flexor tendons of the calf, predominantly the FHL, which overlies the posterior tibia and the talus.

There is no synovial sheath surrounding the Achilles tendon. The peritendon covers the endotendon and is composed of a thin sheath, called the epitenon, and another fine outer sheath, the peritenon, composed of fatty areola tissue, which fills the interstices of the fascial compartment in which the tendon is situated.[73] The peritenon is able to stretch 2–3 cm with tendon movement, which allows the Achilles tendon to glide smoothly.[74]

Posterior Deep Compartment

This compartment contains the flexors of the foot. These muscles course behind the medial malleolus. They include the posterior tibialis, flexor digitorum longus, and FHL (see Fig. 21-7).

The primary function of the tibialis posterior muscle is to invert and plantar flex the foot. It also provides support to the medial longitudinal arch.[75] The flexor digitorum longus functions to flex the phalanges of the lateral four toes and assists with plantar flexion of the foot.

The FHL flexes the great toe and also assists with plantar flexion of the foot.

Lateral Compartment

This compartment contains the fibularis (peroneus) longus and brevis (see Fig. 21-5). The fibular (peroneal) tendons lie behind the lateral malleolus in a fibro-osseous tunnel formed by a groove in the fibula and the superficial fibular (peroneal) retinaculum. The fibular (peroneal) retinaculum and the posterior CFL form the posterior wall of this tunnel.

CLINICAL PEARL

The fibularis (peroneal) muscles serve as both plantar flexors and evertors of the foot.[76,77] The fibularis (peroneus) longus also abducts the forefoot in the transverse plane, thereby serving as a support for the medial longitudinal arch.[78]

INTRINSIC MUSCLES OF THE FOOT

Beneath the plantar aponeurosis–plantar fascia are the four muscular layers of the intrinsic muscles of the anterior (plantar) foot (Table 21-5), as well as the plantar ligaments of the rear- and midfoot. The intrinsic muscles provide support to the foot during propulsion.[79]

First Layer

The first layer is the most anterior (plantar) and consists of the following:

- ***Abductor hallucis (Fig. 21-8).*** This muscle arises from the medial process of the calcaneal tuberosity and inserts into the medial side of the base of the proximal phalanx of the great toe.
- ***Abductor digiti minimi (see Fig. 21-8).*** This muscle arises from the lateral process of the calcaneal tuberosity as well as the plantar aponeurosis and inserts into the lateral side of the base of the proximal phalanx of the little toe.
- ***Flexor digitorum brevis (see Fig. 21-8).*** This muscle arises from the medial process of the calcaneal tuberosity, lateral to the abductor hallucis and deep into the central portion of the

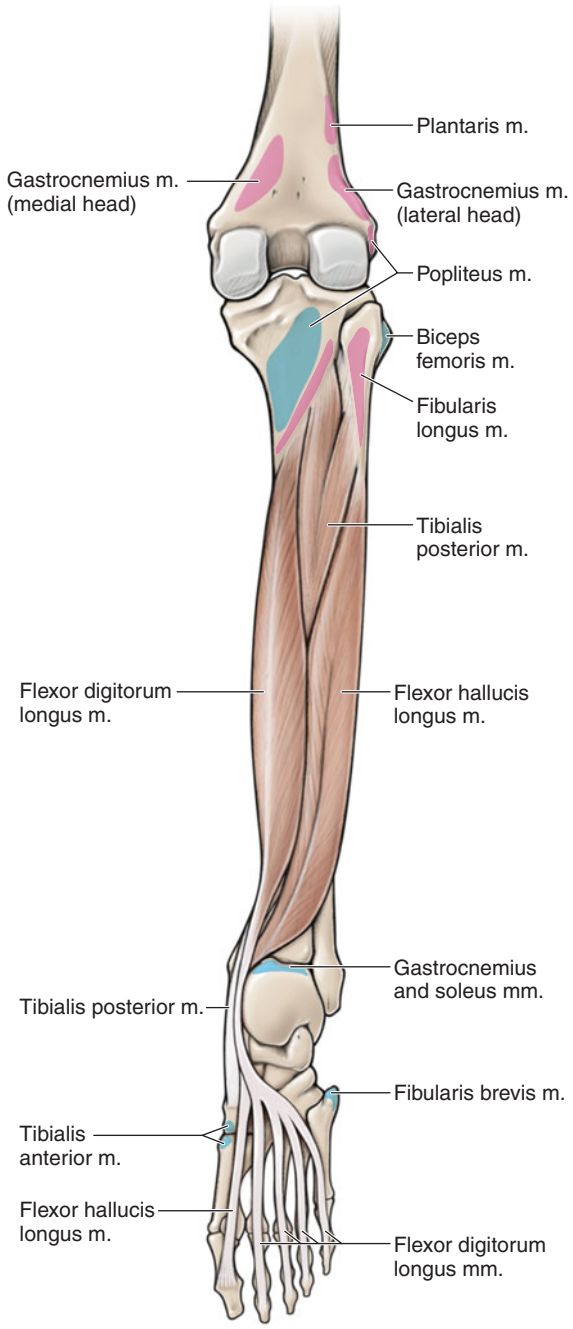

FIGURE 21-7 Posterior Deep Muscle Compartment. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

plantar fascia, and inserts into the middle phalanx of the lateral four toes.

Second Layer

- ***Flexor digitorum accessorius (quadratus plantae; Fig. 21-8).*** This muscle arises from the calcaneal tuberosity via two heads. The medial head arises from the medial surface of the calcaneus and the medial border of the long plantar ligament, whereas the lateral head arises from the lateral border of the anterior (plantar) surface of the calcaneus and the lateral border of the long plantar ligament. The muscle terminates in tendinous slips, joining the long flexor tendons to the second, third, fourth, and occasionally fifth toes.
- ***Lumbricales.*** There are four lumbricales (see Fig. 21-8), all of which arise from the tendon of the flexor digitorum longus. The first arises from the medial side of the tendon of the second toe, the second from adjacent sides of the tendons for the second and third toes, the third from adjacent sides of the tendons for the third and fourth toes, and the fourth from adjacent sides of tendons for the fourth and fifth toes. They insert with the tendons of the extensor digitorum longus and interossei into the bases of the terminal phalanges of the four lateral toes. The function of the lumbricales is to flex the MTP joint and extend the proximal IP (PIP) joint.

Third Layer

- ***Flexor hallucis brevis (Fig. 21-8).*** This muscle arises from the medial part of the anterior (plantar) surface of the cuboid bone, the adjacent portion of the lateral cuneiform, and the posterior tibialis tendon and inserts on the medial and lateral side of the proximal phalanx of the great toe.
- ***Flexor digiti minimi (see Fig. 21-8).*** This muscle arises from the sheath of the fibularis (peroneus) longus, the base of the fifth metatarsal bone, and inserts into the lateral side of the base of the proximal phalanx of the little toe.
- ***Adductor hallucis (see Fig. 21-8).*** This muscle arises via two heads: an oblique and a transverse head. The oblique head arises from the bases of the second, third, and fourth metatarsal bones and the sheath of the fibularis (peroneus) longus. The transverse head arises from the joint capsules of the second, third, fourth, and fifth MTP heads and the deep transverse metatarsal ligament. The adductor hallucis inserts on the lateral side of the base of the proximal phalanx of the great toe.

Fourth Layer

- ***Posterior (dorsal) interossei.*** The four posterior (dorsal) interossei are bipennate, and they arise from adjacent sides of the metatarsal bones. The first inserts into the medial side of the proximal phalanx of the second toe. The second inserts into the lateral side of the proximal phalanx of the second toe. The third inserts into the lateral side of the proximal phalanx of the third toe, and the fourth inserts into the lateral side of the proximal phalanx of the fourth toe. The posterior (dorsal) interossei function to abduct the second, third, and fourth toes from an axis through the second metatarsal ray.
- ***Anterior (plantar) interossei (Fig. 21-8).*** The three anterior (plantar) interossei are unipennate and arise from the bases and medial sides of the third, fourth, and fifth metatarsal bones. They insert into the medial sides of the bases of the proximal phalanges of the third, fourth, and fifth toes. The anterior (plantar) interossei function to adduct the lateral three toes.

TABLE 21-5 Intrinsic Muscles of the Foot

Muscle	Proximal	Distal	Innervation
Extensor digitorum brevis	Distal superior surface of calcaneus	Posterior (dorsal) surface of second through fourth toes and base of proximal phalanx	Deep fibular (peroneal) S1 and S2
Flexor hallucis brevis	Plantar surface of cuboid and third cuneiform bones	Base of proximal phalanx of great toe	Medial plantar S3 (S2)
Flexor digitorum brevis	Tuberosity of calcaneus	One tendon slip into base of middle phalanx of each of the lateral four toes	Medial and lateral plantar S3 (S2)
Extensor hallucis brevis	Distal superior and lateral surfaces of calcaneus	Posterior (dorsal) surface of proximal phalanx	Deep fibular (peroneal) S1 and S2
Abductor hallucis	Tuberosity of calcaneus and plantar aponeurosis	Base of proximal phalanx and medial side	Medial plantar L5 and
Adductor hallucis	Base of second, third, and fourth metatarsals and deep plantar ligaments	Proximal phalanx of first digit lateral side	Medial and lateral plantar S1 and S2
Lumbricals	Medial and adjacent sides of flexor digitorum longus tendon to each lateral digit	Medial side of proximal phalanx and extensor hood	Medial and lateral plantar L5, S1, and S2 (L4)
Plantar interossei			
First	Base and medial side of third metatarsal	Base of proximal phalanx and extensor hood of third digit	
Second	Base and medial side of fourth metatarsal	Base of proximal phalanx and extensor hood of fourth digit	Medial and lateral plantar S1 and S2
Third	Base and medial side of fifth metatarsal	Base of proximal phalanx and extensor hood of fifth digit	
Posterior (dorsal) interossei			
First	First and second metatarsal bones	Proximal phalanx and extensor hood of second digit medially	
Second	Second and third metatarsal bones	Proximal phalanx and extensor hood of second digit laterally	Medial and lateral plantar S1 and S2
Third	Third and fourth metatarsal bones	Proximal phalanx and extensor hood of third digit laterally	
Fourth	Fourth and fifth metatarsal bones	Proximal phalanx and extensor hood of fourth digit laterally	
Abductor digiti minimi	Lateral side of fifth metatarsal bone	Proximal phalanx of fifth digit	Lateral plantar S1 and S2

POSTERIOR (DORSAL) INTRINSIC MUSCLES

The posterior (dorsal) intrinsic muscles of the foot are the extensor hallucis brevis (EHB) and extensor digitorum brevis (EDB). The EHB inserts into the base of the proximal phalanx of the great toe, whereas the EDB inserts into the base of the second, third, and fourth proximal phalanges. Both of these muscles are innervated by the lateral terminal branch of the deep fibular (peroneal) nerve.

ARCHES OF THE FOOT

The arches of the foot support the foot by three mechanisms[80]

- The osseous relationship of the tarsal and metatarsal bones.
- Ligamentous support from the plantar aponeurosis and anterior (plantar) ligaments.
- Muscle support.[81] There are three main arches: the medial longitudinal, the lateral longitudinal, and the transverse arches.

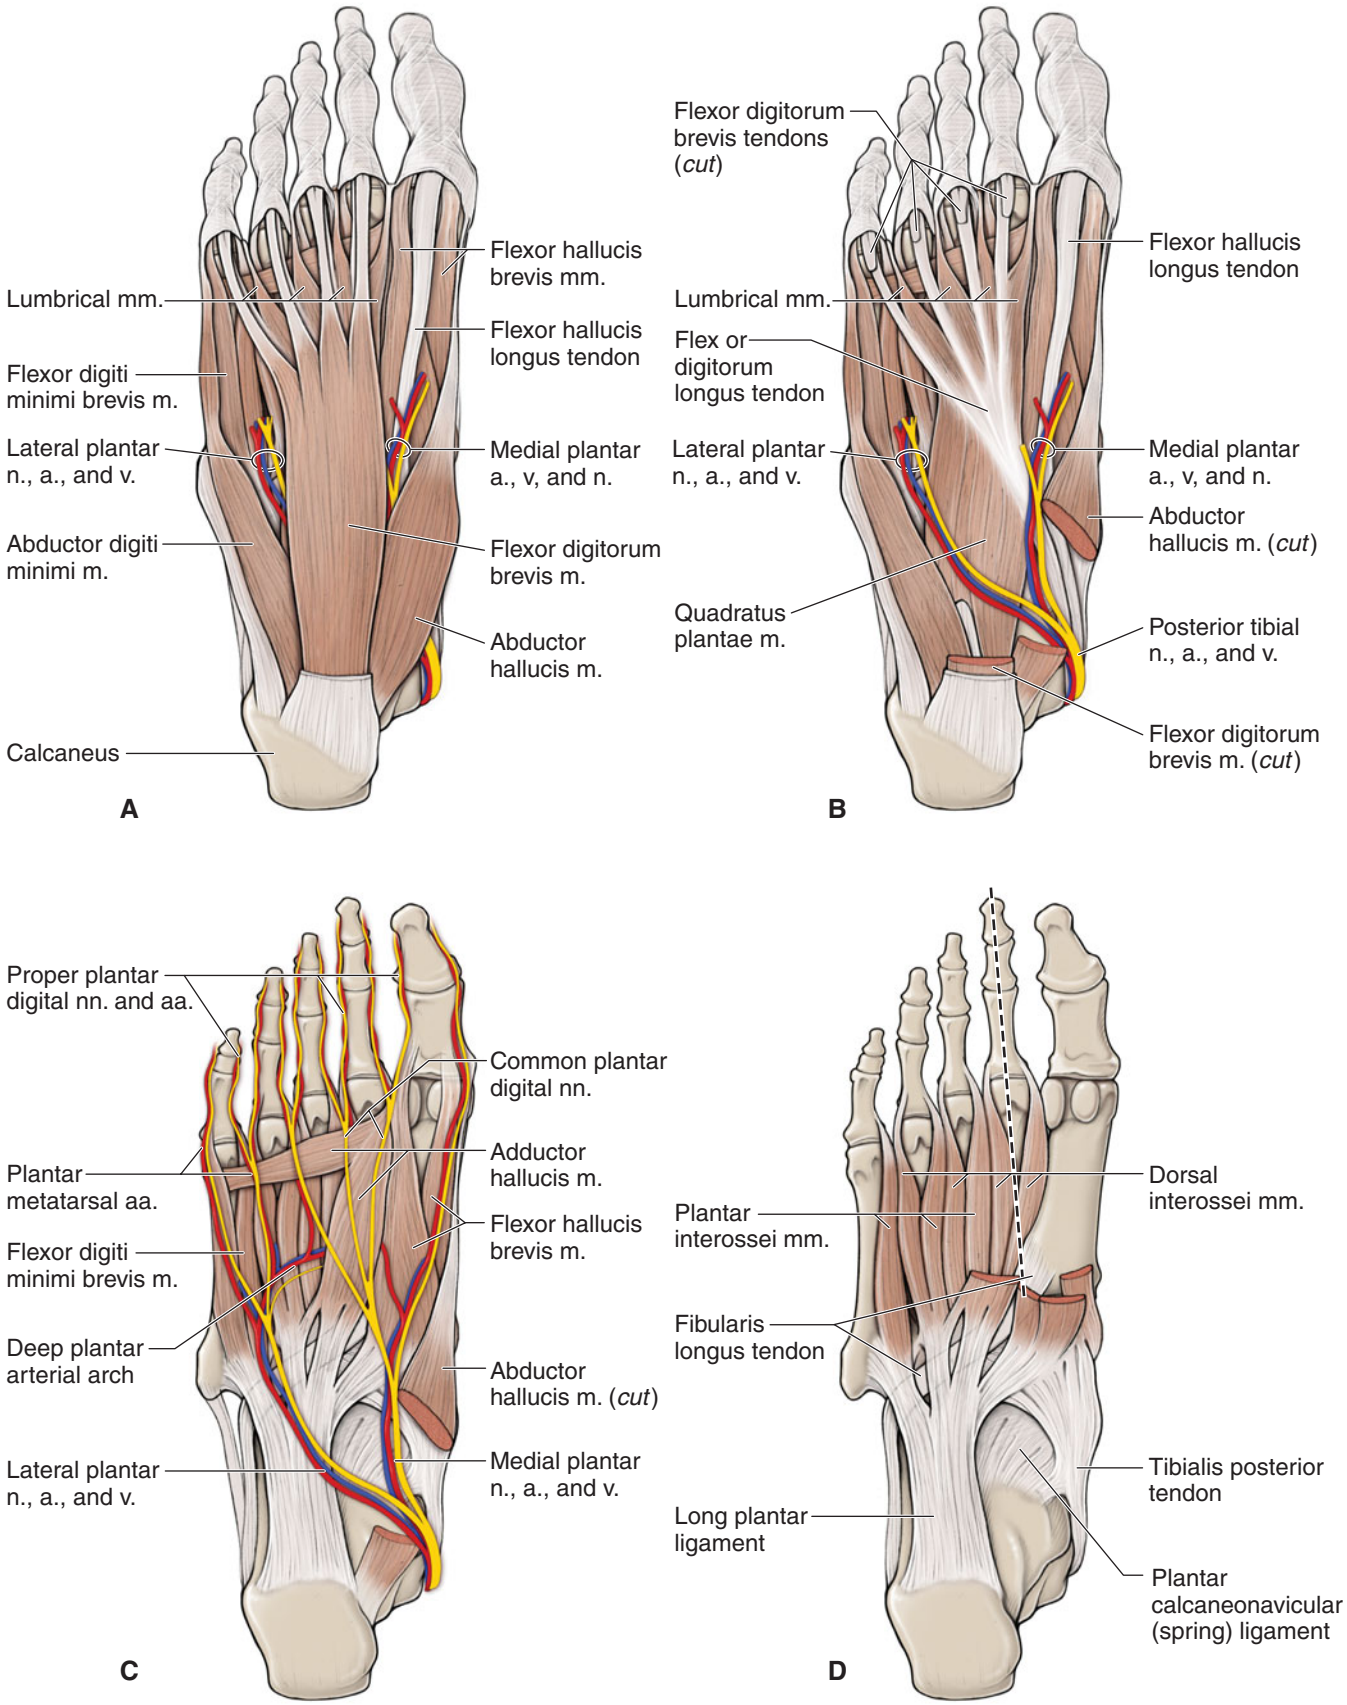

FIGURE 21-8 Intrinsic Muscles of the Foot. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

- The *medial longitudinal arch* plays an important role in foot function during weight-bearing activities. The arch comprises the calcaneus, talus, navicular, three cuneiforms, and the three medial metatarsals (including the two sesamoids). Although some of the integrity of the arch depends on the bony architecture, support is also provided by the ligaments and muscles, including the anterior (plantar) calcaneonavicular (spring) ligament, the plantar fascia, the tibialis posterior, fibularis (peroneus) longus, flexor digitorum longus, FHL, and fibularis (peroneus) longus.[78,82,83] The soleus and gastrocnemius muscle group has also been noted to have an effect on the arch and can flatten it with adaptive shortening.[78] Not only is the arch a major source of frontal plane motion of the foot, but it also is a major load-bearing structure.[84] Analysis of the medial longitudinal arch has long been used by clinicians to make determinations about foot abnormalities, with a high arch indicating a supinated foot and a low or collapsed arch being associated with a pronated or flatfoot, respectively.[85] Studies have found a higher incidence of stress fractures, plantar heel pain, metatarsalgia, and lower extremity injuries, including knee strains and iliotibial band syndrome, in individuals with high arches, compared with those who have low arches.[86–88] This difference has always been attributed to the decreased shock-absorbing ability of the higher-arched foot,[89] although one study reported that arch height does not affect shock absorption.[90]
- The *lateral longitudinal arch*, which is more stable and less mobile than the medial longitudinal arch, consists of the calcaneus, cuboid, and fourth and fifth metatarsals. The superior and deep longitudinal plantar ligament supports the calcaneocuboid and cubometatarsal joints, together with the fibularis (peroneus) brevis, longus, and tertius, and the abductor digiti minimi and FDB muscles.[91]
- The *transverse arch* forms the convexity of the posterior aspect of the foot and consists of metatarsal heads one through five, including the sesamoids (arch I); cuneiforms one through three and the cuboid (arch II); and the navicular and cuboid (arch III). The adductor hallucis, fibularis (peroneus) longus, posterior tibialis, and anterior tibialis all add dynamic support to this arch.

NAIL PLATE

The nail plate is composed of keratinized squamous cells, bordered by proximal and lateral nail folds.[92] The hyponychium lies between the distal portion of the nail bed and the distal nail fold and marks the transition to normal toe epidermis.[92] Fingernail plates grow on average at a rate of 3 mm per month, and toenail plates grow at one-half to one-third that rate.[92]

NEUROLOGY

The saphenous nerve, the largest cutaneous branch of the femoral nerve, provides cutaneous distribution to the medial aspect of the foot. Branches of the sciatic nerve provide the sensory and motor innervation for the foot and leg (see Chap. 3). The branches are the common fibular (peroneal) and tibial nerves. The common fibular (peroneal) nerve, in turn, divides into the superficial fibular (peroneal) and deep fibular (peroneal) nerves (Fig. 21-9). The tibial nerve divides into the sural, medial calcaneal, medial anterior (plantar), and lateral anterior (plantar) nerves.[92]

VASCULAR SUPPLY

Two branches of the popliteal artery, the anterior tibial artery and the posterior tibial artery, form the main blood supply to the foot (Fig. 21-9).

Anterior Tibial Artery

The anterior tibial artery supplies the anterior compartment of the leg and enters the posterior aspect of the foot under the superior and inferior retinacula as the posterior (dorsal) pedis artery. The posterior (dorsal) pedis artery gives rise to the arcuate artery and the first posterior (dorsal) and anterior (plantar) metatarsal artery, which serve the posterior aspect of the foot and the digits.

Posterior Tibial Artery

The posterior tibial artery, which supplies the posterior and lateral compartments and 75% of the blood to the foot, enters the foot after traveling around the medial malleoli. At this point, the artery divides into the medial and lateral anterior (plantar) arteries, which serve the anterior (plantar) aspect of the foot. A main branch of the posterior tibial artery, the fibular (peroneal) artery, supplies the lateral compartment as well as many hindfoot structures.

BIOMECHANICS

Terminology

Motions of the leg, foot, and ankle consist of single- and multiplane movements. The single-plane motions include the following:

- ***The frontal plane motions of inversion and eversion.*** Eversion is a frontal plane motion of the foot about an anteroposterior axis, in which the medial aspect of the sole of the foot moves in an anterior (plantar) direction (Fig. 21-10). Inversion is a frontal plane motion of the foot about an anteroposterior axis, in which the lateral aspect of the sole of the foot moves in an anterior (plantar) direction (Fig. 21-10).
- ***The sagittal plane motions of dorsiflexion and plantar flexion.*** These movements at the ankle and at the midtarsal jointoccur in the sagittal plane about a M-L axis.[93] Plantar flexion is a movement of the foot downward toward the ground, and dorsiflexion is a movement of the foot upward toward the tibia.

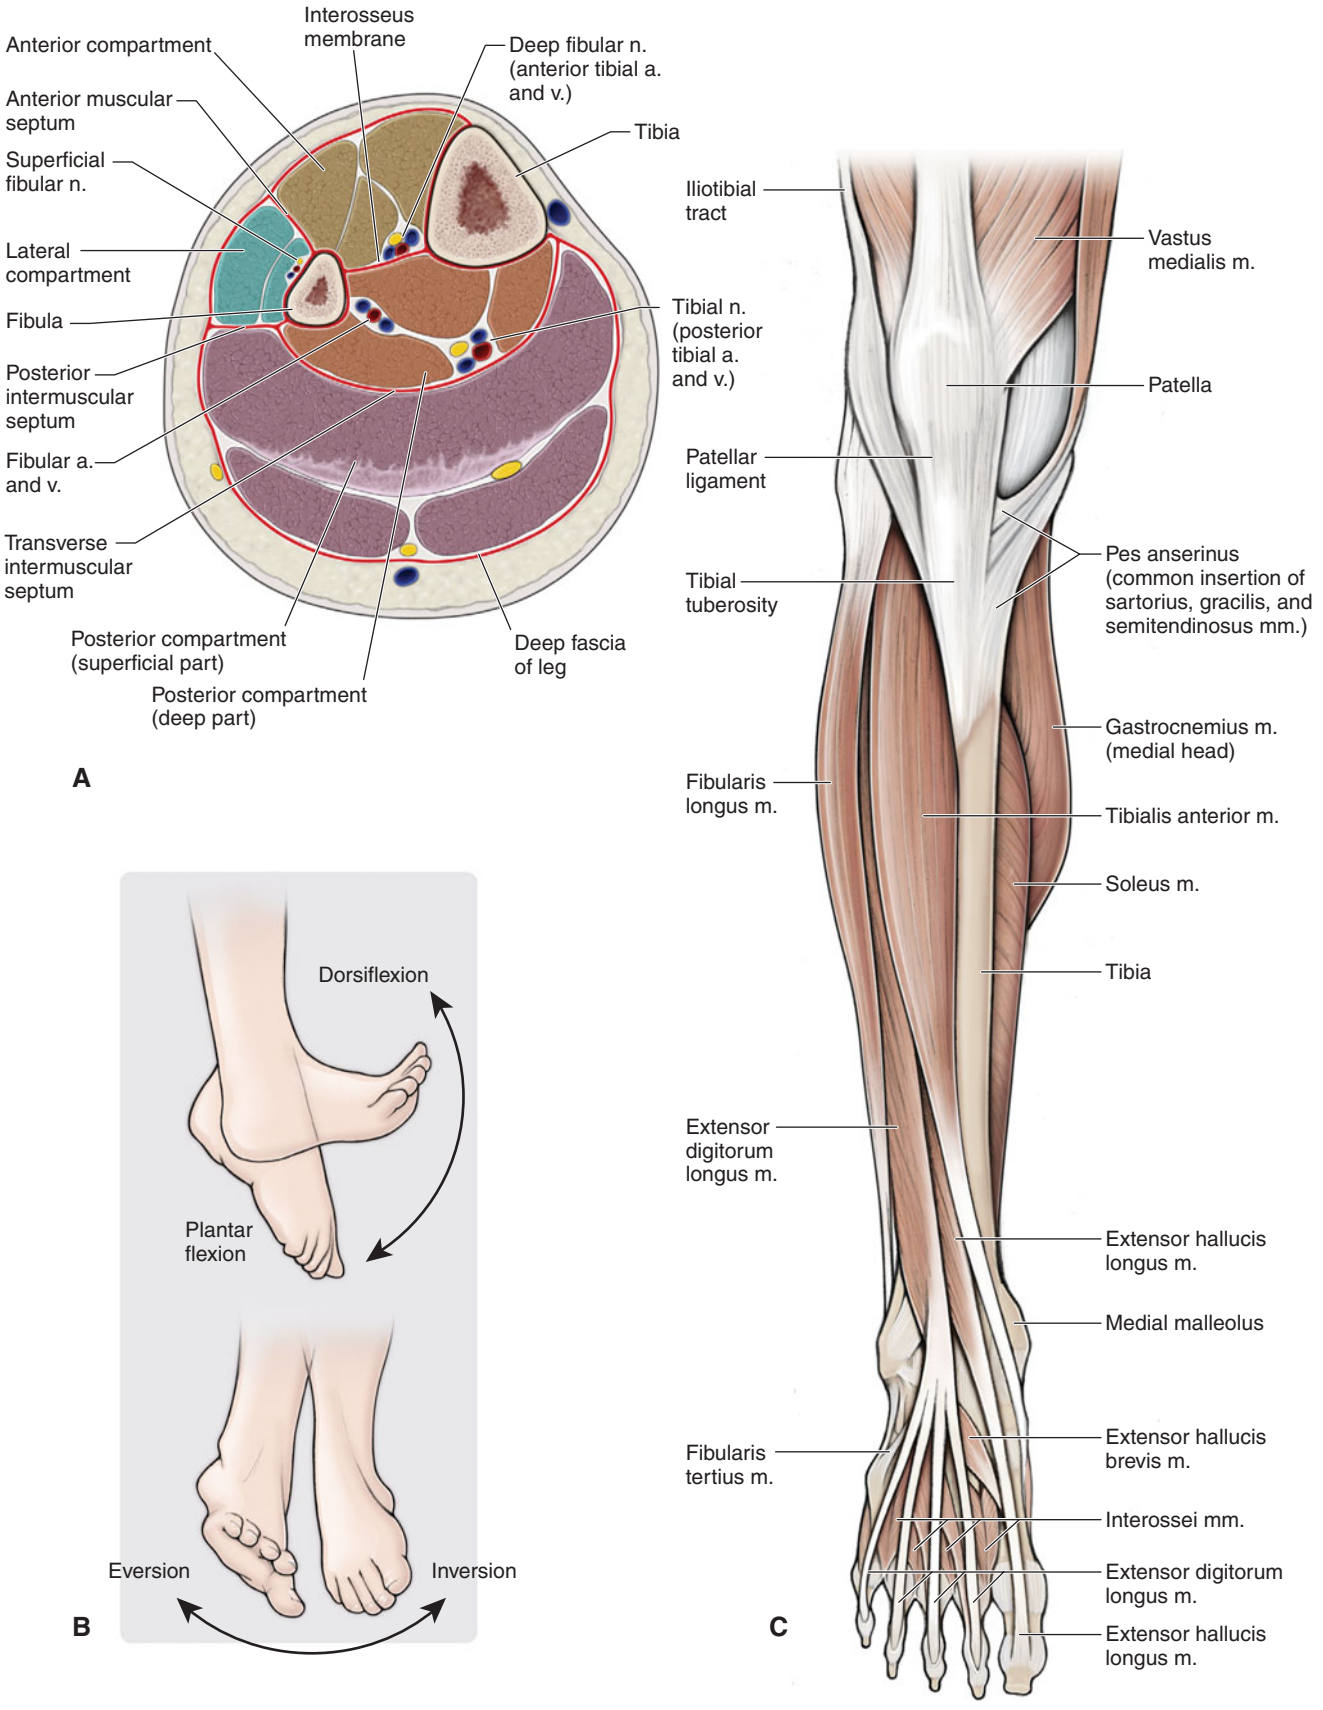

FIGURE 21-10 Ankle motions and related musculature. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

FIGURE 21-11 Pronation in non–weight-bearing.

- ***The horizontal plane motions of adduction and abduction.*** These motions of the forefoot occur in the horizontal plane about a superoinferior axis.[93] Abduction moves the forefoot laterally, whereas adduction moves the forefoot medially.

A triplane motion describes a movement about an obliquely oriented axis through all three body planes. Triplanar motions occur at the talocrural, subtalar, and midtarsal joints and at the first and fifth rays.[94] Pronation and supination are examples of triplanar motions. The three body plane motions in pronation are abduction in the transverse plane, dorsiflexion in the sagittal plane, and eversion in the frontal plane (Fig. 21-11).[94] The three body plane motions in supination are adduction, plantar flexion, and inversion (Fig. 21-12).[94] In pronation, the forefoot is rotated in such a manner so that the big toe moves downward and little toe moves upward, whereas in supination, the reverse occurs.

Distal Tibiofibular Joint

Although the two tibiofibular joints (proximal and distal) are described as individual articulations, they function as a pair. The movements that occur at these joints are primarily a result of the ankle's influence.

FIGURE 21-12 Supination in non–weight-bearing.

- Supination of the foot produces a distal and posterior glide of the head of the fibula.
- Pronation produces a proximal and anterior glide with an external rotation of the fibula.
- Plantar flexion of the foot produces a distal glide with a slight medial rotation of the fibula.
- Dorsiflexion of the ankle yields a proximal glide. The fibula rotates externally around its longitudinal axis.

During these movements, however, it is the tibia that performs the greatest amount of movement, as it rotates around the fibula. This is probably a consequence of more body weight falling through the larger bone. During ipsilateral rotation, both the tibia and the fibula rotate laterally, but in relative terms, the tibia moves more laterally than the fibula, causing a relative anterior and superior glide of the fibular head on the tibia at the superior joint. During contralateral rotation, the tibia rotates more medially, producing a relative posterior and inferior fibular glide at the joint.

The ligaments of the distal tibiofibular joint are more commonly injured than the ATFL.[95] Injuries to the ankle syndesmosis most often occur as a result of forced external rotation of the foot or during internal rotation of the tibia on a planted foot.[17] Hyperdorsiflexion may also be a contributing mechanism.[96]

The capsular pattern of this joint is probably pain with weight-bearing dorsiflexion of the ankle, as this produces the greatest ligamentous tension (Table 21-1). For the same reason, the close-packed position is considered as weight-bearing dorsiflexion of the ankle.

CLINICAL PEARL

Because of the interaction between the proximal and distal tibiofibular joints with the knee and the ankle function, the clinician should always assess the functional mobility of both these complexes when treating one or the other.

Talocrural Joint

The talocrural joint is classified as a synovial hinge or modified sellar joint. There is general agreement that motion between the tibia and the foot is a complex combination of talocrural and subtalar joint motion, which is limited by the shape of the articulations and soft tissue interaction.[22] Stability for this joint in weight-bearing is provided by the articular surfaces, while in non–weight-bearing, the ligaments appear to provide the majority of stability.[24]

The primary motions at this joint are dorsiflexion and plantar flexion (Fig. 21-10), with a total range of 70–80 degrees. The maximum amount of dorsiflexion necessary at the talocrural joint during human gait is approximately 10 degrees of the normally available 20 degrees,[94,97,98] and occurs during the stance phase, just prior to heel rise.[99] The orientation of the talocrural joint axis, which is oriented on average 20–30 degrees posterior to the frontal plane as it passes posteriorly from the medial malleolus to the lateral malleolus,[23,83,100] can be estimated clinically as a line that

passes inferiorly from the medial malleolus to the lateral malleolus (with a mean orientation of 10 degrees to the horizontal plane), with the adult distal leg being oriented vertically.[83,100,101] Although the majority of talocrural motion occurs in the sagittal plane, an significant amount of horizontal motion occurs in the horizontal plane, especially during internal rotation of the tibia or pronation of the foot.[83,100]

Because of the fit of the saddle-shaped talus within the mortise, the talus is able to produce a slight separation of the tibial and fibula malleoli during the extremes of dorsiflexion and plantar flexion.[102] In addition, because of this fit, the tibia follows the talus during weight-bearing so that the talocrural joint externally rotates with supination and internally rotates with pronation.[103] Conversely, the tibia internally rotates during pronation and externally rotates during supination.[104]

Theoretically, the capsular pattern of the ankle joint is more restriction of plantar flexion than dorsiflexion, although clinically this appears to be reversed (Table 21-1). The close-packed position is weight-bearing dorsiflexion, whereas the open-packed position is midway between supination and pronation.

Subtalar Joint

The subtalar (talocalcaneal) joint functions to provide inversion and eversion of the hindfoot—approximately 50% of apparent ankle inversion observed actually comes from the subtalar joint.[105] The axis of motion for the subtalar joint, which is approximately 45 degrees from horizontal and 20 degrees medial to the midsagittal plane,[21,36,83] moves during subtalar joint motion,[106–108] which allows the subtalar joint to produce a triplanar motions of pronation/supination. This motion has been compared with a ship on the sea or an oblique mitered hinge.[109] The various components of the triplanar motion at this joint vary according to whether the joint is weight-bearing or non–weight-bearing.[110]

- During weight-bearing (close chain) activities, pronation involves a combination of calcaneal eversion, adduction, and plantar flexion of the talus and internal rotation of the tibia, whereas supination involves a combination of calcaneal inversion, abduction and dorsiflexion of the talus and external rotation of the tibia.[111]
- During non–weight-bearing (open chain) activities, pronation involves a combination of calcaneal eversion and abduction and dorsiflexion of the talus (see Fig. 21-11), whereas supination involves a combination of calcaneal inversion and adduction and plantar flexion of the talus (see Fig. 21-12).[111]

The subtalar joint controls supination and pronation in close conjunction with the transverse tarsal joints of the midfoot. Subtalar joint supination and pronation are measured clinically by the amount of calcaneal or hindfoot inversion and eversion. In normal individuals, there is an inversion to eversion ratio of 2:3 to 1:3, which amounts to an average of approximately 20 degrees of inversion and 10 degrees of eversion.[20,83,94,109] For normal gait, a minimum of 4–6 degrees of eversion and 8–12 degrees of inversion are required.[108]

During normal gait, the foot needs to pronate and supinate 6–8 degrees from the neutral position.[112] If the foot pronates excessively, a compensatory internal rotation of the tibia may occur. This produces an increased amount of rotatory stress and dynamic abduction moment at the knee, which has to be absorbed through the peripatellar soft tissues at the knee joint.[113–116] These stresses can force the patella to displace laterally and may result in patellofemoral dysfunction.[3,117] In addition, a change in the position of the talus can affect the functional leg length. Subtalar supination may cause the leg to lengthen, while subtalar pronation shortens the leg. Thus, the mid-position of the subtalar joint, subtalar joint neutral, is considered the range at which the subtalar joint should act to prevent dysfunction. The subtalar joint neutral position is actually a measurement of the angle between a line that bisects the distal third of the lower leg and a line that bisects the calcaneus.[118] The bisection of the calcaneus represents the position of the anterior (plantar) condyles, because the calcaneus is almost perpendicular to the condyles. The angle between the bisections should be 0 degree in the normal foot but is actually 2–3 degrees of varus (inverted in most subjects).[119]

CLINICAL PEARL

Mathematically, the subtalar joint neutral position is that angle at which the ratio of calcaneal inversion to eversion is approximately 2:1.[94]

Stability for the subtalar joint is provided by the CFL, the cervical ligament, the interosseous ligament, the lateral talocalcaneal ligament, the fibulotalocalcaneal ligament (ligament of Rouviere), and the extensor retinaculum.[120]

The capsular pattern of this joint varies. In chronic arthritic conditions, there is an increasing limitation of inversion, but with traumatic arthritis, eversion appears most limited clinically. The close-packed position for this joint is full inversion, whereas the open-packed position is inversion/plantar flexion (Table 21-1).

Midtarsal (Transverse Tarsal) Joint Complex

The function of the midtarsal joint complex is to provide the foot with an additional mechanism for raising and lowering the arch and to absorb some of the horizontal plane tibial motion that is transmitted to the foot during stance.[103,121] Motions around the two axes at the midtarsal joint involve[80]

- a rotational motion about a longitudinal axis into inversion and eversion, which can be observed in the elevation and depression of the medial arch of the foot during the stance phase of gait,[20,21]
- an oblique axis, producing the near sagittal motions of forefoot dorsiflexion and abduction, and forefoot plantar flexion and adduction.[20]

Both axes are dependent on the position of the subtalar joint.[20,108,121] When the subtalar joint is pronated, the two sets of axes are parallel to one another, allowing for the maximum amount of motion at the midtarsal joint. When

the subtalar joint is supinated, the two sets of axes are in opposition, allowing little motion to occur, thereby enhancing stability.

During gait, the midtarsal joint has following two functions[80]:

- To permit adaptation of the foot to uneven terrain in the early stance
- To provide a stable foot during terminal stance

Theoretically, as a modified ovoid, the joint complex can sublux into dorsiflexion/plantar flexion, abduction/adduction, with or without rotation. In practice, the most commonly found subluxations may be considered as inversion/dorsiflexion or eversion/plantar flexion lesions.[46] The capsular pattern of the midtarsal joint complex is a limitation of dorsiflexion, plantar flexion, adduction, and internal rotation (Table 21-1). The close-packed position for the midtarsal joint is supination (Table 21-1). The open-packed position is midway between the extremes of ROM.

Cuneonavicular Joint

The cuneonavicular joint has one to two degrees of freedom: plantar/dorsiflexion, inversion/eversion. The capsular pattern of this joint is a limitation of dorsiflexion, plantar flexion, adduction, and internal rotation. The close-packed position is supination. The open-packed position is considered to be midway between the extremes of ROM (Table 21-1).

Intercuneiform and Cuneocuboid Joints

Due to their very plane curvature, these joints have only one degree of freedom: inversion/eversion. The close-packed position for these joints is supination. The open-packed position is considered to be midway between extremes of ROM (Table 21-1).

Cubometatarsal Joint

The capsular pattern of this joint is a limitation of dorsiflexion, plantar flexion, adduction, and internal rotation. The close-packed position is pronation. The open-packed position is considered to be midway between extremes of ROM (Table 21-1).

Cubonavicular Joint

The close-packed position for this joint is supination. The open-packed position is midway between extremes of ROM (Table 21-1).

Intermetatarsal Joints

The close-packed position for these joints is supination. The open-packed position is midway between extremes of ROM (Table 21-1).

MTP Joints

The MTP joints have two degrees of freedom: flexion/extension and abduction/adduction. ROM of these joints is variable, ranging from 40 to 100 degrees dorsiflexion (with a mean of 84 degrees), 3–43 degrees (mean, 23 degrees) plantar flexion, and 5–20 degrees varus and valgus.[122] The closed-packed position for the MTP joints is full extension. The capsular pattern for these joints is variable, with more limitation of extension than flexion. The open-packed position is 10 degrees of extension.

First MTP Joint

The function of the great toe is to provide for normal propulsion during gait and to provide stability to the medial aspect of the foot. Normal alignment of the first MTP joint varies between 5 degrees varus and 15 degrees valgus.[123] The most important motion at the first MTP is dorsiflexion. During normal gait, the first MTP joint dorsiflexes approximately 60 degrees. During sprinting (running sports), squatting (football and baseball), and relevé (in dance), greater than 90 degrees of dorsiflexion is necessary.

The first MTP is characterized by having a remarkable discrepancy between active and passive motion.The first ray of the foot consists of the first metatarsal and the first (medial) cuneiform bone. These two bones act as a functional unit, playing an important role in providing structural integrity to the foot during weight-bearing activities.[83] Three extrinsic muscles of the foot insert at the base of the first ray: the anterior tibialis, posterior tibialis, and fibularis (peroneus) longus. The need for clinical assessment of the posterior (dorsal) mobility of the first ray is based on its functional role during weight-bearing activities. Any disruption to its normal motion (hypo- or hypermobility) reduces the ability of the first ray to adequately stabilize the medial column of the foot and the longitudinal arch, increasing the potential for injury to the head of the first metacarpal.[124]

IP Joints

Each of the IP joints has one degree of freedom: flexion/extension. The capsular pattern is more limitation of flexion than of extension. The close-packed position is full extension (Table 21-1). The open-packed position is slight flexion.

EXAMINATION

The examination is used to identify static and dynamic, and structural or mechanical foot abnormalities. The clinical diagnosis is based on an assessment of the changes in joint mobility and tissue changes at the foot and ankle and the effect these have on the function of the foot and ankle and the remainder of the lower kinetic chain.

The exact form of the examination is very much dependent on the acuteness of the condition. For example, weight-bearing tests cannot be done if the patient cannot bear weight, and most stress tests will prove impossible if the joints cannot be taken to their full range. In these cases, the clinician must rely heavily on the history.

CLINICAL PEARL

With an acute lesion, the purpose of the examination is to try to determine if a serious injury might have occurred, and whether there is a need to refer the patient back for further medical examination or treatment. Due to the acute pain and inflammatory state of the tissues in the acute stage, the physical examination may need to be modified and sometimes curtailed.

HISTORY

The primary purposes of the history are to do the following:

- Determine the patient's chief complaint.
- Determine the mechanism of injury, if any. Information about the mechanism of injury should include when, where, how, and if an injury occurred. Details about the mechanism of injury allow the clinician to infer the pathologic status and structures involved, although it must be remembered that the patient's recollection of the mechanism involved frequently does not necessarily correspond to the structures damaged.[16,125] Most ankle sprains occur when the foot is plantar flexed, inverted, and adducted (Table 21-6). This same mechanism can also lead to a malleolar or talar dome fracture. A history involving sudden changes in training patterns may indicate an overuse injury. A dorsiflexion injury with associated snapping and pain on the lateral aspect of the ankle that rapidly diminishes may indicate a tear of the fibular (peroneal) retinaculum.[126] If there is no traumatic event, the clinician must determine if there has been a change in exercise or activity intensity (e.g., increased mileage with runners), training surface, or changes in body weight or shoe wear (causal agents).[16,125] In addition, the clinician must determine whether the symptoms vary with activity, type of terrain, or changes in position. Complaints of cramping may accompany muscular fatigue or intermittent claudication from arterial insufficiency. Plantar heel pain associated with plantar fasciitis is typically associated with an insidious onset. Achilles tendinitis is an overuse injury associated with an insidious onset of posterior calcaneal pain. Increased symptoms when walking or running on uneven terrain as compared with an even terrain may suggest ankle instability. Increased symptoms when walking or running on hard surfaces as compared with a softer surface may suggest a lack of shock absorbency of the foot or shoe. Pain that is related to a certain time of day may indicate an activity-related problem or a condition such as plantar heel pain if the pain is felt when first bearing weight in the morning.
- Determine the patient's occupation, if any. The impact of the injury on the patient's personal life, work, and athletic demands will largely direct the early intervention.[16,125]
  - If painless ambulation is essential, then rigid immobilization (i.e., a cast) may be appropriate.
  - If rapid return to sports competition is of paramount importance, functional immobilization is preferred.

TABLE 21-6 Examination Sequence in the Presence of a History of Inversion Trauma of the Foot and Ankle

History of Inversion Trauma
Possible pathology/structure involved
Ligamentous
Lesion of the anterior talofibular/calcaneofibular ligament
Lesion of the bifurcate ligament
Lesion of the cuboid-fifth metatarsal ligament
Lesion of the anterior tibiotalar and tibionavicular ligaments
Lesion of the tibiofibular interosseous ligament
Articular
Traumatic arthritis of the talocrural joint (TCJ)
Traumatic arthritis of the subtalar joint (STJ)
Traumatic arthritis of the transverse tarsal joints (TTJ)
Posterior tibiotalar compression syndrome
Sinus tarsi syndrome
Tibio fibular syndesmosis instability
Muscular
Tenosynovitis of the fibularis muscles
Tendinitis of the fibularis muscles
Rupture of the superior extensor retinaculum
Achillodynia
Tenosynovitis or tendinitis of the EHL
Tenosynovitis or tendinitis of the EDL
Neurologic
Overstretching of common fibular nerve/superficial fibular/deep fibular nerve
Osseous
Avulsion fracture of the base of the fifth metatarsal
Fracture of the shaft of the fifth metatarsal
Avulsion fracture at the lateral calcaneus
Avulsion fracture at the cuboid
Fracture of the anterior calcaneal process
Osteochondral fracture of the talus
Fracture of the lateral tubercle of the talus
Navicular fracture
Talar neck fracture
Talar head fracture

Data from Winkel D, Matthijs O, Phelps V: Appendix F. In: Winkel D, Matthijs O, Phelps V, eds. *Diagnosis and Treatment of the Lower Extremities*. 1997, Gaithersburg, MD: Aspen, 1997:645–646.

- Determine the location and severity of the condition. Most often, the patient can point to the location of the pain. The site and severity of the pain can be measured using a body diagram and visual analog scale, respectively. The distribution of pain is important, and the clinician should determine whether the pattern is referred, associated with a structure, related to a dermatome or peripheral nerve, or systemic in nature.[127] A stress fracture or tendinitis typically has a localized site of pain, whereas diffuse pain is associated with compartment syndromes.

- Determine which activities and positions aggravate the symptoms. Information should be gleaned about whether activities aggravate the symptoms and if so, which. For example, pain with forced dorsiflexion and eversion and with squatting activities may suggest ankle instability. Pain after activity suggests an overuse or chronic injury. Pain during an activity suggests stress on the injured structure.
- Ascertain the area, nature, and behavior of the symptoms.[128] Information about the time of injury, the time of the onset of swelling, and its location are important. The patient may report hearing a "snap," "crack," or "pop" at the time of injury, which could indicate a ligamentous injury or a fracture. The patient may report that their ankle felt weak and/or unstable at the time of the initial trauma or sometime thereafter. An inability to bear weight or the presence of severe pain and rapid swelling indicates a serious injury such as a capsular tear, fracture, or grade III ligament sprain.[129–132]
- Help determine the specific structure at fault.[133]
- Detect systemic conditions (e.g., collagen disease, neuropathy, radiculopathy, and vascular problems) or the presence of serious pathology.

In addition, questions regarding previous ankle injury, goals of the patient regarding functional goals, level and intensity of sports involvement, and past medical history are important to help the clinician individualize the intervention to the patient.

SYSTEMS REVIEW

As symptoms can be referred distally to the leg, foot, and ankle from a host of other joints and conditions, the clinician must be able to differentially diagnose from the presenting signs and symptoms (see Chap. 5). The cause of the referred symptoms may be neurologic or systemic in origin. If a disorder involving a specific nerve root (L4, L5, S1, or S2) is suspected, the necessary sensory, motor, and reflex testing should be performed. Peripheral nerve injuries may also occur in this region and often go unrecognized. These include Morton's neuroma and entrapment of the tibial nerve or its branches, the deep fibular (peroneal) nerve, superficial fibular (peroneal) nerve, and sural and saphenous nerves.[134]

Systemic problems that may involve the leg, foot, and ankle include diabetes mellitus (peripheral neuropathy), osteomyelitis, gout and pseudogout, sickle cell disease, complex regional pain syndrome, peripheral vascular disease, and rheumatoid arthritis (refer to Chap. 5). A systemic problem such as rheumatoid arthritis may be associated with other signs and symptoms, including other joint pain, although the other joint pain may also be the result of overcompensation in the rest of the kinetic chain.

Warning signs at the ankle and foot that should alert the clinician to a more insidious condition include:

- immediate and continuous inability to bear weight, which may indicate a fracture;
- nocturnal pain, which may indicate a malignancy, hemarthrosis, fracture, or infection;
- gross pain during ankle valgus and tenderness with pressure on the distal fibula, which may indicate a fractured fibula;
- pain and weakness during resisted eversion, which may indicate fracture of the fifth metatarsal bases;
- calf pain and/or tenderness, swelling with pitting edema, increased skin temperature, superficial venous dilatation, or cyanosis, which may indicate the presence of a deep vein thrombosis (DVT), requiring immediate medical attention (see Chap. 5);
- feelings of warmth or coldness in the foot. An abnormally warm foot can indicate local inflammation but can also originate from a tumor in the pelvic or lumbar region.[135] An abnormally cold foot usually indicates a vascular problem.[135]

TESTS AND MEASURES

Observation

Observation of the lower extremity is extensive. It is extremely important to observe the entire kinetic chain when assessing the leg, foot, and ankle. Weight-bearing and non–weight-bearing postures of the foot are compared.

Observing the patient while they move from sitting to standing and walk to the treatment area gives the clinician a sense of the patient's functional ability in weight-bearing and provides the first opportunity for gait analysis.[101] An important part of the examination of the foot and ankle is the gait assessment (see Chap. 6). During gait, the transverse and longitudinal arches can be grossly assessed—the lateral longitudinal arch bears the body weight in the early stance, whereas the medial longitudinal arch provides support in the mid- and late-stance phase of gait.[136] The foot should touch the ground, the heel first and the heel should begin to rise at approximately 35% of the gait cycle.[136] Early heel rise may occur due to tightness of the gastrocnemius–soleus complex, whereas late heel rise may be secondary to weakness of the calf musculature.[136] Normally, the foot pronates during the early stance phase, but the foot should not remain pronated during heel rise and toe off.[136]

CLINICAL PEARL

Patients with an ankle injury usually avoid the normal heel-to-toe progression to decrease weight-bearing and painful ankle dorsiflexion.[137] Instead, the patient is likely to adopt a toe-to-heel progression, with varying amounts of hip circumduction and external rotation of the lower leg, or steppage gait, to further unload the ankle.[138]

The following are assessed with the patient standing:

- ***Shoulder and pelvic heights (see Chaps. 16 and 29).***
- ***Spinal curvature (see Chap. 27).***
- ***Pelvic rotation (see Chap. 29).***

- ***The degree of hip rotation.*** In the femur, anteversion and retroversion angles should be noted (refer to Chap. 19). Excessive internal rotation of the hip toward the opposite hip (anteversion) may result in a flattening of the medial longitudinal arch and toeing-in/internal torsion of the tibia (pigeon toes). Excessive external rotation of the hip away from the opposite hip (retroversion) may result in an elevation of the medial longitudinal arch.
- ***The degree of knee flexion or hyperextension.*** A genu recurvatum (hyperextension) places the talocrural joint in more plantar flexion than normal and can often be a compensatory mechanism in the longer limb of individuals who have a leg-length inequality; see Chap. 29.[139] An increase in knee flexion accomplishes the same compensation for a leg-length inequality.[139]
- ***The degree of varus and valgus of the knee and tibia.*** Excessive tibia varum, genu varus, or forefoot varus can increase the frontal angle of the talocrural joint, which promotes excessive weight-bearing on the lateral aspect of the foot unless compensatory pronation is available within the foot to bring the medial aspect of the foot to the support surface.[139] Tibia varum refers to the frontal plane position of the distal one-third of the leg, as it relates to the supporting surface.[107]
- ***Rotational components of the tibia.*** Tibial torsion is assessed with the patient in sitting, with their feet hanging over the end of the bed so that their knees are in approximately 90 degrees of flexion.[101] The thumb of one hand is placed over the apex of one malleolus, and the index finger of the same hand is placed over the apex of the other malleolus. A qualitative estimate of the direction and magnitude of tibial torsion can be made by envisioning a line that passes through the malleoli and estimating its orientation to the frontal plane of the proximal tibia.[139] Alternatively, tibial torsion can be measured with the patient in prone with the knee flexed to 90 degrees and the subtalar joint positioned and stabilized in subtalar neutral.*

CLINICAL PEARL

The neutral subtalar position is calculated based on a normal 2:1 ratio of inversion to eversion. To locate subtalar neutral, the patient is positioned in prone with the opposite hip flexed, abducted, and externally rotated. If evaluating the right ankle, the clinician uses the thumb and forefinger of the left hand to palpate the hollows over the neck of the talus on either side of the anterior portion of the ankle. Using the thumb and forefinger of the other hand, the clinician grasps the head of the fourth and fifth metatarsals and rocks the foot back and forth. As the foot is inverted, a bulge can be felt on the lateral aspect of the foot. With eversion, the bulge can be felt to bulge medially. The point at which the talar head is felt to bulge equally on the medial and lateral sides is the subtalar neutral position.

*The subtalar neutral position refers to the position in which all bones of the subtalar joints and the talocrural joints line up optimally in their open-packed positions—a position of neither pronation nor supination.

Once the subtalar neutral position has been established, a line is drawn on the sole of the foot parallel to the length of the femur. A second line is drawn in line with the foot. The angle between these lines is the tibial torsion angle.[64] There is normally an angle of 12–18 degrees to the frontal plane.[140] Tibial torsion is generally less in children. A position of relative internal rotation of the tibia produces an increase in rigidity to the subtalar joint prior to midstance, due to premature stabilization of the longitudinal arch of the foot.[141] Excessive external rotation of the tibia places an increased strain along the longitudinal arch, as well as the first MTP joint.[141]

- ***Rearfoot to leg orientation.*** This can be an indicator of weight-bearing subtalar position. It is assessed by measuring the acute angle formed between a line representing the posterior aspect of the distal third of the leg, and a line approximately 1-cm distal to the first mark, representing the midline of the posterior aspect of the calcaneus (see Fig. 21-13).[139] The angle is assessed as the patient shifts weight on the lower extremity to simulate single-limb support. If the lines are parallel or in slight varus (2–8 degrees), the leg–rearfoot orientation is considered normal.[142] Movement of the rearfoot into eversion (rearfoot valgus) during this maneuver is indicative of subtalar pronation.[94] Pronation of the foot is manifested by eversion of the heel, abduction of the forefoot, a decrease in the medial longitudinal arch, internal rotation of the leg in relation to the foot, and dorsiflexion of the subtalar and midtarsal joints. If the heel is in too much valgus, the forefoot is excessively abducted, or there is excessive external rotation of the tibia, more toes can be seen on the affected side than the normal side when viewing the leg from behind ("too-many-toes sign").[42] If the patient is asked to raise up on the toes, the calcaneus should be observed to move into a position of inversion. An inability of the calcaneus to invert with this maneuver could

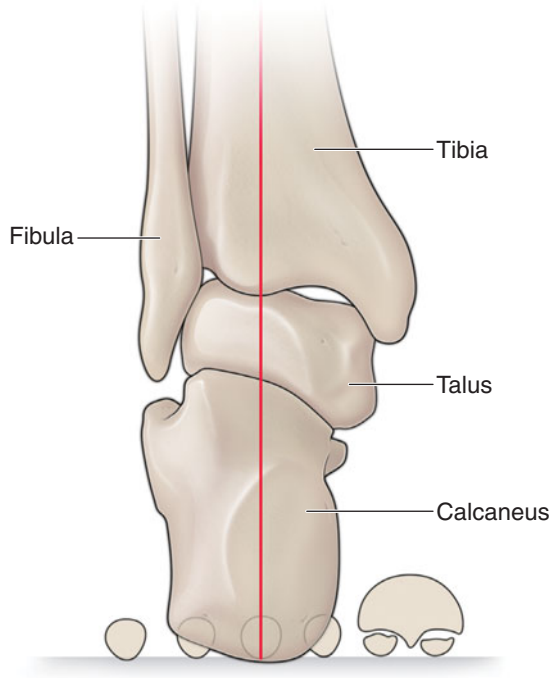

FIGURE 21-13 Rearfoot to leg orientation.

indicate the presence of an abnormality within the subtalar joint mechanism or a weakness of the posterior tibialis.[42,141]

- ***The weight-bearing foot.*** The following are major components of the normal weight-bearing foot:[119,143]
  - Both planar condyles of the calcaneus are on the floor surface. An imaginary plane representing the ground surface is applied to the anterior (plantar) surface of the calcaneus. The metatarsal heads should rest upon this plane. If the plane of the metatarsal heads is perpendicular to the bisection of the calcaneus, the forefoot-to-rearfoot relationship is normal, or neutral.
  - The "normal" foot should demonstrate 6–8 degrees of calcaneal eversion during gait. The foot should pronate initially, just after initial contact (see Chap. 6).
  - All of the metatarsal heads lie in one plane, which is in the same plane as the anterior (plantar) condyles of the calcaneus[94]
  - The ball of the foot is level with the plantar surface of the heel.
  - A normal forefoot-to-rearfoot relationship (see later).
  - The orientation of the distal third of the lower leg should be vertical, to position the foot properly for the stance phase.
  - The midtarsal joint is maximally pronated, while the subtalar joint, MTP, and IP joints are in neutral.
  - The presence of a well-formed static medial arch should be noted, as well as its dynamic formation with heel raising.
- ***Forefoot-to-rearfoot relationship.*** Goniometric measurement of forefoot position relative to the rearfoot is a routine procedure used by rehabilitation specialists. This measurement is also frequently made by visual estimation. Neutral alignment of the forefoot relative to the rearfoot is present when a line representing the anterior (plantar) aspect of the metatarsal heads is perpendicular to the line bisecting the rearfoot. The forefoot-to-rearfoot angle is approximately 10–12 degrees.[119,143] Forefoot varus is the term used to describe inversion of the forefoot away from this neutral position, while forefoot valgus describes an everted forefoot position.[139] The relationship can be assessed with the patient positioned in prone with their knee extended and their feet over the end of the table. The subtalar neutral position is located using the method described previously. Slight pressure is applied to the metatarsal heads while maintaining subtalar neutral. This will determine the relationship of the forefoot to rearfoot, and both of these to the bisection of the lower leg. A varus or valgus tilt of the forefoot in relation to the hindfoot becomes significant when the first metatarsal is in a plantar flexed position, as this positions the hindfoot into an inverted position during weight-bearing.[141] Somers et al. examined the reliability of goniometric and visual estimation of forefoot position measurements when experienced and inexperienced testers performed the evaluation. Two clinicians ($\geq$ 10 years' experience) and two physical therapy students were recruited as testers. Ten subjects (20–31 years old), free from pathology, were measured. Each foot was evaluated twice with the goniometer and twice with visual estimation by each tester. Intraclass correlation coefficient (ICC) and coefficients of variation method error were used as estimates of reliability. There was no dramatic difference in the intratester or intertester reliability between experienced and inexperienced testers, regardless of the evaluation used. Estimates of intratester reliability (ICC 2,1), when using the goniometer, ranged from 0.08 to 0.78 for the experienced clinicians and from 0.16 to 0.65 for the inexperienced clinicians. When using visual estimation, ICC (2,1) values ranged from 0.51 to 0.76 for the experienced clinicians and 0.53 to 0.57 for the inexperienced clinicians. The estimate of intertester reliability [ICC (2,2)] for the goniometer was 0.38 for the experienced clinicians and 0.42 for the inexperienced clinicians. When using visual estimation, ICC (2,2) values were 0.81 for the experienced clinicians and 0.72 for the inexperienced clinicians. Although experience does not appear to influence forefoot position measurements, of the two evaluation techniques, visual estimation may be the more reliable.
- ***Foot deviations in weight-bearing.*** These include pes planus (low inclined subtalar joint axis), pes cavus (high inclined subtalar joint axis), talipes equinus (plantar flexed foot), talipes equinovarus (supinated foot), and hallux valgus.[101]
- ***Degree of foot pronation or supination in non–weight-bearing.*** The patient lies in the prone position, with the foot over the edge of the table. The clinician holds the foot over the fourth and fifth metatarsal heads with one hand. Both sides of the talus are palpated on the posterior aspect of the foot using the thumb and index finger of the other hand. The clinician then passively dorsiflexes the foot until a resistance is felt. At this point, and while maintaining the dorsiflexed position, the clinician moves the foot back and forth through the arc of supination and pronation. During supination, the talus should be felt to bulge laterally, while during pronation, the talus should be felt to bulge medially. Supination at the subtalar joint occurs in association with 20 degrees of calcaneal inversion, while pronation occurs in association with 10 degrees of calcaneal inversion.
- ***Degree of toe-out.*** The normal foot in relaxed standing adopts a slight toe-out position of approximately 12–18 degrees from the sagittal axis of the body (Fick angle).[134]
- ***Forefoot equinus.*** To assess for forefoot equinus, the clinician stabilizes the rearfoot with one hand and applies pressure on the entire forefoot via pressure across the metatarsal heads, into dorsiflexion. If the plantar declination of the lateral structures cannot be reduced so that the plantar flexed attitude is no longer visible, a positive identification of forefoot equinus can be made.[143]
- ***Presence of a talar bulge.*** The patient is positioned in standing, and the clinician observes to see whether the talar head bulges excessively on the medial side of the midfoot, indicating excessive subtalar joint pronation in weight-bearing. Adaptive shortening of the gastrocnemius/soleus group is indicated with a prominence of the soleus, particularly on the medial side of the teno-calcaneum.

Other areas that should be examined include the following:

- ***Condition of the nails.*** When examining the nails a systematic approach is used, involving an inspection of the shape, contour, and color of the nails. The clinician should observe for the presence of subungual hematomas, subungual exostosis, onychocryptosis, onychia, onychauxis, onychomycosis, paronychia, tinea pedis, or blisters.
- ***Toe deformities.*** Contractions of the capsule of the IP or MTP joints of the toes in association with tendon shortening may produce a series of deformities, ranging from hammer toe to mallet toe to claw toe. *Hammer toe* usually involves a flexion contracture of the anterior (plantar) surface of the PIP, with a mild associated extension contracture of the MTP joint. *Mallet toe* results from a flexion deformity of the distal interphalangeal joint (DIP) with plantar contracture. Often a corn or callus is present on the posterior aspect of the affected joint. Corns are similar to calluses but have a central nidus. *Claw toe* deformity is a more advanced contracture of capsules and intrinsic musculature, which may also be associated with pes cavus and neurologic or primary muscle pathology to the lumbrical and interosseous muscles. The claw toe results in hyperextension of the MTP joints and flexion of the PIP and DIP joints.
- ***Functional hallux limitus.*** Clinically, the presence of functional hallux limitus, an inability of the first MTP joint to extend, can be determined by assessing the ROM available at the first MTP joint, while the first ray is prevented from plantar flexing. The patient is positioned in standing, the feet shoulder-width apart. The patient is asked to actively raise the great toe off the floor, while keeping the remaining toes and foot on the ground. The amount of hallux extension is measured; less than 10 degrees is considered limited.[144] This test has been found to have a sensitivity of 0.72 and a specificity of 0.66.[144]
- ***The leg, foot, and ankle are examined for the presence of bruising, swelling, or unusual angulation.*** Ecchymosis may be present, but the blood usually settles along the medial or lateral aspects of the heel.[16,125] The appearance of bluish-black plaques on the posterior and posterolateral aspect of one or both heels in a young distance runner is found in a condition called *black-dot heel*, which results from a shearing stress or a pinching of the heel between the counter and the sole of the shoe at initial contact during running.

Extracellular fluid pools on the posterior aspect of the foot and around the malleoli after injury or surgery.[101] Shortly after a lateral ligament sprain, the swelling is limited to the lateral ankle. Subsequently, the swelling is diffuse, and the localization of tenderness may be difficult. An objective measure of the amount of swelling present can be made using the figure-of-eight method (see "Special Tests" section).

- ***Callus formation.*** Calluses provide the clinician with an index as to the degree of shear stresses applied to the foot and clearly outline abnormal weight-bearing areas.[145] In adequate amounts calluses provide protection, but in excess they may cause pain. Callus formation under the second and third metatarsal heads could indicate excessive pronation in a flexible foot, or Morton's (interdigital) neuroma (see Chap. 5) if under the second through fourth. A callus under the fifth and sometimes the fourth metatarsal head may indicate an abnormally rigid foot.
- ***Any evidence of circulatory impairment or vasomotor changes.*** Brick-red coloring or cyanosis when the leg is dependent is an indication of vascular impairment, especially if the color changes when the leg is elevated. Vasomotor changes include toenail changes, changes in skin texture, abnormal skin moisture or dryness, and loss of hair on the foot. Vasomotor changes may be associated with complex regional pain syndrome (see Chap. 5).
- ***The type of shoes.*** High-heeled shoes have been associated with adaptive shortening of the gastrocnemius soleus complex, knee pain, and low-back pain.[50,146] They have also been associated with an increased potential for ankle sprains, hallux valgus, bunions, metatarsalgia, interdigital neuromas, peripheral nerve compression, and stress fractures.[50,146] Shoes with a negative heel may result in hyperextension of the knees.
- ***The weight-bearing and wear patterns of the shoe.*** The greatest amount of wear on the sole of the shoe should occur beneath the ball of the foot, in the area corresponding to the first, second, and third MTP joints and slight wear to the lateral side of the heel. Old running shoes belonging to patients who excessively pronate tend to display overcompression of the medial arch of the midsole and extensive wear of the lateral regions of the heel counter and medial forefoot. The upper portion of the shoe should demonstrate a transverse crease at the level of the MTP joints. A stiff first MTP joint can produce a crease line that runs obliquely, from forward and medial to backward and lateral.[147] The cup at the rear of the shoe, which is formed by the heel counter (Fig. 21-34), should be vertical and symmetrical with respect to the shoe and should be of a durable enough material to hold the heel in place.[148] A medial inclination of the cup, with bulging of the lateral lip of the counter, indicates a pronated foot.[147] A lateral bulge of the heel counter indicates a supinated foot. Scuffing of the shoe might indicate tibialis anterior weakness.[80] The shape of the last influences the amount of motion that the shoe permits.[149] As the degree of curvature in the last increases, more foot mobility is available.

The non–weight-bearing component of the examination is initiated by having the patient seated on the edge of the bed, feet dangling. The feet should adopt an inverted and plantar flexed position. A mobile or nonstructural flatfoot will take on a more normal configuration in non–weight-bearing, whereas a fixed or structural flatfoot will maintain its planus state. By placing one hand on the patella and the other hand on the tips of the malleoli, the clinician should note approximately 20–30 degrees of external rotation of the ankle in relation to the knee.[141]

Palpation

Careful palpation should be performed around the leg, foot, and ankle to differentiate tenderness of specific ligaments and other structures. Areas of localized swelling and ecchymosis over the ligaments on the medial or lateral aspects of the foot and ankle should be noted.

Posterior Aspect of Foot and Ankle

Achilles Tendon

The Achilles tendon is inspected for contour changes such as swelling, erythema, and thickening. Any gaps or nodules in the tendon and specific sites of pain should be carefully examined. Palpable gaps in the tendon accompanied by an inability to rise up on the toes could indicate a rupture of the tendon.

Calcaneus

At the distal end of the Achilles tendon is the calcaneal tuberosity. The posterior aspect of the calcaneus and surrounding soft tissue is palpated for evidence of exostosis ("pump bump" or Haglund's deformity) and associated swelling (retrocalcaneal bursitis). The inferior medial process of the calcaneus, just distal to the weight-bearing portion of the calcaneus, serves as the attachment of the plantar fascia and is often tender with plantar heel pain.

Anterior and Anteromedial Aspects of the Foot and Ankle

While reading the next section, the reader may find it helpful to remove a shoe and sock and self-palpate.

Great Toe and the Phalanges

Beginning medially, the clinician locates and palpates the great toe and its two phalanges. The first metatarsal bone is more proximal, the head of which should be palpated for tenderness on the lateral aspect (bunion) and inferior aspect (sesamoiditis).

Moving laterally from the phalanges of the great toe, the clinician palpates the phalanges and metatarsal heads of the other four toes.

Tenderness of the second metatarsal head could indicate the presence of Freiberg's disease, an osteochondritis of the second metatarsal head (see Chap. 5). A callus under the second and the third metatarsal head may indicate a fallen metatarsal arch. Palpable tenderness in the region of the third and fourth metatarsal heads could indicate a Morton's neuroma, especially if the characteristic sharp pain between the toes of this condition is relieved by walking barefoot. Tenderness on the lateral aspect of the fifth metatarsal head could indicate the presence of a tailor's bunion.

Cuneiform

The first cuneiform is located at the proximal end of the first metatarsal (see Fig. 21-1) and is palpated for tenderness.

Navicular

The navicular is the most prominent bone on the medial aspect of the foot. The navicular tuberosity can be located by moving proximally from the medial aspect of the first cuneiform (see Fig. 21-1). The talonavicular joint line lies directly proximal to the navicular tuberosity. In addition, the posterior tibialis, which can be made more prominent with resisted plantar flexion, adduction, and supination, can be used as a reference as it inserts on the plantar surface of the navicular (see later). Tenderness of the navicular could indicate the presence of a fracture or osteochondritis of the navicular (Köhler's disease).

FIGURE 21-14 Dorsal pedis pulse.

Second and Third Cuneiforms

These two bones can be palpated by moving laterally from the first cuneiform (see Fig. 21-1). Tenderness of these bones may indicate a cuneiform fracture.

Posterior (Dorsal) Pedis Pulse

The pulse of the posterior (dorsal) pedis artery, a branch of the anterior tibial artery, can be palpated over the talus, cuneiform bones (Fig. 21-14), between the first and second cuneiforms, or between the first and second metatarsal bones.

Medial Malleolus

The medial malleolus is palpated for swelling or tenderness. Moving proximally from the anterior aspect of the medial malleolus, the distal aspect of the tibia is palpated. Distal to that is the talus bone. Moving distal from the tibia, the clinician palpates the long extensor tendons, the tibialis anterior, and the superior and inferior extensor retinaculum. The tendon of the tibialis anterior is visible at the level of the medial cuneiform and the base of the first metatarsal bone, especially if the foot is positioned in dorsiflexion and supination.

Talus

The talus can be located by moving from the distal aspect of the medial malleolus along a line joining the navicular tuberosity. It can be more easily located by everting and inverting the foot. Eversion causes the talar head to become more prominent, while inversion causes the head to be less visible.

Sustentaculum Tali

Distal and inferior to the medial malleolus, a shelf-like bony prominence of the calcaneus, the sustentaculum tali, can be palpated. At the posterior aspect of the sustentaculum tali, the talocalcaneal joint line can be palpated.

Posterior Tibialis Tendon

This tendon is palpable at the level of the medial malleolus, especially with the foot held in plantar flexion and supination. Distal and medial to this tendon, the crossing of the flexor digitorum longus and flexor hallucis tendons can be felt.

Posterior Tibial Artery

The posterior tibial artery (Fig. 21-9) can be located posterior to the medial malleolus and anterior to the Achilles tendon.

Medial (Deltoid) Ligament of the Ankle

The medial (deltoid) ligament of the ankles is very difficult to differentiate, so they are usually palpated as a group on the medial aspect of the ankle (see Fig. 21-4).

Anterior and Anterolateral Aspects of the Foot and Ankle

Tibial Crest

The tibial crest is palpated for tenderness, which may indicate the presence of shin splints. Swelling in this area may indicate the presence of anterior compartment syndrome. The muscles of the lateral (peronei) and anterior compartments (tibialis anterior and the long extensors) are palpated here for swelling or tenderness. Swelling or tenderness of these structures usually indicates inflammation.

Lateral Malleolus

The lateral malleolus is located at the distal aspect of the fibula. Distal to the lateral malleolus is the calcaneus.

Fibularis (Peroneus) Longus

The tendon of the fibularis (peroneus) longus runs superficially behind the lateral malleolus. Resisted pronation and plantar flexion of the foot make the tendon more prominent.

Fibularis (Peroneus) Brevis

The origin for the fibularis (peroneus) brevis is more distal to the fibularis (peroneus) longus and lies deeper. It becomes superficial on the lateral aspect of the foot, at its insertion at the tuberosity of the fifth metatarsal.

Anterior Talofibular Ligament

The ATFL can be palpated two to three finger-breadths anteroinferior to the lateral malleolus (see Fig. 21-5).[129] This is usually the area of most extreme tenderness following an inversion sprain. The anterior aspect of the distal tibiofibular syndesmosis may also be tender following this type of sprain.

Calcaneofibular Ligament

The CFL can be palpated one to two finger-breadths inferior to the lateral malleolus (see Fig. 21-5).[129]

Posterior Talofibular Ligament

The PTFL can be palpated posteroinferior to the posterior edge of the lateral malleolus (see Fig. 21-5).[129]

Sinus Tarsi

The sinus tarsi is visible as a concave space between the lateral tendon of the extensor digitorum longus muscle and the anterior aspect of the lateral malleolus. The origin of the EDB is at the level of this tunnel.

Cuboid

The cuboid bone can be palpated by moving distally approximately one finger-breadth from the sinus tarsi.

Active and Passive Range of Motion

ROM testing is divided into active range of motion (AROM) and passive range of motion (PROM), with overpressure being superimposed at the end of available range to assess the end-feel. AROM tests are used to assess the patient's willingness to move and the presence of movement restriction patterns such as a capsular or noncapsular pattern. The end-feel may provide the clinician with information as to the cause of a motion restriction. The normal ranges of motion and end-feels for the lower leg, ankle, and foot are outlined in Table 21-7. The open- and close-packed positions and capsular patterns for the ankle and foot are outlined in Table 21-1.

General AROM of the foot and ankle in the non–weight-bearing position is assessed first, with painful movements being performed last. The hip and knee joints may also be examined as appropriate. Weight-bearing tests are usually performed after the non–weight-bearing tests.

If the symptoms are experienced during the general tests, then passive, active, and resisted tests of specific structures must be performed. If the general tests are negative, there is probably no immediate need to proceed with a more detailed examination, although this may have to be done if no other region appears to be the cause of the problem.

Although specific motions at the distal tibiofibular joint cannot be produced voluntarily, the function of this joint can be assessed indirectly by asking the patient to twist around both feet in each direction while bearing weight.

TABLE 21-7 Normal Ranges of Motion and End-Feels for the Lower Leg, Ankle, and Foot

Motion	Normal Range (Degrees)	End-Feel
Plantar flexion	50	Tissue stretch
Dorsiflexion	20	Tissue stretch
Supination	45–60	
Pronation	15–30	
Hindfoot inversion	20	Tissue stretch
Hindfoot eversion	10	Tissue stretch
Toe flexion	Great toe: MTP, 45; IP, 90 Lateral four toes: MTP, 40; PIP, 35; DIP, 60	Tissue stretch
Toe extension	Great toe: MTP, 70; IP, 0 Lateral four toes: MTP, 40; PIP, 0; DIP, 30	Tissue stretch

Data from Rasmussen O: Stability of the ankle joint. *Acta Orthop Scand Suppl* 211:56–78, 1985; Seto JL, Brewster CE: Treatment approaches following foot and ankle injury. *Clin Sports Med* 13:295, 1985.

FIGURE 21-15 Ankle dorsiflexion.

Dorsiflexion

The patient lies in the supine position, with the knee slightly flexed and supported by a pillow, while the clinician stands at the foot at the table, facing the patient **VIDEO**.

Active dorsiflexion is initially performed with the knee flexed (Fig. 21-15). Care must be taken to prevent pronation at the subtalar and oblique midtarsal joint during dorsiflexion. The foot is slightly inverted to lock the longitudinal arch.[141] Passive overpressure is applied. With the knee flexed to approximately 90 degrees, the length of the soleus muscle is examined. Passive overpressure into dorsiflexion when the knee is flexed assesses the joint motion, as well as the soleus length. The soleus is implicated if pain is produced in this test, especially if resisted plantar flexion is painful or more painful with the knee flexed than with the knee extended. With the knee flexed, 20 degrees of dorsiflexion past the anatomic position (the foot at 90 degrees to the bones of the leg) is found in the normally flexible person.[150] The flexibility of the soleus muscle may also be assessed in standing in able-bodied individuals by asking the patient to perform a deep squat or a lunge.

- *Squat*. If the muscle length is normal, the patient should be able to place the whole foot on the floor, including the heel, while in the full squat position (Fig. 21-16). If the soleus is short, the heel will not touch the floor.
- *Lunge*. A standard goniometer is aligned along the lateral aspect of the leg and the floor. The subject steadies

FIGURE 21-16 Ankle dorsiflexion during squat.

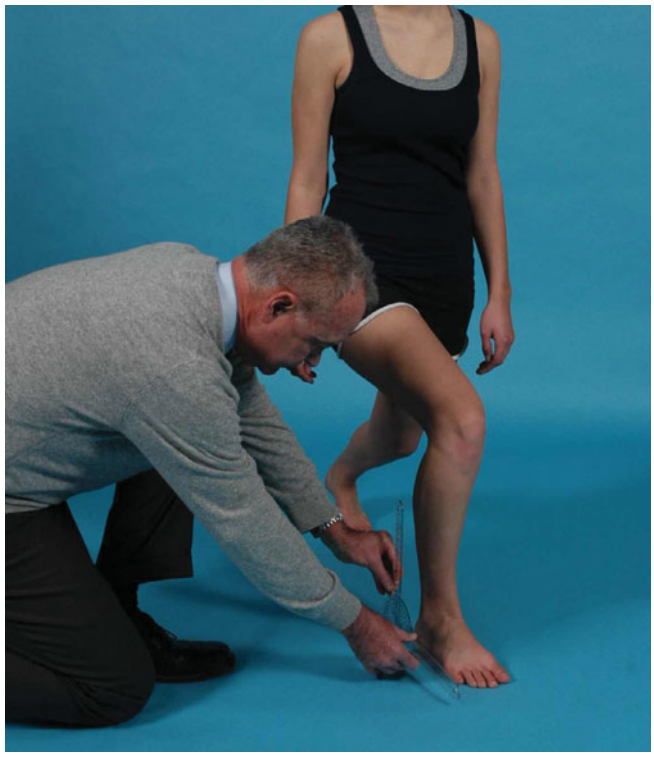

FIGURE 21-17 Ankle dorsiflexion during lunge with goniometer.

themselves and then performs a weight-bearing lunge maneuver (Fig. 21-17). The angle recorded on the goniometer indicates the range of dorsiflexion under load. If the goniometer is set so that vertical is zero, the arm of the goniometer always aligns to the vertical and the scale rotates to indicate the inclination from the vertical. This angle is then recorded as the ankle dorsiflexion range. This method is considered the most appropriate method of measuring ankle dorsiflexion range, as it reflects the functionally available range for the individual. Bennell et al.[151] evaluated the interrater and intrarater reliability of a weight-bearing dorsiflexion lunge using a gravity goniometer in 13 healthy subjects. Two methods were used to assess the dorsiflexion lunge: (1) the distance from the great toe to the wall and (2) the angle between the tibial shaft and the vertical using an inclinometer. The average of three trials was used in data analysis. Intrarater ICCs ranged from 0.97 to 0.98. Interrater ICC values were 0.97 (angle) and 0.99 (distance), indicating excellent reliability for both methods of assessing a DF lunge.[151]

CLINICAL PEARL

Chronic adaptive shortening of the soleus muscle can be caused by excessive running, a weak posterior tibialis, or a weak quadriceps. Adaptive shortening of the soleus can result in forefoot pronation and a valgus stress at the knee.

To assess the length of the gastrocnemius, the patient is placed in the supine position with the knee extended, and the ankle positioned in subtalar neutral. The patient is then asked to dorsiflex the ankle (Fig. 21-18). Passive overpressure into

FIGURE 21-18 Active ankle dorsiflexion (knee extended).

dorsiflexion is applied. The normal range is 20 degrees. If the gastrocnemius is shortened, dorsiflexion of the ankle will be reduced as the knee is extended, and increased as the knee is flexed. A muscular end-feel should be felt with the knee extended, and a capsular end-feel should be felt with the knee flexed.

CLINICAL PEARL

A decrease in the flexibility of the gastrocnemius can result from a number of dysfunctions, including dysfunction of the subtalar joint or transtarsal joint, an ankle sprain, high-heeled footwear, or poor gait/running mechanics.

Plantar Flexion

The patient is placed in the supine position, while the clinician stands at the foot of the table, facing the patient **VIDEO**. The patient is asked to plantar flex the ankle (Fig. 21-19). Plantar flexion of the ankle is approximately 30–50 degrees.[94] When tested in weight-bearing with the unilateral heel raise, heel inversion should be seen to occur. Failure of the foot to invert may indicate instability of the foot/ankle, posterior tibialis dysfunction, or adaptive shortening.[152]

FIGURE 21-19 Ankle plantar flexion.

FIGURE 21-20 Ankle inversion.

Hindfoot Inversion (Supination) and Hindfoot Eversion (Pronation)

Both hindfoot inversion (Fig. 21-20) and hindfoot eversion (Fig. 21-21) are tested by lining up the longitudinal axis of the leg and vertical axis of the calcaneus. Passive motion of hindfoot inversion (supination) is normally 20 degrees.[94] The amount of hindfoot eversion (pronation) is normally 10 degrees.[94]

Great Toe Motion

The patient is positioned in supine, with the leg being supported by a pillow, while the clinician stands at the foot at the table, facing the patient. Active extension of the great toe is performed and assisted passively without dorsiflexing the first

FIGURE 21-21 Ankle eversion.

ray. The amount of posterior (dorsal) mobility is usually classified as normal, hypomobile, or hypermobile. Although this method of assessment is common, its reliability and validity have been shown to be poor.[122] Extension of the great toe occurs primarily at the MTP joint. Passive extension of the great toe at the MTP joint should demonstrate elevation of the medial longitudinal arch (windlass effect), and external rotation of the tibia.[153] Passive MTP joint extension of between 55 and 90 degrees is necessary at terminal stance,[154] depending on length of stride, shoe flexibility, and toe-in/toe-out foot placement angle.[139] Forty-five degrees of first MTP flexion and 90 degrees of IP joint flexion are considered normal.[141]

FIGURE 21-22 Manual muscle testing of the plantar flexors.

Strength Testing

Ankle

Gastrocnemius and Plantaris Muscles. Plantar flexion strength can be tested initially in non–weight-bearing (Fig. 21-22). If no plantar flexion weakness is apparent in non–weight-bearing, a heel raise test is performed in the functional position, standing with the knee extended and the opposite foot off the floor **VIDEO**. Technically, one heel raise through full ROM, while standing with support on one leg, scores a 3/5 (fair) with manual muscle testing, with five single-limb heel raises scoring a 4/5 (good) and 10 single-limb heel raises scoring a 5/5 (normal). From a functional viewpoint, a wider range of scoring can sometimes prove more useful. Table 21-8 outlines an alternative scoring method.

TABLE 21-8 Functional Testing of the Foot and Ankle

Starting Position	Action	Functional Test
Standing on one leg	Lift toes and forefeet off ground (dorsiflexion)	10–15 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor 0 repetition: nonfunctional
Standing on one leg	Lift heels off ground (plantar flexion)	10–15 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor 0 repetition: nonfunctional
Standing on one leg	Lift lateral aspect of foot off ground (ankle eversion)	5–6 repetitions: functional 3–4 repetitions: functionally fair 1–2 repetitions: functionally poor 0 repetition: nonfunctional
Standing on one leg	Lift medial aspect of foot off ground (ankle inversion)	5–6 repetitions: functional 3–4 repetitions: functionally fair 1–2 repetitions: functionally poor 0 repetitions: nonfunctional
Seated	Pull small towel up under the toes or pick up and release small object (i.e., pencil, marble, cotton ball) (toe flexion)	10–15 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor 0 repetitions: nonfunctional
Seated	Lift toes off ground (toe extension)	10–15 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor 0 repetitions: nonfunctional

Data from Palmer ML, Epler M: *Clinical Assessment Procedures in Physical Therapy*. Philadelphia, PA: JB Lippincott, 1990.

FIGURE 21-23 Manual muscle testing of the tibialis anterior.

Soleus Muscle. The soleus muscle produces plantar flexion of the ankle joint, regardless of the position of the knee. To determine the individual functioning of the soleus as a plantar flexor, the knee is flexed to minimize the effect of the gastrocnemius muscle. The soleus is tested in a similar manner to that of the gastrocnemius, except that the patient performs the unilateral heel raise with some degree of knee flexion. Ability to perform 10–15 raises in this fashion is considered normal, five to nine raises graded as fair, one to four raises graded as poor, and zero repetitions graded as nonfunctional. Alternatively, the strength of the soleus can be tested with the patient in prone VIDEO.

Tibialis Anterior Muscle. The tibialis anterior muscle produces the motion of dorsiflexion and inversion. The knee must remain flexed during the test to allow complete dorsiflexion. The patient's foot is positioned in dorsiflexion and inversion. The leg is stabilized, and resistance is applied to the medial posterior aspect of the forefoot into plantar flexion and eversion (Fig. 21-23) VIDEO.

Tibialis Posterior Muscle. The tibialis posterior muscle produces the motion of inversion in a plantar flexed position. The leg is stabilized in the anatomic position, with the ankle in slight plantar flexion. Resistance is applied to the medial border of the forefoot into eversion and dorsiflexion (Fig. 21-24) VIDEO.

FIGURE 21-24 Manual muscle testing of the tibialis posterior.

FIGURE 21-25 Manual muscle testing of the fibularis (peroneus) muscle group.

Fibularis (Peroneus) Longus, Fibularis (Peroneus) Brevis, and Fibularis (Peroneus) Tertius Muscles. VIDEO The lateral compartment muscles and the fibularis (peroneus) tertius muscle VIDEO produce the motion of eversion. The patient is positioned in supine, with the foot over the edge of the table and the ankle in the anatomic position. Resistance is applied to the lateral border of the forefoot (Fig. 21-25).

Digits. Grades for the toes differ from the standard format because gravity is not considered a factor.

0: No contraction.

Trace or 1: Muscle contraction is palpated, but no movement occurs.

Poor or 2: Subject can partially complete the ROM.

Fair or 3: Subject can complete the test range.

Good or 4: Subject can complete the test range but is able to take less resistance on the test side than on the opposite side.

N or 5: Subject can complete the test range and take maximal resistance on the test side as compared with the normal side.

Flexor Hallucis Brevis and Longus Muscles. The flexor hallucis brevis VIDEO and FHL muscles VIDEO produce MTP joint flexion and IP joint flexion. The foot is maintained in midposition. The first metatarsal is stabilized, and resistance is applied beneath the proximal and distal phalanx of the great toe into toe extension.

Flexor Digitorum Brevis and Longus Muscles. The flexor digitorum longus and brevis muscles produce IP joint flexion. The motion is tested with the foot in the anatomic position. If the gastrocnemius muscle is shortened, preventing the ankle from assuming the anatomic position, the knee is flexed. The toes may be tested simultaneously.

The foot is held in the midposition and the metatarsals are stabilized. Resistance is applied beneath the distal and proximal phalanges VIDEO.

Extensor Hallucis Longus and Brevis Muscles. VIDEO The extensor hallucis longus and the EHB muscles produce the motion of extension of the IP and MTP joints. The foot is maintained in midposition. Resistance is applied to the posterior aspect of both phalanges of the first digit into toe flexion.

Extensor Digitorum Longus and Brevis Muscles. The extensor digitorum longus and the EDB muscles produce the motion of extension at the MTP and IP joints of the lateral four digits from a flexed position VIDEO. Resistance is applied to the posterior (dorsal) surface of the proximal and distal phalanges into toe flexion.

Intrinsic Muscles of the Foot. The intrinsic muscles of the foot are tested with the patient in either the supine or the sitting position. Most subjects are unable to voluntarily contract the intrinsic muscles of the foot individually.

Abductor Hallucis Muscle. The metatarsals are stabilized, and resistance is applied medially to the distal end of the first phalanx VIDEO.

Adductor Hallucis Muscle. The metatarsals are stabilized, and resistance is applied to the lateral side of the proximal phalanx of the first digit VIDEO.

Lumbrical Muscles. The lateral four metatarsals are stabilized, and resistance is applied to the middle and distal phalanges of the lateral four digits.

Plantar Interossei Muscles. The lateral three metatarsals are stabilized, and resistance is applied to the middle and distal phalanges.

Posterior (Dorsal) Interossei and Abductor Digiti Minimi Muscles. The metatarsals are stabilized and resistance is applied:

- ***Posterior (Dorsal) interossei.*** Applied to the middle and distal phalanges.
- ***Abductor digiti minimi.*** Applied to the lateral side of the proximal phalanx of the fifth digit.

Functional Tests

Subjective Tests

The Ankle Joint Functional Assessment Tool. The Ankle Joint Functional Assessment Tool (AJFAT)[155] is composed of 12 questions rating the ankle's functional ability (Table 21-9). The AJFAT questions are based on assessment tools previously used for evaluating the functional level of the knee.[156–158]

The Foot Function Index. The Foot Function Index (FFI)[159] is a functional outcome measure that consists of three subsections: pain, disability (Table 21-9), and activity. A study by Budiman-Mak et al.[159] examined test–retest reliability (intraclass correlation coefficient, ICC = 0.87), internal consistency (0.96), and construct and criterion validity of the questionnaire.

Objective Tests

Weight-Bearing Tests

In weight-bearing, with the feet fixed, the patient should be asked to perform the following while the clinician notes any reproduction of pain or abnormal motion:

TABLE 21-9 Ankle Joint Functional Assessment Tool (AJFAT)

1. How would you describe the level of pain you experience in your ankle?
   _____(0) Much more than the other ankle
   _____(1) Slightly more than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly less than the other ankle
   _____(4) Much less than the other ankle
2. How would you describe any swelling of your ankle?
   _____(0) Much more than the other ankle
   _____(1) Slightly more than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly less than the other ankle
   _____(4) Much less than the other ankle
3. How would you describe the ability of your ankle when walking on uneven surfaces?
   _____(0) Much less than the other ankle
   _____(1) Slightly less than the other ankle
   _____(2) Equal in ability to the other ankle
   _____(3) Slightly more than the other ankle
   _____(4) Much more than the other ankle
4. How would you describe the overall feeling of stability of your ankle?
   _____(0) Much less stable than the other ankle
   _____(1) Slightly less stable than the other ankle
   _____(2) Equal in stability to the other ankle
   _____(3) Slightly more stable than the other ankle
   _____(4) Much more stable than the other ankle

(Continued)

TABLE 21-9 Ankle Joint Functional Assessment Tool (AJFAT) *(Continued)*

5. How would you describe the overall feeling of strength of your ankle?
   _____(0) Much less strong than the other ankle
   _____(1) Slightly less strong than the other ankle
   _____(2) Equal in strength to the other ankle
   _____(3) Slightly stronger than the other ankle
   _____(4) Much stronger than the other ankle
6. How would you describe your ankle's ability when you descend stairs?
   _____(0) Much less than the other ankle
   _____(1) Slightly less than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly more than the other ankle
   _____(4) Much more than the other ankle
7. How would you describe your ankle's ability when you jog?
   _____(0) Much less than the other ankle
   _____(1) Slightly less than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly more than the other ankle
   _____(4) Much more than the other ankle
8. How would you describe your ankle's ability to "cut," or change direction, when running?
   _____(0) Much less than the other ankle
   _____(1) Slightly less than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly more than the other ankle
   _____(4) Much more than the other ankle
9. How would you describe the overall activity level of your ankle?
   _____(0) Much less than the other ankle
   _____(1) Slightly less than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly more than the other ankle
   _____(4) Much more than the other ankle
10. Which statement best describes your ability to sense your ankle beginning to "roll over"?
    _____(0) Much later than the other ankle
    _____(1) Slightly later than the other ankle
    _____(2) At the same time as the other ankle
    _____(3) Slightly sooner than the other ankle
    _____(4) Much sooner than the other ankle
11. Compared with the other ankle, which statement best describes your ability to respond to your ankle beginning to "roll over"?
    _____(0) Much later than the other ankle
    _____(1) Slightly later than the other ankle
    _____(2) At the same time as the other ankle
    _____(3) Slightly sooner than the other ankle
    _____(4) Much sooner than the other ankle
12. Following a typical incident of your ankle "rolling," which statement best describes the time required to return to activity?
    _____(0) More than 2 days
    _____(1) 1 to 2 days
    _____(2) More than 1 hour and less than 1 day
    _____(3) 15 minutes to 1 hour
    _____(4) Almost immediately

Data from Rozzi SL, Lephart SM, Sterner R, et al: Balance Training for Persons with Functionally Unstable Ankles. *J Orthop Sports Phys Ther* 29:478–486, 1999.

- ***Weight-bearing on the foot borders.*** The patient is asked to bear weight on the medial borders of the feet while keeping the knees extended. The patient is then asked to bear weight on the lateral borders of the feet while maintaining the knee extension.
- ***Heel raising.*** In addition to being a general screening test, heel raising also assesses the ability of the medial arch to increase and produce a supinated/inverted arch. Under normal conditions, the tibialis posterior tendon inverts the hind foot as the patient raises their heel. With poor or absent tibialis posterior function, the patient just rolls on the outside of the foot and demonstrates a decreased ability to unilaterally raise the heel.
- ***Twisting of the lower leg.*** Twisting tests the ability of the foot to supinate on the ipsilateral side, and its ability to pronate on the contralateral side.

The results of these tests may not be helpful in forming an actionable diagnosis, but they may be the only way to reproduce the patient's symptoms and will therefore be of use in the formation of a diagnosis.

Single-leg Stance Test

Chronic ankle instability is a frequent consequence after lateral ankle sprain. The inability to maintain quiet stance during single standing has consistently been shown to be associated with ankle instability.[160]

Star Excursion Balance Test

The star excursion balance test (SEBT) is a clinical test purported to detect functional performance deficits associated with lower extremity pathology in otherwise healthy individuals.[160] The SEBT consists of a series of lower extremity reaching tasks in directions that challenge subjects' postural control, strength, ROM, and proprioceptive abilities. The farther a subject can reach with one leg while balancing on the opposite leg, the better the functional performance they are deemed to have. The subject stands barefoot at the center of the grid with eight lines extending in a star pattern at 45-degree increments from the center of the grid.[161] Subjects are asked to maintain a single-leg stance while reaching with the contralateral leg to touch as far as possible along the chosen line, and then to return to a bilateral stance while maintaining their equilibrium.[161] The test is then repeated using the other leg.

Functional Examination

See Table 21-8.

Passive Articular Mobility

Passive articular mobility tests assess the accessory motions available between the joint surfaces. These same techniques can be used to increase joint play using the varying grades of mobilization (see "Joint Mobilizations" in Techniques to Increase Joint Mobility). As with any other joint complex, the quality and quantity of joint motion must be assessed to determine the level of joint involvement. The joint play movement tests must be performed on both sides so that comparisons can be made. The patient is positioned in lying.

FIGURE 21-26 Mobility testing of the distal tibiofibular joint.

Distal Tibiofibular Joint

Although the glide at this joint would appear to be negligible, Mulligan has proposed that some ankle inversion injuries may be the result of a distal fibular positional fault. One study[162] examined the distal tibiofibular posterior glide of the ankles of 25 subjects for joint excursion. Of the 50 ankles, six had been diagnosed with an acute ankle sprain. Two ankles exhibited an increase in excursion, both of which of had been sprained suggesting that in approximately one-third of diagnosed ankle sprains, the true cause might be an anterior positional fault of the distal fibular on the tibia.

To perform the mobility tests of this joint, the patient is placed in supine and the clinician grips the tibia and fibula using one hand for each (Fig. 21-26). While one hand prevents downward motion of the medial malleolus, the other hand glides the fibula anteriorly and posteriorly in relation to the tibia. To assess the motion of the tibial component, one hand stabilizes the fibula and lateral malleolus, while the other hand glides the tibia anteriorly and posteriorly in relation to the fibula. Theoretically, a superior and inferior glide can be assessed at this joint, but it is unclear whether information provided by such testing would help the clinician in making a diagnosis or designing a plan of care.

Long-Axis Distraction of Ankle and Foot

The clinician stabilizes the proximal segment and applies traction to the distal segment. This test is performed at the talocrural joint (Fig. 21-27), the subtalar joint (Fig. 21-28), the MTP joints (Fig 21-29), and the IP joints (Fig 21-30).

Anterior–Posterior Glide

To test the anterior glide of the talocrural joint, the clinician stabilizes the tibia and fibula and draws the talus and foot forward together (Fig. 21-31). Pushing the talus and foot together in a posterior direction on the tibia and fibula (Fig. 21-32) tests the posterior movement. The anterior glide of the talus assesses the joint's ability to move into plantar flexion,

FIGURE 21-27 Long-axis distraction of talocrural joint.

FIGURE 21-28 Long-axis distraction of subtalar joint.

FIGURE 21-29 Long-axis distraction of the IP joint.

whereas the posterior glide of the talus assesses the joint's ability to move into dorsiflexion.

The anterior–posterior glides can also be applied to the midtarsal (Fig. 21-33), intertarsal (Figs. 21-34 and 21-35), MTP (Fig. 21-36), and IP (Fig. 21-37) joints.

FIGURE 21-30 Long-axis distraction of the MTP joint.

FIGURE 21-31 Anterior glide of the talocrural joint.

FIGURE 21-32 Posterior glide of the talocrural joint.

Calcaneal Inversion–Eversion (Subtalar)

Subtalar joint motion is extremely important to normal foot function. A loss of eversion causes weight-bearing to occur along the lateral side of the ankle joint. The patient lies in the prone position with the knee slightly flexed and supported by a

FIGURE 21-33 A-P glide of mid-tarsal joints.

FIGURE 21-34 A-P glide of intertarsals.

FIGURE 21-35 A-P glide of intertarsals.

pillow, while the clinician stands at the foot of the table, facing the patient. The clinician grasps the calcaneus in one hand, while the other hand locks the talus. The calcaneus is passively inverted (varus) and everted (valgus) on the talus (Fig. 21-38). The amount and quality of the motions as compared with the other foot are noted. Although some differences exist, generally calcaneal eversion will measure 5–10 degrees, while calcaneal inversion will measure approximately 20–30 degrees.[20,94,141] A similar technique can be used to assess

FIGURE 21-36 A-P glide of MTP.

FIGURE 21-37 A-P glide of IP joints.

FIGURE 21-38 Calcaneal inversion and eversion.

FIGURE 21-39 Mobility testing midtarsal inversion/eversion.

medial and lateral gapping at this joint. Medial gapping is associated with subtalar joint eversion, whereas lateral gapping is associated with subtalar joint inversion.

Midtarsal Joint Motion

The rotational movements of the midtarsal joint, which allow the forefoot to twist on the rearfoot, can be observed in the non–weight-bearing position. The clinician stabilizes the calcaneus with one hand, while inverting and everting the foot at the midtarsal joint with the other hand (Fig. 21-39).[85]

First MTP Joint (First Ray) Motion

The patient lies in supine position, with the clinician at the foot of the table facing away from the patient. The clinician grasps and locks the first MTP joint, before grasping the great toe and moving it into extension and flexion (posteriorly (dorsally) and anteriorly (ventrally), respectively) (Fig. 21-40). Long-axis distraction and compression can also be applied (Fig. 21-41) to assess capsular and articular integrity, respectively.

Limited range may result from a combination of biomechanical factors such as excessive pronation or joint glide restriction.[163] To examine the conjunct rotation of the metatarsals, the clinician locks the second metatarsal to evaluate the first and locks the third to evaluate the second. The quantity and quality of motion is noted and compared with the other side.

Special Tests

Special tests are merely confirmatory tests and should not be used alone to form a diagnosis. Selection for their use is at the discretion of the clinician and is based on a complete patient history. The results from these tests are used in conjunction with the other clinical findings. To assure accuracy with these tests, both sides should be tested for comparison.

FIGURE 21-40 First MTP motion.

Assessing Ankle Girth

Physical therapists need a reliable method by which to measure ankle girth following injury so that there can be clinical quantification of the volume of edema. Two methods are described:

- ***Figure-of-eight tape method.*** The patient lies in the supine position or seated. The clinician places a tape measure midway between the tibialis anterior tendon and lateral malleolus. The tape is then drawn medially and is placed just distal to the navicular tuberosity. The tape is then pulled across the arch and just proximal to the fifth metatarsal. The tape is then pulled across the tibialis anterior tendon and around the ankle to a point just distal to the medial malleolus, before being finally pulled across the Achilles tendon and placed just distal to the lateral malleolus and across the start of the tape. Tatro-Adams et al.[164] reported the ankle figure-of-eight method to be a reliable tool for measuring ankle girth. (Fig. 21-42)
- ***Volumetry method.*** A volumeter is filled with water, and the patient's foot is placed into the volumeter with toe tips

FIGURE 21-41 Long-axis distraction and compression at the 1st MTP joint.

FIGURE 21-42 Figure-of eight tape method.

touching the front wall. The amount of water displaced is measured.

Petersen et al. performed a study to determine the interrater and intrarater reliability of water volumetry and the figure-of-eight method on subjects with ankle joint swelling and found high interrater reliability for both the water volumetry (ICC = 0.99) and the figure-of-eight methods (ICC = 0.98). In addition, intrarater reliability was high for both (ICCs = 0.98–0.99). The authors concluded that both methods are reliable measures of ankle swelling, although they recommended the figure-of-eight method because of its ease of use, time efficiency, and cost effectiveness. However, water volumetry may be more appropriate when measuring diffuse lower extremity swelling.

Ligamentous Stress Tests

The examination of the ligamentous structures in the ankle and foot is essential, not only because of their vast array but also because of the amount of stability that they provide. Positive results for the ligamentous stability tests include excessive movement, as compared with the same test on the uninvolved extremity, pain (depending on the severity), or apprehension.

Mortise/Syndesmosis

Cotton (Clunk) Test

The patient lies in supine position with their foot over the end of the bed. One hand is used to stabilize the distal leg on the bed, while the clinician uses the other hand to grasp the heel and move the calcaneus laterally (see Fig. 21-43).[165] A clunk can be felt as the talus hits the tibia and fibula, if there has been significant mortise widening.[129] Beumer et al.[166] found this test to have a sensitivity of 46%.

Kleiger (External Rotation) Test

The Kleiger (external rotation) test[17,137,167] is a general test to implicate the syndesmosis if pain is produced over the anterior or posterior tibiofibular ligaments and the interosseous membrane, but can also be used to assess the integrity of the medial (deltoid) ligament of the ankle complex.[168,169] If this test is positive, further testing is necessary to determine the source of the symptoms.

FIGURE 21-43 Cotton (Clunk) Test.

The patient sits with their legs dangling over the end of the bed, the knee flexed to approximately 90 degrees, and the foot relaxed. The clinician stabilizes the lower leg with one hand and, using the other hand, grasps the foot and externally rotates it (Fig. 21-44). Pain experienced at the anterolateral aspect of the distal tibiofibular syndesmosis is a positive sign for syndesmosis injury,[170] whereas pain on the medial aspect of the ankle and/or displacement of the talus from the medial malleolus (depending on severity) with the ankle positioned in plantar flexion may indicate a tear of the medial (deltoid) ligament of the ankle. Alonso et al.[170] reported data that indicate that the external rotation stress test is more reliable than the squeeze test and the dorsiflexion–compression test for diagnosing syndesmosis injuries.

FIGURE 21-44 Kleiger (external rotation) test.

FIGURE 21-45 The point test.

The Point Test[170,171]

The point test, also referred to as the palpation test, is used to impose pressure on the anterior distal tibiofibular syndesmosis. The patient can be positioned in supine or sitting. The clinician applies pressure directly over the anterior aspect of the distal tibiofibular syndesmosis (Fig. 21-45). Pressure is applied gradually, and a positive test involves a report of pain by the patient.

The Dorsiflexion Maneuver[171,172]

The dorsiflexion maneuver is performed to force the wider anterior portion of the talar dome into the ankle mortise, thereby inducing separation of the distal fibula and tibia. The patient sits at the edge of the examination table, and the clinician stabilizes the patient's leg with one hand, while the clinician's other hand passively moves the foot into dorsiflexion (Fig. 21-46). Pain experienced at the distal tibiofibular syndesmosis is a positive test result. A variation of the dorsiflexion maneuver exists, known as the dorsiflexion compression test,[170] which involves patients moving their ankle joints into extreme dorsiflexion in bilateral weight-bearing. Patients are asked to note the pain they experience in this position and the position of the tibia is noted with an inclinometer. The patient then assumes an upright position, and the clinician applies medial–lateral compression with two hands on the malleoli of the injured leg. The clinician maintains the medial–lateral compression, as the patient is asked to move the ankles into dorsiflexion again and to report if the end-range pain has changed compared with the previous movement. A positive test result is either a reported reduction in the end-range pain or an increase in dorsiflexion ROM.

FIGURE 21-46 The dorsiflexion maneuver.

FIGURE 21-47 Fibula translation test.

Fibula Translation Test

The patient is placed in the side-lying position with the tested leg uppermost. The clinician applies an anterior and posterior force on the fibula at the level of the syndesmosis (Fig. 21-47). A positive test is pain during translation and more displacement of the fibula than the compared side. Although a cadaver study by Beumer et al.[166] found this test to have a sensitivity of 82% and specificity of 88% (LR+ 6.8; LR− 0.2), the study only found increased translation when all ligaments were removed in the cadavers.

The One-legged Hop Test[171,173]

The one-legged hop test is performed by having the patient stand on the injured leg and hop continuously. Nussbaum et al.[173] reported that patients with syndesmosis injuries could not complete 10 repetitions of unilateral hopping without significant pain. However, the one-legged hop test should be used with caution, and perhaps only if the other special tests are negative, because performing this test may impose further separation of the distal tibiofibular syndesmosis.[171]

The Crossed-Leg Test[171,174]

The crossed-leg test mimics the squeeze test (see later) and attempts to induce separation of the distal syndesmosis. The patient sits in a chair, with the injured leg resting across the knee of the uninjured leg. The resting point should be at approximately mid-calf. The clinician then applies a gentle

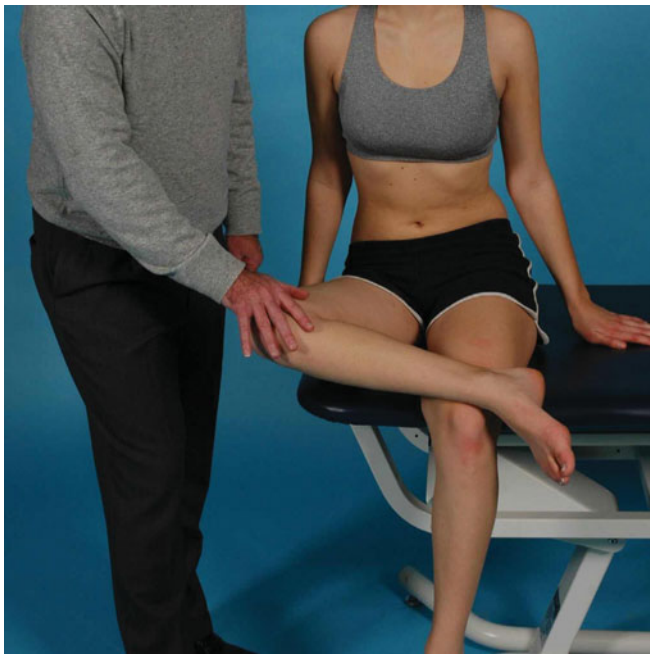

FIGURE 21-48 The crossed-leg test.

force on the medial aspect of the knee of the test leg (Fig. 21-48). Pain experienced in the area of the distal syndesmosis suggests the presence of injury. This test may not be useful for patients with knee or hip pathology because it may be difficult for them to assume the test position. Reliability and validity data for this test are not yet available.

The Heel-Thump Test[171,175]

The heel-thump test is performed to force the talus into the mortise, in an attempt to impose separation of the distal syndesmosis. The patient lies at the edge of the examination table, with the ankle resting in plantar flexion. The clinician holds the patient's leg with one hand and with the other hand applies a gentle but firm thump on the heel with their fist (Fig. 21-49). This force is applied at the center of the heel and in line with the long axis of the tibia. Pain experienced at the distal tibiofibular syndesmosis suggests the presence of injury. Although the heel thump test has been recommended to help differentiate between a syndesmotic sprain and a lateral ankle sprain, this test may not be specific for a syndesmotic sprain as the test has also been recommended to assess the possible presence of tibial stress fractures.[176] Reliability and validity data for this test are not yet available.

FIGURE 21-49 The heel-thump test.

FIGURE 21-50 Posterior drawer test.

Posterior Drawer Test

The posterior drawer test can also be used to test for the presence of instability at the distal tibiofibular joint. The patient is supine. The hip and knee are flexed to provide as much dorsiflexion of the ankle as possible. This drives the wide anterior part of the talus back into the mortise. An anterior stabilizing force is then applied to the cruris, and the foot and talus are translated posteriorly (Fig. 21-50). If the distal tibiofibular joint is stable, there will be no drawer available, but if there is instability, there will be a drawer.

Squeeze (Distal Tibiofibular Compression) Test

In the squeeze test, the patient lies in supine or side-lying position and the clinician squeezes the upper to middle third of the leg at a point approximately 6–8 inches below the knee (Fig. 21-51).[137] Pain felt in the distal third of the leg may indicate a compromised syndesmosis, if the presence of a tibia and/or fibula fracture, calf contusion, or compartment syndrome has been ruled out.[126,168]

FIGURE 21-51 Squeeze test.

FIGURE 21-52 Calcaneus tilt.

Lateral Collaterals

The lateral collateral ligaments of the ankle resist inversion. An additional function is to prevent excessive varus movement, especially during plantar flexion. In extreme plantar flexion, the mortise no longer stabilizes the broader anterior part of the talus, and varus movement of the ankle is then possible.

Calcaneus Tilt

The patient lies in the supine position. The lower leg is stabilized using a lumbrical grip, while the other hand grasps the foot and calcaneus. The clinician applies a medially directed force in an attempt to adduct the calcaneus, thereby gapping the lateral side of the ankle (Fig. 21-52). Pain on the lateral aspect of the ankle with this test, and/or displacement (depending on severity), may indicate a sprain of the ligament. Hertel et al.[177] found this test to have a sensitivity of 78% and a specificity of 75% (LR+ 3.1; LR− 0.29).

Talar Tilt

This test is used to determine whether the CFL is torn. The patient lies in a supine or side-lying position with the foot relaxed and the knee flexed. The clinician places the foot in the anatomical (90 degrees) position to bring the CFL perpendicular to the long axis of the talar. The talus is then tilted from side to side into adduction and abduction (Fig. 21-53). Adduction tests the CFL and, to some degree, the ATFL, whereas abduction stresses the deltoid ligament. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

FIGURE 21-53 Talar tilt.

Anterior Drawer Test

The anterior drawer stress test is performed to estimate the stability of the ATFL.[28,178,179] The test is performed with the patient seated at the end of the bed or lying supine with their knee flexed, to relax the gastrocnemius–soleus muscles, and the foot supported perpendicular to the leg.[180,178] The clinician uses one hand to stabilize the distal aspect of the leg, while the other hand grasps the patient's heel and positions the ankle in 10–15 degrees of plantar flexion (Fig. 21-54). The heel is very gently pulled forward, and if the test is positive, the talus, and with it the foot, rotates anteriorly out of the ankle mortise around the intact medial (deltoid) ligament of the ankle, which serves as the center of rotation. Tohyama et al.[179] reported that a relatively low anterior load (30 N) during this test was more sensitive than a higher load (60 N) in distinguishing a significant distance between injured to normal anterior displacement. This seemingly occurs because a greater load would tend to elicit a protective muscle contraction that could mask the anterior talar displacement.

This test has limited reliability, particularly if it is negative or if it is performed without anesthesia in the presence of muscle guarding.[181] It has been reported that 4 mm of laxity in the ATFL, resulting from posttraumatic attenuation or fibrosis, will give a clinically apparent anterior drawer (2 mm is normal)—false-positive findings may be seen in up to 19%

FIGURE 21-54 Anterior drawer test.

of uninjured ankles in those with ligamentous laxity.[182–184] As is often the case, when combining the results from several tests, diagnostic accuracy can be enhanced. For example, van Dijk et al.[185] reported that when the combination of pain on lateral ligament palpation, hematoma formation of the lateral ankle, and a positive anterior drawer test were used a lateral ligament lesion was correctly diagnosed in 95% of cases.

The Dimple Sign

Another positive sign for a rupture of the ATFL, if pain and spasm are minimal, is the presence of a dimple located just in front of the tip of the lateral malleolus during the anterior drawer test.[186] This results from a negative pressure created by the forward movement of the talus, which draws the skin inwards at the site of the ligament rupture.[187] This dimple is also seen with a combined rupture of the ATFL and CFLs.[186] However, the dimple is only present within the first 48 hours after injury, due to organized hematoma and repair tissue blocking the communication between the joint and the subcutaneous tissues.[186]

Medial Collaterals (Deltoid Complex)

The medial collaterals function to resist eversion. Given their strength, these ligaments are usually only injured as the result of a major trauma.

Tendon Tests

Thompson Test for Achilles Tendon Rupture

In this test, the patient lies in the prone position or in kneeling with the feet over the edge of the bed (Fig. 21-55). With the patient relaxed, the clinician gently squeezes the calf muscle and observes for the production of plantar flexion. An absence of plantar flexion indicates a complete rupture of the Achilles tendon.[188] This test has been found to have surprisingly low sensitivity (40%).[188]

Matles Test for Achilles Tendon Rupture

The patient lies in the prone position with the foot over the end of the table and the clinician stands at the end of the table. The patient is asked to actively flex the knee to 90 degrees while the position of the foot is observed throughout the motion (Fig. 21-56). If the foot falls into neutral or slight dorsiflexion, the test is positive for Achilles tendon rupture (in normal patients, the foot remains in plantar flexion). Maffulli[189] found this test to have a sensitivity of 0.88, a specificity of 0.85, and a positive predictive value of 0.92.

FIGURE 21-55 Patient position for the Thompson test.

FIGURE 21-56 Matles test for Achilles tendon rupture.

Articular Stability Tests

Navicular Drop Test

The navicular drop test is a method to assess the degree to which the talus plantar flexes in space on a calcaneus that has been stabilized by the ground, during subtalar joint pronation.[190,191]

The clinician palpates the position of the navicular tubercle as the patient's foot is non–weight-bearing but resting on the floor surface, with the subtalar joint maintained in neutral. The clinician then attempts to quantify the amount of inferior displacement of the navicular tubercle, as the patient assumes 50% weight-bearing on the tested foot (relaxed standing).[139] A navicular drop that is greater than 10 mm from the neutral position to the relaxed standing position suggests excessive medial longitudinal arch collapse of abnormal pronation.[191,192]

This test has been found to have an intratester reliability that ranged from ICC = 0.61 to 0.79 and intertester reliability of ICC = 0.57.[139] However, it is questionable whether a significant drop is also indicative of dysfunction.

FIGURE 21-57 Feiss line.

Feiss Line[193]

The Feiss line test is used to assess the height of the medial arch, using the navicular position. With the patient non–weight-bearing, the clinician marks the apex of the medial malleolus and the plantar aspect of the first MTP joint, and a line is drawn between the two points (Fig. 21-57). The navicular is palpated on the medial aspect of the foot, and an assessment is made of the position of the navicular relative to the imaginary line. The patient is then asked to stand with their feet approximately 3–6 inches apart. In weight-bearing, the navicular normally lies on or very close to the line. If the navicular falls one-third of the distance to the floor, it represents a first-degree flatfoot; if it falls two-thirds of the distance, it represents a second-degree flatfoot; and if it rests on the floor, it represents a third-degree flatfoot. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Vascular Status

Homans' Sign

This was the traditional test used to detect a deep vein thrombophlebitis (DVT). The patient lies in the supine position with their knee extended. The clinician stabilizes the thigh with one hand and passively dorsiflexes the patient's ankle with the other. Pain in the calf with this maneuver was considered a positive sign for DVT. However, a positive Homan's sign has been found to be insensitive, nonspecific, is present in fewer than 30% of documented cases of DVT,[194,195] and the performance of the test may increase the risk of producing a pulmonary embolism (PE).

Buerger's Test

The patient is placed in the supine position with the knee extended. The clinician elevates the patient's leg to approximately 45 degrees and maintains it there for at least 3 minutes. Blanching of the foot is positive for poor arterial circulation, especially if, when the patient sits with the legs over the end of the bed, it takes 1–2 minutes for the limb color to be restored.

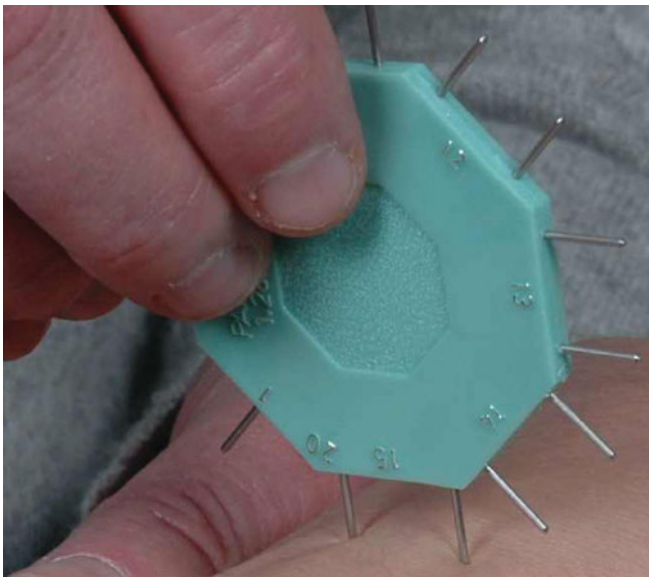

FIGURE 21-58 Sensory testing using pinprick.

Posterior (Dorsal) Pedis Pulse

The posterior (dorsal) pedis pulse can be palpated just lateral to the tendon of the extensor hallucis longus over the posterior aspect of the foot (see Fig. 21-14).

Neurologic Tests

The applicable sensory, motor, and reflex tests should be performed if a disorder related to a spinal nerve root (L4–S2) or peripheral nerve is suspected. A neurogenic cause of foot pain must be considered in a patient, especially if the pain is refractory. The patient usually complains of pain that is poorly localized, which is aggravated by activity but may also occur at rest. Any difference in sensation between extremities should be noted and can be mapped out in more detail by testing pinprick sensation (Fig. 21-58). The segmental and peripheral nerve innervations are listed in Chapter 3. Common muscle stretch reflexes tested in this area are the Achilles reflex (S1–2) and the posterior tibialis reflex (L4–5). Specific pathologies associated with peripheral nerve entrapment are described in the intervention strategies section.

The pathologic reflexes (Babinski and Oppenheim), tested when an upper motor neuron lesion is suspected, are described in Chapter 3.

Morton's Test.[196]

The patient is positioned in supine. The clinician grasps the foot around the metatarsal heads and squeezes the heads together. The reproduction of pain with this maneuver indicates the presence of a neuroma or a stress fracture. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Tinel's Sign

The posterior tibial nerve may be tapped behind the medial malleolus (Fig. 21-59). Tingling or paresthesia with this test is considered a positive finding. As with all Tinel's test

FIGURE 21-59 Tinel's sign.

throughout the body, this test provides only marginal sensitivity (58%).[197]

Imaging Studies

Radiography

According to the Ottawa rules for ankle X-rays (with Buffalo modifications),[198,199] X-rays are indicated to rule out fracture of the ankle when there is bone tenderness in the posterior half of the lower 6 cm of the fibula or tibia and an inability to bear weight immediately after injury.[198–200] Similarly, if there is bone tenderness over the navicular and/or fifth metatarsal, and an inability to bear weight immediately after injury, then radiographs of the foot are indicated (see Chap. 7).[198,200]

Other imaging techniques include arthrography, fibular (peroneal) tenography, and magnetic resonance imaging (MRI).

THE EVALUATION

Following the examination, and once the clinical findings have been recorded, the clinician must determine a specific diagnosis or a working hypothesis, based on a summary of all of the findings. This diagnosis can be structure related (medical diagnosis) (Table 21-10) or a diagnosis based on the preferred practice patterns as described in the *Guide to Physical Therapist Practice*.

INTERVENTION STRATEGIES

Due to the incorporated nature of the foot and ankle structures in functional activities, the rehabilitation for this region is best organized around a common framework for most foot and ankle pathologies.[201]

The techniques to increase joint mobility and the techniques to increase soft tissue extensibility are described in the "Therapeutic Techniques" section.

Acute Phase

The goals during the acute phase include:

- decreasing pain, inflammation, and swelling;
- protecting the healing area from reinjury;
- re-establishing pain-free ROM;
- preventing muscle atrophy;
- increasing weight-bearing tolerance;
- increasing neuromuscular control;
- maintaining fitness levels;
- attaining patient independence with a home-exercise program.

The control of pain, inflammation, and swelling is accomplished by applying the principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication). Icing for 20–30 minutes several times a day, concurrent with nonsteroidal anti-inflammatory drugs (NSAIDs) can aid in reducing pain and swelling.

The injured ankle should be positioned and supported in the maximum amount of dorsiflexion allowed by pain and effusion. Maximal dorsiflexion places the joint in its close-packed position or position of greatest congruency.[202] This allows for the least capsular distention and resultant joint effusion. With ankle sprains, this position produces an approximation of the torn ligament ends in grade III injuries to reduce the amount of gap scarring and reduces the tension in the grades I and II injured ligaments.[16,125]

The means by which to support or protect the joint during this phase will vary depending on the severity of the injury and the anticipated compliance of the patient to any restrictions placed on them by the physician.[16,125] For example, mild-to-moderate ankle sprains (grade I and II sprains) can be readily supported by the use of an elastic bandage, open Gibney strapping (with or without felt-pad incorporation), taping,[203–208] or the use of some type of thermoplastic stirrup such as an Air Cast (see next section).[209,210] One of the main advantages of this type of immobilization is that pain-free protected plantar flexion and dorsiflexion are possible, whereas inversion and eversion are minimized.

To increase ROM, the clinician can perform gentle capsular stretches and grades I–II joint mobilizations. Exercises in this phase include towel stretches **VIDEO** (Fig. 21-60), ankle circles **VIDEO** and pumps, **VIDEO** low-level biomechanical ankle platform system (BAPS) exercises (Fig. 21-61), and active and active assist exercises in straight planes (plantar flexion, dorsiflexion, inversion, and eversion) and proprioceptive neuromuscular facilitation (PNF) planes. Exercises for the foot intrinsics may include toe curl exercises with a towel **VIDEO** (Fig. 21-62) or having the patient pick up marbles from the floor with their toes and place the marbles in a small container or bowl **VIDEO**.

Isometric exercises within the patient's pain tolerance and pain-free ROM are initiated for all motions. These exercises are initially performed submaximally at multi-angles, progressing to maximal isometric contractions as tolerated. Mild manual resistive isometrics in all planes may also be started throughout the pain-free range. Active motion and exercise

TABLE 21-10 Differential Diagnosis of Common Causes of Leg, Foot, and Ankle Pain

Condition	Patient Age	Mechaism of Injury	Area of Symptoms	Symptoms Aggravated by	Observation	AROM	PROM	Resisted	Special Tests	Tenderness with Palpation
Gastrocnemius strain	20–40	Sudden overload	Upper calf	Heel raise	Antalgic gait	Painful and limited DF	Pain with overpressure into DF Restricted range of DF with knee extended	Pain on PF		Mid to upper calf
Plantar fascitis	20–60	Gradual with no known cause	Sole of foot (under heel)	Weight-bearing especially first thing in the morning	Unremark able Flattened arches Pronated foot	Full and pain free	Pain with overpressure into great toe extension	Weak foot intrinsics	Pressure applied over plantar fascial insertion site on the calcaneus	Plantar aspect of heel
Achilles tendinitis	20–40	Overuse	Posterior ankle	Jumping, running	Minor swelling of posterior ankle	Painful and limited DF	Pain with overpressure into DF Restricted range of DF with knee extended	Pain on PF		Posterior ankle
Posterior tibialis tendinitis	20–40	Overuse with a flat pronated foot	Medial ankle, along the course of the tendon	Activities involving weight-bearing plantar flexion	Possible peritendinous swelling over medial ankle	Pain on eversion Pain on PF	Pain with overpressure into eversion Pain with overpressure into PF	Pain on resited inversion with the foot plantar flexed	Rule out tear with heel raise symmetry	Medial ankle
Morton's neuroma	40–60	Gradual with no known cause	Sole of foot	Weight-bearing	Pronated foot Flattened arches	Full and pain free	Pain with overpressure into toe extension	Strong and painless		Web spaces of toes

Retrocalcaneal bursitis	Varies	Direct irritation of bursa, usually from shoe	Hindfoot	Friction	Possible swelling, erythema of hindfoot	Usually unremarkable	Usually unremarkable	Usually unremarkable	Palpation	Just above the insertion site of the Achilles tendon on the calcaneus
Anterior tibialis tendinitis	15–45	Overuse	Anterior lower leg	Activities involving repetitive dorsiflexion	Unremarkable	Pain with combined PF and inversion	Pain with overpressure into PF	Pain on DF		Anterolateral lower leg
Tarsal tunnel syndrome	25–50	Posttraumatic, neoplastic, inflammatory, rapid weight gain, fluid retention, abnormal foot/ankle mechanics, or a valgus foot deformity	Medial malleolus, distribution of posterior tibial nerve up the leg, or down into the medial arch, plantar surface of the foot and toes	Excessive dynamic pronation in walking or running	Pronated foot, pes planus, possible swelling	Full and pain free	Pain with extreme plantar flexion and eversion	Weak toe flexion (late)	Positive Tinel's over tarsal tunnel	No tenderness usually
Midfoot Sprain	15–40	High impact landing sports Foot twisted when in fixed position	Midfoot	Walking on toes	Usually unremarkable	Usually unremarkable	Usually unremarkable	Usually unremarkable	Weight-bearing lateral and anterior–posterior radiographs	Generalized tenderness of midfoot
Medial tibial stress syndrome	15–30	Overuse	Anterior lower leg Posterior-medial lower leg	Exercise involving involved lower extremity		Pain with combined PF and inversion	Full and pain free	Pain on PF Pain on eversion		Posteromedial calf

(Continued)

TABLE 21-10 Differential Diagnosis of Common Causes of Leg, Foot, and Ankle Pain *(Continued)*

Condition	Patient Age	Mechaism of Injury	Area of Symptoms	Symptoms Aggravated by	Observation	AROM	PROM	Resisted	Special Tests	Tenderness with Palpation
Metatarsal stress fracture	15–45	Overuse	Forefoot	Weight-bearing activities	Possible edema over fracture site	Usually unremarkable	Usually unremarkable	Usually unremarkable	Palpation, ultrasound, tuning fork, bone scan, MRI, CT scan	Maximal point tenderness over the bone at the fracture site
Referred	Varies	Symptoms can be referred from the lumbar spine, hip, knee, or from systemic diseases such as diabetes mellitus (DM), spondyloarthropathy (Reiter's syndrome)	May be dermatomal if spinal nerve involved; stocking-like if DM, bilateral heels if Reiter's	Activities unrelated to foot and ankle; unrelated to activity	Varies, but may be unremarkable	Usually unremarkable	Usually unremarkable	Usually unremarkable, but weakness may be present if spinal nerve root involved	Sensation, DTR, lab tests	Tenderness of joint if spondyloarthropathy

FIGURE 21-60 Towel stretch.

FIGURE 21-61 BAPS exercise.

may also be used to effectively increase local circulation and further promote the resorption of any persistent edema.[211,212] Exercises are progressed to include concentric exercises, once the isometric exercises are pain free. Seated lower extremity closed kinetic-chain exercises (Fig. 21-63) may also be performed during this phase.

Each muscle or muscle group should be strengthened with a specific exercise that isolates the muscle or group. Resistance

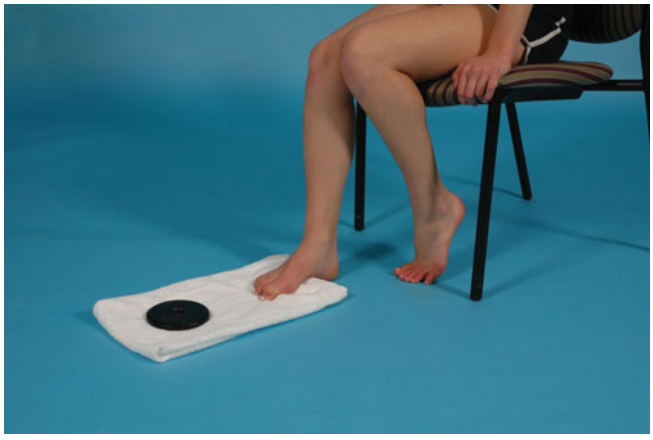

FIGURE 21-62 Towel toe curls.

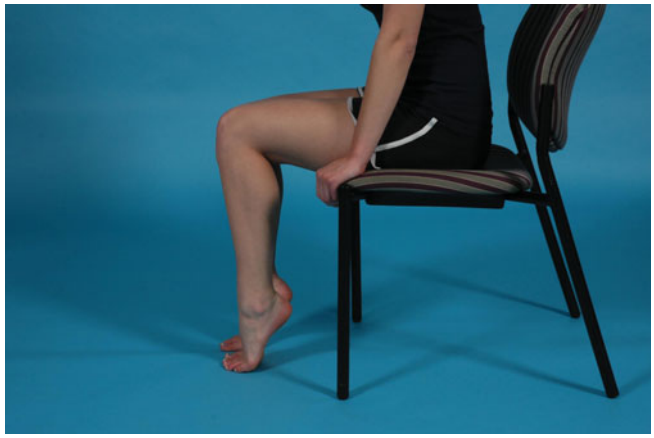

FIGURE 21-63 Seated heel raises.

(rubber tubing/bands, weights, isokinetic devices, body weight exercises, etc.) is increased as tolerated. Emphasis should initially be at low resistance and endurance in all pain-free positions. As the program progresses, the joint range is increased from a stress-free position to a more stressful position. As with all exercises, the patient should become an active participant at the earliest opportunity. The exercises learned in the clinic need to be integrated appropriately into a home-exercise regimen.

Pain-free weight-bearing as tolerated is encouraged with the use of any appropriate support or assistive device, such as taping, a brace, a cane or crutches **VIDEO**.[213,214] The use of an assistive device is usually continued until the patient has a pain-free uncompensated gait. Even when using an assistive device, pain-free ankle motion during the normal gait cycle and as normal a gait as possible continues to be encouraged **VIDEO**.

Specific joint mobilization techniques[215] and muscle stretching are initiated to begin to increase ROM.

Bracing

Braces can play an important role in both the initial intervention and prevention of ankle injuries. Acutely, their role is to compress, protect, and support the ankle. They also function to limit ROM of the injured ankle, most importantly plantar flexion and inversion, which is a precarious position for the sprained ankle.[129]

Functional braces that provide medial–lateral stabilization such as the Air Cast (Air Cast, Inc., Summit, NJ) also provide compressive force that assists in decreasing effusion.[16,125] Patients who suffer a grade III ligament injury may require more protection and support than can be afforded by a thermoplastic device. In cases such as this, consideration should be given to using a functional walking orthosis, either with a fixed ankle or a hinged ankle (which can be motion restricted) that allows only plantar flexion and dorsiflexion.[16,125] The advantage of the orthosis is that it is removable to allow the patient to continue to ice to minimize inflammation.

Overall, braces have been demonstrated to be biomechanically effective in preventing, decreasing, or slowing motions that cause injury to the lateral ankle ligaments.[216]

Although, one study[217] reported that braces were not as effective as freshly applied tape (see taping), clinically, braces appear to be as effective, if not more effective, than tape in the prevention of lateral ankle sprains.[218–222] The injury rate in one study by Sitler et al.[220] reported that the ankle injury rate was more than triple in the nonbraced players compared with braced players during intramural basketball at West Point.

In the presence of instability, the ankle joint is best supported by a commercial brace, with or without taping, depending on the stress of the sport.[16,125]

Night Splinting

Night splinting of the ankle in dorsiflexion has been postulated to prevent nocturnal contracture of the gastrocnemius–soleus complex, which is thought to be detrimental to plantar fascia healing.[223–225] The splint holds the ankle fixed in 5 degrees of dorsiflexion and the toes slightly stretched into dorsiflexion (i.e., at a functional length).[38] For most patients, this orthosis reduces morning pain considerably.[225] Powell et al.[224] performed a crossover study using splinting with the ankle in dorsiflexion as the sole method of treatment in 47 patients. This study also showed improvement in 80% of involved feet.

Functional Phase

For the patient to progress to the functional phase of the rehabilitation program, pain-free weight-bearing, and an uncompensated gait pattern must be present. However, pain may still be felt with activities more vigorous than walking. In addition, there should be minimal pain and tenderness, full PROM and strength rated at 4/5 to 5/5 with manual muscle testing as compared with the uninvolved side.[201] A recurrence of symptoms should not be provoked. The goals of this phase are as follows:

- to restore normal joint kinematics;
- to attain full range of pain-free motion;
- to improve neuromuscular control of the lower extremity in a full-weight-bearing posture on both level and uneven surfaces;
- to improve or regain lower extremity strength and endurance through integration of local and kinetic chain exercises;
- to return to previous level of function or recreation.

Exercises during this phase include manually resisted exercises, concentric exercises with tubing into dorsiflexion (Fig. 21-64), **VIDEO** plantar flexion **VIDEO**, inversion **VIDEO**, and eversion (Fig. 21-65) **VIDEO**. Exercise tubing can also be used for toe flexion **VIDEO** and extension **VIDEO**. Closed-chain exercises include, but are not limited to, seated marching on the floor **VIDEO** or pillow **VIDEO**, unilateral stance on the floor **VIDEO**, weight shifting **VIDEO**, standing bilateral or unilateral heel raises **VIDEO**, standing gastrocnemius stretch **VIDEO**, wall slide **VIDEO**, toe walking **VIDEO**, heel walking **VIDEO**, and supine leg press **VIDEO**. Emphasis should be placed on regaining any dorsiflexion that was lost. Regaining dorsiflexion can also be assisted by the use of a tilt board or heel cord stretching box. The gastrocnemius is stretched by keeping the knee straight (Fig. 21-66) and the soleus is stretched by flexing the knee (Fig. 21-67).[205,214]

FIGURE 21-64 Dorsiflexion PRE with resistive tubing.

FIGURE 21-65 Eversion PRE with resistive tubing.

Proprioceptive exercises are especially important for full functional return and injury prevention.[16,125] Three factors are thought to cause functional instability of the ankle joint:[226]

- Anatomic or mechanical instability.
- Muscle weakness.
- Deficits in joint proprioception.

One of the all-to-common consequences of an ankle injury is an alteration of the motor conduction velocity of the fibular (peroneal) nerve and the protective function of the fibularis (peroneal) muscles on the ankle joint.[209,227,228] A decrease in fibular (peroneal) reaction time has been demonstrated to continue for up to 12 weeks after injury[209,227] despite a nearly full return of strength (96%) in comparison with the contralateral side.[227] An increase in the latency response of the fibularis (peroneal) muscles has also been demonstrated in normal subjects with an increase in plantar flexion, indicating a loss of protective reflexes when in this position.[229] The patient must train and be rehabilitated in all potential positions of injury.[16,125]

FIGURE 21-66 Gastrocnemius stetch.

A study by Rozzi et al.[155] demonstrated that a 4-week course of single-leg balance training showed an improvement in balance ability in both the trained and the untrained limbs. Examples of exercises to perform to enhance proprioception include unilateral stance on a pillow **VIDEO**, side (lateral) step up **VIDEO**, standing unilateral heel raise **VIDEO**, lunges onto **VIDEO**, or over **VIDEO** a pillow, backward step ups **VIDEO**, and cross-over walking **VIDEO**.

FIGURE 21-67 Soleus stretch.

After isolated strength exercises are initiated in the early portion of this phase, multidirectional, multijoint exercises should begin. Ankle PNF exercises are started based on the patient's tolerance.[230]

Multidirectional balance activities should progress from the non–weight-bearing, open-chained exercises until the ROM is full and painless, at which time closed-chain exercises are introduced with a progression to full-weight-bearing.[16,125] The greater the severity of injury, the more significant the need for multidirectional balance and weight-bearing rehabilitation activities.[231–238] These activities are effective in progressing the patient toward a progressive return to function. This progression involves beginning with a phase of walking or jogging on flat surfaces, ascending and descending stairs both forwards and backwards, with a progression to turning, changing directions and lateral movements while running, and eccentric loading with stair running.[127]

Further work is needed to fully determine the effect of training the responsiveness to ankle musculature to counteract potentially injurious stimuli. Until then, multidirectional balance activities and proprioceptive training should continue to be stressed as part of a clinical rehabilitation program.

Tests found to correlate well with good recovery are descending stairs, walking on heels and toes, and balancing on a square beam.[127,239] For some patients, the goal may be to return to sport. Progression to this level occurs when there is[201]:

- full pain-free active and passive ROM;
- no complaints of pain or tenderness;
- 75–80% strength of the plantar flexors, dorsiflexors, invertors, and evertors compared to the uninvolved side;
- adequate unilateral stance balance (30 seconds with eyes closed).

Before being allowed to return to full competition, the patient should be put through a functional test that simulates all requirements of his or her sport.[16,125] Observational analysis should be made of the patient's quality of movement and whether or not they are favoring the injured extremity in any way.[16,125] Activities during this phase involve cutting drills, shuttle runs, carioca crossover drills, and sports-specific activities such as lay-ups and dribbling.[129]

Full-strength, fibular (peroneal) latency response time and proprioceptive sense about the ankle may not return for many weeks even though the patient has returned to activity.[209,227,240]

Taping

Historically, ankle taping has been the athletic trainer's method of choice to attempt to prevent ankle sprains. Ankle taping is effective in restricting the motion of the ankle and has also been proved to decrease the incidence of ankle sprains.[241–246]

However, although taping initially restricts motion, the tape loses 50% of its net support after as little as 10 minutes of

exercise.[217,246–254] Because of this deterioration of support, and the cost of tape, removable and reusable ankle braces were designed as an alternative to taping.[16,125]

The use of tape for increased proprioception remains controversial. It is hypothesized that the tape can either provide additional cutaneous cues or provide a general facilitation at spinal or higher levels, thereby enhancing the perception of movement signals from other proprioceptive sources,[255–258] although this has yet to be proved conclusively.[256,259,260]

The more common instabilities treated with taping include splaying of the mortise, inversion instability of the ankle, plantar instability of the talonavicular joint, and inversion or eversion instability of the talocalcaneal joint.[16,125]

- The mortise is taped circumferentially around the lateral and medial malleolus.
- Talocalcaneal instabilities are taped around the neck of the talus and the heel. With the exception of the inferior tibiofibular joint (which is a syndesmosis), the taping can effect a temporary improvement in symptoms and function.

The decision whether or not to use some type of protective taping or bracing upon return to activity to prevent reinjury is a decision based on the individual athlete and his or her case. No type of taping or bracing will prevent all injuries.[16,125]

CLINICAL PEARL

Often a player may argue that their performance will be adversely affected by the use of taping or bracing.[16,125] A review of the literature demonstrates that for normal athletic movement and function there does not appear to be an adverse impact on function or performance.[218,253,261–265] Indeed, one study involving soccer players, demonstrated a fivefold decrease in the incidence of recurrent ankle sprains when using semirigid orthoses, without significantly affecting sports performance.[222]

Footwear

The type of sneaker worn during basketball, high top versus low top, has been studied and shown to have no relationship to the incidence of injury.[242] However, it does appear that increased shoe height can enhance the passive resistance to inversion when the foot is in plantar flexion and can also increase the passive resistance afforded by tape and orthoses.[217]

One of the many contributing factors to running injuries is improper or worn out footwear. On average, running shoes wear out between 300 to 500 miles, although these figures are merely estimates and the actual distance at which a shoe breaks down may vary according to running style, training techniques and environmental conditions, including terrain and weather. Running in a shoe that no longer provides the correct protection in terms of cushioning, traction, and support may lead to heel pain, shin splints, tendinitis, and stress fractures.

CLINICAL PEARL

In general, a runner with a high medial longitudinal arch and a C-shaped foot, often characterized as a "supinator," tends to underpronate during midstance and should therefore be using a shoe with a softer midfoot and one that is more cushioned, especially on the lateral edge of the shoe.

Similarly, a runner with a low medial longitudinal arch, often characterized as a "pronator," tends to produce an excessive medial roll of the foot during the stance phase and should therefore be using a shoe designed for motion control of the rearfoot and with hard or rigid midsoles made from plastic or high-density foam that permit only minimal pronation.[266]

Orthotics

An orthosis can be defined as any device used to support, align, or protect joints or body segments, thus improving function.[267] If significant biomechanical variations from normal are noted during the examination, an orthosis may be indicated.

The principal purpose of a foot or ankle orthosis is as follows[267]:

- evenly distribute the weight-bearing forces on the plantar aspect of the foot;
- reduce stress on anatomic structures local or proximal to the foot and ankle by either force attenuation or control of joint motion;
- prevent, correct, or compensate for the presence of foot or ankle deformities.

A wide variety of materials are available for the fabrication of custom-made orthotics, which vary in elasticity, plasticity, compliance, and rigidity. A rigid orthosis is usually constructed from a hard thermoplastic, graphite, or fiberglass material. Semirigid devices can be composed of materials including leather, rubber, cork, polypropylene, and copolymers.

Biomechanical foot orthoses incorporate the concept of posting. The posts may be an addition of an extrinsic (relatively noncompressible) material to the shell of the orthoses, or an intrinsic post (using relatively rigid material) built into the design of the shell, which functions to balance the malalignment of the foot. Extrinsic posts offer the advantage of being easy to adjust, whereas intrinsic posts are much more difficult to adjust. Despite the widespread use of orthoses, questions are arising as to the theoretical basis for their use for the following reasons:[267]

- Any definition of "normal" foot alignment assumes that anything that falls outside the criteria for "normal" must be abnormal and associated with pathology; yet, studies have shown that the criteria we use to describe "normal" apply to very few individuals and that many asymptomatic individuals display foot abnormalities but meet those criteria.[268–270] Before correcting a malalignment using an orthotic, the clinician needs to determine more definitively

the causal relationship between the malalignment and the patient's symptoms.

- The determination of subtalar neutral, the measurement that is the cornerstone for the prescription of orthotics, is relatively unreliable. While the intrarater reliability in determining subtalar neutral has been found to be acceptable,[271] the interrater reliability scores have demonstrated that therapists are frequently unable to agree with other therapists in determining subtalar neutral.[268,271]

Heel Lifts

The use of heel lifts is advocated in the literature for a variety of conditions, including Achilles tendinitis, plantar fasciitis, and calcaneal apophysitis.[43]

The material used to make the heel lift can be modified to increase shock absorption in cases of calcaneal bruising and heel spurs.[272]

Heel Cups

Heel cups are used for similar conditions as heel lifts, with the added benefit that the heel cup is able to help redistribute the forces through the heel better, and because the medial and lateral walls help contain the fat pads of the calcaneus, thus improving the natural shock-absorptive ability.[39,267,273]

Wedges

Prefabricated or custom-made wedges are referred to as a "post" when used in functional foot orthoses. Wedges are typically used to slant the entire foot or part of the foot either medially or laterally to prevent motion or change the weight-bearing aspect of the foot.

PREFERRED PRACTICE PATTERN 4B: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM ASSOCIATED WITH IMPAIRED POSTURE

Clinical findings with this pattern can include pain with sustained positions, structural deformities and deviations, limited ROM in a noncapsular pattern of restriction, and altered kinematics.

The Pronated Foot

In the normal foot, the angle of the rearfoot and forefoot intersect at 90 degrees, with a downward projection of the center of mass at 135 degrees, such that all of the forces counteract one another, resulting in zero net force and zero rotational velocity.[274] Any changes in this anatomical relationship can affect the static equilibrium. Pronation of the foot creates an angle greater than 90 degrees between the rearfoot and the forefoot. Static equilibrium can only now be maintained through a counteracting force such as the passive stretch of the passive plantar mechanism. Pronation of the ankle and foot during the stance phase of gait is in essence a temporary collapse of the ankle, rearfoot, and midfoot, which serves to provide a more adaptable structure. This adaptability allows for shock absorption and ground terrain changes and helps to prevent excessive strain on the joints or ligaments.[85] Although some pronation of the foot is necessary during functional activities, excessive pronation has been linked to lower limb overuse injuries, because maintenance of the equilibrium becomes the function of the muscles, specifically the fibularis (peroneus) brevis and the posterior tibialis.[43,275–278] Excessive pronation can occur as a result of a number of different factors, including the following:[143]

- Congenital, including tarsal coalitions, metatarsus varus, and convex pes valgus.[4,48,279]
- Developmental, including talipes calcaneovalgus, talipes calcaneovarus, ligament laxity, and/or a tight Achilles tendon and forefoot varus.[4,48,279,280]
- Equinus at the ankle, resulting in increased dorsiflexion of the forefoot at the rearfoot around the oblique midtarsal joint axis;
- Subtalar varus;
- A plantar flexed lateral column, which results in pronation due to the fact that the fourth and fifth metatarsals are lower than the adjacent third metatarsal, which produces a pronatory force with weight-bearing;
- Rearfoot varus associated with excessive forefoot pronation and delayed resupination.

The patient with a symptomatic pronated foot typically complains of pain along the medial longitudinal arch. Occasionally, there is pain laterally beneath the tip of the fibula secondary to impingement of the calcaneus against the fibula. The pain is usually aggravated with prolonged standing and walking and relieved with rest.[281] Often these patients become symptomatic when they suddenly increase their level of activity.

The examination often reveals a flattening of the longitudinal arch associated with a valgus deformity of the heel, a medial bulge at the talonavicular joint, a low medial longitudinal arch, and abduction of the forefoot on the rearfoot at the transverse tarsal joint.[281,282]

Two terms can be used to describe the pronated foot: weak and hypermobile. Both the weak and the hypermobile flatfoot can cause symptoms in everyday weight-bearing activities due to postural fatigue.

The Weak Foot

The weak foot produces moderate pronation. Severe pronation with flattening of the foot is associated with congenital or ligamentous laxity and is deemed to be occurring if the foot is pronating beyond 25% of the stance phase.[4,112,143,283] Acquired flatfoot deformity is a symptomatic and progressive flatfoot deformity, resulting from the loss of function of the tibialis posterior muscle/tendon and/or the loss of

integrity of the ligamentous structures supporting the joints of the arch and the rearfoot. The weak foot is characterized by a general increase in the ROM at the subtalar and midtarsal joints, with the heel positioned in valgus, and the medial arch is dropped. In addition, the forefoot is externally positioned on the rearfoot, and the foot is usually toed out.[143]

The Hypermobile Foot

Occasionally, a foot that appears normal in non–weight-bearing (static examination) can excessively pronate during running (dynamic examination). Consequently, it is usual for this type of foot to only give symptoms with running, which emphasizes the importance of performing both a static and a dynamic examination of the foot.

Hypermobility at the foot and ankle can lead to increased stress on the bone and soft tissues, especially the ligaments, and an overreliance on muscular support.[80]

The intervention for an abnormally and symptomatic pronated foot depends on the type, but typically involves the following:

- Removal or alleviation of the abnormal tissue stress.
- Stretching of the gastrocnemius–soleus complex.
- Activity and shoe modification.[80,284] A straighter last is more desirable for a person with excessive pronation.
- Taping or arch strapping: can be used to limit excessive pronation.[285,286]
- Orthotics.

THE FLATFOOT

A flatfoot or pes planus is manifested by little or no longitudinal arch with full-weight-bearing, which is present beyond the the age of 6 years.[287]

In most cases, a pes planus is flexible demonstrated by the fact that the arch can be recreated with the patient standing up on their toes. Flexible pes planus has been reported to occur in 15% of the general population,[288] with the majority being asymptomatic.[289] If a flatfoot is painful, other causes must be sought out, such as tarsal coalition, vertical talus, or accessory navicular.[58]

A rigid flatfoot, a relatively rare condition, positions the calcaneus in a valgus position and the midtarsal region in pronation, resulting in a displaced navicular (posteriorly (dorsally)) and a talus that faces medially and inferiorly.

Extrinsic congenital deformities can cause abnormal pronation. These include hip dysplasia, femoral anteversion, tibial torsions, and genu varum or valgus. These deformities produce a rotation of the lower limb, which can have the following consequences:

- ***Excessive external rotation of the lower limb.*** This may shift the center of gravity in weight-bearing to the medial aspect of the foot. Ideally, the center of gravity during weight-bearing should pass through the center of the foot. This increase in medial stress causes the talus to plantar flex and adduct, while the calcaneus tilts laterally (into valgus).
- ***Excessive internal rotation of the lower limb.*** This produces excessive weight-bearing on the lateral aspect of the foot. In an attempt to shift the center of gravity more medially, the forefoot abducts on the rearfoot, or the foot abducts on the leg. These compensations produce excessive pronation of the subtalar joint.

THE STIFF FOOT

Pes cavus is an abnormally supinated and stiff foot. While normal supination is designed to allow the foot to function as a rigid lever during push-off, torque conversion, and a lengthening mechanism of the leg,[85] the stiff foot prevents normal pronation from occurring during the stance phase of gait. Without the normal amount of pronation needed to allow the dissipation of stresses, the foot loses its ability to absorb shock. The stiff foot is characterized by a high arch, increased external rotation of the tibia, and increased forefoot varus.

There are three classifications of abnormal supination:[4,143]

- ***Pes cavus.*** This classic type is characterized by a fixed plantar flexed forefoot, or an equinus forefoot, which places the rearfoot in neutral during weight-bearing.[280] The high longitudinal arch of the cavus foot results in limited weight-bearing on the plantar aspect of the foot. This produces increased pressure on the heel and on the metatarsal heads.[281] The physical examination reveals a varus configuration of the heel, a marked elevation of the longitudinal arch, no medial bulge at the talonavicular joint, an adducted forefoot relative to the rearfoot, and external rotation of the leg.[281,282]
- ***Pes cavovarus.*** This type is characterized by a fixed plantar flexed medial column or first ray. This places the calcaneus in varus or inversion during weight-bearing, so that the foot lands on its lateral border.[280]
- ***Pes equinovarus.*** This foot type demonstrates a fixed plantar flexed forefoot and rearfoot, with no compensation occurring with weight-bearing.

The intervention for a symptomatic case of cavus foot is supportive and involves having the patient wear a soft shoe with adequate padding to increase the weight-bearing surface of the foot and provide more midsole cushion for the plantar aspect of the foot.[281290]

SPECIFIC JOINT DEFORMITIES AND DEVIATIONS

Talocrural Joint

Talipes Equinus

The lack of a minimum of 10 degrees of dorsiflexion at the talocrural joint is termed as talipes equinus.[94] A common cause for a lack of dorsiflexion at the ankle is adaptive shortening of the gastrocnemius and soleus muscle groups. Other causes include trauma, spasticity, structural bone deformities, and inflammatory disease. This dysfunction often

results in excessive forces being transferred to the forefoot and increased pronation at the subtalar joint.[140]

Common problems associated with this foot type include medial arch pain, posterior leg pain, plantar heel pain, metatarsalgia, lateral ankle sprain, and talonavicular pain.[80]

Subtalar Joint

Rearfoot Varus

This is the most common structural foot deformity and is the most common abnormality of the subtalar joint. The most important component of a rearfoot varus is a calcaneal varus (subtalar varus). A calcaneus varus is characterized by an inverted position of the calcaneus when in the subtalar joint neutral position. This may result in limited eversion and pronation of the subtalar joint when the foot is in contact with the ground. The combination of calcaneal varus and any medial inclination of the tibia produce a total rearfoot varus. A 2–3-degree rearfoot varus is common and generally presents no problems.[291]

The practical significance of a rearfoot varus is that at heel strike, the calcaneus is inverted more than normal and the medial condyle of the calcaneus is farther from the ground, resulting in an increase in lateral heel contact. To bring the medial side of the foot to the ground, the calcaneus must evert. Eversion of the calcaneus is produced by the subtalar joint pronating.

Thus, a rearfoot varus forces the subtalar joint to go through an excessive amount of pronation. In addition, the pronation occurs too rapidly. Rapid pronation from this varus contact position can result in retrocalcaneal exostosis.

Partial compensation occurs if the subtalar joint pronates abnormally but does not have enough available pronation ROM to bring the medial condyle of the calcaneus to the ground.[119] In response to a rearfoot varus, a callus will often form under the second metatarsal head and, to a lesser degree, under the third and fourth metatarsal heads.[119] The callus does not occur under the first metatarsal head, because the stability of the latter depends on the fibularis (peroneus) longus muscle.

If no compensation occurs at the subtalar joint, the midtarsal may compensate with increased mobility and medial longitudinal arch collapse.[85]

When the rearfoot varus is large, the metatarsal joint and the forefoot may be excessively mobile, when the heel rises from the ground during propulsion. In addition, the foot may not become rigid until after the heel rises, instead of just before heel rise.

Other tissue disorders that can result from rearfoot varus include plantar heel pain, metatarsalgia, or stress factors of the second ray and hallux valgus. The proximal effects of subtalar joint compensation for a rearfoot varus are substantial. The excessive and rapid pronation that occurs during the contact phase of gait puts a tremendous stress on the primary muscle that decelerates subtalar joint pronation, the tibialis posterior muscle, producing symptoms of overuse in this muscle.[119]

In addition to the extreme stress placed upon the tibialis posterior muscle, abnormal subtalar joint pronation may produce an excessive internal rotation of the lower leg.[119] Normally, the tibia rotates an average of 19 degrees during ambulation.[20] At the beginning of the stance phase, the tibia internally rotates as the talus plantar flexes and adducts. At the end of the stance phase, the tibia must externally rotate, pushing the talus into dorsiflexion and abduction. Any extra rotation must be absorbed in the knee, hip, or sacroiliac joint, or between the lumbar vertebral segments. For example, abnormal subtalar joint pronation increases the valgus stress on the knee, and symptoms of a mild strain of the medial collateral ligament can arise.[119]

Rearfoot varus commonly occurs with tibia vara or pes cavus.[80]

Rearfoot Valgus

Rearfoot valgus involves eversion of the calcaneus when the subtalar joint is in its neutral position. The midtarsal and subtalar joints supinate to compensate. This structural deformity is often associated with genu valgum, or with tibia valgus, and can lead to excessive pronation and limited supination.

Midtarsal Joint

Forefoot Varus

Forefoot varus is defined as inversion of the forefoot on the rearfoot, when the subtalar joint is held in neutral.[94] Some forefoot varus is normal, and in asymptomatic individuals, there is usually approximately 7 degrees of forefoot varus.[292]

This sagittal plane osseous deformity of the forefoot/first ray,[293] with increased stress applied to the medial plantar aspect of the foot, is considered to be the single most common intrinsic cause of mechanical pain and dysfunction within the foot, lower one-third of the leg, and knee (Table 21-11).[280]

TABLE 21-11 Effects of a Forefoot Varus

Talus adducts/plantar flexes
↓
Foot muscles fire out of sync
↓
Lower extremity internally rotates
↓
Midtarsal joint hypermobile
↓
Cuboid pulley is less efficient
↓
Fibularis tendon less functional
↓
First ray hypermobile
↓
Second and third metatarsals bear too much weight
↓
Metatarsals splay apart
↓
Bunions, fractures, and calluses

Data from Hunter S, Prentice WE: Rehabilitation of the ankle and foot. In: Prentice WE, Voight MI, eds. *Techniques in Musculoskeletal Rehabilitation*. New York: McGraw-Hill, 2001:605. With permission from McGraw-Hill.

Since the medial side of the foot is higher than the lateral side, the forefoot assumes an inverted or varus position. To assist the medial side of the forefoot in reaching the ground, the subtalar joint may excessively pronate as the midstance phase begins. This compensation places the midtarsal joint in its maximally mobile position, at the time when it should be in a stable supinated position (just before and during propulsion). The compensation can create the following:

- extreme stresses on the fibularis (peroneus) longus and the forefoot;
- dorsiflexion and subsequent hypermobility of the first ray.[94,119]
- plantar heel pain;[119]
- hallux valgus, bunion deformity, and a subluxation of the first MTP joint.[280]

Since the first-ray complex cannot effectively contribute to propulsion, the second metatarsal head will experience excessive loading, with the potential for callus formation under the second metatarsal head, or metatarsalgia or stress fracture of the second metatarsal.[119,294]

In addition, the forefoot-to-rearfoot alignment in the frontal plane is abnormal, which predisposes the fifth toe to receive pressure from the shoe, which can result in a fifth-digit hammer toe.[143] Terminal knee extension during the midstance phase requires the tibia to externally rotate on the femur. If the knee joint compensates by having the femur rotate medially with the tibia, the problem is transferred to a more proximal structure, mainly the hip joint, or the sacroiliac joint, increasing stress to both contractile and noncontractile tissues.[119]

Forefoot Valgus

This dysfunction occurs when the plane of the metatarsal head is in an everted, or valgus, position. Two structural types of forefoot valgus deformities exist.

- All of the metatarsal heads may be everted.
- The first metatarsal head may be plantar flexed, while the second to fifth metatarsal heads lie in the appropriate plane (pes cavovarus).

If the first ray is plantar flexed, compensation may occur at the subtalar joint in the form of rapid supination of the subtalar joint. This shifts the weight laterally to the fifth metatarsal head.[94,280] If no subtalar joint compensation occurs in response to a forefoot valgus, the body weight is borne on the medial side of the forefoot.[119] To bring the lateral side of the foot to the ground, compensatory supination must occur at the subtalar joint.[119] This supination occurs at a rate that is much sooner than in a normal foot.[143] One of the distal effects of the abnormally supinated foot is that the midtarsal joint is unable to adapt to uneven surfaces, which leads to an increased susceptibility to lateral inversion sprains (Table 21-12).[119]

In addition, the shock-absorbing ability of the knee is also compromised, as the necessary internal rotation of the lower leg required for flexion is delayed. This may play a role in the development of problems around the lateral aspect of the knee or patellofemoral joint.[94,118] The increased forces may also travel up the lower extremity and contribute to the development of sacral and low-back dysfunction.

TABLE 21-12 Effects of a Forefoot Valgus

Talus adducts/dorsiflexes
↓
Lower extremity externally rotates
↓
Midtarsal joint hypomobile
↓
Cuboid pulley is less mobile
↓
Fibularis tendon held more rigid
↓
First ray hypomobile
↓
First and fifth metatarsals bear most weight

Forefoot Equinus

This is also a forefoot deformity, but it occurs in the sagittal plane. The metatarsal heads, although possibly perpendicular to the calcaneal bisection, are not level with the plantar condyles of the calcaneus. This results in a relative plantar flexion of the forefoot structures when compared with the rearfoot. The functional effect of this deformity is that the ankle joint must move through a greater excursion of dorsiflexion to allow the body to move forward over the foot during the midstance phase.[119]

The subtalar joint itself is unable to compensate directly for a forefoot equinus because it has very little dorsiflexion. Thus, the midtarsal joint usually becomes the source of the dorsiflexion. If the midtarsal joint is to provide the necessary dorsiflexion, the subtalar joint must be pronated. However, the time when maximum subtalar pronation is needed by the midtarsal joint (at terminal stance) coincides with the time when the subtalar joint should be in a supinated position for propulsion.

More proximally, if the foot and ankle are not able to provide the necessary dorsiflexion, the motion in the sagittal plane may be achieved at the knee joint. This may result in a hyperextension force at the knee, as the body progresses forward over the foot and the tibia.

Combined Rearfoot and Forefoot Deformities

Combinations of deformities frequently occur together.

- A rearfoot varus can occur with either a forefoot varus or a forefoot valgus.[119] In a foot that exhibits a rearfoot and a forefoot varus, the compensatory subtalar joint pronation is accentuated throughout the initial contact, midstance, and terminal stance phases of the gait cycle.[119]

- A rearfoot varus may be combined with a flexible forefoot valgus.[119] Clinically, this foot type demonstrates a significant amount of pronation during stance. As the subtalar joint begins to pronate, the midtarsal joint mobility increases and the forefoot valgus becomes flexible.[119] The foot is abnormally pronated, but the abnormal pronation occurs at the midtarsal joint as well as at the subtalar joint.
- A rigid forefoot valgus can occur with a rearfoot varus.[119] This combination creates extreme bone stress in the middle of the foot, particularly the tarsal bones. Degenerative joint changes and tarsal stress fractures are potential problems, as are lateral ankle sprains and the more proximal problems that occur with a forefoot valgus.[119]

Congenital Variations of the Foot

Clubfoot

The term *clubfoot* encompasses a wide range of deformities, most of which involve the heel to some degree. The most common clubfoot deformity is talipes equinovarus. Two categories exist: a flexible form and a resistant form. The former is amenable to conservative intervention with orthotics and footwear modification. The latter type is invariably associated with stiffness and requires surgical intervention.

Convex Pes Valgus

This deformity is also known as "rocker bottom" foot. It is characterized by a primary posterior (dorsal) and lateral dislocation of the talocalcaneonavicular joint. This results in the navicular articulating with the posterior aspect of the talus, locking it in the vertical position and preventing normal dorsiflexion of the rearfoot.[280,295] The compensation for this loss of rearfoot dorsiflexion is dorsiflexion at the midfoot.[85]

Metatarsal Deformities

Four metatarsal deformities are commonly recognized[293]:

- ***Metatarsus adductus.*** This is a transverse plane deformity with adduction of all of the five metatarsals, which occurs at the tarsometatarsal joint.
- ***Metatarsus varus.*** This deformity is characterized by a medial subluxation of the tarsometatarsal joints with an adduction and inversion deformity of the metatarsals. This results in an inability of the forefoot to be passively abducted to the neutral position.[280]
- ***Metatarsus adductovarus.*** This is a combined transverse and frontal plane deformity of forefoot adduction and inversion that occurs at the tarsometatarsal joint.
- ***Forefoot adductus.*** This is a combined transverse and frontal plane deformity of forefoot adduction and inversion that occurs at the midtarsal joint.

PREFERRED PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Seronegative Spondyloarthropathies

Ankylosing spondylitis (AS), psoriatic arthritis, and Reiter's syndrome are all capable of producing foot and ankle pain. Although AS predominantly affects the axial skeleton, it can also affect the MTP joints.[281]

Psoriatic arthritis usually occurs with accompanying skin lesions. However, in 10–15% of cases, no dermatologic problems exist.[281] The condition is characterized by symmetrical involvement of the hands and feet, most often at the level of the DIP joints.[281]

Reiter's syndrome consists of a triad of conjunctivitis, urethritis, and asymmetric arthritis. This condition usually affects the knees, feet, and ankles.[281]

Posttraumatic Arthritis

Posttraumatic arthritis, which is associated with repeated inversion sprains, is more common than osteoarthritis at the ankle. The trauma may result from direct injuries to the cartilage and/or altered biomechanics (malalignment, altered weight-bearing forces, and incongruent joint loading). Individuals with posttraumatic arthritis of the ankle generally report isolated ankle pain and stiffness and complaints of catching, locking, clicking, and painful giving-way episodes.[296] The objective examination typically reveals swelling and limited and painful ankle dorsiflexion and plantar flexion ROM. Because of unique set of challenges presented, posttraumatic arthritis in this region is difficult to treat conservatively. The conservative treatment approach can include medication (NSAIDs, corticosteroid), patient education (weight loss, activity modification or avoidance, the use of a cane), shoe modification (heel lift to reduce dorsiflexion) bracing (AFO), stretching, mobilization, strengthening, and symptom management (heat, ice, and/or electrical stimulation), as appropriate. Surgical options include ankle arthrodesis and arthroplasty.

Osteochondrosis

Osteochondrosis is an injury to an ossification center, resulting in inflammation, degeneration, recalcification, necrosis, and/or fragmentation. It can occur at an epiphyseal center of a long bone or apophyseal area where a tendon inserts. Osteochondrosis at an apophyseal area is typically referred to as an apophysitis. An adolescent may develop apophysitis due to an overuse injury, while an adult typically develops tendinitis.[297] Common examples of osteochondrosis include Sever disease (see later) and Freiberg disease.

- Freiberg disease. Osteochondrosis of the epiphyseal center of the metatarsal (the second metatarsal is most commonly involved) due to abnormal stress on the metatarsal, resulting

in localized pain and swelling. Freiberg disease can result from abnormal pronation or an excessively long second metatarsal. The intervention for Freiberg disease includes the restoration of normal biomechanics, including the use of a metatarsal pad or bar to reduce the weight-bearing forces on the metatarsal.

Osteochondritis Dissecans

Osteochondritis dissecans[297] and osteochondral lesions represent the same entity and relate to an injury of the articular cartilage and/or the underlying bone. The anterolateral and posteromedial locations on the talus are susceptible to injury when the talocrural joint undergoes torsional stress, through either impact or cyclical loading.[298] When the subchondral bone is involved, avascular necrosis with resulting bone infarction can occur. If the overlying articular cartilage remains intact, a space is created between the living bone and articular cartilage. An in-growth of fibrous tissue may result, and, if this tissue is not displaced, healing takes place. The associated symptoms are related to the stability of the fragment and can be similar to those commonly reported after an ankle sprain. If the fragment is maintained by the cartilage, symptoms may be mild. The symptoms will be more severe if a fragment breaks off into the joint, with sensations of giving way secondary to sharp pain, catching, and/or locking. The intervention and prognosis depend on the size and location of the lesion as well as the stability of the fragment. Activities that may disrupt the healing fragment must be avoided. This would include weight-bearing activities where twisting may occur, such as challenging balance and proprioceptive exercises. Surgical treatment can involve debridement and stabilization of the fragment. In cases when significant bone necrosis has occurred, bone grafting may be required.

Hallux Rigidus

Hallux rigidus is characterized by decreased dorsiflexion of the first MTP joint, and pain and swelling in the posterior (dorsal) aspect of the joint.[50] Two types of hallux rigidus have been described: adolescent and adult.

- ***Adolescent.*** The adolescent type is consistent with an osteochondritis dissecans or localized articular disorder.
- ***Adult.*** The adult type is a more generalized degenerative arthritis.[49] The cause of this degenerative process is unknown. Possible etiologies include crystal-induced arthropathy (gout and pseudogout), rheumatoid arthritis, the seronegative spondyloarthropathies, posttraumatic degeneration, an intra-articular fracture, or an osteochondrotic lesion of the first metatarsal head.[49,299] Repetitive dorsiflexion of the first MTP joint could also potentially lead to the development of hallux rigidus, although no studies have linked levels of physical activity to the development of hallux rigidus.[299]

The characteristics of both types include stiffness and pain in the MTP joint. This is associated with difficulty during the gait cycle, especially when walking or running up hills, climbing stairs or during the terminal stance phase of gait.[49] Since approximately 75 degrees of hallux dorsiflexion is needed for normal gait, limited extension of the great toe gives the feeling of vaulting over the toe. This may necessitate external rotation of the foot to allow for toe clearance. Thus, patients may present with lateral stress transfer as they attempt to unload the hallux MTP joint. This may produce synovitis of the lesser MTP joints or even stress fractures of the lesser metatarsals.[49]

A posterior (dorsal) metatarsal head osteophyte, or posterior (dorsal) bunion, may rub against footwear, causing an abrasion or ulceration. The patient may also experience tingling and numbness on the posterior aspect of the toe due to compression of the cutaneous nerves.

Tenderness is usually present on palpation of the posterior (dorsal), and especially lateral, aspects of the joint. Radiographs demonstrate loss of the first MTP joint space, the formation of posterior (dorsal) and lateral osteophytes on the metatarsal head, and occasionally loose fragments about the joint.[163]

The initial intervention involves shoe modifications, rest, and NSAIDs. A shoe with an extra-deep toe box can be helpful to decrease posterior (dorsal) pressure on the first MTP joint, while a stiff-soled shoe or a rigid custom orthotic with a Morton's extension can be helpful in limiting toe dorsiflexion. A rocker-bottom sole can also help to decrease the extension of the hallux during normal gait. An intra-articular corticosteroid injection may be considered as a temporizing measure. If symptoms increase, or when conservative measures fail, surgical intervention may provide the solution.

The most common surgical procedure is the cheilectomy, which is an excision of the posterior (dorsal) 25–33% of the metatarsal head. This removes the offending osteophytes, improves toe dorsiflexion, and preserves the good articular cartilage on the middle and plantar aspects of the metatarsal head.[300] A dorsiflexion osteotomy of the proximal phalanx (Moberg procedure) may be used concurrently with a cheilectomy in selected patients to increase functional toe dorsiflexion.[301]

Tarsal Coalition

Tarsal coalition is a fibrous, cartilaginous, or bony connection of two or more bones in the midfoot or hindfoot.[58,302] It usually presents during adolescence, at an average age of 13 years,[303] when the coalition is ossifying and subtalar motion becomes more limited. Most tarsal coalitions are bilateral,[302,304] and have been reported to occur in less than 1% of the general population.[302] Calcaneonavicular and talocalcaneal are the most common coalitions seen.[58,302,303,305,306]

A partial or complete talocalcaneal coalition significantly alters the mechanics of the ankle joint complex, as compensatory motions occur at the ankle joint level.

The patient with a tarsal coalition typically presents with pain that is vague and has an insidious onset. They may present with a history of frequent "ankle sprains" or generalized hindfoot or midfoot pain.[303] Symptoms often begin or are exacerbated by athletic training.

The physical examination will show limited or no subtalar motion compared with the other foot and occasional tight fibularis (peroneal) muscles.[307] Spastic fibularis (peroneal)

muscles have been reported to occur in less than 1% of these patients.[306]

The diagnosis of such malformations is often very difficult. Plain radiographs should include AP, lateral, and oblique views of the foot.[58,302]

The goal of conservative treatment of tarsal coalition is to reduce stress in the foot, relax the fibularis (peroneal) muscles, and support the foot. This can usually be accomplished with orthotics and exercise, although temporary casting may be necessary.[58,302] If conservative treatment fails, however, a resection may be necessaryto restore mobility and decrease pain.[302,303]

Os Trigonum

An os trigonum has been reported to be present in approximately 10% of the general population and is often unilateral.[60,134,308,309] The origin of this ossicle may be congenital or acquired. Congenitally, it can be a persistent separation of the secondary center of the lateral tubercle from the remainder of the posterior talus secondary to repeated microtrauma during development.[60,309] The acquired form may be secondary to an actual fracture that has not united.[60,309,310]

Symptoms associated with os trigonum include pain with maximum plantar flexion as the posterior talus impinges on the posterior tibia.[297] The intervention involves symptom reduction with restoration of normal strength, ROM, and biomechanics as needed. If symptoms persist, surgical removal of the bone may be required but is delayed until skeletal maturity is achieved.[297]

Hallux Valgus

Hallux valgus describes a deformity of the first MTP joint, in which the proximal phalanx is deviated laterally with respect to the first metatarsal. It may also be used to describe varying degrees of metatarsus primus varus/valgus deviation of the proximal phalanx, medial deviation of the first metatarsal head, and bunion formation.

Hallux valgus occurs almost exclusively in populations that wear shoes, although there are also some predisposing anatomic factors. Women are more likely than men to have hallux valgus (a ratio of 9:1),[311] and the condition has been reported to affect 22–36% of adolescents.[312–317]

The deformity results from a lateral subluxation of the FHL muscle, which transforms the FHL and brevis from flexors to adductors, which then pull the PIP medially and the DIP laterally.[163] In addition, the abductor hallucis muscle slides underneath the metatarsal head and brings about pronation of the great toe, approaching 70–90% of pronation in severe cases.[318]

With increasing lateral deviation of the hallux, the MTP joint becomes incongruent, the sesamoids subluxate laterally, the hallux pronates, the medial aspect of the first metatarsal head becomes more prominent, and weight-bearing shifts from the first metatarsal head to the second metatarsal, and possibly the third.[50,141] This weight transfer may result in the formation of a painful plantar keratosis, or a hammer toe or a crossover toe deformity of the second toe.[50]

The cause of hallux valgus is unclear, but various factors are cited such as tight shoes, metatarsus primus varus, pes planus, forefoot pronation, joint hyperlaxity, and heredity.[312,313] Hallux valgus is often associated with medial deviation of the first metatarsal, known as metatarsus primus varus.[50]

A compensated bunion is a mild deformity without MTP joint subluxation and without marked lateral sesamoid subluxation.[319] A decompensated bunion is a moderate-to-severe deformity characterized by hallux valgus angle greater than 25 degrees, intermetatarsal angle greater than 15 degrees, lateral sesamoid subluxation, and great toe pronation.

The intervention for hallux valgus begins conservatively and the intervention for the bunion includes advice on wearing wider shoes, or an orthotic prescription.[312,313,315] A silicone bunion pad placed over the bunion may be helpful in alleviating direct pressure on the prominence.[50] Other interventions are based on the causative factors:

- Achilles stretching is used in cases of Achilles contracture.
- A simple toe spacer can be used between the first and second toes if they require separating.
- In cases of pes planus associated with hallux valgus, a medial longitudinal arch support with Morton's extension under the first MTP joint can be used to help alleviate symptoms.[50]

If pain persists, however, structural realignment of the first metatarsal varus is usually necessary, as the bunion deformity becomes more severe and decompensated.

Turf Toe

The term "turf toe" is used to describe a sprain of the first MTP joint.[50] Turf toe is more common in football, baseball, and soccer players. Football players are at higher risk of this injury, if they are tackled while landing from a jump or if another player lands on the back of their heel, forcing the first MTP joint into hyperdorsiflexion.[7,320] Soccer players tend to develop the sprain in the great toe of the nonkicking foot due to the forced dorsiflexion on the stance leg as the other leg kicks the ball. It was originally thought that the artificial grass surface on football fields caused athletes to stop more quickly during planting and cutting, thus, slamming the toe into the front of the shoe. However, it is more likely that the lighter flexible turf shoes that are designed for the surface are more responsible. This increase in shoe flexibility causes a repetitive hyperextension injury of the great toe. The tendency of artificial turf to become hard and stiff over time may be a contributing factor.[321] Hypermobility of the first ray reportedly leads to biomechanical problems. It has been theorized that during gait, the medial longitudinal arch collapses because of excess posterior (dorsal) motion of the first ray. This collapse decreases the ability of the foot to effectively propel the body forward during walking. The increased posterior (dorsal) excursion of the first ray causes the foot to roll inward (pronation), and the second metatarsal must support an excessive proportion of the body weight.[125] The resulting increased magnitude and duration of pronation significantly diminishes the ability of the fibularis (peroneus) longus muscle to stabilize the first metatarsal.[124] As a result, ligamentous tissues that usually limit the end-range dorsiflexion movement of the first metatarsal undergo increased stress, and joint laxity occurs.[124] Because of these mechanical consequences, hypermobility of the first ray has been implicated in numerous conditions frequently

accompanied by excessive or prolonged for pronation, including lesser metatarsalgia, acquired flatfoot, posterior tibialis tendinitis, plantar fasciitis, and shin splints.[124,322]

The mechanism of injury for turf toe can also involve hyperflexion and varus and valgus stresses of the first MTP joint.[7,320] With forced hyperflexion of the hallux, tearing of the plantar plate and collateral ligaments can occur. In the more severe injury, the capsule can actually tear off from the metatarsal head.[57] A fracture of the sesamoids can also occur, and posterior (dorsal) dislocation of the first MTP joint is possible.[53]

Clinically, patients with turf toe present with a swollen, stiff, and red, first MTP joint. They may have a history of a single dorsiflexion injury or multiple injuries to the great toe. The joint may be tender, both plantarly and posteriorly (dorsally). Players may have a limp and be unable to run or jump because of pain.

Turf toe typically develops into a chronic injury and long-term results include decreased first MTP joint motion, impaired push-off, and hallux rigidus.[320] Fifty percent of athletes will have persistent symptoms 5 years later.[323]

Clanton and Ford[323] have classified the severity of turf toe injuries from grades I to III:

- Grade I: a minor stretch injury to the soft tissue restraints with little pain, swelling, or disability.
- Grade II: a partial tear of the capsuloligamentous structures with moderate pain, swelling, ecchymosis, and disability.
- Grade III: a complete tear of the plantar plate with severe swelling, pain, ecchymosis, and inability to bear weight normally.

The intervention for turf toe in the acute phase is rest, ice, a compressive dressing, and elevation. NSAIDs are often prescribed, and the toe is taped with multiple loops of tape placed over the posterior (dorsal) aspect of the hallucal proximal phalanx and criss-crossed under the ball of the foot plantarly to limit dorsiflexion.[53] Occasionally, a forefoot steel plate is used.[57] Passive ROM and progressive resistance exercises are begun as soon as patient tolerance allows.[53,163] return to normal activities is based on the initial severity:

- Patients with grade I sprains are usually allowed to return to sports as soon as symptoms allow, sometimes immediately.
- Patients with grade II sprains usually require 3–14 days' rest from athletic training.
- Grade III sprains usually require crutches for a few days and up to 6 weeks' rest from sports participation.

A return to sports training too early after injury could result in prolonged disability. Return to play is indicated when the toe can be dorsiflexed 90 degrees.[323]

Sprains

Ankle sprains are the most common injuries in sports and recreational activities,[324] and they remain a difficult diagnostic and therapeutic challenge. If left untreated, ankle sprains can lead to chronic instability and impairment.[129]

Ankle ligament injuries constitute 4.7–24.4% of all injuries incurred in an individual sport,[325] and 10–28% of all injuries that occur in running and jumping sports.[326,327] Most acute ankle injuries occur in people 21–30 years old, although injuries in the younger and older age groups tend to be more serious.[328] More than 40% of ankle sprains can potentially progress to chronic problems.[184,329–338]

Dynamic stability is provided to the lateral ankle by the strength of the fibularis (peroneus) longus and brevis tendons.

Stormont et al.[24] recently showed that ankle instability, and thus sprains, could only occur during systematic loading and unloading, but not while the ankle is fully loaded, due to the articular restraints. In the neutral position or dorsiflexion, the ankle is stable because the widest part of the talus is in the mortise. However, in plantar flexion, ankle stability is decreased, as the narrow posterior portion of the talus is in the mortise.[129] Thus, the most common mechanism of an ankle sprain is one of inversion and plantar flexion.[16,57] With eversion and external rotation, the deltoid and/or ligaments of the distal tibiofibular joint can be injured, producing the so-called medial and central sprains, respectively. Eversion injuries to the medial (deltoid) ligament of the ankles account for 5% of ankle sprains.[11,131,339]

The prognosis for ankle sprains is inversely proportional to the severity and grade of the initial injury (Table 21-13),[340] the age of the patient (younger patients do not fair as well), and the rate of recurrence (the prognosis is worse when the ankle has been previously sprained).[16,125,332]

Lateral Ankle (Inversion) Sprain

Sprains of the lateral ligamentous complex represent 85% of ankle ligament sprains.[206,324] In the younger population, serious ankle sprains are unusual in the skeletally immature, because the ligaments are usually stronger than the bone,[304,341,342] necessitating a physeal fracture to be ruled out.[16,57]

The ATFL, which is the least elastic of the lateral ligaments,[145] is involved in 60–70% of all ankle sprains, while 20% involve both the ATFL and the CFL.[11,131,339] The sequence of lateral ligament tears is first the ATFL, then the anterolateral capsule, then the distal tibiofibular ligament, then the CFL, and finally the PTFL, the strongest of the lateral ligaments.[13,206] This rupture may be associated with ankle dislocation, distal lateral malleolar avulsion or spiral fracture, medial malleolar fracture, or talar neck or medial compression fractures.[206] Most (86%) ankle ligament tears are midsubstance; thus, only 14% are avulsion injuries.[131]

The high-ankle sprain, or syndesmotic sprain, which involves disruption of the ligamentous structures between the distal fibula and tibia, just proximal to the ankle joint, is a less-understood form of ankle sprain injury in comparison with the lateral ankle sprain. The mechanisms of injury for syndesmotic ankle sprains include[171,174,343]:

- forceful external rotation of the foot, resulting in widening of the ankle mortise, as the talus is driven into external rotation within the ankle mortise;
- forceful eversion of the talus, which widens the mortise;
- forceful dorsiflexion, which widens the mortise, as the wider anterior aspect of the talar dome enters the joint space.

TABLE 21-13 The West Point Ankle Sprain Grading System

Criterion	Grade I	Grade II	Grade III
Location of tenderness	ATFL	ATFL and CFL	ATFL, CFL, and PTFL
Edema and ecchymosis	Slight and local	Moderate and local	Significant and diffuse
Weight-bearing ability	Full or partial	Difficult without crutches	Impossible without significant pain
Ligament damage	Stretched	Partial tear	Complete tear
Instability	None	None or slight	Definite

ATFL, anterior talofibular ligament; CFL, calcaneofibular ligament; PTFL, posterior talofibular ligament.
Data from Gerber JP, Williams GN, Scoville CR, et al.: Persistent disability associated with ankle sprains: A prospective examination of an athletic population. *Foot Ankle Int* 19:653–660, 1998.

With all of the above mechanisms, the distal fibula is pushed laterally away from its articulation with the distal tibia. Chronic instability of the syndesmosis may then result in increased shear stress and altered contact pressure patterns that might predispose the individual to degenerative articular cartilage changes in the ankle joint.[171,174,343]

Although a physical examination is reliable for the diagnosis of an ankle fracture,[198] the reliability for detecting lateral ankle sprains may not be as definitive, especially if the examination is performed immediately after the injury.[187] The place of a physical examination in diagnosis has been reviewed in a series of 160 patients,[187] comparing the accuracy within 48 hours of injury with that at 4–7 days. The specificity and sensitivity of delayed physical examination for the presence or absence of a lateral ligament injury were 84% and 96%, respectively, indicating that a reasonably precise clinical diagnosis is possible if the examination is delayed for approximately 4 days post-injury.[344] Injuries to the foot and ankle may quickly be dismissed as ankle sprains, particularly in the adolescent population (Table 21-14). A clinician examining the foot and ankle needs to be aware of other potential pathologies to consider when an adolescent patient is referred to physical therapy with the diagnosis of ankle sprain. These pathologies include osteochondrosis, osteochondritis dissecans, accessory ossicle, anterior impingement syndrome, sinus tarsi syndrome, tarsal coalition, and epiphyseal fractures.[297]

The mechanism of injury can afford some clues. As mentioned, a history of a forced dorsiflexion can result in a sprain

TABLE 21-14 Potential Pathologies Associated with Adolescent Ankle Injuries

Pathology	Definition	Signs and Symptoms
Sever ostoechondrosis	Calcaneal apophysitis	Localized pain and tenderness at the Achilles attachment
Talocrural osteochondritis dissecans	Injury to articular cartilage and/or underlying bone	Catching, locking, and/or sudden sharp stabbing pains
Accessory ossicles at the distal tiba or fibula	Ossification centers that have not fused	Localized pain and tenderness Accessory bone with rounded edges on radiographs
Accessory os trigonum	Accessory ossicle on the posterior-lateral process of the talus	Pain posteriorly with maximum plantar flexion Accessory bone with rounded edges on radiographs
Anterior ankle impingement	Thickening of joint capsule with or without bone spurs at the anterior talocrural joint	Pain anteriorly with sudden dorsiflexion Decreased dorsiflexion ROM—a hard end-feel if bone spurs are present
Sinus tarsus syndrome	Injury to the structures contained within the sinus tarsus	Hindfoot instability Tenderness inferior and anterior to the anterior talofibular ligament
Tarsal coalition	Congenital union between two tarsal bones: usually calcaneonavicular or talocalcaneal coalition	Localized tenderness over the involved joint Rigid flatfoot and peroneal muscle spasm with inversion
Distal tibal epiphyseal fractures	Growth plate injury	Tenderness at the distal tibia Inability to weight bear

Data from Martin R: Considerations for differential diagnosis of an ankle sprain in the adolescent. *Orthop Pract* 16:21–22, 2004.

of the distal tibiofibular syndesmosis. Distal tibiofibular syndesmosis sprains are usually accompanied by complaints of pain that greatly exceed the amount of swelling and that increase with external rotation of the foot.[129] Forced plantar flexion can result in anterior capsular sprains. These are characterized by pain that worsens with passive plantar flexion and resisted dorsiflexion.[129]

No single symptom or test can provide a completely accurate diagnosis of a lateral ankle ligament rupture, but the collection of findings can be strongly indicative[187]:

- The absence of swelling at the time of the delayed (after 4 days) physical examination suggests that there is no ligament rupture, whereas extensive swelling at this time is indicative of ligament rupture.[345]
- Pain on palpation of the involved ligament suggests involvement.
- Presence of a hematoma suggests a rupture.
- Positive anterior drawer test suggests a rupture.
- Impairment of walking ability after injury suggests involvement.

One study[187] demonstrated that a combination of tenderness at the level of the ATFL, a lateral hematoma, discoloration, and a positive drawer test indicated a ligament rupture in 95% of cases, whereas the absence of these findings always indicated an intact ligament.

Lateral ankle sprains can be categorized as follows:

- Grade I: characterized by minimal to no swelling and localized tenderness over the ATFL. These sprains require on the average 11.7 days before the full resumption of athletic activities.[346]
- Grade II: characterized by localized swelling and more diffuse lateral tenderness. These sprains require approximately 2–6 weeks for return to full athletic function.[347,348]
- Grade III: characterized by significant swelling, pain, and ecchymosis and should be referred to a specialist.[349] Grade III injuries may require greater than 6 weeks to return to full function. For acute grade III ankle sprains, the average duration of disability has been reported to be anywhere from 4.5 to 26 weeks, and only 25–60% of patients are symptom free 1–4 years after injury.[350] In a summary of all prospective and controlled studies on grade III sprains, it was concluded that the long-term prognosis is good to excellent in 80–90% of patients with this injury, regardless of the type of intervention chosen.[351]

Intervention

Conservative intervention has been found to be consistently effective in treating grades I and II ankle sprains,[352] and high-ankle sprains (Table 21-15).

TABLE 21-15 Summary of Conservative Treatment for Ankle Sprains

Phase/Criteria	Description of Intervention
Phase I	
	Pain and edema control: rest, ice, compression, elevation, electrical stimulation, toe curls, ankle pump, and cryotherapy
	Temporary immobilization/stabilization (i.e., short leg cast, splint, brace, and heel lift)
	Non–weight-bearing with crutches
Phase II	
Pain and swelling subside	Patient can ambulate using partial weight-bearing without pain.
Partial weight-bearing with assistive device	Lower-level balance training: bilateral standing activity or standing on a balance pad or several layers of towels
	Lower-level strengthening using theraband
Phase III	
Patient can ambulate full-weight-bearing without pain, possibly still needing protection from heel lift or ankle brace.	Unilateral balance training
	Progress from double-heel raises to single-heel raises
	Treadmill walking or over ground walking
	Progress to fast walking
Phase IV	
Able to perform heel raises in unilateral stance	Fast pain-free walking without heel lift
	Jog to run progression
	Shuttle runs and cutting maneuvers
	Sport-specific training

The timeline for progression of an individual patient is dependent on the severity of the injury and the ability of the patient and the criteria listed in the table for progression to each phase.

Data from Lin CF, Gross ML, Weinhold P: Ankle syndesmosis injuries: Anatomy, biomechanics, mechanism of injury, and clinical guidelines for diagnosis and intervention. *J Orthop Sports Phys Ther* 36:372–384, 2006.

Intervention in the acute stage centers around aggressive attempts as follows:

- minimize effusion so as to speed healing;
- promote early protected motion;
- foster early supported/protected weight-bearing as tolerated;
- foster protected return to activity;
- prevent reinjury.

Early intervention incorporates cryotherapy, compression, and elevation to assist in the reduction of pain, swelling, and secondary hypoxic effects.[353] Although early motion and mobility rather than immobilization have demonstrated the stimulation of collagen bundle orientation and the promotion of healing,[354] it must be remembered that full ligamentous strength is not regained for several months or longer.[355–358]

Active ROM exercises, such as ankle pumping and toe curls (30 reps, four times/day each), are encouraged during this phase, but within pain-free limits.[137]

Protected weight-bearing with an orthosis is permitted, with weight-bearing to tolerance as soon as possible following injury.[17] As the healing progresses and the patient is able to bear more weight on his or her ankle, there is a corresponding increase in the use of weight-bearing (closed-chain) exercises. A recommended activity during this phase is the "cross drill." The patient stands independently or with minimal assistance on the involved limb, with the other leg flexed. The patient then moves the uninvolved limb into hip flexion, hip extension, hip abduction, and hip adduction. The exercise is performed initially on a firm surface with the eyes open, and then, as the patient improves, the exercise is performed on a foam surface or balance board, first with the eyes open and then with the eyes closed.

In the subacute stages of the rehabilitation process (4–14 days), the patient begins dynamic balance and proprioceptive exercises. The external support may still be required during this phase. Using a balance board, the patient balances on the involved limb, while playing "catch" with the clinician. The intensity of this exercise can be varied by using balls of different sizes and different weights. The clinician may also make the exercises more challenging by throwing the ball to a variety of locations. This will require a shift in the center of gravity and an instantaneous adjustment of balance from the patient.

Long-sitting gastrocnemius stretching with a strap or sheet can be introduced in this phase (six reps of 20 seconds each) to promote ankle dorsiflexion past the neutral position, enabling a closer to normal walking pattern.[137] Open-chain (non–weight-bearing) progressive resistive exercises with elastic resistance are performed (two sets of 30 reps each) for isolated plantar flexion, dorsiflexion, inversion, and eversion. Stationary cycling can also be performed (at a comfortable intensity for up to 30 minutes), to provide cardiovascular endurance training and controlled ankle ROM.[142]

In the advanced healing stage (2–4 weeks postinjury), the goals are as follows:

- the restoration of normal AROM;
- normal gait without an assistive device;
- pain-free performance of full-weight-bearing functional activities;
- enhancement of proprioception.

Activities to help achieve these goals include heel-to-toe anterior–posterior walking (10 m for 20 reps), carioca drills, and mini-trampoline balancing exercises (unilateral stance with eyes open and then closed, and catching and passing activities with a medicine ball).

Plyometric activities are introduced during the functional challenge/return to activity phase. These can include two-foot ankle hopping, single-ankle hops, and then multidirection single-ankle hops. If appropriate, barrier jumps or hops may be introduced.

Recurrent Ankle Sprains

Recurrent ankle sprains may be due to the following[16,125]:

- healing of the ligaments in a lengthened position;
- weakness of the healed ligaments due to inherent weakness of the scar;
- fibular (peroneal) muscle weakness (the incompletely rehabilitated ankle sprain);
- distal tibiofibular instability;
- hereditary hypermobility;
- loss of ankle proprioception;
- impingement by the distal fascicle of the anterior tibiofibular ligament, and/or impingement of capsular scar tissue (meniscoid tissue) in the talofibular joint;
- undiagnosed associated problems such as cuboid subluxation or subtalar instability.

The associated complication of ankle sprains include early degenerative changes.[179,334] Talar displacement of greater than 1 mm reduces the ankle's weight-bearing surface by 42.3%,[359–361] resulting in asymmetric load-bearing of the articular surface.

Chronic lateral instability is manifested by recurrent injuries with pain, tenderness, and sometimes bruising over the lateral ligaments.[184,332,362–365] Many, approximately 30%,[332] may be asymptomatic between the events. Others may manifest with chronic lateral pain, tenderness, swelling, or induration with great difficulties in sports and daily activities.[184,332,363] A history of insecurity, instability, and giving way[27,364,366] is far more important in diagnosis than the physical examination in acute and recurrent sprains.[332,367]

In general, subjective complaints include

- frequent sprains[330,336];
- difficulty in running on uneven surfaces;[330]
- difficulty in cutting and jumping in athletic events.[184,330,337]
- feelings of "giving way."[330,333,336]
- Recurrent pain[184,331,333,335,336] and swelling.[330,333,335–337]
- Tenderness.[330,331,333]
- Inability to run.[329]
- Weakness.[184,329]

Recurrent ankle sprains are typically treated conservatively for 2–3 months,[329,330,338,368,369] using a combination of some or all of the following: a lateral heel wedge, fibular (peroneal) muscle strengthening, proprioceptive/coordination exercises, taping, elastic or thermoplastic ankle supports, and/or a short leg brace.

If the conservative trial fails late repair or reconstruction of the lateral ligaments is recommended.[332,370–375]

According to Hinterman et al.,[22] a number of conditions can mimic ankle instability:

- Fibularis (peroneal) tendon subluxation.
- Instability of the Chopart joint. Inversion and plantar flexion trauma of the foot may result in avulsion by the bifurcate ligament and, sometimes, additionally by the talonavicular ligament. Injuries at the Chopart joint level are, however, frequently missed acutely and misdiagnosed as lateral ankle sprain, if the clinical examination is not carefully carried out.[376]
- Talocalcaneal and talonavicular coalition.
- Posterior tibial dysfunction.

MIDFOOT SPRAIN

A sprain of the tarsometatarsal joint usually occurs from an indirect axial load on a plantar flexed and rotated foot, with or without abduction.[377] On examination, the patient will have tenderness to palpation directly over this area, and pain with passive midfoot pronation and supination while the rearfoot is stabilized.[377]

Radiographs of the foot should include weight-bearing AP and lateral and oblique views to rule out dislocation. The metatarsals should be lined up with their respective cuneiforms.[57]

Conservative intervention can proceed if displacement of the metatarsals on a radiograph is less than 2 mm and includes an orthotic or a fracture boot if the patient is unable to bear weight comfortably.[57] A stiff shoe and orthotics to support the medial longitudinal arch are recommended for return to athletics.[378]

Sinus Tarsi Syndrome

The sinus tarsi is located between the inferior neck of the talus and the superior aspect of the calcaneus. It is inferior and slightly anterior to the ATFL. Sinus tarsi syndrome is a sprain of the subtalar joint, with injury to the talocalcaneal interosseous ligament. The mechanism of injury involves an inversion sprain in a plantar flexed position that injures both the talocrural and subtalar joint and is sometimes difficult to distinguish from a routine ankle sprain.[57]

Symptoms can include a feeling of hindfoot instability when walking on uneven ground. Observation usually reveals swelling in the sinus tarsi. There is usually pain with palpation and pronation,[342] usually due to scarring in the soft tissue elements of the sinus tarsi.[378]

The intervention may include joint-specific mobilization and manipulation, followed by strengthening and proprioceptive exercises. An orthotic can be used to limit pronation and maintain the foot in a functional neutral position.

Selective cortisone injection into the subtalar joint can also be diagnostic and therapeutic.[342]

Cuboid Syndrome

Cuboid syndrome (locked cuboid, calcaneal cuboid fault syndrome, and subluxed cuboid) is common but poorly recognized.[379] The calcaneocuboid joint is usually very mobile but can be repetitively subluxed laterally and posteriorly (dorsally) with strong forces. The subluxation is usually a temporary occurrence. The etiology has been proposed to be secondary to overuse, increasing body weight, training on uneven surfaces, or a lateral ankle or lateral foot sprain.[379,380]

Cuboid syndrome usually presents with a gradual onset of lateral midfoot pain. The pain is usually localized near the fourth and fifth metatarsals at the posterior (dorsal) aspect of the cuboid or the calcaneocuboid joint.[379] Often, the patient feels as if he or she is walking with a small stone in their shoe. Maximum discomfort is elicited by pressure directed over the fibular (peroneal) groove on the plantar surface of the calcaneus.[57] On occasion, the hook of the bone under the cuboid breaks or the short plantar ligament tears, producing heel pain.

Common findings in the physical examination are a subtle forefoot valgus and a pronated foot, as well as a tight fibularis (peroneus) longus tendon.[379,381,382] The pronated foot produces an unstable midtarsal joint. Careful gait analysis will often reveal that the pain is reproduced in terminal stance, at the onset of heel rise. Other findings include asymmetrical weakness of the fibularis (peroneus) longus muscle and decreased ROM of the lateral foot.

The intervention for this condition includes a manipulation of the midfoot (see "Cuboid Whip" section), stretching the fibularis (peroneal) tendons and strapping/plantar padding.[379,381]

Talocrural Joint Subluxation

There are essentially two types of subluxations at this joint, anterior and posterior, which result in a loss of plantar flexion and dorsiflexion, respectively.

- The anterior subluxation is commonly caused by an inversion, plantar flexion force. The clinical findings include a limitation of dorsiflexion, a decreased posterior talar glide, and/or conjunct external rotation of the talus.
- The posterior subluxation may be from a compensatory or other type of flatfoot or from a dorsiflexion injury. The clinical findings include a loss of the plantar flexion talar swing, anterior glide, and/or medial conjunct talar rotation.

The intervention for this type of injury is usually a high-velocity thrust technique applied to the joint.

PREFERRED PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM ASSOCIATED WITH LOCALIZED INFLAMMATION

The list of potential pathology for soft tissue injuries to the foot, accompanied with localized inflammation, is extensive.

Inflammation or Infection of the Nails and Skin

Subungual Hematoma

A subungual hematoma is also called "black toenails" or "runner's toe" and results from bleeding under the toenails due to chronic friction or bumping of the toe against ill-fitting shoes, or from overt trauma to the posterior (dorsal) aspect of the toe.[383] Due to the extreme sensitivity of the nail bed, significant pulsating pain is often associated with this problem, with or without palpation.

In the case of poorly fitting shoes, prophylactic treatment is recommended. Athletic shoes should be one size longer than street shoes in most cases.[145]

For an existing hematoma, the treatment of choice involves decompression of the hematoma using a red-hot paper clip or 18-gauge needle, heated in an alcohol burner, which is used to burn a hole through the nail.[384]

Subungual Exostosis

A subungual exostosis is a hypertrophic bone, usually affecting the medial border of the hallux, as the result of excessive pressure, that produces pain on ambulation.[385] An accurate diagnosis of this condition requires a radiograph.[384]

Conservative intervention involves using a deep toe box and decreasing the width of hypertrophic nails.

Onychocryptosis

Onychocryptosis is more commonly referred to as ingrown toenails. It is commonly associated with a secondary pyogenic infection or paronychia. Onychocryptosis without paronychia is treated conservatively by removing the offending portion of the nail and then smoothing the nail border with a curette.[384]

Onychia

Onychia is an infection of one or both sides of the nail and nail plate, which can result from a number of factors including chronic pressure on the nail plate, allergies, nail polish, improperly cutting the nails, or certain soaps.[384]

Onychauxis

Onychauxis is an overgrowth of the nail that can be the result of microtrauma or macrotrauma, peripheral neuritis, old age, nutritional disturbances, or decreased circulation, producing future nail growth distortion.[383,384,386] The diagnosis is made by the hallmark characteristics of a hypertrophic, dystrophic, and discolored nail plate.[387]

The conservative intervention for this condition involves the mechanical or chemical debridement of the nail plate.[387]

Onychomycosis

Onychomycosis is a chronic fungal condition of the nails, which is often responsible for causing onychauxis.[388]

Tinea Pedis

Tinea pedis is more commonly known as athlete's foot. It usually presents with redness or itchiness but can also appear as dry and flaky skin.[384]

Treatment is simple and involves soaking the foot in one-half cup of vinegar in a pan of water once a day and applying a topical antifungal agent.[384]

Blisters

Blisters occur secondary to friction and shearing and can give the clinician valuable information as to where the stresses of the foot are occurring. Besides the obvious fact that tight shoes cause blisters, other causes include excessive motion such as pronation and supination.

Tendinitis

Overuse of the ankle and foot tendons occurs as the result of training errors, abrupt changes in training patterns, muscle–tendon imbalances, anatomic malalignment, or improper footwear.[342] This overuse causes the tendons to break down, resulting in tendinitis. Although more common in the adult population, tendinitis can also be seen in the adolescent due to a sudden growth spurt or the resumption of play after a period of decreased training.[389] The intervention for tendinitis/tenosynovitis includes identifying and removing the causative factor, an initial period of PRICEMEM followed by a program of stretching and strengthening of the tendon. On occasion, the intervention may require casting, orthotics, and/or prophylactic bracing.

Fibularis (Peroneal) Tendinitis

This form of tendinitis is particularly common in young ice skaters and dancers, but can also be seen in any running athlete. A number of conditions are associated with fibularis tendinitis including repeated inversion strains, which stretch and inflame the sheaths of the fibularis (peroneus) longus and brevis tendons (runner's foot), or with instability between the fourth and fifth metatarsals.

The patient usually presents with pain behind and distal to the lateral malleolus.[389] There may be associated swelling in the acute phase. There will also be pain with resisted foot eversion.

Fibularis (Peroneal) Tendon Subluxation

Subluxation of the fibularis (peroneal) tendons is an infrequent but potentially disabling condition that mainly affects young athletes.[390] In its early and later phases, the condition is often difficult to distinguish from a lateral ankle sprain, as the acute symptoms include pain at the posterior distal fibula, swelling, ecchymosis, and apprehension, or inability to evert the foot against resistance.[57,391] The chronic symptoms include lateral ankle pain, popping or snapping, and instability.[57] Confusing the issue is the fact that a chronic fibularis tendon

subluxation can both mimic and coexist with chronic ankle instability.

One of the causes of this condition is that, in some individuals, there may be a number of anatomic anomalies that predispose the fibularis tendon to sublux including, an absent or shallow fibula groove,[76,342,392,393] probably combined with pes planus, hindfoot valgus, or lax/absent fibular retinaculum.[76,77,389,392,394] A subluxation can also occur from a traumatic rupture of the retinaculum as the result of a violent forced dorsiflexion of the ankle with reflex contraction of the fibularis muscles and subsequent dislocation.[76,77,308,342,394–396]

As with many tendon conditions, fibularis tendon subluxation can be an acute episode that turns into a chronic problem due to misdiagnosis.[57] Many of these subluxations are incorrectly diagnosed at the acute stage as simple ankle sprains.[397] The young patient may present acutely after a supposed ankle sprain, with pain and swelling over the posterolateral aspect of the ankle. More commonly though, the initial presentation may occur weeks to months after the injury.[307] The adolescent may complain of recurrent inversion ankle sprains and lateral ankle instability, with a painful snapping across the ankle.[398] Chronic ankle instability can also contribute to chronic fibularis tendon subluxation, with the development of an incompetent superficial fibular retinaculum.[76,398] This can also be confused with the rare isolated injury to the PTFL.[76,77,393,394]

On physical examination, subluxation may be provoked with forceful ankle dorsiflexion and eversion. There may be pain posterior to the lateral malleolus in an acute situation, as well as a negative anterior drawer test.[57]

A number of surgical procedures have been described for a chronic fibularis tendon subluxation, including tendon transfer, repair of the fibular retinaculum, groove deepening procedures, and tendon rerouting.[76,390,394,396,397]

Tibialis Posterior Tenosynovitis

The tibialis posterior tendon is lined with a tenosynovial sheath that can become inflamed, resulting in a tenosynovitis. If the tenosynovitis is left untreated, it can progress to an eventual rupture of the tibialis posterior tendon.[399]

Posterior tibial dysfunction is a complex disorder of the hindfoot. Controversy exists as to whether a persisting rotational instability after ankle sprain may cause posterior tibial dysfunction or vice versa. Posterior tibial dysfunction may cause ankle instability by overloading the ankle ligaments, especially the medial (deltoid) ligament of the ankle.[42]

The symptoms associated with this condition are usually felt in one of three locations:

- Distal to the medial malleoli in the area of the navicular.
- Proximal to the medial malleoli.
- At the musculotendinous origin, or insertion.

Posterior tibialis tenosynovitis is seen relatively frequently in participants of dance and ice-skating who have a pronated foot and flattened longitudinal arch.[150] The condition is also seen in running sports that require rapid changes in direction (basketball, tennis, and soccer) as abrupt changes in direction place increased stress across the tendon.[75] Other contributing factors include an adaptive shortening of the gastrocnemius–soleus complex and weakness of the posterior tibialis.

On physical examination, the patient will present with pain on resisted ankle plantar flexion and inversion,[75] with tenderness to palpation along the tendon's course posterior to the medial malleolus through to its insertion into the navicular. Swelling may sometimes be seen. Sometimes pain may be secondary to an accessory navicular.[75] With a complete rupture, the navicular subluxes inferiorly, and the patient ambulates in a flat-footed position, as they are unable to produce any toe-off at terminal stance.

Plain radiographs are rarely helpful, although MRI or bone scan[400] may aid in the diagnosis.

Patla and Haxby[152] describe a condition called tibialis posterior myofascial tightness (TPMT) as a factor in heel pain. In contrast to tibialis posterior tenosynovitis, TPMT is not characterized by inflammation of the tendon sheath. The patient with TPMT complains of immediate heel pain on weight-bearing in the morning. The pain is increased with increased load from activities but typically decreases during the day. There is no specific injury or activity identified as the cause. Physical findings include[152]

- depression of the medial arch with standing;
- neutral or inverted calcaneus in standing;
- flatfoot appearance and diminished push-off with gait;
- decreased full ROM of plantar flexion and calcaneal inversion with weight-bearing heel raising;
- full PROM of dorsiflexion and plantar flexion, with possible end-range discomfort;
- that posterior tibialis length test (see "Special Tests" section) shows decreased extensibility and often produces pain.

The intervention for this condition is geared toward correcting the impairments of the tibialis posterior muscle. The same technique and contacts used in the test are used for treatment, except that the manual stretch is maintained for approximately 2 minutes and is repeated approximately four times, with slightly stronger pressure being used each time.

Tibialis Anterior Tendinitis

Tibialis anterior tendinitis is most commonly seen in runners, especially in those who participate in up or down hill training. The examination will show point tenderness over the tendon, as it crosses the ankle.

FHL Tenosynovitis

As with the posterior tibialis, the FHL is lined by a tenosynovial sheath, which can become inflamed. FHL tendinitis is characterized by pain posterior to the medial malleolus, which is most often confused with posterior tibialis tenosynovitis.[401]

FHL tendinitis will usually present itself as pain with resisted great toe flexion in the young patient, as well as pain posterior and inferior to the medial malleolus. Dancers who assume the repeated plantar flexed posture of demipointe or pointe are particularly susceptible to this condition.[381,402,403] Runners and gymnasts are also susceptible.

The tendon sheath becomes inflamed due to forceful push-offs with the forefoot, where the FHL is stretched between the posterior talar tubercle and the sustentaculum tali. The tendon sheath can also be irritated with plantar flexion, where it is compressed over the posterior talar tubercle.[401,404]

Achilles Tendinitis

It is probably no accident that Homer decided that the heels of his Greek hero, Achilles, would be the one vulnerable area of the body.[405] This vulnerability of the heel continues to this day, with Achilles tendinitis being the most common overuse syndrome of the lower leg,[71] accounting for 5–18% of the total number of running injuries.

The Achilles tendon is placed under extreme and rapid eccentric loading forces during such activities as running, standing up while cycling, ballet, gymnastics, soccer, and basketball.[404,406]

The underlying mechanism of Achilles tendinitis is not well understood, but a number of mechanisms have been proposed of which the biomechanical hypothesis is the most popular. Immediately after the foot makes contact with the ground in a supinated position, it pronates and then supinates again as the propulsion phase approaches.[43,115] The pronated foot imparts an internal rotation force through the tibia, whereas knee extension imparts an external rotation force through the tibia.[406] The overpronated foot places the medial aspect of the tendon under tension, generating an obligatory internal tibial rotation, which tends to draw the Achilles tendon medially.[407] The rapid and repeated transitions from pronation to supination cause the Achilles tendon to undergo a "whipping" or "bow-string" action.[408] Moreover, if the foot remains in a pronated position after knee extension has begun, the external tibial rotation at the knee and the internal tibial rotation at the foot result in a "wringing" or twisting action of the tendon.[43]

Another proposed mechanism involves the eccentric contraction of the triceps surae during support. Maximal triceps sural contraction is associated with adduction and supination of the foot. At heel strike, the calf muscles undergo a rapid shortening before lengthening, as the tibia rotates forward over the foot. The calf muscles then shorten again during the forward propulsion phase.[409] These abrupt alternations in muscle action may cause microtears in the tendon.

In addition to those causes already described, a number of other factors appear to have some influence on the development of Achilles tendinitis:

- ***Stretching.*** McCrory et al.[408] determined that injured runners were less likely to incorporate stretching into their regular training routines. However, whether stretching habits can be related to the incidence of overuse injuries remains uncertain.[410–413]
- ***Training variables.*** Overuse injuries of the tendons have been strongly associated with a number of training variables including training at a faster pace,[66,410,414] and hill training.[68,409,415]
- ***Fatigue.*** Overtraining has been found to correlate with muscle fatigue and microtears of a tendon.[43,115]
- ***Exercise variables.*** Muscular insufficiency has been proposed as a significant factor in the inability to eccentrically control dorsiflexion during the beginning of the initial contact phase of running.[408,414–416]
- ***Anthropometric variables.*** One study determined that 20% of the injured runners with Achilles tendinitis had cavus feet.[115] Clement et al.,[415] suggested that a potential cause was compensatory overpronation resulting from the inflexibility of the cavus foot. A high-arched foot has also been found to be related to the incidence of various overuse syndromes by a number of other studies.[66,277,417,418]
- Age. Some studies have found a correlation between age and the pathogenesis of running injuries,[408,419] whereas others[412,418,420–422] have found no associations.
- ***Shoe type.*** Spiked running shoes, which provide minimal shock absorption and which lock the feet on the surface during the single support phase during running have been correlated with Achilles tendinitis. Theoretically, this type of shoe transfers the lateral and vertical torque shear forces directly to the foot and ankle and through the Achilles tendon, thereby increasing the overloading of the tendon, and causing microtrauma and inflammation of the tendon.[407,423]
- Sacroiliac joint dysfunction.[407] The primary function of the pelvis appears to be as a shock absorber, transmitting the weight of the trunk and upper extremities to the lower limbs and distributing the ground reaction forces.[93,424] The ground forces, which tend to rotate the innominate posteriorly, and the trunk forces combine to provide a mechanism of stability.[93,424] Posterior dysfunction is reported to be the most common lesion of the sacroiliac articulation by several authors.[425–427] This results in a functional shortening and external rotation of the involved leg,[428–430] both of which may influence the kinematic chain of the lower extremity in the following manner:[407]
- The ankle and foot position will be in external rotation, instead of neutral, at heel strike.
- Due to the transfer of body weight over the involved leg during the rest of the stance phase, the loading of the lateral aspect of the heel will be short, the following pronation prolonged, and the inversion delayed. This may decrease the amount of dorsiflexion in the ankle, thus minimizing the tension in the plantar soft tissues. This, in turn, decreases the leverage of the Achilles tendon and the truss mechanism[423] may not be activated due to insufficient hyperextension of the big toe.
- Because of the relative ineffectiveness of the foot's truss mechanism at terminal stance, together with the decrease in leverage of the Achilles tendon, the triceps surae will have to activate more motor units to ensure continued performance, thus putting additional loading on the Achilles tendon.

Achilles tendinitis typically occurs as one of two types of tendinitis: insertional and noninsertional, with the former involving the tendon–bone interface and the latter occurring just proximal to the tendon insertion on the calcaneus in or around the tendon substance.[406]

Noninsertional tendinitis can be referred to as peritendinitis, peritendinitis with tendinosis, or tendinosis.[406,431]

- ***Peritendinitis.*** The inflammation in peritendinitis is limited to the peritendon, and thickening can result.
- ***Peritendinitis with tendinosis.*** This condition describes a second stage of inflammation, in which a portion of the Achilles tendon itself is involved in the disease process.

- ***Pure tendinosis.*** This condition, which typically affects the *weekend warrior*, is characterized by microscopic and macroscopic mucoid degeneration of the tendon.

Clinical symptoms associated with Achilles tendinitis consist of a gradual onset of pain and swelling in the tendon 2–3 cm proximal to its insertion, which is exacerbated by activity. Some patients will present with pain and stiffness along the Achilles tendon when rising in the morning or complain of pain at the start of activity, which improves as the activity progresses. In fact, in the early stages of the condition, morning stiffness may be the only symptom, whereas pain is felt even at rest in the advanced stages.[65]

The vast majority of symptomatic patients are runners who complain of pain in the posterior aspect of the heel, approximately 2 cm proximal to the superior margin of the calcaneus, which increases during running activities.[73] The pain typically worsens over time, until it inhibits the individual from running, at which point they usually seek medical attention.

The differential diagnosis for posterior heel pain includes retrocalcaneal bursitis,[73] metabolic diseases, arthritis and chondropathic diseases of the ankle joint, tibia vara, os trigonum, a calcaneal contusion, plantar heel pain, calcaneal stress fracture impingement syndrome and stress fractures of the fibula or tibia (see Chap. 5).[407,432]

The Achilles tendon and heel may be examined with the patient in sitting or prone. Upon observation, the patient will often be found to have pronated feet, and the presence of swelling around the tendon is common.

Systematic palpation is performed along the tendon, over the heel, along the posterior border of the calcaneus, and down to the heel pad. Localization of the tenderness is extremely important. Tenderness located 2–6 cm proximal to the insertion is indicative of noninsertional tendinitis, whereas pain at the bone–tendon junction is more indicative of insertional tendinitis.[406] If there is an area in the tendon itself, which is discrete and painful with side-to-side pressure of the fingers, this often indicates an area of mucoid degeneration or a small partial rupture of the tendon.[73] If the tenderness is in the area of the retrocalcaneal bursa, which is noted by side-to-side pressure in that area, this is the primary area of involvement.[73]

A lack of 20 degrees of dorsiflexion in knee extension signifies adaptive shortening of the gastrocnemius, and an inability to dorsiflex 30 degrees in knee flexion implicates the soleus as well.[73]

Analysis of gait may reveal an antalgic gait, with the involved leg held in external rotation during both the stance and swing phases. There is often pain with resisted testing of the gastrocnemius/soleus complex.

The intervention for Achilles tendinitis in relation to exercise intensity varies according to the severity of the symptoms[72]:

- ***Type I.*** Characterized by pain that is only experienced after activity. These patients should reduce their exercise by 25%.
- ***Type II.*** Characterized by pain that occurs both during and after activity but does not affect performance. These patients should reduce their training by 50%.
- ***Type III.*** Characterized by pain during and after activity that does affect performance. These patients should temporarily discontinue running.

The conservative intervention, which almost always involves modification of extrinsic factors (training errors including a sudden increase in mileage, excessive hill running, and improper shoes), includes Achilles stretching, eccentric strengthening of the calf muscles, the correction of any lower chain asymmetries (low-back, pelvic, and hip flexor asymmetries; knee flexion contracture; femoral anteversion; and foot pronation),[433,434] electrotherapeutic modalities as appropriate, correct shoe wear, and orthotics—appropriately designed orthoses made from a mold of the foot held in subtalar neutral, and non–weight-bearing can be of significant benefit.[65]

A literature review [435] that investigated the best intervention for a patient with recurrent Achilles tendinitis, based on its validity and strength, recommended the 12-week eccentric program as outlined by Alfredson et al.[436] The program consists of two types of eccentric exercises—eccentrically loading the calf muscles with the knee bent and the knee straight and three sets of 15 repetitions using just body weight to start, with the patient instructed to continue unless the pain becomes disabling. The exercises are performed two times per day, each day of the week, for 12 weeks. If only minor pain or discomfort is experienced, the patient is instructed to increase the load by using a backpack loaded with weight. The 37-year-old patient in this study was compliant with the program and was able to successfully progress to marathon training within 3 weeks of beginning the program.[435]

Rupture of the Achilles Tendon

Rupture of the Achilles tendon was first described in 1575, and first reported in the literature in 1633.[437] Although the etiology of a spontaneous rupture remains incompletely understood, a number of theories have been proposed, including microtrauma,[438] inhibitor mechanism malfunction,[439] hypoxic and mucoid tendon degeneration,[440] decreased perfusion,[441] and systemic or locally injected steroids.[442] However, the fact that the peak incidence of Achilles' tendon rupture occurs in the middle age group rather than in the older population tends to lend credence to a mechanical etiology.[443] Three specific activities have been implicated in rupturing the Achilles tendon:[444]

- Pushing off on the forefoot while extending the knee.
- Sudden dorsiflexion with full-weight-bearing as might occur with a slip or fall.
- Aggressive dorsiflexion such as that occurs when jumping or falling from a height and landing on a plantar flexed foot.

The diagnosis of an Achilles tendon rupture is based almost solely on the history and physical findings. The classic history includes reports of sudden pain in the calf area, often associated with an audible snap, followed by difficulty in stepping off on the foot.[443] Physical examination reveals swelling of the calf as well as a palpable defect in the tendon (hatchet strike), as well as ecchymosis around the malleoli.[445] Perhaps, the most reliable sign of a complete rupture is a positive result on the Thompson squeeze test (see Fig. 21-51).[188,446]

Treatment options for an Achilles tendon rupture include surgical and non-surgical approaches, although opinions are divided as to what is the best course of action. The conservative intervention of Achilles tendon rupture traditionally consisted

of short- or long-leg cast immobilization in the gravity equinus position (10–20 degrees of plantar flexion). However, this approach was found to result in a high incidence of re-rupture (10–30%)[447–450] and a decrease in maximal function.[439,451,452] This may be because it is impossible to restore the correct length of the Achilles' tendon with nonoperative treatment.[443] Recent studies have produced superior results with a much quicker rehabilitation using fixed or hinged boots.[453–456]

The results from the surgical approaches have varied with the recent studies reporting small, but statistically significant benefits from surgery. [457,458]

Sever Disease (Calcaneal Apophysitis)

Sever disease is a traction apophysitis at the insertion of the Achilles tendon and is a common cause of heel pain in the athletically active child, with 61% of cases occurring bilaterally.[459]

The calcaneal apophysis serves as the attachment for the Achilles tendon superiorly and for the plantar fascia and the short muscles of the sole of the foot inferiorly.[460] This os calcis secondary center of ossification appears at 9 years of age and usually fuses at 16 years of age.[57] The average age of onset for this condition is 8–13 years.[461]

Factors involved in the etiology of Sever disease include beginning a new sport or season, foot pronation, and a tight gastrocnemius–soleus complex.[462] Young gymnasts and dancers are particularly susceptible to this condition because of their repetitive jumping or landing from a height.[462] The tight Achilles' tendon is usually associated with a recent growth spurt and is not related to a specific injury.[57]

Although radiographs are often normal, sclerosis or fragmentation of the apophysis may be seen on plain radiographs.[57]

The location of the pain differs from that of plantar heel pain in that its focal point is more posterior than it is plantar.

The intervention for Sever disease begins with stretching the heel cord, using heel cups or heel wedges, and avoiding barefoot walking until becoming asymptomatic.[342]

Iselin's Disease

Iselin's disease is a traction apophysitis of the tuberosity of the fifth metatarsal. It is more commonly seen in athletically active older children and adolescents. The secondary center of ossification appears as a small, shell-shaped fleck of bone oriented slightly oblique to the metatarsal shaft and is located on the lateral plantar aspect of the tuberosity of the fifth metatarsal. This apophysis is located within the insertion site of the fibularis (peroneus) brevis tendon. The center appears in girls at an average of 9 years and in boys at 12 years and usually fuses to the shaft by 11 and 14 years, respectively.

The patient is usually involved in sports with running, cutting, and jumping. These activities may result in an inversion stress to this area. There is usually pain over the area, but no specific history of trauma. Resisted eversion typically reproduces the pain. A bone scan will usually be positive. Iselin's disease can be differentiated from an avulsion fracture of the base of the fifth metatarsal because the apophysis is located parallel to the long axis of the shaft and an avulsion fracture is usually transverse in nature.

The intervention for Iselin's disease includes immobilization for acute pain and physical therapy for strengthening of the fibularis (peroneal) tendons.[463]

Plantar Heel Pain

Plantar heel pain, which is the term used to describe pain arising from the insertion of the plantar fascia, with or without heel spur, has been experienced by 10% of the population.[464–466] The condition, often referred to as plantar fasciitis, is an inflammatory process. Waugh[467] has recently proposed that previously accepted inflammatory conditions, such as epicondylitis and plantar fasciitis, may be more accurately referred to as chronic pain syndromes.[468]

A number of factors have been proposed for the etiology of this condition:

- ***Obesity.***[469] Obesity has been shown to occur in 40% of men and 90% of women with plantar heel pain.[470,471] A body mass index greater than 30 kg/m^2 increases the risk of developing plantar heel pain.[472]
- ***Occupational.*** There is an association between plantar heel pain and prolonged standing or walking ("policeman's heel"),[62] or a sudden change in the stresses placed upon the feet likening this condition to other repetitive stress disorders such as carpal tunnel syndrome and tennis elbow.
- ***Acute injury.*** Although less common, plantar heel pain may be associated with an acute injury to the heel. Some people recall stepping on a pebble, or other hard object, before the pain began ("stone bruise").[62]
- ***Anatomical.*** The heel pad is specially constructed as an efficient shock absorber to attenuate peaks in dynamic forces and to dampen vibrations.[473] Part of the impact energy involved in displacement of the heel pad during ambulation is dissipated, and part of the energy is recovered in the subsequent elastic recoil. Two studies that examined the mechanical properties of the heel pad[474,475] found that thickness and compressibility index (CI; ratio of thickness of the loaded heel pad to that of the unloaded one) were greater in patients with plantar heel pain. This finding implies that loss of elasticity of the heel pad may be a factor in plantar heel pain syndrome.
- ***Biomechanical causes.*** People with high arches (pes cavus) or low arches (pes planus) are at increased risk because of the increased repetitive stress being placed on the fascia.[62] Likewise, adaptive shortening of the calf muscles and Achilles tendon, excessive rearfoot motion (especially overpronation), or a rigid varus hindfoot may also put the patient at risk, by placing excess stress on the plantar fascia.[277,476–478] Amis et al.[477] found that 78% of patients with painful heels had ankle dorsiflexion limitations of at least 5 degrees. Kibler et al.[478] noted that 90% of running athletes with plantar fasciitis had either a lack of 5 degrees dorsiflexion beyond neutral on the affected side or a lack of 10 degrees or more dorsiflexion compared with the noninvolved side. Weakness of the intrinsic foot muscles has also been cited as a cause. These factors may increase the moment of maximum tension in the fascia, which, even under normal circumstances, endures tension that is approximately two times body weight during walking at the

moment when the heel of the trailing leg begins to lift off the ground. Thus, an accurate history of footwear should be obtained: Often patients wear shoes with poor cushioning or inadequate arch support or they walk barefoot on hard floors.

Although more common in active individuals, plantar heel pain can also affect the sedentary, although the reasons for this remain elusive. Despite the fact that modern shoes are designed with every conceivable type of heel cushioning, plantar heel pain continues to be a pervasive entity. Although more common in middle-aged individuals, plantar heel pain can occur in the younger individual, although it rarely exists alone in this age group and usually coincides with calcaneal apophysitis.[57] As the plantar fascia assists in the development of the push-off power during running and jumping, it is not surprising that plantar heel pain is particularly prevalent in joggers and tennis players, as well as in athletes participating in racquet sports, soccer, gymnastics, and basketball.[62]

The role of the heel spur in plantar heel pain is controversial.[62] Half of patients with plantar heel pain have heel spurs,[470] whereas 16–27% of the population have heel spurs without symptoms.[148,479] The greater pull of the plantar fascia was thought to lead to periosteal hemorrhage and inflammatory reaction and to laying down of new bone and heel spur formation,[480] but the heel spur is more often associated with the FDB muscle than the plantar fascia.[150,404,477,481–484]

Since chronic subcalcaneal heel pain is a common manifestation of many conditions, the following diagnoses must be excluded:

- ***Inflammatory spondyloarthropathies.*** These disorders should be considered when multiple joints or areas are involved. Up to 16% of patients presenting with subcalcaneal pain will later be diagnosed with a systemic arthritic disorder.[38,62]
- ***Calcaneal stress fracture.***[485] The history for calcaneal stress fractures usually involves a sudden increase in a running activity, such as that seen in a military recruit at boot camp or a reservist.
- ***Nerve entrapment.***[485–487] Heel pain was recently reported to involve the nerve to abductor digiti quinti, the first branch of the lateral plantar nerve.[488] In a fifth of cases of inferior heel pain, the pain may be caused by this nerve being trapped between the abductor digiti quinti muscle and the quadratus plantae muscle or affected by inflammation of the plantar fascia.[488] Positive percussion (Tinel's sign) on the medial aspect of the heel should lead to a suspicion of entrapment of the nerve to abductor digiti quinti or a tarsal tunnel syndrome (TTS).[38]
- ***Tumors.*** Tumors in this area are quite rare, presenting as palpable masses or bony erosions of the calcaneus.
- ***Infections.***[489] As with infections in other parts of the body, there will usually be some swelling and/or erythema and a history of malaise or fever.
- ***Neuropathy (diabetic, alcoholic).***[485] A history of burning pain, numbness, or paresthesias can often be elicited in patients with neuropathic pain. A thorough neurologic exam will confirm the diagnosis.
- ***The fat-pad syndrome.***[37,490] Pain while hopping on the toes may help distinguish this entity from the fat-pad syndrome.

The diagnosis of plantar heel pain is typically made on the basis of clinical findings. Common findings include a history of pain and tenderness on the plantar medial aspect of the heel, especially during initial weight-bearing in the morning. This is thought to be due to the fact that in the morning, the plantar fascia is cold, contracted, or stiff.[491] The patient may also report pain that radiates up the calf and toward the toes. In severe cases, the pain may have a throbbing or burning quality. Interference with daily activities is common.[492] Plantar heel pain is usually unilateral, although in 15–30% of people, both feet are affected.[62,493] The heel pain often decreases during the day but worsens with increased activity (such as jogging, climbing stairs, or going up on the toes) or after a period of sitting.

On physical examination, there will be localized pain on palpation along the medial edge of the fascia or at its origin on the anterior edge of the calcaneus, although firm finger pressure is often necessary to localize the point of maximum tenderness.[38] The main area of tenderness is typically just over and distal to the medial calcaneal tubercle, and usually there is one small extremely painful area. Tenderness in the center of the posterior part of the heel may be due to bruising or atrophy of the heel pad or to subcalcaneal bursitis.[470] Slight swelling in the area is common.[477] Tightness of the Achilles tendon is found in 78% of patients.[470,477]

To test for plantar heel pain, the fascia needs to be put on stretch with a bowstring-type test. The patient's heel is manually fixed in eversion. The clinician takes hold of the first metatarsal and places it in dorsiflexion before extending the great toe as far as possible. Pain should be elicited at the medial tubercle.

It has been reported that almost 90% of patients with plantar heel pain who undergo a conservative intervention improve significantly within 12 months, although approximately 10% can develop persistent and often disabling symptoms.[494] This time frame for resolution of symptoms suggests that present interventions are ineffective and that time alone heals the patient. A recent review of the literature at the plantar heel pain interventions concluded that there was no quality information regarding the effectiveness of treatments of the heel pain.[465] The interventions thus far attempted include the following:

- ***Night splinting.*** There is limited evidence for night splints to treat chronic symptoms.[495]
- ***Orthotics.*** Most of the orthotics are designed to correct biomechanical faults, especially over pronation.
- ***Heel cups/taping.*** Lynch et al.[496] performed an unblinded prospective trial of 103 subjects with plantar heel pain randomized into one of three groups of treatment: anti-inflammatory (NSAIDS and steroid injections), accommodative (viscoelastic heel cup), or mechanical (taping for 4 weeks followed by custom orthoses). At the end of 3 months, there was no significant difference in activity level and first step pain between the groups. However, the mechanical treatment group (taping) had significantly better visual analog scales (VAS) scores than the accommodative group (heel cup) and had a significantly better rate of fair or

excellent outcomes. A randomized controlled trial by Hyland et al.[468] found calcaneal taping to invert the heel and raise the medial longitudinal arch to be a more effective tool for the relief of plantar heel pain than stretching, sham taping, or no treatment after 1 week. Taping can be considered as a means of reinforcing either the calcaneal fat pad and/or the medial longitudinal arch. The tape of choice is a low-die 1-inch tape.[73] Prior to applying the tape, the patient should be relaxed and the heel and foot placed in neutral. Excessive tension through the strips will lead to complaints during activity. The patient should be in weight bearing throughout the foot before applying the final closing strips. Care must be taken when applying the tape on the medial, lateral, or posterior (dorsal) aspect of the foot. Tension in the tape flow is critical, if skin breakdown is to be avoided with repeated taping.[73]

- ***Stretching and strengthening.*** Some evidences exist for plantar fascia stretching to address chronic plantar fasciitis.[497]
- ***Deep frictional massage.*** This can be applied manually VIDEO or through the use of a tennis ball VIDEO, or golf ball VIDEO.
- ***Corticosteroid injection.*** There is limited evidence for topical corticosteroids administered via iontophoresis for pain relief.[495]
- ***Dexamethasone iontophoresis.***
- ***Shoe modifications.***
- ***NSAIDs.***
- ***Casting.*** Recalcitrant or long-standing cases of plantar heel pain may require casting. This can take the form of a short-leg walking cast positioned in neutral (plantigrade) for 4–6 weeks. Patients with severe pain and marked limitation of activity are best treated with a molded, below-knee, walking cast for 3–4 weeks.[39] It provides relative rest, reduces pressure on the heel at heel strike, provides an arch support, and prevents tightening of the Achilles tendon. A night splint positioned in 5 degrees of dorsiflexion is worn for an additional 6 weeks once the cast is removed, and the patient can resume the stretching and strengthening program for an additional 6 weeks once the cast is removed.[62]
- ***Extracorporeal shock wave lithotripsy***[498]
- ***Radiofrequency lesioning.***
- ***Open and endoscopic plantar fasciotomy and surgical neurolysis (in extremely recalcitrant cases).*** It has been reported that approximately 5% of patients who are diagnosed with plantar heel pain undergo surgery for the condition.[496,499]

A number of clinical trials have attempted to examine the efficacy of intervention combinations for plantar heel pain. The University of Pittsburgh Medical Center Foot and Ankle Clinic has advocated nonsurgical treatment of insertional plantar heel pain using a standardized regimen since 1992.[500] The regimen is as follows:

- Take NSAIDs as directed for 4 weeks.
- Attend the University of Pittsburgh Sports Medicine Clinic for a one-time instructional home-exercise program of Achilles stretching (four exercises) and plantar fascia stretching (two exercises). The subject is instructed to continue the exercises for six sets, holding each for 30 seconds × 3/day.
- Wear a night splint every night to bed.
- Use an orthosis or heel cup at all times when wearing shoes.

The reported outcomes in this study were not as good as the average outcome reported in other published studies, with only 51% being asymptomatic after 4 months.[500] The authors cited that the reasons for this were that other studies may have included subjects with causes of subcalcaneal heel pain other than true plantar heel pain, making direct comparison difficult.

The lack of a universal intervention for plantar heel pain, and the poor level of long-term success, likely stems from its many causes. A poor response to an intervention may be due, in part, to inappropriate and nonspecific techniques or an inaccurate diagnosis. The etiological trauma for plantar heel pain occurs after the peak loads of initial contact are reached and as the center of mass advances beyond the ankle. This would tend to indicate that the forces associated with initial contact are not directly linked with the stresses that are applied to the plantar fascia. Indeed, the highest force loads on the foot during gait occur at the forefoot. These forces have been found to be 15–25% higher than those occurring during initial contact. Fortunately, the foot has a built-in mechanism to deal with these loads—the Windlass mechanism. As the heel rises about the rotating MTP joints, the plantar fascia, through its insertion into the bases of the digits, "winds" itself around the drum-like metatarsal heads. This creates a winch-like effect that pulls the proximal aspect of the heel closer to the ball of the foot and elevates the medial longitudinal arch, which, in turn, provides a stable platform upon which propulsion can occur. Critical to the efficiency of the Windlass mechanism is the ability of the first MTP joint to dorsiflex during the heel-raise phase of gait. An inability to dorsiflex the first MTP is called functional hallux limitus (see "Examination" section).

Given that plantar heel pain appears to be impairment based, an impairment-based physical therapy examination and intervention approach would appear to be logical.[495] Such an approach has been investigated in several randomized controlled trials. Pollard and So[501] reported full recovery in a 35-year-old male with a 3-month history of right inferior heel pain, using a combination of talocrural and talocalcaneal joint mobilization, stretching, strengthening, custom orthosis, and pain modalities. Patla and Abbott[152] reported restoration of pain-free functional activities with the use of manual posterior tibialis stretching in two patients with primary complaints of heel pain. Young et al.,[495] in a case series, treated four patients with plantar heel pain, using an impairment-based physical therapy approach, which emphasized manual therapy. All four patients demonstrated complete pain relief and full return to activities.[495]

On the basis of the above-mentioned studies, the intervention for plantar heel pain should include the following:

- Rest or at least aviodance of any activity that continually provides axial loading of the heel and tensile stresses on the fascia.
- A recommendation of shoes that provide good shock absorption at the heel and support to the medial longitudinal arch and plantar fascia.
- The identification of the cause of any tissue overloading that is occurring, as well as any functional biomechanical deficits (plantar flexor inflexibility and weakness) and functional adaptations (running on toes, shortened stride length, and foot inversion).
- Strengthening exercises. A number of strengthening exercises have been devised for plantar heel pain:
  - ***Towel curls.*** A towel is placed on a smooth surface, with the foot placed on the towel. The patient is instructed to pull the towel toward the body by curling up the toes, and then attempt to move the towel in the reverse direction **VIDEO**.
  - ***Marble pick-ups.*** A few marbles are placed on the floor near a cup. While keeping the heel on the floor, the patient uses the toes to pick up the marbles and drop them in the cup.
  - ***Toe taps.*** The patient is instructed to keep the heel on the floor and lift all of the toes off the floor. The patient is asked to tap the big toe to the floor, while keeping the outside four toes in the air. Next, the patient keeps the big toe in the air, while tapping the other four toes to the floor.
- A regimen of stretching of the gastrocnemius and the medial fascial band, especially before arising in the morning and after sedentary periods during the day, as well as before and after exercise.[502]
  - ***Gastrocnemius and soleus.*** Patients are taught how to stretch the gastrocnemius and soleus **VIDEO** components of the triceps surae independently while minimizing stress on the plantar fascia. After a warm-up, the patient stands against a wall, with his or her hands placed against the wall. With one foot forward and one behind, the patient leans his or her trunk toward the wall, shifting their weight over the front foot, while straightening the knee of the back leg. The heel of the back foot should remain on the floor while the front of the foot is internally rotated and supinated, to stabilize the medial longitudinal arch, putting the foot in the close-packed position and allowing for the stretch to be isolated to the Achilles tendon.[62] The stretch is then repeated on the other leg. A similar stretch can be done by standing on a stair step, with only the toes on the stairs and the back two-thirds of the feet hang off the step. By leaning forward to balance, the heel, Achilles tendon, and calf will be stretched. The stretch can also be performed when standing, where the heel is on the floor and the front part of the foot is on a wooden 2 × 4.
  - ***Plantar fascia stretch.*** The plantar fascia stretch is performed with the patient sitting with their legs crossed, with the involved leg over the contralateral leg. Then, while using the hand on the affected side, the patient places his or her fingers across the base of the toes on the bottom of the foot (distal to the MTP joints) and pulls the toes back toward the shin until a stretch is felt in the arch of the foot. The correct stretch is confirmed by palpating the tension in the plantar fascia with the contralateral hand, while performing the stretching. In a prospective randomized trial from DiGiovanni et al.,[497] 101 patients who had chronic proximal plantar heel pain for at least 10 months were randomized into one of two treatment groups. The mean age was 46 years. All patients received prefabricated soft insoles and a 3-week course of celecoxib, and they also viewed an educational video on plantar heel pain. The patients received instructions for either a plantar fascia tissue-stretching program (Group A) or an Achilles-tendon-stretching program (Group B). All patients completed the pain subscale of the FFI and a subject-relevant outcome survey that incorporated generic and condition-specific outcome measures related to pain, function, and satisfaction with treatment outcome. The patients were reevaluated after 8 weeks. Eighty-two patients returned for follow-up evaluation. With the exception of the duration of symptoms ($P < 0.01$), covariates for baseline measures revealed no significant differences between the groups. The pain subscale scores of the FFI showed significantly better results for the patients managed with the plantar fascia-stretching program with respect to item 1 (worst pain; $P = 0.02$) and item 2 (first steps in the morning; $P = 0.006$).[497] Analysis of the response rates to the outcome measures also revealed significant differences with respect to pain, activity limitations, and patient satisfaction, with greater improvement seen in the group managed with the plantar fascia-stretching program.

The stretches are performed twice daily, beginning with a sustained stretch for 1 minute and progressing to 3 minutes based on tolerance.[488] The rest period should involve gentle active dorsiflexion and plantar flexion exercises, while resting the Achilles tendon and calf on a hot pack to enhance the stretch.[62] Massage to the foot in the area of the arch and heel or rolling the foot over a tennis ball or a 15-ounce can may also be helpful.

- Orthotics may be prescribed, but only after careful examination of the footwear to ensure a firm, well-fitting heel counter, good heel cushioning, and an adequate longitudinal arch support.[503] A wide variety of rigid, semirigid, and soft shoe inserts are commercially available, although rigid plastic orthoses rarely alleviate the symptoms and often aggravate the heel pain.[472] Orthoses made of softer materials provide cushioning by reducing the shock of walking by up to 42%.[38] Since the plantar fascia is stretched during flattening of the foot, orthoses should be designed to maintain the medial longitudinal arch during ambulation, and should be prescribed in full length or three-quarters length-accommodative inlays of medium-density plastazote.[38]

The type of orthotic prescribed depends on the findings:[62]

- ***Normal foot.*** Off-the-shelf heel cups should be used to cushion the heel. Cyriax recommended heel lifts to relieve the strain on the plantar fascia during early treatment,[133] and bilateral heel lifts of ¼ to ⅜ inch are sometimes

successful, but their use should be discontinued at the earliest possible time.[73]

- ***Pes planus (flatfoot).*** For this foot type, the orthotic is used to stabilize the arch and thereby decrease the strain on the plantar fascia. A University of California-Biomechanics Laboratory (UC-BL) type of orthotic is indicated.
- ***Pes cavus (high arch).*** An excessively high arch or cavus foot can cause an inability to evert the foot to dissipate stress. In this situation, the orthotic of choice would be one that focuses on cushioning to increase the total contact area of the foot.

Bursitis

Retrocalcaneal Bursitis

Retrocalcaneal bursitis is a distinct entity denoted by pain that is anterior to the Achilles tendon, just superior to its insertion on the os calcis. This type of bursitis appears to be more common in older individuals and low-level recreational athletes.[73,504]

The bursa becomes inflamed, hypertrophied, and adherent to the underlying tendon, resulting in deep pain and visible swelling.[39,74] Characteristic findings include pain with a two-finger squeeze just superior and anterior to the Achilles insertion and pain with passive dorsiflexion.[57]

Retrocalcaneal bursitis is treated conservatively with shoe modifications (open backed if necessary) and a heel lift.[57] In rare cases, a bursectomy with associated resection of the posterior superior margin of the os calcis is necessary.

A small percentage of the population has an adventitious subcalcaneal bursa, which may become inflamed and cause heel pain.[478]

Anterior Ankle Bursitis

Anterior ankle bursitis is commonly seen in young figure skaters and ice hockey players.[57] This condition can present with swelling over the anterior ankle or over either malleoli. A doughnut pad inside the skate over the irritable area will usually decrease the pressure at this point.[57]

Haglund's Deformity

Haglund's deformity[505] refers to an abnormal prominence of the posterior superior lateral border of the calcaneus. Because of its association with various shoe types, it is often referred to as a "pump bump,"[506] "high heel,"[507] and "winter heel."[508,509]

The prominence is frequently a bony spur or osteophyte acquired as the result of poorly fitting of shoes in adolescent females, ice skaters, soccer players, and runners,[150] but is also thought to be a congenital variation.

Whatever the etiology of these various prominences, they frequently aggravate the retrocalcaneal bursa on the deep surface of the Achilles tendon, producing an associated retrocalcaneal bursitis or Achilles tendinitis.[57]

On physical examination, a bump, which is 2–3 cm in diameter, is usually located more to the lateral side of the heel, and there is often an accompanying thickening of the overlying skin. Pain is often noted on palpation just proximal and slightly lateral to the insertion of the Achilles tendon.[502] Sometimes a varus hindfoot is found. A cavus or high-arched foot is believed to change the calcaneal position and increase the prominence of this ridge.[502]

Before intervention is initiated, the differential diagnosis must be considered, including systemic disease, Achilles tendinitis, or intrinsic conditions of the calcaneus, such as infection and tumor.[57]

Intervention involves relieving the friction imposed by the shoe counter by using a softer heel counter, increasing shoe size by one-half, padding the prominence, or using a heel lift to actually raise the heel out of the shoe.[74,509,510] Achilles stretching and strengthening and the use of local modalities, such as ultrasound, are also recommended.[57]

Surgical excision of the deformity is reserved for persistent symptoms in the young athlete.[506,509,511]

Metatarsalgia

During the normal gait cycle, the center of pressure progresses along the plantar aspect of the foot from the heel at initial contact to the toes at terminal stance. The center of pressure is initially located in the central heel and then accelerates rapidly across the midfoot to reach the forefoot, where it is located under the second and the third metatarsal head, rather than under the first and the fifth metatarsal head and the calcaneus, as was once thought.[50,85,89] This weight-bearing force is approximately equal to the body weight, which is more than twice the load carried by the other toes combined.

Any biomechanical intrinsic or extrinsic condition that increases stress on the metatarsal heads may result in metatarsal head pain and the development of painful plantar keratoses or calluses.[149] Plantar keratoses may be diffuse and large or small and discrete.

- A Morton's foot with a short first metatarsal and a relatively long second metatarsal may result in increased loading of the second metatarsal head and the development of a painful callus.[512]
- Patients with abnormally lax first metatarsal–cuneiform joints, resulting in a hypermobile first ray, can experience increased weight-bearing under the second and third metatarsals, which often results in painful diffuse calluses.[50]
- A prominent lateral condyle of a lesser metatarsal can result in a smaller discrete plantar keratosis, which can be exquisitely tender to palpation.
- A tight Achilles tendon can increase the forefoot load in late stance phase and may result in metatarsalgia.[50]
- The use of high-heeled shoes extrinsically increases forefoot load and may lead to diffuse metatarsalgia.

The intervention for metatarsalgia involves the use of a metatarsal pad that is placed proximal to the painful metatarsal heads. Adhesive-backed metatarsal pads of different shapes and sizes are available to unload one or several metatarsal heads. Custom orthotics may also be molded specifically for the cavus foot to decrease load on the plantar flexed first and second rays, to distribute weight evenly across the forefoot. A patient with a hypermobile first ray will benefit from a custom longitudinal arch support with medial forefoot post. A trial of Achilles stretching is helpful in the initial treatment of

metatarsalgia. The wearing of high heels should be discouraged in patients with metatarsalgia.

If unresponsive to conservative intervention, surgical plantar condylectomy may be required for resolution of a discrete plantar keratosis. More generalized diffuse painful calluses such as those seen under the first and second metatarsal heads in the cavus foot may require posterior (dorsal) closing wedge osteotomies of the metatarsal bases to achieve pain relief.[149]

Idiopathic Synovitis

Idiopathic synovitis of the second or third MTP joint is another cause of metatarsalgia. This condition results in painful distension of the joint, swelling of the second toe, warmth, and limited MTP joint motion.[513] Second MTP joint synovitis probably occurs as a result of attrition of the plantar plate due to a long second metatarsal.[514] Posterior (dorsal) instability of the MTP joint may develop with joint subluxation or dislocation. A hammer toe or claw toe deformity is common.

Initially, the patient develops pain on palpation in the plantar and posterior (dorsal) aspects of the MTP joint. Joint instability can be diagnosed with passive articular mobility testing.

Conservative intervention includes NSAID, a metatarsal pad, taping the toe in a plantar flexed position, and an accommodative shoe. An intra-articular corticosteroid injection in combination with a rocker-sole modification has been shown to result in improvement in 93% of 15 cases.[515] Persistent pain in the second MTP joint despite conservative measures may necessitate operative synovectomy to avert toe dislocation or deformity.

Metatarsalgia of the Fifth Toe

This is usually due to overwork of the fibularis (peroneus) longus/brevis secondary to an unstable ankle. The overwork of the brevis leads to an instability of the fifth metatarsal at the intermetatarsal or cubometatarsal joints. The patient will point to the tubercle of the fifth metatarsal and complain of pain along the proximal part of the fibularis (peroneus) muscle. Conservative intervention involves taping a strip of tape over the posterior aspect of the foot and then one strip on the medial aspect, going proximal to distal. These two strips are then connected with strips of tape under the foot, across the sole.

Anterior Ankle Impingement

Anterior ankle impingement can be bony or soft tissue related. Patients with this problem usually present with anterior ankle pain exacerbated by extreme dorsiflexion.[16,57]

A bony impingement can be seen in young ballet dancers who exercise in extreme ankle dorsiflexion, irritating the periosteum on the talar neck, and leading to an exostosis and discomfort with pliés.[462]

A form of soft tissue impingement can be secondary to generalized synovitis or capsulitis. This can develop after acute or recurrent episodes of an inversion ankle sprain or in adolescent gymnasts who sustain repeated forced dorsiflexion in landing and dismount.

Chronic anterolateral ankle impingement due to a thickened and scarred joint capsule is a frequent sequela of recurrent ankle sprains. Wolin et al.[516] reported in 1950 that recurrent pain and swelling after injury to the lateral ligaments without instability in patients with a history of previous ankle sprains was due to hyalinized connective tissue arising from the anteroinferior portion of the talofibular joint capsule. They believed that the symptoms resulted from this connective tissue becoming pinched in the talofibular joint with motion. As this mass of tissue and synovium increases in size, impingement of the tissue mass between the talus, tibia, and fibula causes further irritation and pain. This has since been confirmed arthroscopically and by MRI.[517–524]

Bassett et al.[525] reported a cause of chronic pain in the ankle after inversion sprain in seven patients as being due to talar impingement by a distal fascicle of the anterior–inferior tibiofibular ligament.

On physical examination, there is usually pain to palpation anteriorly, with no palpable swelling.[304] Plain ankle radiographs can be helpful in determining a bony problem, but a bone scan is usually necessary for a definitive diagnosis. MRI may also be diagnostic.

The intervention for the soft tissue impingement variety includes discontinuing landing temporarily, icing,[404] antiinflammatories, and exercises to stretch the Achilles tendon and strengthen the dorsiflexors. Occasionally, a pad taped over the anterior ankle may provide temporary relief.[304] Arthroscopy may be indicated if conservative treatment fails. A partial synovectomy[526] or excision of osteophytes is successful but must be followed by exercises to prevent recurrence.

Posterior Ankle Impingement

Posterior ankle impingement or talar compression syndrome[60] is seen most often in young female dancers, ice skaters, or gymnasts.[57] These sports require excessive plantar flexion of the ankle, compressing the posterior structures of the ankle.[60,401]

On physical examination, the patient will have pain on palpation of the posterior ankle, dramatically increased with forced plantar flexion.[57]

Plain radiographs of the ankle can be taken to rule out a bony etiology (i.e., os trigonum).[60] Soft tissue etiology includes FHL irritation, a thickened or invaginated posterior capsule, synovitis, and calcific debris.[401,527,528]

Sesamoiditis

This condition has been defined as inflammation and swelling of the peritendinous structures of the sesamoids. The tibial (medial) and fibular (lateral) sesamoids are situated under the first metatarsal head. These sesamoids are prone to injury in repetitive high-impact and contact sports.[50] Since the tibial sesamoid bears most of the force under the first metatarsal head, it is most commonly injured.[50]

Although direct trauma or forced dorsiflexion of the great toe can acutely fracture the sesamoids, most sesamoid injuries are overuse injuries. Twelve percent of injuries to the great toe complex are sesamoid injuries.[51]

The etiologies of sesamoid injuries include stress fracture (40%), acute fractures (10%), chondromalacia, synovitis, sesamoiditis (30%), osteochondritis (10%), arthritis (5%), and bursitis (5%).[51] Bipartite or multipartite sesamoids occur in 5–33% of the population and are bilateral in 25%.[54,529]

The diagnosis of sesamoiditis is one of exclusion.[530] Sesamoiditis is associated with local trauma, pain on weight-bearing, and plantar soft tissue swelling.[531] Passive dorsiflexion of the MTP joint while palpating the sesamoids exacerbates the pain. Sesamoidal bursitis presents with swelling, erythema, and tenderness with a side-to-side pinch. A plantar fullness or fluid-filled bursal cyst may be palpated under the sesamoids.

Conservative intervention involves rest from the offending activity, NSAIDs, and low-heeled shoes with a soft metatarsal support proximal to the metatarsal head, to decrease the load on the involved sesamoid.[532] One or two injections of corticosteroids into the region of the sesamoids may be helpful.[50] Failure of several months of conservative care may result in the need for surgical excision of the offending sesamoid to alleviate symptoms.[532]

MEDIAL TIBIAL STRESS SYNDROME

Exercise-induced anterior and medial leg pain has been reported to account for 60% of all injuries causing leg pain in athletes.[533] A number of generic terms such as "medial tibial syndrome," "tibial stress syndrome," "shin splints," "posterior tibial syndrome," "soleus syndrome," and "periostitis" have evolved over the years to describe exercise-related leg pain. Of all these terms, medial tibial stress syndrome (MTSS) is the most appropriate.

MTSS appears to involve periosteal irritation indicated by a diffuse linear uptake on a bone scan along the length of the tibia.[534] The anatomic site of the abnormality has been fairly well localized to the fascial insertion of the medial soleus.

The characteristic complaint in these patients is a dull aching pain along the middle or distal posteromedial tibia. Early in this process, the pain usually occurs at the beginning of a run, resolves with continued exertion, only to recur toward the end or after a workout.[535] At this stage, the pain typically subsides quickly with rest.[535] With continued training the pain usually becomes more severe, and persistent, and with increasing chronicity, the pain may be present with ambulation or at rest.[535]

Overuse or weakness of the tibialis anterior, EDL, or EDB may be the causative factors in anterior shin splints, as are excessive or abnormal pronation, restricted ankle joint dorsiflexion, training errors, and inadequate footwear.[80]

With the exception of pain and point tenderness at the anteromedial aspect of the tibia, which is increased with active dorsiflexion and passive stretching into plantar flexion, there are few objective findings. However, the pain is usually provoked with activity and relieved with rest.

As with most overuse injuries, the intervention for shin splints involves activity modification, followed by a gradual return to sports, making sure to identify and correct any training errors or abnormal foot biomechanics.

PREFERRED PRACTICE PATTERN 5F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM, OR REFLEX INTEGRITY SECONDARY TO PERIPHERAL NERVE INJURY

An entrapment neuropathy is characterized by an entrapment of a peripheral nerve by fascia, a ligament, a bony groove, or a tendinous arch of a muscle origin. Sural nerve neuropraxias and fibular (peroneal) nerve palsies are an infrequent complication of lateral ligamentous injuries of the ankle but are quite problematic.[16,125] EMG evaluation of patients with ankle sprains reveals that up to 80% of patients with severe ankle sprains have some evidence of fibular (peroneal) nerve injury.[16,125]

Interdigital Neuroma

The name of the condition is a misnomer, as a true neuroma does not exist. Rather, there is a thickening of the tissues around the nerve due to perineural fibrosis, fibrinoid degeneration, demyelination, and endoneural fibrosis.[50,536] In a study of 91 patients with interdigital neuromas, the male: female ratio was 1:9.[537]

Although a common cause of this condition is chronic compression of the interdigital nerve, it can also occur due to an acute dorsiflexion injury to the toes, with an associated injury to the collateral ligaments of the MTP joint.[50,146]

Symptoms are usually aggravated with weight-bearing and somewhat relieved by rest and forefoot massage.[50,146] Incorrect shoe selection, such as wearing a cross-training or racket shoe for long-distance running, may increase the impact forces on the forefoot and contribute to the symptoms.[50] Narrow shoes and high-heeled shoes have also been implicated.

Physical examination reveals tenderness in the web space plantarly between the metatarsal heads.[50] Squeezing the forefoot with one hand, while carefully palpating the involved interspace with the thumb and index fingers of the other hand, will usually elicit marked discomfort,[50] or produce a painful audible click, known as Mulder's sign.[538] Careful palpation of the MTP joint, metatarsal head, and proximal phalanx should be performed to rule out localized joint or bone pathology such as MTP joint synovitis, stress fracture, or Freiberg's disease, which can also cause symptoms of forefoot pain.[50] A positive Tinel's sign over the tarsal tunnel or multiple symptomatic web spaces should alert the clinician to the possibility of a more proximal nerve compression or underlying peripheral neuropathy.[50] EMG studies and nerve conduction velocity testing should be performed in these cases.[146]

The intervention initially involves an avoidance of the offending activity, cross-training using lower-impact sports, and a modification of footwear—a switch to wider, more accommodating shoes with soft soles and better shock absorption.[50] In addition, a metatarsal pad, placed proximal to the symptomatic interspace, may prove helpful.[50] The metatarsal pad can also be incorporated into a custom-made full-length

semirigid orthotic.[50] A trial of NSAIDs is indicated in an attempt to decrease inflammation around the interdigital nerve.[50] A trial of vitamin B6 has been used successfully in the treatment of carpal tunnel syndrome and may also be useful in the treatment of interdigital neuritis.[539]

Recalcitrant cases that fail to respond after 2–3 months of the above conservative measures may benefit from an injection of corticosteroids.[50] One to two injections can be tried, but multiple injections should be avoided, as corticosteroids may cause atrophy of the plantar fat pad.[50] Surgery is the intervention of last resort.

Deep Fibular (Peroneal) Nerve Entrapment/Anterior TTS

Entrapment of the deep fibular (peroneal) nerve was first reported in 1963[540] and was given the name anterior TTS in 1968.[541]

At the ankle level, both motor and sensory branches of the deep fibular (peroneal) nerve are present.

Anterior tarsal syndrome[542] occurs when there is a contusion to the terminal branch of the deep fibular (peroneal) nerve, as it travels beneath the posterior tibialis and EHB tendons, and above the first and second cuneiforms, where it is relatively unprotected.[543] The compression usually results from tight boots or from the shoe straps of high heels, a ganglion, pes cavus, or from direct trauma.[542,544] A partial anterior TTS[545] occurs when either the motor branch to the EDB or only the sensory branch of the deep fibular (peroneal) nerve is compressed beneath the inferior extensor retinaculum.[543]

Patients with anterior TTS complain of a deep aching pain in the medial and posterior (dorsal) aspect of the foot, burning around the nail of the great toe, and pins and needles at the adjacent borders of the great and second toes that are exacerbated with plantar flexion and improved with rest.[543,544,546,547]

The examination reveals weakness or atrophy of the EDB muscle and diminished movement with toe extension.[543]

Conservative intervention for these patients involves an alteration of daily and sports activities, alteration in footwear, orthotics, and if necessary NSAIDs.[543]

Surgical intervention, reserved for those who do not respond to conservative measures within 3 months, involves decompression of the nerve.[543]

Superficial Fibular (Peroneal) Nerve

Although injuries to the superficial nerve at the level of the ankle are relatively rare, the nerve can be stretched with lateral (inversion) ankle sprains or can become entrapped as it pierces the deep fascia to become subcutaneous approximately 4–5 inches above the lateral malleolus.[146,548–552]

Patients complain of diminished sensation on the posterior aspect of the foot, which is exacerbated with activity.

Tarsal Tunnel Syndrome

TTS is an entrapment neuropathy of the tibial nerve, as it passes through the anatomic tunnel between the flexor retinaculum and the medial malleolus (also see Chap. 5). In addition, the terminal branches of the tibial nerve, the medial, and lateral plantar nerves, may be involved. These latter nerves are often collectively called the posterior tibial nerve. The onset of TTS may be acute or insidious. Differential diagnosis includes plantar heel pain, chronic heel pain syndrome, and FHL tenosynovitis. The clinical findings for TTS are outlined in Chapter 5. Etiologic factors for TTS can be classified as internal or external. Internal factors include anatomical variations such as an accessory flexor digitorum longus muscle. External factors include excessive pronation, which can tighten the flexor retinaculum and the calcaneonavicular ligament. Conservative intervention for TTS includes the use of orthotics to correct biomechanical gait abnormalities. Specifically, a foot orthosis with a rearfoot varus post can limit excessive pronation. In cases of early excessive rearfoot pronation and subtalar joint pronation at heel strike, an orthosis with a deepened heel cup can help to control rearfoot motion. In cases of severe hyperpronation, a rearfoot wedge may be helpful.

Peripheral Neuropathy

Peripheral neuropathy is characterized by a progressive loss of nerve fibers that predisposes the patient to painful or insensitive extremities, vascular compromise, and neuropathic ulceration.[553,554] In more severe cases, uncontrolled peripheral neuropathy can result in amputation. Affected nerve functions associated with peripheral neuropathy include reduced nerve conduction velocity, decreased temperature sensation, decreased tendon reflex response, alterations in autonomic function, and a decreased ability to detect vibration and touch. Peripheral neuropathy is a complication of both insulin-dependent (type 1) and noninsulin-dependent (type 2) diabetes mellitus.[543,554]

A loss of sensation in the legs and feet prevents the patient from detecting minor cuts or trauma, which can become infected, placing these patients at high risk of developing a neuropathic ulcer. Motor neuropathy may cause muscle atrophy and imbalances, which can lead to foot deformity and increased pressure on the plantar aspect of the foot. This is particularly true with the diabetic patient who participates in sports, where the forces acting on the sole of the foot can be significant. Autonomic dysfunction may lead to decreased perspiration and sebaceous oil production, which can cause dryness, cracking, and, eventually, fissures in the skin. Good foot care is thus essential for these patients. It is recommended that the clinician regularly assess the general skin condition of the patient's foot and leg (dryness, cracks, and fissures) and the skin temperature. Red and warm skin may indicate the presence of infection, cellulitis, or an undetected bone infection or fracture. Cold skin and pallor may indicate decreased blood flow. Other signs of vascular compromise can include diminished pulses and toe pressures, dry and shiny skin with no hair growth, and thickened flaky nails. Skin rashes and foul odor may be indicative of a fungal infection. Callus and corn formation, blisters, and bunions may highlight the presence of an ill-fitting shoe or a deformity (equinus contracture, claw toes, and charcot arthropathy). Charcot (rocker-bottom) foot occurs when the bones at the plantar aspect are prominent, resulting in a diminished longitudinal arch and an increased

potential for fracture. Other conditions to observe for include plantar warts and ingrown toenails.

Sensation of the foot can be tested using Semmes–Weinstein filaments, which are calibrated nylon monofilaments with increasing stiffness indicated by increasing numbers (see Chap. 3).[553,554] Protective sensation of the foot has been defined as the ability to sense a 5.07 monofilament, whereas absent sensation is defined as the inability to sense a 6.10 monofilament.[553]

The primary focus of intervention with this patient population is patient education regarding proper foot and nail inspection and care.

The following advice should be given:

- The feet should be washed everyday in warm, not hot, water. Hot water dries the skin and can easily burn the foot. The water temperature can be tested using a thermometer. The feet should not be soaked to avoid skin maceration.
- The skin should be inspected at least once a day for cuts, bruises, blisters, swelling, and calluses. A mirror can be used where necessary. If the skin is dry, lotion can be applied on the tops, bottoms, and sides of the feet, but not between the toes, which can create a moist environment for fungal and bacterial infections.
- Toenails should be trimmed straight across with a nail clipper once a week. Rounding off the corners of the nails increases the potential of ingrown toenails and increases the potential for cutting the skin. If the patient has retinal neuropathy and poor eyesight, the nails are best trimmed by a family member or by a professional.
- The patient should avoid walking barefoot or wearing sandals.
- The feet should be protected from hot or cold temperatures.
- The patient should exercise a little every day. Appropriate nonimpact exercises include cycling or swimming. Gait training may be appropriate to maintain mobility and alter gait patterns to decrease abnormal plantar pressures.[553]
- If possible, the patient should stop smoking. Smoking causes the blood vessels to constrict.

Appropriate footwear and orthotics should be prescribed where appropriate to reduce plantar pressures and increase the weight-bearing area of the foot.[80] The total contact cast is considered the gold standard for ambulating patients, due to its ability to reduce pressure on the midfoot and forefoot by distributing pressure over the total foot surface.[80] Alternatively, the patient may be prescribed a prefabricated walker boot, or a bivalved ankle foot orthosis.

In the presence of a diabetic wound, frequent sharp debridement of nonviable tissue has been shown to be an effective method to speed wound healing.[555] This can be performed with a scalpel and tweezers. Enzymatic and autolytic debridements can be used as adjuncts to sharp debridement.[555] Enzymatic debridement uses ointments that contain papain-urea or other enzymes that help break the bonds between necrotic tissue and wound bed. Autolytic debridement uses moisture-retentive secondary dressings (hydrogels and hydrocolloids) to provide a moist environment, which helps to keep the wound fluids in contact with the wound bed.

Complex Regional Pain Syndrome

The more classic patient with complex regional pain syndrome will present with severe regional pain, swelling, dysesthesia to light touch (allodynia) and vasomotor instability, and the subjective report will be one of pain out of proportion to the degree of injury (see Chap. 5).[556]

Myofascial Pain Syndrome

Ankle or foot pain can arise, and trigger points in the tibialis anterior, extensor digitorum, or fibularis (peroneus) longus muscle are the most likely causes.[557]

Tibialis Anterior

Trigger points of this muscle can refer pain, tenderness, and stiffness deep into the anterior ankle and the great toe. These trigger points can be activated due to excessive pronation of the foot and excessive dorsiflexion.[557]

Extensor Digitorum

Trigger points of this muscle can refer pain and tenderness over the posterior aspect of the foot and into the middle three toes.

Fibularis (Peroneus) Longus

Trigger points of this muscle can refer to just posterior to the lateral malleolus. This muscle is usually strained on inversion sprain injuries of the ankle and can therefore be the source of residual pain at the lateral ankle.[557]

PREFERRED PRACTICE PATTERN 4G: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM ASSOCIATED WITH FRACTURES

Stress Fractures

A stress or fatigue fracture involves a break that develops in bone after cyclical, submaximal loading. A number of extrinsic factors are associated with stress fractures of the leg and foot including running on hard surfaces, improper running shoes, or sudden increases in jogging or running distance. Biomechanical factors, including malalignment of the lower extremity, particularly excessive pronation, should also be considered when evaluating stress fractures. In the foot, the two most common locations for stress fractures are the metatarsal shaft and the calcaneus.[558]

Metatarsal Stress Fracture

The second and third metatarsals are the most frequently injured.[559] A number of studies have found stress fractures to be more common in women, older individuals, and Caucasians.[560,561] Amenorrhea is present in up to 20% of robustly exercising women and may be as high as 50% in elite runners and dancers.[562] Patients with amenorrhea for more than 6 months experience the same bone loss as postmenopausal women, predisposing them to stress

fracture.[563] Muscular fatigue of the foot may also play a role in the etiology.[564]

Although numerous studies have attempted to correlate foot shape, footwear, and orthotics to the incidence of stress fractures, none have conclusively shown a direct relationship,[272,565–567] although one study showed a decrease in the incidence of metatarsal fractures in low-arched feet by using a semirigid orthotic.[86]

The typical clinical findings with this type of fracture include reports of mild forefoot discomfort, which may initially be relieved by rest, but which occurs while walking and even at rest as the fracture worsens.[50] Occasionally, there is point tenderness over the involved metatarsal, swelling, and a palpable mass.[559,568]

Anteroposterior, lateral, and oblique radiographs of the foot may not show a fracture for 3–6 weeks, although a technetium bone scan is positive as early as 48–72 hours after onset of symptoms.[50]

The intervention for metatarsal stress fractures includes rest from the offending activity and cross-training in a low-impact sport.[50] Weight-bearing to tolerance may be allowed in comfortable shoes of choice or a wooden shoe. If weight-bearing is painful, or the fracture is diagnosed late, a short leg cast or hard-soled shoe is worn for 4–6 weeks until healing callus is seen radiographically.[559,568]

Proximal Second Metatarsal

This type of metatarsal stress fracture differs from other metatarsal stress fractures since it can be difficult to heal and may result in chronic nonunion. The anatomy in this area tends to encourage an abnormal amount of stress, particularly in young ballet dancers.[569–572]

Other predisposing factors can include amenorrhea, anorexia nervosa, cavus foot, and anterior ankle impingement with resulting hyperpronation.[569]

On physical examination, there will be pain in the first web space, usually accompanied by proximal second metatarsal pain.[573]

Initial foot radiographs will most often be negative; hence, a bone scan is usually necessary. The bone scan may be nonspecific, with synovitis, stress reaction, and stress fracture as differential.[573]

The intervention for second metatarsal stress fracture usually consists of 6–8 weeks of rest in a hard shoe or cast,[569,573] with gradual return to activities when the tenderness resolves.

Navicular Stress Fracture

Although navicular stress fractures occur infrequently, they are the most common midfoot fracture. A navicular fracture typically presents with an insidious onset or with a history of acute flexion and inversion.[7] The patient complains of chronic pain that is vague in nature but tender to palpation on the posterior aspect of the foot and/or medial aspect of the midfoot.[559]

This condition is most commonly seen in basketball players, hurdlers, and runners, in whom repeated cyclic loading results in fatigue failure through the relatively avascular central portion of the tarsal navicular.[57,308,574] The cyclic loading across the navicular may be exacerbated due to a short first metatarsal, metatarsus adductus, or limited dorsiflexion or subtalar motion.[57]

To confirm the diagnosis, bone scan or CT scan may be necessary, as plain films are rarely diagnostic.[574]

The intervention varies according to the type of fracture. Nondisplaced fractures are treated with a short-leg non–weight-bearing cast for 6–8 weeks.[342,574]

If the fracture fails to heal or is displaced, operative intervention of fixation with compression screw, and additional bone grafting where necessary, is used.[342,574]

Return to sport may take as long as 16–20 weeks.[559]

Sesamoid Stress Fracture

The young patient with a sesamoid stress fracture will present with the insidious onset of pain and swelling over the plantar aspect of the first MTP joint.[308,575] Pain is usually aggravated by activity and relieved with rest. Differential diagnosis includes metatarsalgia, bursitis, sesamoiditis, and bipartite sesamoid.[575]

The intervention for a sesamoid fracture is initially rest from the offending high-impact activity and a wooden-soled shoe or a short-leg cast for 6–8 weeks. If cast, a CT scan is performed at 8 weeks to detect signs of avascular necrosis. If avascular necrosis is present and the young patient has persistent symptoms, re-section may be necessary.[52] Surgical choices include excision of the involved sesamoid or bone grafting, in an attempt to achieve union and preserve the sesamoid.

An alternative treatment is the use of a "C" or "J" pad, which unloads the injured sesamoid. Pads with adhesive backing may be fixed to the insole of the shoe or may be incorporated into a custom-molded orthotic to unload the sesamoid.

Fractures

Pilon Fractures

These fractures result from an axial compression force, where the tibia is driven inferiorly into the talus, splitting and shattering the distal end of the tibia and completely disrupting the ankle joint, resulting in long-term morbidity in the majority of cases.[576]

Talar Dome Fractures

These are the most common chondral fractures and are also known as osteochondritis dissecans, transchondral fractures, or flake fractures.[7]

These injuries, which present with persistent swelling, pain with walking, locking of the ankle, and crepitus, tend to present as a "sprained ankle that did not heal."[7]

Intervention varies from none, to casting, to arthroscopy for larger fragments.[7]

Talar Fractures

Major fractures of the talar head, neck, and body are associated with high-energy mechanisms, with one-half of major talar injuries involving fractures of the talar neck, 15–20% involving talar body fractures, and the remainder involving talar head fractures.[7] The mechanism of injury usually involves an axial load with the foot positioned in plantar flexion or excessive

dorsiflexion, resulting in compression of the talar head against the anterior aspect of the tibia.[577]

The intervention varies according to location and severity, with nondisplaced fractures treated with a short-leg non–weight-bearing cast for 6–8 weeks and displaced fractures involving immediate reduction.[7]

Unimalleolar Fractures

Unimalleolar fractures are the most common fractures of the ankle.[7] The degree of stability of these fractures is dependent on their location, with those located below the tibiotalar joint tending to be stable.[7] Approximately 85% of lateral malleolar fractures occur without damage to the medial aspect of the ankle joint and do not cause abnormal displacement of the talus.[578,579]

Medial malleolar fractures are often seen in conjunction with other fractures.

Bimalleollar and Trimalleolar Fractures

These fractures, as their name implies, involve two or three malleoli. The bimalleolar fracture usually results from a severe pronation/abduction/external rotation force, which shears the lateral malleoli and avulses the medial malleolus. The trimalleolar fracture involves a fracture of the medial, lateral, and "posterior" malleolus, which typically results from an abduction and severe external rotation force so strong that the talus moves sufficiently posteriorly to shear off the posterior margin of the tibia.

The intervention for bimalleolar fractures remains controversial, whereas it is generally agreed that trimalleolar fractures require open reduction and internal fixation.[580]

Calcaneus

The calcaneus is the most frequently fractured tarsal, accounting for over 60% of foot fractures,[581] and one that can be a frequent and often misdiagnosed cause of heel pain.[582] With the increasing number of middle-aged and elderly people involved in active recreational pursuits, sports medicine has had to incorporate the way these conditions are related to these different age groups.[57] Jumping activities or unaccustomed activities may precipitate crushing of the fragile architecture of an osteoporotic calcaneus, leading to fractures.[57]

Tenderness on M-P compression of the heel (squeeze test) should lead to a suspicion of a stress fracture of the calcaneus.[38]

Conservative intervention of calcaneal fractures has shown poor long-term clinical results with significant loss of ankle function.[583,584]

Fifth Metatarsal Fractures

All fractures of the proximal fifth metatarsal have been arbitrarily labeled a "Jones fracture." The most common fifth metatarsal base fracture is an avulsion fracture of the tuberosity caused by traction of the fibularis (peroneus) brevis and lateral band of the plantar fascia during hindfoot inversion.[585]

The proximal fifth metatarsal has a poor blood supply and is at significant risk for delayed union or nonunion. These fractures should be treated with non–weight-bearing short-leg cast immobilization for 6–8 weeks or until healing is seen radiographically. If an established nonunion develops, screw fixation and/or bone grafting may be required.[586]

THERAPEUTIC TECHNIQUES

Techniques to Increase Joint Mobility

Joint Mobilizations

With some slight variations, the same techniques that are used to examine the joint glides described in the test and measures section can be used to mobilize the joints, with the clinician varying the intensity of the mobilizations based on the intent of the technique, the patient's response, and the stage of tissue healing. The purposes for the various mobilizations include the following:

- Posterior glide of the talocrural joint can be used to increase ankle joint dorsiflexion, whereas an anterior glide of the talocrural joint can be used to increase ankle joint plantar flexion.
- Medial gapping of the subtalar joint can be used for increasing ROM into subtalar joint eversion, whereas lateral gapping of the subtalar joint can be used for increasing ROM into subtalar joint inversion.
- A posterior glide of the intermetatarsal joints can be used to assist flattening of the transverse arch of the foot, whereas an anterior glide can be used to help increase the transverse arch of the foot.
- A posterior glide of the MTP joint can be used to increase ROM into MTP joint extension, whereas an anterior glide of the MTP joint can be used to increase ROM into MTP joint flexion.
- A posterior glide of the interphalangeal joint can be used to increase ROM into interphalangeal joint extension, whereas an anterior glide of the interphalangeal joint can be used to increase ROM into interphalangeal joint flexion.

Intervention following successful manual treatment should consist of strengthening of the plantar flexors, particularly the fibularis (peroneal) muscles. If the patient has a history of recurrent ankle sprains, then appropriate proprioceptive retraining should be instituted. Pain relief and improved function should be immediate and long lasting; however, if the condition reoccurs, follow-up care could include foot taping (for example using the Low-dye technique), use of arch supports or foot orthoses (over the counter or custom made), stretching and/or soft tissue mobilization of the fibularis (peroneus) muscles, and adjustment to any asymmetrical training or daily habitual usage patterns.

CASE STUDY

BILATERAL HEEL PAIN

HISTORY

History of Current Condition

A 54-year-old female presents with insidious onset of a constant dull ache in both heels, which is worse in the morning, especially when first putting her feet on the ground and at the end of the day. The patient denies numbness or tingling in either foot or ankle area or any history of trauma. Pain has increased this past week, prompting her to see an MD who prescribed physical therapy and an anti-inflammatory medication.

Past History of Current Condition

Bilateral heel pain of approximately 2 months duration a few years ago, which resolved spontaneously.

Past Medical/Surgical History

Unremarkable.

Medications

NSAIDs are prescribed for pain relief and decreasing the inflammation.[470]

Other Tests and Measures

Radiographs showed the presence of a heel spur in both heels.

Social Habits (Past and Present)

Sedentary lifestyle.

Growth and Development

Overweight as a child.

Living Environment

Lives in a ranch-type home with carpeting throughout, except for a tiled bathroom.

Occupational/Employment/School

Works in a warehouse stacking boxes of tissues and has been working there for 6 years.

Functional Status/Activity Level

Soreness occurs first hour in morning, especially when she initially bears weight, and again at the end of the day after working. Walking on the concrete floor at work is reported to aggravate the condition.

Health Status

General good health, but feels her pain interferes with tasks at home and at work.

Questions

1. List all of the structures that could be at fault with complaints of bilateral heel pain of an insidious onset.
2. Does the history of heel pain with initial weight-bearing in the morning give the clinician any clues as to the diagnosis?
3. Why do you think the patient's symptoms are worsened with weight-bearing?
4. What additional questions would you ask to help rule out referral from the hip, knee, or lumbar spine?
5. Do you have a working hypothesis at this stage? List the various tests you would use to rule out each of the possible causes.
6. Does this presentation/history warrant a scan? Why or why not?

CASE STUDY

HEEL PAIN

HISTORY

History of Current Condition

A 34-year-old female complains of insidious onset of pain in the posterior aspect of the right ankle, which began approximately 3 months ago when she began a jogging program but which had not worsened significantly until last week. The pain is worse in the morning and after prolonged positions. The patient denies numbness or tingling in the foot or ankle area. The increase in pain this past week had prompted the patient to visit her MD, who prescribed physical therapy and gave her a heel lift to wear in each of her shoes.

Past History of Current Condition

Similar right posterior heel pain of approximately 1-month duration a few years ago, which resolved spontaneously.

Past Medical/Surgical History

Unremarkable.

Medications

Naproxen (daily).

Functional Status/Activity Level

Soreness occurs first hour in the morning.

Health Status

In good health but feels the pain interferes with tasks at home and at work.

Questions

1. List the structure(s) and differential diagnoses that may be involved with complaints of unilateral heel pain related to running.
2. What does the history of no significant worsening of the pain tell the clinician?
3. Why do you think the patient's symptoms are worse after rest?
4. What additional questions would you ask?
5. What is your working hypothesis at this stage? If you have a number of hypotheses, which tests would you use to rule out each one?
6. Does this presentation/history warrant a lower quarter scanning examination? Why or why not?

REVIEW QUESTIONS*

1. Name the three ligaments associated with the distal tibiofibular joint.
2. Which nerve is involved with TTS?
3. What structures maintain the longitudinal arch?
4. Supination of the foot in weight-bearing is a combination of which movements of the calcaneus and talus?
5. Morton's neuroma most commonly involves which nerve?

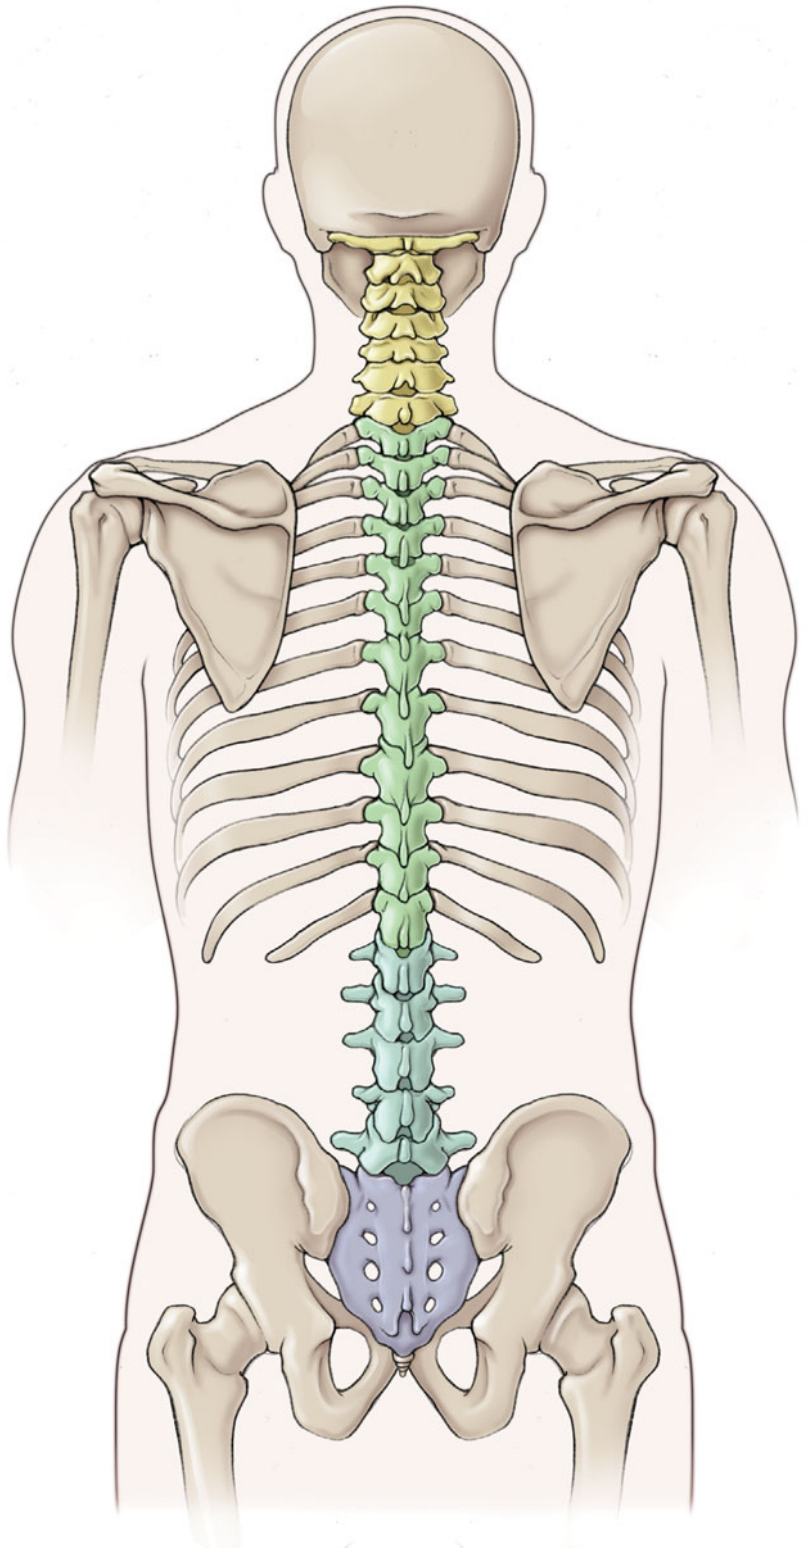
SECTION V

THE SPINE AND TMJ



This page intentionally left blank

CHAPTER 22 Vertebral Column

STRUCTURE

The design specification for the human vertebral column is the provision of structural stability affording full mobility as well as protection of the spinal cord and axial neural tissues.[1] While achieving these seemingly disparate objectives, the spine also contributes to the functional requirements of gait and to the maintenance of static weight-bearing postures (see Chap. 6).[1]

At the component level, the basic building block of the spine is the vertebra. The vertebra serves as the weight-bearing unit of the vertebral column, and it is well designed for this purpose. Although a solid structure would provide the vertebral body with sufficient strength, especially for static loads, it would prove too heavy and would not have the necessary flexibility for dynamic load bearing.[2] Instead, the vertebral body is constructed with a strong outer layer of cortical bone and a hollow cavity, the latter of which is reinforced by vertical and horizontal struts called *trabeculae*.

The term *vertebral column* describes the entire set of vertebrae excluding the ribs, sternum, and pelvis (Fig. 22-1). The normal vertebral column is made up of 29 vertebrae (7 cervical, 12 thoracic, 5 lumbar, and 5 sacral) and four coccygeal segments. The adage that "function follows form" is very much applicable when studying the vertebral column. Although all vertebrae have similar characteristics, each has specific details that reflect its unique function (Table 22-1). The overall contour of the normal vertebral column in the coronal plane is straight. In contrast, the contour of the sagittal plane changes with development. At birth, a series of primary curves give a kyphotic posture to the whole spine. With development of the erect posture, secondary curves develop in the cervical and lumbar spines, producing a lordosis in these regions. The curves in the spinal column provide it with increased flexibility and shock-absorbing capabilities.[2]

A motion segment in the vertebral column is defined as two adjacent vertebrae and consists of three joints. One joint is formed between the two vertebral bodies and the intervertebral disk (IVD). The other two joints are formed by the articulation of the superior articular processes of the inferior vertebra and the inferior articular processes of the superior vertebra(Fig. 22-2). These latter joints are known as the facets or zygapophyseal joints.

The vertebral column contains 24 pairs of zygapophyseal joints, which are located posteriorly, and project from the neural arch of the vertebrae. The regional characteristics of the zygapophyseal joints are described in the relevant chapters. Mechanically, zygapophyseal joints are classified as plane joints as the articular surfaces are essentially flat.[3] The articular surfaces are covered in hyaline cartilage and like most synovial joints, have small fatty or fibrous synovial meniscoid-like fringes that project between the joint surfaces from the margins.[4] These intra-articular synovial folds act as space fillers during joint displacement and actively assist in the dispersal of synovial fluid within the joint cavity.[1] The articular processes act as a mechanical barricade, particularly against excessive torsion and shear, permitting certain movements while blocking others[3]:

- Horizontal articular surfaces favor axial rotation.
- Vertical articular surfaces (in either sagittal or frontal planes) act to block axial rotation.

Most zygapophyseal joint surfaces are oriented somewhere between the horizontal and vertical planes. In the cervical spine, the zygapophyseal joints are relatively horizontal while progressively increasing toward 45 degrees to the horizontal from the upper to the lower segments.[5–8] In the thoracic region, the joints assume an almost vertical direction while remaining essentially in a coronal orientation, which facilitates axial rotation and resists anterior displacement.[9] In the lumbar spine, the zygapophyseal joints are vertical with a curved, J-shaped surface predominantly in the sagittal plane, which restricts rotation and also resists anterior shear.[1] Understanding the variable structure and function of the human zygapophyseal joints and their relationship with the other components of the vertebral column is an important requirement in the examination and intervention of individuals with mechanical spinal pain disorders.[1]

The IVDs of the vertebral column lie between the adjacent superior and inferior surfaces of the vertebral bodies from C2 to S1 and are similar in shape to the bodies (Fig. 22-3). The IVD forms a symphysis or amphiarthrosis between two adjacent vertebrae and represents the largest avascular structure in the body.[10] Each disk is composed of an inner *nucleus pulposus* (NP), an outer *annulus fibrosus* (AF), and limiting cartilage end plates. The annulus and end plates anchor the IVD to the vertebral body. The IVDs contribute 20–25% of

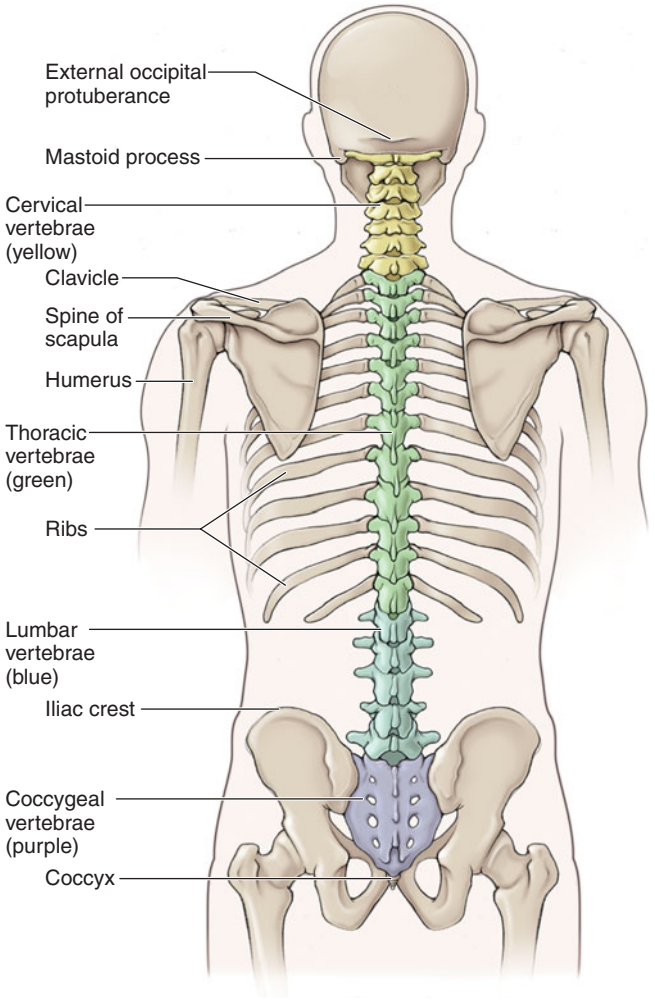


FIGURE 22-1 The vertebral column. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

the length of the vertebral column. In cervical and lumbar regions, the IVDs are thicker anteriorly and this contributes to the normal lordosis. In the thoracic region, each of the IVDs is of uniform thickness. Phylogenically, the IVD is a relatively new structure. In the human spinal column, the combined

heights of the IVDs account for approximately 20–33% of the total length of the spinal column.[11] The presence of an IVD not only permits motion of the segment in any direction up to the point that the disk itself is stretched, but also allows for a significant increase in the weight-bearing capabilities of the spine.[12] A normally functioning disk is extremely important to permit the normal biomechanics of the spine to occur and to reduce the possibility of mechanical interference among any of the neural structures. Although the disk is incapable of independent motion, movement of the disk does occur during the clinically defined motions of flexion–extension, side bending, and axial rotation.[13] The major stresses that must be withstood

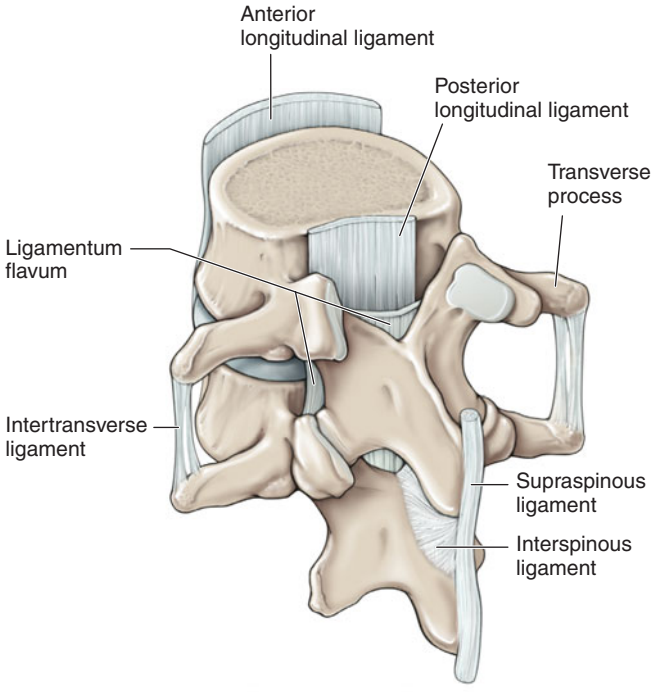

FIGURE 22-3 The intervertebral disk and intervertebral motion. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

by the IVD are axial compression, shearing, bending, and twisting, either singly or in combination with each other.

The role of the IVD is unique because it operates as an osmotic system, holding neighboring vertebral bodies together, while simultaneously pushing them apart. As such, the IVD is a dynamic structure that responds to stresses applied from vertebral movement or from static loading.

There are regional differences within the spine, each with its own specific demands and function. As discussed, all vertebral disks have traditionally been described as being composed of three parts: the AF, the vertebral end plate, and a central gelatinous mass, called the NP (Fig. 22-1). However, this description is based on the anatomy of a lumbar disk, the region where most research has occurred and for which many authors have extrapolated the anatomy to all IVDs.[14] An appreciation of the differing anatomy of the IVDs throughout the spine is important when developing clinical examination and intervention models.[14]

SPINAL JUNCTIONS

The spine contains four junctions, each of which is different in posterior element orientation and spinal curvature. Transitional vertebrae can occur at any of the junctions. The transition can be "complete" but is more commonly partial. These junctions, described by Schmorl and Junghanns[15] as *ontogenically restless,* are often rich in anomalies[16]:

- The craniovertebral junction is located between the cervical spine and the atlas, axis, and head. This region is covered in Chapter 23.
- The cervicothoracic junction represents the region where the mobile cervical spine and the relatively stiffer superior segments of thoracic spine meet, and where the powerful muscles of the upper extremities and shoulder girdle insert. The cervicothoracic junction is described in Chapters 25 and 27.
- The thoracolumbar junction is located between the thoracic spine, with its large capacity for rotation, and the lumbar spine, with its limited rotation. This region is described in Chapter 27.
- The lumbosacral junction is located between the lumbar spine, with its ability to flex and extend, and the relative stiffness of the sacroiliac joints. This region is described in Chapters 28 and 29.

Although highly variable, the line of gravity acting on a standing person with ideal posture passes through the mastoid process of the temporal bone anterior to the second sacral vertebra, posterior to the hip, and anterior to the knee and ankle (see Chap. 6).[3] In the vertebral column, the line of gravity is on the concave side of the apex of each region's curvature. As a consequence, ideal posture allows gravity to produce a torque that helps maintain the optimal shape of each spinal curvature.[3]

SPINAL STABILITY

Spinal stability is characterized by the behavior of the spinal column and the coordination of muscles that surround the spine. There are two types of stability:

- Static. This type of stability refers to a state of equilibrium where the velocity of the object or body is zero. When a person is standing perfectly still with no swing back and forth, the person said to be in static equilibrium.
- Dynamic. This type of stability implies a change over time but the velocity is constant. Theoretically, if a perturbation is applied to the spine and the spine behaves as it did in its undisturbed state, it is said to be stable, whereas if the spine's kinematic behavior changes as a result of the disturbance, it is unstable.[17] States requiring dynamic stability are far more common than those requiring static stability.

From the mechanical point of view, the spinal system is inherently unstable. Panjabi[18,19] indicates that there are three subsystems that contribute to spinal stability:

- Passive system. The spinal column, which includes the vertebrae, IVDs, zygapophyseal joints, joint capsules, and ligaments (Fig. 22-4) are the load-bearing units and the source of passive stiffness for stabilizing the spine. Passive stiffness of the ligaments and joint capsules is mainly a factor at the extremes of range of motion (ROM). The effectiveness

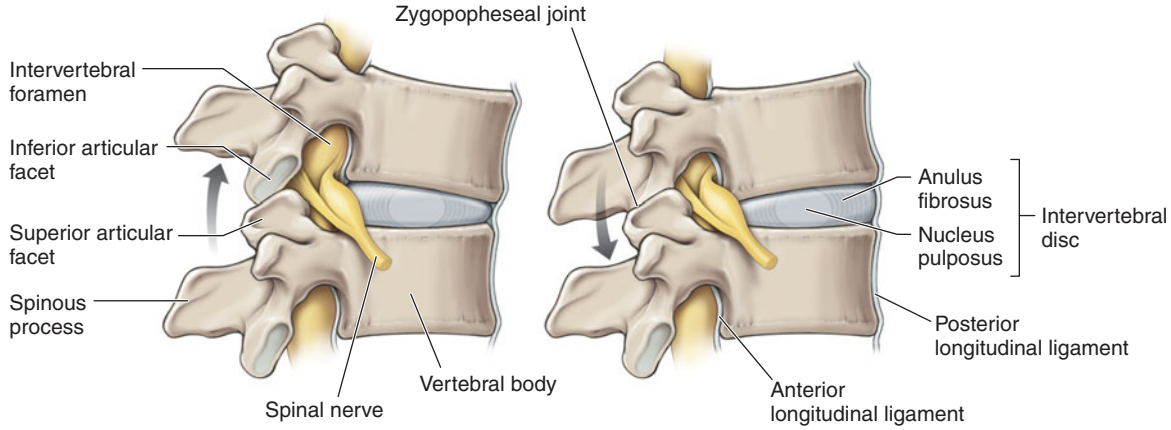

FIGURE 22-4 Ligaments of the spine. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

of the passive support system is a factor of the ability of its structures to resist the forces of translation, compression, and torsion.

- Active system. Muscles, which serve to reduce or prevent movement and are the source of active stiffness (i.e., muscles act like stiff springs) by using stored elastic energy and the level of activation or force.[18,20] Because the passive stiffness is mainly engaged at the extremes of range, the primary source of stiffness for stability during movements in healthy individuals is from the active stiffness of the trunk muscles and not the passive stiffness from ligaments. A large number of muscles have a mechanical effect on the spine and pelvis and all muscles are required to maintain optimal control.[20] Muscle activity must be coordinated to maintain control of the spine within a hierarchy of interdependent levels: control of intervertebral translation and rotation, control of spinal posture/orientation, and control of body with respect to the environment, in addition to maintaining a number of homeostatic functions such as respiration and continence.[20–22] The concept of different trunk muscles playing differing roles in the provision of dynamic stability to the spine was proposed by Bergmark[23] and later refined by others.[24–29] The specific muscles that provide stability and their interactions are described in the relevant chapters.
- Central nervous system (CNS), which utilizes feedforward (anticipatory) control to generate active muscle stiffness and uses feedback (reflex) control to augment the stiffness.[30] The CNS must continually interpret the status of stability, plan mechanisms to overcome predictable challenges, and rapidly initiate activity in response to unexpected challenges.[20]

CLINICAL PEARL

Although trunk muscles must have sufficient strength and endurance to satisfy the demands of spinal control, the efficacy of the muscle system is dependent on its controller, the CNS.[18,20]

The *neutral zone* is a term used by Panjabi[18] to define a region of laxity around the neutral resting position of a spinal segment. The neutral zone is the position of the segment in which minimal loading is occurring in the passive structures (IVD, zygapophyseal joints, and ligaments) and the active structures (the muscles and tendons that control spinal motion), and within which spinal motion is produced with minimal internal resistance.[2] Panjabi and colleagues[31] have studied the effect of intersegmental muscle forces on the neutral zone and ROM of a lumbar functional spinal unit subjected to pure moments in flexion–extension, side bending, and rotation. Simulated muscle forces were applied to the spinous process of the mobile vertebra of a single motion segment using two equal and symmetric force vectors directed laterally, anteriorly, and inferiorly. The simulated muscle force maintained or decreased the motions of the lumbar segment for intact and injured specimens with the exception of the flexion ROM which increased.[31]

CLINICAL PEARL

Mechanoreceptors throughout the spine play an important role in spinal stability and provide excitatory or positive feedback control during rapid elongation of the ligaments.[32] For example, when large unexpected perturbations cause the spine to rapidly flex, the subsequent quick stretch to the posterior ligaments of the spine leads to a rapid activation of the trunk extensor muscles.[33] In addition, the mechanoreceptors can become desensitized when exposed to tissue creep, leading to impaired muscle responses.[34]

The interaction between the passive and active systems of the spine changes when there has been prolonged tension or cyclic loading of the passive system resulting in a change to the muscle responses in the form of a delayed response. Furthermore, it is hypothesized that these changes in muscle activation may lead to increased spinal compression forces, which have been recognized as a risk factor for vertebral end-plate fracture, especially if applied repetitively.[35,36] An alternate consequence is that muscle insufficiency resulting from fatigue may shift the loading to the passive tissues,[37,38] which may put the spine at increased risk of injury.

CLINICAL PEARL

Activities such as acute repetitive loading have been shown to have a significant effect on reducing the stiffness of the passive tissues of the spine, because of the viscoelastic nature of the muscles, tendons, ligaments, and IVDs.[39,40]

Under normal circumstances, when large perturbations are expected, preparatory coactivation of the spinal muscles enhances active stiffness, and reflexes augment the stiffness at the appropriate time.[41] These anticipatory postural adjustments and corrective responses are part of a motor control strategy executed by the CNS that was learned from previous experience when performing similar movements or activities.[42–45]

The emphasis on spinal stability exercises should be to:

- Strengthen the trunk muscles so that they are able to produce sufficiently large forces and active stiffness. The timing and sequencing of muscle activity, coupled with the appropriate magnitude of muscle activation, produces smooth, accurate, and efficient movement behavior that is adjusted to the immediate demands and consequences within the environment.[30]
- Increase the endurance of the trunk muscles so that the force output of the muscles does not deteriorate.
- Incorporate sound motor learning principles to address impaired motor control strategies.

The various strategies to incorporate with the intervention for spinal instability are addressed in the appropriate chapters.

SPINAL MOTION

The movements of the vertebral column occur in diagonal patterns as a combination of flexion or extension with a coupled motion of side bending and rotation. Movements of the spine, like those elsewhere, are produced by the coordinated action of nerves and muscles. Agonistic and synergistic muscles initiate and perform the movements, whereas the antagonistic muscles control and modify the movements. The amount of motion available at each region of the spine is a factor of a number of variables. These include

- disk-vertebral height ratio
- compliance of the fibrocartilage
- dimensions and shape of the adjacent vertebral end plates
- age
- disease
- gender

The type of motion available is governed by

- the shape and orientation of the articulations
- the ligaments and muscles of the segment, and the size and location of its articulating processes

Including translations and rotations around three different axes, the spine is considered to possess 6 degrees of freedom.[46] Although the ROM at each vertebral segment varies, the relative amounts of motion that occur at each region is well documented[11,47]:

- In the upper craniovertebral region (occiput to C2), there is comparatively little flexion–extension, whereas the mid to lower cervical spine permits increasing flexion–extension movements from approximately 10 degrees at the C2–3 level to about 20 degrees at C5–6 and C6–7. Axial rotation in the upper cervical spine is 30–40 degrees in each direction, whereas it is 5–6 degrees in the lower cervical spine.
- Flexion–extension movements (see Fig. 22-3) are about 4 degrees in the upper thoracic spine, 6 degrees in the midthoracic spine, and 12 degrees in the lower thoracic spine. Side bending in the upper thoracic spine is approximately 6 degrees. Axial rotation in the upper thoracic spine is 5–6 degrees.
- In the lumbar spine, there is a gradual increase of flexion–extension movements from about 12 degrees at L1–L2 to 20 degrees at the L5–S1 level. Side bending in the lumbar spine is greatest at L3–L4 where it is approximately 8–9 degrees. Axial rotation in the lumbar spine is minimal.
- Although various motion patterns have been proposed for the sacroiliac joint,[48–51] the precise model for sacroiliac motion has remained fairly elusive (see Chap. 29).[52–54] Postmortem analysis has shown that until an advanced age, small movements are measurable under different load conditions.[55,56]

In general, the human zygapophyseal joints of the spine are capable of only two major motions: gliding upward and gliding downward. If these movements occur in the same direction, flexion or extension occurs. If the movements occur in opposite directions, side bending occurs. Although rotation does occur as a motion component within intervertebral segments, it is always coupled and never an isolated motion.[57] Indeed during functional rotation of the spine, the actual motion occurring at any given zygapophyseal joint is a linear glide. Because the orientation of the articular facets of the zygapophyseal joints do not correspond exactly to pure planes of motion, pure motions of the spine occur very infrequently.[46] In fact, most motions of the spine occur three-dimensionally because of the phenomenon of coupling. Coupling involves two or more individual motions occurring simultaneously at the segment and has been found to occur throughout the lumbar,[58] thoracic,[59] and cervical regions.[60] Descriptions about the types of coupling that occurs in these regions are provided in the respective chapters. All normal motion in the cervical, thoracic, and lumbar regions involves both sides of the segment moving simultaneously around the same axis. That is to say, a motion of the right side of a segment produces an equal motion on the left side of that same segment. If both sides of a vertebral segment are equally impaired (equally hypomobile or hypermobile), there is no change in the axis of motion except in the case where it ceases to exist, as in a bony ankylosis. Where a symmetric motion impairment exists, there is no noticeable deviation from the path of flexion or extension (impaired side bending and rotation), but rather, the path is shortened with a hypomobility (producing decreased motion) or lengthened with a hypermobility (producing increased motion).

An alteration to the structures of the motion segment can result in a loss of motion, a loss of segment integrity (instability), or a loss of function. These changes result mainly from injury, developmental changes, fusion, fracture healing, healed infection, or surgical arthrodesis.[47] The loss of motion segment integrity, which can be measured with flexion–extension roentgenograms, is defined as an anteroposterior motion of one vertebra over another that is greater than 3.5 mm in the cervical spine, greater than 2.5 mm in the thoracic spine, and greater than 4.5 mm in the lumbar spine.[61] Loss of motion segment integrity also may be defined as a difference in the angular motion of two adjacent motion segments greater than

- 11 degrees in the cervical spine
- 15 degrees at L1–L2, L2–L3, and L3–L4
- 20 degrees at L4–L5
- 25 degrees between L5 and S1

Fryette's Laws of Physiologic Spinal Motion[62]

Although listed as laws, Fryette's descriptions of spinal motion are better viewed as concepts because they have undergone review and modifications over time. These concepts serve as useful guidelines in the evaluation and intervention of spinal dysfunction and are cited throughout many texts describing spinal biomechanics.

Fryette's First Law

"When any part of the lumbar or thoracic spine is in neutral position, side bending of a vertebra will be opposite to the side of the rotation of that vertebra."

The term *neutral*, according to Fryette, is interpreted as any position in which the zygapophyseal joints are not engaged in any surface contact, and the position where the ligaments and capsules of the segment are not under tension. This law describes the coupling for the thoracic and lumbar spines. The cervical spine is not included in this law because the zygapophyseal joints of this region are always engaged. When a lumbar or thoracic vertebra is side bent from its neutral position, the vertebral body will turn toward the convexity that is being formed, with the maximum rotation occurring near the apex of the curve formed.

Dysfunctions that occur in the neutral range are termed by osteopaths as *type I dysfunctions*.

Fryette's Second Law

"When any part of the spine is in a position of hyperextension or hyperflexion, the side bending of the vertebra will be to the same side as the rotation of that vertebra."

Put simply, when the segment is under load, the coupling of side bending and rotation occurs to the same side. The term *non-neutral*, according to Fryette, is interpreted as any position in which the zygapophyseal joints are engaged in surface contact, the position where the ligaments and capsules of the segment are under tension, or in positions of flexion or extension. This law describes the coupling that occurs in the C2–T3 areas of the spine.

Dysfunctions occurring in the flexion or extension ranges are termed by osteopaths as *type II dysfunctions*.

Fryette's Third Law

Fryette's third law tells us that if motion in one plane is introduced to the spine, any motion occurring in another direction is thereby restricted.

CLINICAL PEARL

Whereas it is commonly believed that coupled motions in the lower cervical spine occur toward the same side (a side bend to the right is accompanied with rotation to the right), it is important to remember that results from numerous studies are inconsistent regarding the specific spinal motions that are coupled with one another in the upper cervical, lumbar, and thoracic spines.[63]

Combined Motions

It would appear that, irrespective of the coupling that occurs, there is a great deal of similarity between a motion involving flexion followed by left side bending, and a motion involving left side bending followed by flexion. However, although both motions have the same end result, they use different methods to arrive there. The same could be said of the following combined motions:

- Flexion and right side bending followed by right side bending and flexion.
- Extension and right side bending followed by right side bending and extension.
- Extension and left side bending followed by left side bending and extension.

By using combined motions, the clinician can often reproduce a patient's symptom that was not reproduced using the planar motions of flexion, extension, side bending, and rotation.[64–66] However, care should be taken when utilizing combined motions, especially with the acute and subacute patient, when a reduction of symptoms through modalities and gentle exercise might be preferable to exacerbating the patient's condition through a comprehensive movement examination.

Using a biomechanical model, a restriction of extension, side bending, and rotation to the same side of the pain is termed a *closing* restriction, whereas a restriction of the opposite motions (flexion, side bending, and rotation to the opposite side of the pain) is termed an *opening* restriction. Motions that involve flexion and side bending away from the symptoms tend to invoke a stretch to the structures on the side of the symptoms, whereas motions that involve extension and side bending toward the side of the symptoms produce a compression of the structures on the side of the symptoms.[64–66] An example of a stretching pattern would be pain on the right side of the spine that is increased with either flexion followed by a left side-bending movement or a left side-bending motion followed by a flexion movement. A compression pattern would involve pain on the right side of the spine that is increased with a movement involving either extension followed by right side bending or right side bending followed by extension.

The symptom reproduction that occurs with combined motions usually follows a logical and predictable pattern. However, there are situations in which illogical patterns are found. Because the vertebral column consists of many articulating segments, movements are complex and usually involve several segments resulting in restrictions that may be complex and apparently illogical. An example of such a pattern would be pain on the right side of the spine that is increased with a flexion and right side bending combination but decreased with an extension and right side bending combination. The movements just described involve a combination of stretching and compression movements. These illogical patterns typically indicate that more than one structure is involved.[64–66] Of course, they could also indicate to the clinician that the patient does not have a musculoskeletal impairment.

EXAMINATION OF THE VERTEBRAL COLUMN AND PELVIS

The examination of the spine is complicated by the number of conditions that can cause pain in this region of the body. In addition, there is little scientific evidence for the establishment of many of the diagnostic labels attributed to spinal pain, such as instability, degenerative disc disease, and subluxation.[67]

The purpose of the examination is to correctly identify those patients who will benefit from a physical therapy intervention. The correct identification of a diagnosis requires the use of evidence-based measuring tools that are valid, specific, and sensitive. There are numerous methods for examining and evaluating the spine, and each results in a conclusion that

determines the course of the intervention.[68,69] Unfortunately, many of the procedures that are used today to examine the spine demonstrate methodologic shortcomings.[67–69] The interventions for spinal conditions fair no better. Despite the ever-increasing numbers of randomized controlled trials evaluating interventions for low back pain (LBP),[70] treatment outcomes remain less than optimal.[71] One reason for this may be the fact that many trials test interventions in a heterogeneous population of patients with LBP and such a diverse group of patients may not correspond to the one treatment approach.[72] This hypothesis has led to the design of classification systems to identify subgroups of patients who may respond preferentially to certain treatments.[73]

Use of Traditional Classification Systems

In recent years, attempts have been made to use a variety of methods to classify spinal pain, particularly LBP, into syndromes. The term *syndrome* implies that the specific diagnosis is unknown. A syndrome is a collection of signs and symptoms that, collectively, characterizes a particular condition. In the spine, where determining a specific diagnosis has historically been proven to be extremely difficult, syndromes have become popular By classifying syndromes, it is proposed that a patient is more likely to respond to a type of intervention unique to that syndrome. The criteria that have thus been used to categorize a syndrome include the following:

- Pathoanatomy.[74,75] This strategy involves using correlations to produce categories. The disadvantage of using pathoanatomy is the difficulty in identifying a relevant pathoanatomic cause for most patients.[76]
- Presence or absence of radiculopathy.[77,78]
- Location and type of pain.[79]
- Duration of the symptoms (acute, subacute, or chronic).[80]
- Activity and work status.[78,81]
- Impairments identified during the physical examination.
- Direction of motion that reproduces, peripheralizes, or centralizes the symptoms.[82,83]

The more common classifications are outlined next. The use of such classification systems may have some prognostic value and can direct clinicians to specific interventions.[84]

Osteopathic System

Osteopaths rely on the results from the active motion tests and position tests to determine their intervention approach. *Note:* Osteopaths use the term side flexion instead of side bending.

Position Testing

Position testing involves palpation of the soft tissues over paired transverse processes of the spine, to detect palpable positional irregularity and altered tissue tension at a segmental level when the spine is positioned in flexion or extension compared with neutral. To locate the transverse process in the lumbar spine, the clinician first locates the spinous process to determine the level and then moves slightly laterally and superiorly by placing the thumbs on either side of the spinous process. Thus, the clinician must be very familiar with so-called *layer palpation* to be sure that the palpating fingers are monitoring the positions of the transverse processes at a particular segmental level. Vertebral dysfunctions occur as a combination of movements in the three planes. The key movement is rotation. Theoretically, the rotational dysfunction, which is a result of the altered axis of rotation produced by the stiffer of the two sides of the segment, will be palpated as a much firmer end-feel to the palpation on that side. The direction of the rotation is named after the more posterior of the two transverse processes, and the positional name is an osteokinematic one having no established relationship with any joint.

Position Testing in Extension. If a marked segmental rotation is evident at the limit of extension, this would indicate that one of the facets is unable to complete its inferior motion (i.e., it is being held in a relatively flexed or superior position). The direction of the resulting rotation (denoted in terms of the anterior part of the vertebral body) informs the clinician as to which of the facets is not moving. For example, if the segment is rotated to the *left* when palpated in extension, the *right* zygapophyseal joint is not moving normally. This impairment can be described in one of the three ways as follows:

1. The right zygapophyseal joint cannot extend or "close."
2. The right zygapophyseal joint is flexed (F), rotated (R), and side-flexed (S) left (L) around the axis of the right zygapophyseal joint.
3. The right zygapophyseal joint is unable to perform any motions that require an inferior glide, such as extension, right side bending, and right rotation.

FRS or extension impairments are more evident in the positional tests than ERS impairments (described next) because there is less overall motion available into extension.

Position Testing in Flexion. If a marked segmental rotation is evident in full flexion, this indicates that one of the facets cannot complete its superior motion. For example, if the segment is found to be left-rotated when palpated in flexion, the left zygapophyseal joint is not moving normally.

This impairment can be described in one of the three ways as follows:

1. The left zygapophyseal joint cannot flex or "open."
2. The left zygapophyseal joint is extended (E), rotated (R), and side-flexed (S) left (L).
3. The left zygapophyseal joint is unable to perform any motion that requires a superior glide such as flexion, right rotation, and right side bending.

Position Testing in Neutral. Positional testing is performed in the neutral spine position for three reasons as follows:

1. If a rotational impairment of a segment exists only in neutral and is not evident in either full flexion or full extension, the cause of the impairment is probably not mechanical in origin but rather neuromuscular. These neuromuscular impairments are usually found at the spinal junctions, particularly the thoracolumbar and cervicothoracic junctions.

2. If a marked rotation is evident at a segment and this rotation is consistent throughout flexion, extension, and neutral, then the cause is probably an anatomic anomaly (e.g., scoliosis) rather than an articular problem.
3. If the cause of the rotational impairment is articular (zygapophyseal joint), the positional testing in neutral gives the clinician an idea as to the starting position of the corrective technique.

The terminology used to describe the rotational disruption of the pure spinal motions (ERS or FRS) describes the positional and kinetic impairments only. It does not indicate what the pathology might be. Reasons for these impairments, other than movement dysfunctions, may include bony anomalies such as a deformed transverse process, compensatory adaptation, structural scoliosis, or a hemivertebra.

The analysis of the change in the rotational impairment between full flexion and full extension theoretically gives clues as to the pathology. Thus, in conjunction with other tests, such as active motion testing, this analysis can assist in ascertaining a biomechanical diagnosis.

Position testing has been found to be very reliable when used by experienced clinicians to identify segmental levels based on the relative position of spinous processes.[85] The results for inter-rater reliability have been mixed when clinicians are asked to determine lumbar segmental abnormality using position testing,[86,87] and poor when attempting to determine the segmental level of a marked spinous process.[88]

CLINICAL PEARL

The clinician should be aware that position testing is insensitive to symmetric impairments and thus can give false negatives.

McKenzie System[82,83]

The McKenzie mechanical diagnostic and classification approach is a noninvasive and an inexpensive method of assessing patients with cervical and LBP that uses physical signs, symptom behavior, and their relation to end range test movements to determine appropriate classification and intervention.

The McKenzie approach focuses on the following three components.

- Providing a mechanical diagnosis.
- Providing a mechanical treatment, based on the mechanical diagnosis.
- Prevention of recurrence which is achieved by
  - emphasizing the patient's responsibility for their own recovery
  - fully exploring the patient's self generated forces before progression to externally applied forces.

According to McKenzie, symptoms of lumbar and/or cervical pathology can demonstrate a phenomenon of centralization and peripheralization.[82,89,90]

- Centralization of symptoms is the immediate or eventual abolition of the most distal extent of referred or radicular pain toward the midline of the spine in response to therapeutic loading strategies. Centralization occurs more commonly with extension, especially with end range repeated movements. Although centralization of the symptoms can be associated with an increase in spinal pain, it normally indicates improvement in the patient's condition and provides the clinician with a directional preference.
- Peripheralization of symptoms indicates movement in the opposite direction and is usually associated with a poorer prognosis.

The history taking is an integral component of the McKenzie approach. The purpose of the history is to provide the clinician with information regarding

- an overall impression of the clinical presentation
- the site of pain
- the stage of the disorder
- the status of the presenting condition. The severity of problem is used to guide the vigor of the examination
- the identification of red flags
- the baseline of symptomatic/mechanical presentation against which improvements can be judged
- any aggravating/relieving factors (especially the role of posture). This helps the clinician to develop a hypothetical diagnosis by syndrome
- functional limits on the patient's quality of life

During the initial observation, the patient's sitting and standing postures are noted to reveal how the spine is habitually subjected to static loading by the patient. In addition, the patient is asked to perform a single movement of each movement plane direction (see below) while the clinician notes the quantity and quality of movement—the ability of the patient to achieve end range with spinal curve reversal and without deviating from the intended movement plane.[91] The accurate assessment of the effect of repeated movements/sustained positions on the patient's pain patterns is a key component of the McKenzie examination (Table 22-2). The movement plane directions evaluated for both the cervical and lumbar spines are those within which the clinically presenting antalgic postures occur.[91]

- ***Cervical spine.*** The movements observed include protrusion, flexion, retraction, extension, side bending right, side bending left, rotation right, and rotation left.
- ***Lumbar spine.*** The movements observed include flexion, extension, side gliding right, side gliding left.

After the quantity and quality of movement is assessed by the performance of single movements in each movement plane direction, dynamic and static tests are performed.[91] The effects of loading in a certain movement plane direction are highlighted best by repetition (dynamic) or sustained (static) loading. Static loading tests are generally used when dynamic tests do not provide a clear preferred loading strategy. With both the static and dynamic tests, loading in a sagittal movement plane direction is typically explored first, unless the patient has significant antalgia in a coronal movement plane direction, in which case, the coronal movement plane is

TABLE 22-2	Various Effects of Test Movements
Term	**Definition**
Produce	No symptoms at rest but are created with movement
Increased	Symptoms present are increased
Decreased	Symptoms present are decreased
Abolished	Movement eliminates those symptoms that occur with rest
Worse	Symptoms increase or remain worse
No worse	Symptoms increase with movement (don't remain worse)
No better	Symptoms reduced/abolished with movement (do not remain)
Better	Presenting symptoms decreased/abolished/ remain better
Pain during movements	Pain during movements
End range pain	Pain occurs at end ranges
No effect	Movement has no effect on symptoms

explored first.[91] Should loading in the coronal plane not provide satisfactory answers, the transverse movement plane is explored.

- ***Dynamic tests.*** These tests involve performing a single motion within the movement plane direction being studied, followed by repetitive motion in the same movement plane direction while the clinician closely monitors how mechanics and symptoms respond during motion, at end range, and after the dynamic loading. The testing progression applied includes the following[91]:
  - Cervical spine: flexion in sitting, retraction in sitting, retraction-then-extension in sitting, retraction in lying, and retraction extension in lying. If required, the following tests are also performed: protrusion in sitting, retracted side bending right in sitting, retracted side bending left in sitting, retracted rotation right in sitting, and retracted rotation left in sitting.
  - Lumbar spine: flexion in standing, extension in standing, flexion in lying, and extension in lying. If required, the following tests are also performed: side gliding right in standing or prone extension with right lateral shift and side gliding left in standing or prone extension with left lateral shift.
- ***Static tests.*** These tests are often used as ancillary tests to confirm dynamic testing or to further explore the effects of loading when dynamic testing yields no definitive conclusion.[91]
  - Cervical spine: protrusion, flexion, retraction (sitting or supine), retraction and extension (sitting, prone, or supine), retracted side bending right or left, and retracted rotation right or left.
  - Lumbar spine: sitting slouched, sitting erect, standing slouched, standing erect, lying prone in extension, long sitting, lateral shift right or left, and rotation in flexion.

The clinical reasoning intrinsic to the McKenzie method classifies mechanical and symptomatic responses to loading into three main syndromes: postural, dysfunction, and derangement (Table 22-3) and (Fig. 22-4).

The *posture syndrome* is proposed to result from sustained loading of the tissues during end range positions/postures. The pain associated with the postural syndrome is of a gradual onset, dull, local, midline, symmetric, and never referred. Prolonged postures worsen the pain, whereas movement abolishes it. On examination, the patient demonstrates no spinal deformity or loss of range and repeated movements do not produce the symptoms. The onset of symptoms, which is time-dependent (usually occurring after more than 15 minutes), is provoked with sustained end-of-range positions.

The *dysfunction syndrome* is proposed to result from an adaptive shortening of some soft tissues and an overstretching of others. The intermittent pain associated with this syndrome is local, adjacent to the midline of the spine, and not referred. The exception occurs in the case of an adherent nerve root (ANR) where the pain may be felt in the buttock, thigh, or calf (Table 22-4). The ANR represents the only time when distal pain is experienced in the dysfunction syndrome, and the only time when distal symptoms are repeatedly reproduced as part of its management. Activities and positions at the end of range worsen the pain of the dysfunction syndrome, whereas activities that avoid end ranges lessen the symptoms. On examination, the patient demonstrates a loss of motion or function that distinguishes this syndrome from the posture syndrome. Repeated movements do not alter the symptoms and the loss of motion, or function, may be symmetric or asymmetric.

The *derangement syndrome* is thought to result from a displacement or an alteration in the position of joint structures. The joint structure most commonly involved is the IVD, and McKenzie divides these disturbances into posterior disk and anterior disk derangements. The posterior derangements are further subdivided into seven derangement categories. Derangements 1 through 6 describe posterior derangements, whereas derangement 7 describes the anterior derangement (Table 22-5).

The pain of a derangement syndrome, which is usually of a sudden onset and associated with paresthesia or numbness, is dull or sharp and can be central, unilateral, symmetric, or asymmetric. Although the pain may be referred into the buttock, thigh, leg, or foot, it varies in both intensity and distribution. Bending, sitting, or sustaining positions worsen a posterior derangement, whereas walking and standing worsen an anterior derangement. Patients with a posterior derangement often feel better when walking and lying, whereas patients with an anterior derangement usually feel better in sitting and other flexed positions. On examination, a lateral shift may be noted. There is always a loss of motion and function. Certain motions produce, increase, or cause the symptoms to peripheralize (move away from the spine),

TABLE 22-3 Summary of the Three McKenzie Syndromes

	Mechanical or Symptomatic Responses	Frequency of Complaints (Responses)	Point of Response Elicitation	Rate of Response Elicitation	Response Persistence After Loading Cessation	Rate of Syndrome Resolution	Responses During Motion	Responses at Mechanically Unimpeded End Range	Responses at Mechanically Impeded End Range	Movement Plane Specific Responses	Preferred Loading Strategies	Reasons for Patient Failure
Postural	Symptomatic only	Intermittent	Sustained end range	Delayed onset after sustained end range positioning	None	Weeks	None	Symptomatic	None exist	Movement plane direction specific	Avoid symptoms	Ignorant, fatigue, self-conscious
Dysfunction	Symptomatic and mechanical	Intermittent	Restricted end range	Immediate at restricted end range	None	Months	None	None	Mechanical and symptomatic	Movement plane direction specific	Pursue symptoms	Avoiding symptoms
Derangement	Symptomatic and mechanical	Intermittent or constant	During motion, obstructed or unobstructed end range	Immediate or delayed, during motion, at obstructed or unobstructed end range	Often persists	Days	Yes	Mechanical and symptomatic	Mechanical and symptomatic	Loading in one movement plane direction may affect another	Pursue centralization, avoid peripheralization	Avoiding symptoms of centralization

TABLE 22-4 Characteristics of the Adherent Nerve Root

The ANR syndrome usually presents following the resolution of a derangement syndrome or postsurgically (6–12 wks).

History

- Sciatic or surgery in the few months that has improved but is now unchanging
- Intermittent leg symptoms, thigh/calf (tightness)
- Consistent activity produces symptoms: touching toes, long sitting, walking
- Pain in leg does not *persist* upon ceasing movement or when changing position

Exam

- Flexion in standing clearly restricted—consistently produces concordant pain/tightness at end range
- No rapid reduction/abolition of symptoms produced; no lasting distal symptoms
- Moderate/major loss of flexion (may demonstrate deviation)
- Flexion movement will improve if knee is flexed
- FIL has no effect
- No rapid change in mechanical presentation with repeated movement testing.

Intervention

- Flexion in sit with increasing knee extension
- Flexion in stand
- Flexion step stand (opposite leg on chair)
- End the session with EIL/EIS
- Monitor mechanical response to extension. Should remain unchanged following repeated flexion

FIL = flexion in lying; EIL = extension in lying; EIS = extension in standing.

whereas other motions decrease, abolish, or centralize the symptoms. McKenzie advocates a variety of loading principles for the reduction of the derangement.

- Extension
- Flexion
- Lateral movement
- Force progression
  - Start position: loaded versus unloaded
  - Positioning to mid range
  - Positioning at end range
- Dynamic patient-generated forces
  - Patient motion to mid range
  - Patient motion to end range
  - Patient motion to extreme ranges using patient over-pressure (sag).
- Clinical generated forces
  - Patient motion to mid range with clinician's overpressure
  - Patient motion to end range with clinician's overpressure
  - Clinician mobilization
  - Clinician high-velocity thrust technique

TABLE 22-5 Comparison of the Lumbar and Cervical McKenzie Derangement Syndromes

Lumbar Derangements	Cervical Derangements
Derangement 1 Central or symmetrical pain across low back; rarely buttock and/or thigh pain; no deformity	**Derangement 1** Central or symmetrical pain about C5–7; rarely scapular and/or shoulder pain; no deformity
Derangement 2 Central or symmetrical pain across low back with or without buttock and/or thigh pain; deformity of lumbar kyphosis	**Derangement 2** Central or symmetrical pain about C5–7 with or without scapular, shoulder, or upper arm pain; deformity of cervical kyphosis
Derangement 3 Unilateral or asymmetrical pain across low back with or without buttock and/or thigh pain; no deformity	**Derangement 3** Unilateral or symmetrical pain about C3–7 with or without scapular, shoulder, or upper arm pain; no deformity
Derangement 4 Unilateral or asymmetrical pain across low back with or without buttock and/or thigh pain; deformity of lumbar scoliosis	**Derangement 4** Unilateral or symmetrical pain about C5–7 with or without scapular, shoulder, or upper arm pain; with deformity or acute wry neck or torticollis
Derangement 5 Unilateral or asymmetrical pain across low back with or without buttock and/or thigh pain with sciatica extending below knee; no deformity	**Derangement 5** Unilateral or symmetrical pain about C5–7 with or without scapular or shoulder pain and with arm symptoms distal to elbow; no deformity
Derangement 6 Unilateral or asymmetrical pain across low back with or without buttock and/or thigh pain with sciatica extending below knee; deformity of lumbar scoliosis	**Derangement 6** Unilateral or symmetrical pain about C5–7 with arm symptoms distal to the elbow with deformity of cervical kyphosis, acute wry neck or torticollis
Derangement 7 Symmetrical or asymmetrical pain across low back with or without buttock and/or thigh pain with deformity of accentuated lumbar lordosis	**Derangement 7** Symmetrical or asymmetrical pain about C4–6 with or without anterior/anterior-lateral pain; no deformity

  - Strategy: sagittal/frontal/or combination
  - Time factor: sustained/repeated
  - Frontal plane angle during combined procedures

Once the subjective history and mechanical evaluation has been performed on the initial visit, the clinician should have an idea regarding which mechanical category the patient may belong. Depending upon the syndrome, a specific self-treatment program is prescribed for home use, and patients are encouraged to accept responsibility for their intervention and recovery. The specific programs relative to the cervical and lumbar spine are described in the respective chapters.

The inter-rater reliability of the McKenzie method in performing clinical tests and classifying patients with LBP into syndromes has been investigated in a number of studies.[68,89,92–99]

Repeated movements have been found to be a reliable part of the examination of the spine in a number of studies.[98,100]

In one study,[98] intertester reliability between two therapists trained in the McKenzie method seemed to be high for classifying patients with LBP into McKenzie syndromes, and excellent for judging pain status change, including the centralization phenomenon, during examination of the lumbar spine.[96,98] The results from a study by Kilpikoski also suggested that intertester reliability in performing clinical tests and classifying patients with LBP into the main McKenzie syndromes is high when the clinicians have been trained in the McKenzie method.[99]

Donahue and colleagues[92] suggested that the McKenzie method was unreliable for detecting the presence of a lateral shift, but that a relevant lateral component could be reliably detected using symptom response to repeated movements. In contrast, Tenhula and associates[95] noted a significant relation between positive results on a contralateral side-bending movement test and a lumbar lateral shift, indicating that the former is a useful clinical test for confirming the presence of a lateral shift in patients with LBP.

Kilby and colleagues[97] found the "McKenzie algorithm" (Fig. 22-5) to be reliable in the examination of pain behavior and pain response with repeated movements but unreliable in the detection of end range pain and lateral shift.

Riddle and Rothstein[68] found that the McKenzie approach was unreliable when physical therapists classified patients into McKenzie syndromes. They suggested that a potential source of unreliability was in determining whether the patient had a lateral shift and, if so, in which direction and whether the patient's pain centralized or peripheralized during test movements.[68]

Treatment-Based Classification System

This system, originally proposed by Delitto and colleagues,[101] uses information gathered from the physical examination and from the patient's self-reports of pain (pain scale and pain diagram) and disability (modified Oswestry questionnaire) to classify the patient with LBP.[101,102] The classification determines whether the patient's condition is amenable to physical therapy or whether care from another practitioner is required. The treatment-based classification (TBC) system is designed for patients judged to be in the acute stage, with the determination of acuity based on the alignment of various body structures, the effect of movements on symptoms, the nature of the patient's symptoms, the degree of disability, and the goals for management, instead of strictly on the elapsed time from injury.[102]

Patients in the acute stage are those with higher levels of disability (modified Oswestry scores generally greater than 30), who report substantial difficulty with basic daily activities such as sitting, standing, and walking. Intervention goals are to improve the ability to perform basic daily activities, reduce disability, and permit the patient to advance in his or her rehabilitation.[102] Patients judged to be in the acute stage are assigned to a classification that guides the initial intervention. Seven classifications are described for patients in the acute stage[101]:

1. Immobilization.
2. Lumbar mobilization.

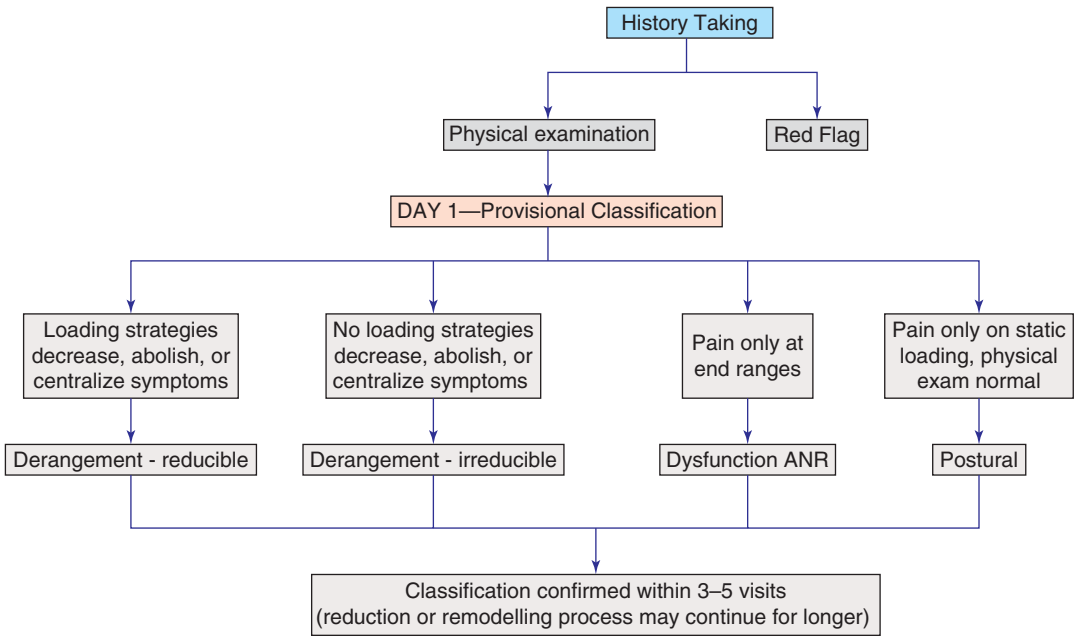

FIGURE 22-5 McKenzie classification algorithm.

3. Sacroiliac mobilization.
4. Extension syndrome.
5. Flexion syndrome.
6. Lateral shift.
7. Traction.

Each of the classifications has key examination findings and recommended interventions. To facilitate comparisons among classifications, these seven classifications may be collapsed further into four classifications based on similarities in the prescribed interventions.

1. Mobilization/manipulation.
2. Stabilization (either sacroiliac or lumbar).
3. Specific exercise (flexion, extension, or lateral shift correction).
4. Traction.

Mobilization/Manipulation

The mobilization classification includes patients believed to have indications for either sacroiliac or lumbar region mobilization or manipulation. Mobilization of the sacroiliac region is indicated by asymmetries of the pelvic landmarks (anterior superior iliac spines, posterior superior iliac spines, and iliac crests) with the patient in the standing position and by positive results in three of four tests as follows:

1. Asymmetry of posterior superior iliac spine heights with the patient sitting.
2. The standing flexion test.
3. The prone-knee flexion test.
4. The supine to long-sitting test.

Acute-stage intervention for this category involves a manipulation technique proposed to affect the sacroiliac joint region, muscle energy techniques, and ROM exercises for the lumbosacral spine.[96]

Lumbar mobilization is believed to be indicated by the presence of the following:

- Unilateral paraspinal pain in the lumbar region.
- Asymmetric amounts of lumbar side-bending ROM with the patient standing in either an "opening" pattern (limited and painful flexion and side-bending ROM to the side opposite the pain) or a "closing" pattern (limited and painful extension and side-bending ROM to the same side as the pain).

The intervention for this category consists of lumbar mobilization or manipulation techniques and ROM exercises for the lumbosacral spine.

Stabilization

The stabilization classification is purported to identify patients with lumbar segmental instability. Key examination findings are typically gleaned from the history and include a history of frequent episodes of symptoms precipitated by minimal perturbations, frequent use of manipulation with short-term relief of symptoms, trauma, or reduced symptoms with the prior use of a corset.[101]

The intervention for this category focuses on strengthening exercises for the back extensor and abdominal exercises as well as stabilization exercises designed to improve dynamic control of the lumbar spine.[102]

Specific Exercise

The key examination finding that places patients into a specific exercise classification is the presence of centralization with movement of the lumbar spine based on the McKenzie method.[82] When either lumbar flexion or extension is found to produce centralization, the patient is treated with specific exercises in the direction producing the centralization. Patients are also educated to avoid positions found to peripheralize symptoms during examination.

The primary examination findings that lead to a classification of a lateral shift, in which the shoulders are offset from the pelvis in the frontal plane, are a visible frontal plane deformity and asymmetric side-bending ROM in standing. If correction of the deformity produces centralization, the patient is taught specific exercises designed to correct the lateral shift (i.e., pelvic translocation).[82]

Traction

The traction classification is reserved for patients with signs and symptoms of nerve root compression who are unable to centralize with any lumbar movements. The acute stage intervention involves the use of mechanical traction or autotraction[103] in an attempt to produce centralization.

Under the TBC, patients judged to be in a more chronic stage are treated with a conditioning program designed to improve strength, flexibility, and conditioning, or with a work-reconditioning program.[101]

A recent cross-sectional study[73] to evaluate the TBC algorithm found that approximately one-half of patients with acute or subacute LBP met the criteria for only one treatment subgroup. In addition, although approximately 25% of the patients met the criteria for more than one subgroup, 25% of the patient's did not meet the criteria for any of the treatment subgroups. This latter finding suggests that further research is needed to refine the algorithm.

Canadian Biomechanical Model[104]

The Canadian model is an eclectic approach founded upon an amalgam of doctrines and techniques that incorporate the biomechanical concepts of the Norwegians,[105–108] the selective tissue tension principles of Cyriax,[79,109] the muscle energy concepts of the American osteopaths,[110–112] the combined movement testing of Edwards,[68] the manipulative techniques of Stoddard,[113] the various approaches to stabilization therapy,[25,114–116] the exercise protocols of McKenzie,[82,83] the muscle balancing concepts of Janda, Jull, and Sahrmann,[117–119] and the movement reeducation principles of the neurodevelopment and sensory integrationist clinicians.[120,121]

The basic tenet of the Canadian approach is that, given an understanding of the anatomy and biomechanics of a joint, segment or region, the pathologic mechanisms can be extrapolated using a series of testing procedures. These tests include the Cyriax upper and lower quarter scanning examinations for differential diagnosis (see Chap. 4), uncombined (plane) and

combined movement testing, passive physiological intervertebral motion (PPIVM) tests, passive accessory intervertebral motion (PAIVM) tests, and segmental stability tests.

Following the active motion tests, the clinician should be able to determine the planar motions (flexion, extension, and side bending and rotation to both sides) that provoke symptoms. However, the clinician cannot yet determine whether a joint or soft tissue is responsible for the pain. Two tests are used to help determine the presence of articular involvement: the PPIVM tests and the PAIVM tests.

Passive Physiologic Intervertebral Mobility Testing

The PPIVM tests are used to determine the amount of segmental mobility available in the spine. The PPIVM tests assess the ability of each segment to move through its normal ROM. The adjacent spinous processes of the segment are palpated simultaneously and movement between them is assessed as the segment is passively taken through its physiologic range. If both spinous processes move simultaneously, there is no movement occurring at the segment and a hypomobility exists. If the movement between adjacent spinous processes appears excessive when compared with the level above or below, a hypermobility or instability may be suspected.

Thus, once the physiologic range has been assessed, it can be categorized as either normal, excessive, or reduced compared with the neighboring segment. Other positive findings for a hypomobility would be a reduced range in a capsular or noncapsular pattern in the active motion tests, a reduced joint glide, and a change in the end-feel from the expected norm for that joint. The end-feel and joint glide are both tested in the PAIVM tests (discussed next).

Therefore, one of three conclusions may be drawn from the PPIVM tests:

1. The joint motion is determined to be normal. If the PPIVM test of a spinal joint has a normal range and end-feel, the joint can usually be considered normal because in the spine, instability will invariably produce a hypermobility. However, in a peripheral joint, it is possible to have a normal range in the presence of articular instability. Thus, if a peripheral joint demonstrates a normal physiologic range, the stability of the joint needs to be tested using the segmental stability tests (see later discussion) before the clinician can deem the joint to be normal.
2. The joint motion is determined to be reduced (hypomobile). A hypomobility can be painful, suggesting an acute sprain of a structure, or painless, suggesting a contracture or an adhesion of the tested structure. If the motion is determined as being reduced (hypomobile), PAIVM testing is performed to determine, using the joint glides, whether the reduced motion is a result of an articular or extra-articular restriction.
3. The motion is determined to be excessive (hypermobile). If the motion is determined to be excessive, segmental stability tests are performed to determine whether a hypermobility or an instability is present (see later discussion).

It is worth noting that the judgments of joint stiffness made by experienced physical therapists examining patients in their own clinics have been found to have poor reliability in a number of studies. In two separate studies, [100,122] manual therapy tests that provoke patient's symptoms were found to be more reliable than judging stiffness in the spine. Smedmark and colleagues[123] investigated the interexaminer reliability of passive intervertebral motion testing. In their study, passive intervertebral motion of the cervical spine was assessed independently by two physical therapists whose backgrounds (education and clinical experience) were equal. Sixty-one patients seeking care for cervical problems at a private clinic were included in the study, in which three segments of the cervical spine and the mobility of the first rib were graded as stiff or not stiff. Data analyzed by percentage agreement and κ coefficient indicated an interexaminer reliability that was greater than expected by chance. Results demonstrated interexaminer reliability of between 70 and 87% and κ coefficients ranging between 0.28 and 0.43, considered to be only fair to moderate.

However, in a study by Gonnella and colleagues[124] the performance of five physical therapists in evaluating passive mobility of the vertebral column of five asymptomatic endomorphic subjects was assessed for the reliability within and between therapists, the criteria for grading, and the subjects themselves. Intratester reliability was found to be reasonable to good; there was no intertester reliability. Reliability was highest at L1–L3 and lowest at L5–S1. Problems identified were idiosyncratic behaviors that may develop with experience, subject characteristics, and the instrument itself.

Passive Accessory Intervertebral Mobility Testing

In the PAIVM tests, the clinician assesses the joint glides or accessory motions of each joint and determines the type of end-feel encountered.

Accessory motions are involuntary motions. With few exceptions, muscles cannot restrict the glides of a joint, especially if the glides are tested in the loose-pack position of a peripheral joint and at the end of available range in the spinal joints.[125] Thus, if the joint glide is restricted, the cause is an articular restriction such as the joint surface or capsule. If the glide is normal, then the restriction must be from an extra-articular source such as a periarticular structure or muscle.

Determining the type of end-feel is very important, particularly in joints that only have very small amounts of normal range such as those of the spine. To execute the end-feel, the point at which resistance is encountered is evaluated for quality and tenderness. Additional forces are needed as the end range of a joint is reached and the elastic limits are challenged. This space, termed as the *end-play zone*, requires a force of over-pressure to be reached and when that force is released, the joint springs back from its elastic limits. Because pain generally does not limit movement in specific and deliberate passive tests, the PAIVM tests are better for gauging the reliability of the limitation based on tissue resistance, rather than patient willingness, and are better at determining the pattern of restriction than the active tests. If pain is reproduced with end-feel testing, it is useful to associate the

pain with the onset of tissue resistance to gain an appreciation of the acuteness of the problem. A normal end-feel indicates normal range, whereas an abnormal end-feel suggests abnormal range, either hypomobile or hypermobile. If the articular restraints are irritable, the range will be about normal but will be accompanied by a spasm end-feel because a reflex muscle contraction can prevent the motion into an abnormal and painful range.[125,126] If nonirritable, the physiologic range will be increased and the end-feel will be softer than the expected capsular one, suggesting a compromise of the structure under examination. A hard, capsular end-feel indicates a pericapsular hypomobility, whereas a jammed end-feel indicates a pathomechanical hypomobility.

The PAIVM tests can be performed symmetrically or asymmetrically. These tests are described in the relevant chapters of this text. Generally speaking, the symmetric tests are used when planar motions have produced pain in the active motion tests, whereas the asymmetric techniques are used when the combined motions have produced pain in the active motion tests.

Caution must be taken when basing clinical judgments on the results of accessory motion testing alone because few studies have examined the validity and reliability of accessory motion testing of the spine or extremities and little is known about the validity of these tests for most inferences.[127]

Hayes and Peterson[128] examined two physical therapists who used standardized positions to evaluate two knee motions and five shoulder motions. Evaluators did not interview subjects and were blinded to previous test results. Evaluators applied overpressure and noted the end-feel while subjects identified the moment their pain was reproduced. Following testing, subjects rated their pain intensity. Analyses included percentage of agreement κ, weighted κ, and maximum κ coefficients and confidence intervals. Analyses were repeated for subjects whose pain intensity during testing did not change between examinations. Intrarater κ coefficients varied from 0.65 to 1.00 for end-feel, and intrarater weighted κ coefficients varied from 0.59 to 0.87 for pain-resistance sequence. Most coefficients remained stable or improved for the unchanged subjects. Inter-rater κ coefficients for end-feel and weighted κ coefficients for pain resistance sequence varied from −0.01 to 0.70. The authors concluded that the reliability of end-feel and pain-resistance judgments at the knee and shoulder was generally good, especially after accounting for subject change and unbalanced distributions. Inter-rater reliability, however, was generally not acceptable, even after accounting for these factors.[128]

In a separate study by the same authors,[129] the relationship between pain and normal and abnormal (pathologic) end-feels during passive physiologic motion assessment at the knee and shoulder were examined. Physical therapists examined subjects with unilateral knee or shoulder pain, and each subject was examined twice. Passive physiologic motions, two at the knee and five at the shoulder, were tested by applying an overpressure at the end of ROM, using standardized positions. Subjects reported the amount of pain (0–10) immediately after the evaluator recorded the end-feel. The authors concluded that abnormal (pathologic) end-feels are associated with more pain than normal end-feels during passive physiologic motion testing at the knee or shoulder. Dysfunction should be suspected when abnormal (pathologic) end-feels are present.[129]

Based on review of the literature of the MEDLINE and CINAHL databases for the period of 1980 through 2000, using the keywords *motion palpation, accessory motion,* and *intervertebral motion*, Huijbregts[130] performed a review of 28 reliability studies. The following conclusions were made from this study:

- Intra-rater agreement varied from less than chance to generally moderate or substantial agreement.
- Inter-rater agreement only rarely exceeded poor to fair agreement.
- Rating scales measuring absence versus presence or magnitude of pain response yielded higher agreement values than mobility rating scales.

Segmental Stability Tests

These are tests for movements that should not exist to an appreciable degree. The tests include maneuvers that induce non-physiologic rotational, anterior, posterior, and transverse shears to the segment. The limitation in the clinical diagnosis of segmental instability lies in the difficulty of accurately detecting excessive intersegmental motion, because even conventional radiologic testing is often insensitive and unreliable.[131,132] Instability should be suspected in the presence of a positive stability test in conjunction with other clinical findings and symptoms of instability. A positive stability test in the absence of other clinical findings is probably irrelevant. Hypermobility is clinically manifested by the presence of increased physiologic range in one or more directions, or normal range with pain and spasm at the end of that range.

Research indicates that skilled clinicians can distinguish subjects with symptomatic spondylolysis from LBP based on the finding of increased intersegmental motion at the level above the pars defect.[133,134]

The various stability tests are described in the specific chapters of this text.

CHAPTER 23

The Craniovertebral Region

CHAPTER OBJECTIVES

***At the completion of this chapter, the reader will be able to*:**

1. Describe the anatomy of the vertebrae, ligaments, muscles, and blood and nerve supply that comprise the craniovertebral segments.
2. Describe the biomechanics of the craniovertebral joints, including coupled movements, normal and abnormal joint barriers, and kinesiology.
3. Perform a comprehensive history and systems review for the craniovertebral region.
4. Perform a detailed examination of the craniovertebral musculoskeletal system, including palpation of the articular and soft tissue structures, specific passive mobility tests, passive articular mobility tests, and stability tests.
5. Evaluate the total examination data to establish a diagnosis.
6. Apply appropriate manual techniques to the craniovertebral joints, using the correct grade, direction, and duration.
7. Describe intervention strategies based on clinical findings and established goals.
8. Evaluate intervention effectiveness in order to progress or modify intervention.
9. Plan an effective home program and instruct the patient in this program.
10. Help the patient to develop self-reliant intervention strategies.

OVERVIEW

The craniovertebral region is a collective term that refers to the occiput, atlas, axis, and supporting ligaments, which accounts for approximately 25% of the vertical height of the entire cervical spine. Injuries to this region have the potential to involve the brain, brain stem and spinal cord, resulting in a myriad of symptoms ranging from headache and vertigo to cognitive and sympathetic system dysfunction.[1] Craniovertebral injuries that involve cognitive and sympathetic system dysfunction demonstrate a poorer prognosis and a lengthy recovery.

ANATOMY

The craniovertebral region is considered as a separate entity from the rest of the cervical spine because of its distinct embryology and anatomical structure. Kapandji[2] notes that the occiput, atlas, and axis actually form a primary kyphotic curve and that this curve serves as a delineation between the craniovertebral region and the cervical spine proper.

Foramen Magnum

The general shape of the foramen magnum is oval, with the longer axis oriented in the sagittal plane (Fig. 23-1).[3] The margin of the foramen is relatively smooth and serves as the most superior attachment for a variety of the ligaments of the vertebral column. The smaller anterior region of the foramen magnum is characterized by a pair of tubercles to which the alar ligaments attach. The posterior portion of the foramen magnum houses the brain stem–spinal cord junction.

On either side of the anterolateral aspect of the foramen magnum are two ovoid projections, called occipital condyles (Fig. 23-1). The long axis of these paired occipital condyles is situated in a posterolateral to anteromedial orientation. The occipital condyles articulate with the first cervical vertebra.

Atlas

The atlas is a ring-like structure that is formed by two lateral masses, which are interconnected by anterior and posterior arches (Fig. 23-1). The demarcation of the two regions is marked by a pair of tubercles to which the transverse ligament of the atlas attaches. Although the atlas has a smaller vertical dimension than any other cervical vertebrae, it is considerably wider. Because this vertebra does not have a spinous process, there is no bone posteriorly between the occipital bone and the spinous process of C2. This results in an increase in the potential for craniovertebral extension.

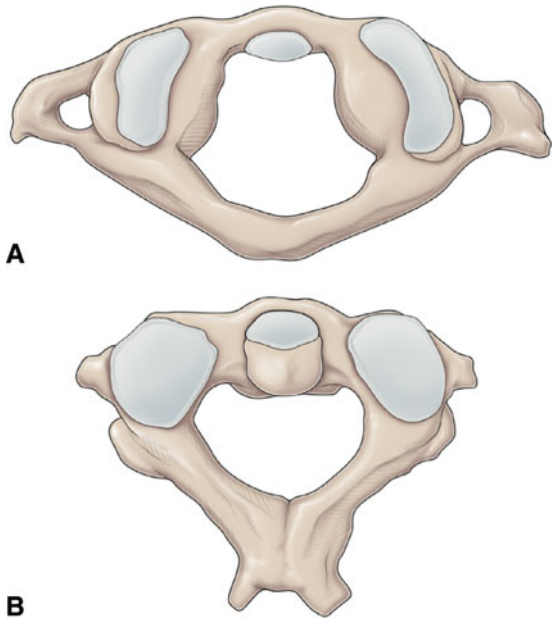

FIGURE 23-1 Bony structures of the craniovertebral joints. **A.** The atlas (C 1). **B.** The axis.

The superolateral aspect of each of the posterior arches has a transverse foramen to accommodate the vertebral artery (see Chap. 24). The articular surface of the inferior facet is circular and relatively flat and slopes inferiorly from medial to lateral. The upper articular facets of C1 are elongated from anterior to posterior, with the anterior ends closer together and more upwardly curved than their posterior counterparts.[3] This arrangement results in much more extension than flexion being available at the articulation between the occipital condyles and the atlas—the occipitoatlantal (O-A) joint.[4]

O-A Joint

The O-A joint represents the most superior zygapophyseal joint of the vertebral column and the only vertebral level that has an articulation characterized by a convex surface (occipital condyle) moving on a concave joint partner (articulating facet of the atlas).[5]

Axis

The axis serves as a transitional vertebra (Fig. 23-1), because it is the link between the cervical spine proper and the craniovertebral region.

The dimensions of the axis are significantly different from those of the atlas. The atlas is considerably wider than the axis, but because of the long spinous process, the axis extends much farther posteriorly and is the first palpable midline structure below the occiput.[6] Like the atlas, the transverse process of the axis has a transverse foramen to allow passage of the vertebral artery (not shown).

A unique feature of the axis is the odontoid process, or dens (Fig. 23-2). The dens, which develops with age, extends superiorly from the body to just above the C1 vertebra, before tapering to a blunt point. Very dense, thick trabecular bone is present in the center of the tip of the dens, and the cortical bone at the anterior base of the body of C2 (where the anterior longitudinal ligament attaches) is uniformly thick.[7] Hypodense bone, however, is present consistently beneath the odontoid process at the upper portion of the body of C2.[8] This area of hypodense bone is susceptible to fracture. The anterior aspect of the dens has a hyaline cartilage-covered mid-line facet for articulation with the anterior tubercle of the atlas (the median atlantoaxial (A-A) joint). The posterior aspect of the dens usually is marked with a groove where the transverse ligament passes. The dens functions as a pivot for the upper cervical joints and as the center of rotation for the A-A joint. The most variable dimension of the axis is the dens angle in the sagittal plane, which can range from –2 degrees (leaning slightly anterior) to 42 degrees (leaning posterior).[9] This extremely variable angle can make assessment of fracture reduction challenging.[7]

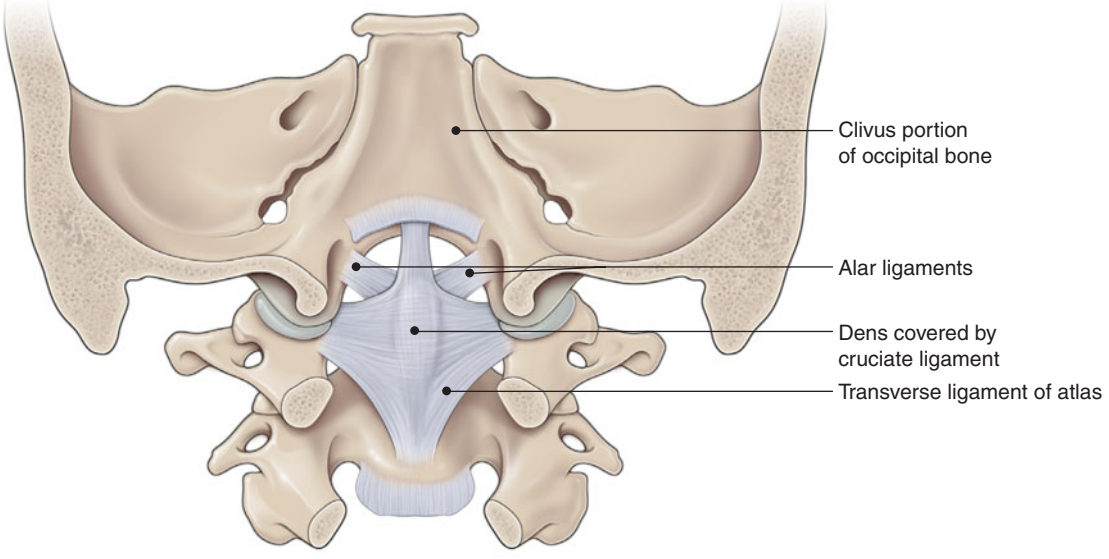

FIGURE 23-2 Ligamentous structures of the craniovertebral joints.

A-A Joint

This is a relatively complex articulation, which consists of

- two lateral zygapophyseal joints between the articular surfaces of the inferior articular processes of the atlas and the superior processes of the axis;
- two medial joints: one between the anterior surface of the dens of the axis and the anterior surface of the atlas, and the other between the posterior surface of the dens and the anterior hyalinated surface of the transverse ligament[6] (Fig. 23-2).

The relatively large superior articular facets of the axis (Fig. 23-2) lie lateral and anterior to the dens. These facets slope considerably downward from medial to lateral in line with the zygapophyseal facets of the mid-low cervical spine.[10] As the lateral A-A joints function to convey the entire weight of the atlas and the head to lower structures, the lamina and pedicles of the axis are quite robust.[11] The stout, moderately long spinous process serves as the uppermost attachment for muscles that are essentially lower cervical in nature and for muscles that act specifically on the craniovertebral joints.

One of the functions of the intervertebral disk (IVD) in the spine is to facilitate motion and provide stability. Thus, in the absence of an IVD in this region, the supporting soft tissues of the joints of the upper cervical spine must be lax to permit motion, while simultaneously being able to withstand great mechanical stresses.

Craniovertebral Ligaments

The craniovertebral region is noted for a variety of ligaments, some of which have been the focus of a number of clinical tests to determine their efficiency in preventing unwanted and potentially dangerous movements. The controlling structures for these segments, which must be considered together, are the

- ***Capsule and accessory capsular ligaments.*** The lateral capsular ligaments (anterolateral O-A ligament) of the O-A joints are typical of synovial joint capsules. These ligaments run obliquely from the basiocciput to the transverse process of the atlas. By necessity, they are quite lax, to permit maximal motion, so they provide only moderate support to the joints during contralateral head rotation.
- ***Apical ligament.*** The apical ligament of the dens extends from the apex of the dens to the anterior rim of the foramen magnum. The ligament is short and thick. It runs from the top of the dens to the basi-occiput and is thought to be a remnant of the notochord. The apical ligament appears to be only a moderate stabilizer against posterior translation of the dens relative to both the atlas and the occipital bone.[11]
- ***Vertical and transverse bands of the cruciform ligament.*** (See Fig. 23-2 and later discussion.)
- ***Alar and accessory alar ligaments.*** (See Fig. 23-2 and later discussion.)
- ***Anterior O-A membrane.*** The anterior O-A membrane is thought to be the superior continuation of the anterior longitudinal ligament. It connects the anterior arch of vertebra C1 to the anterior aspect of the foramen magnum.
- ***Posterior O-A membrane.*** The posterior O-A membrane is a continuation of the ligamentum flavum. This ligament interconnects the posterior arch of the atlas and the posterior aspect of the foramen magnum and forms part of the posterior boundary of the vertebral canal.[11]
- ***Tectorial membrane.*** The tectorial membrane is the most superficial of the three membranes and interconnects the occipital bone and the axis. This ligament is the superior continuation of the posterior longitudinal ligament and connects the body of vertebra C2 to the anterior rim of the foramen magnum. This bridging ligament is an important limiter of upper cervical flexion and holds the occiput off the atlas.[12]

A-A Ligaments

The anterior A-A ligament is continuous with the anterior O-A membrane above. [13] The posterior A-A ligament interconnects the posterior arch of the atlas and the laminae of the axis.

Occipitoaxial Ligaments

The O-A ligaments are very important to the stability of the upper cervical spine.

Alar Ligament[5]

The alar ligaments (see Fig. 23-2) connect the superior part of the dens to fossae on the medial aspect of the occipital condyles, although they can also attach to the lateral masses of the atlas.[14,15] A study of 44 cadavers[16] found the orientation of the ligament to be superior, posterior, and lateral. In another study, [14] 19 upper cervical spine specimens were dissected to examine the macroscopic and functional anatomy of alar ligaments. The study found that the most common orientation (10/19) was cauda-cranial, followed by transverse (5/19). In two of the specimens, a previously undescribed ligamentous connection was found between the dens and the anterior arch of the atlas, the anterior atlantodental ligament. In 12 specimens, the ligament also attached via caudal fibers to the lateral mass of the atlas. The posteroanterior orientation of the ligaments in 17 of the 19 subjects was directly lateral from the dens to the occipital attachment or slightly posterior.

The function of the ligament is to resist flexion, contralateral side bending, and contralateral O-A rotation.[17] In addition, the alar ligaments restrict anteroposterior translation of the occiput on C1 to some degree.[18] Because of the connections of the ligament, side bending of the head produces a contralateral or ipsilateral rotation of C2, depending on the source.[19]

CLINICAL PEARL

Insufficiency of the alar ligaments increases the potential for occipitoaxial instability. The degree of instability can be determined in conjunction with other clinical findings, such as neurologic or vascular compromise, pain, and deformity.

The Cruciform Ligament

The cruciform (cross-shaped) ligament has superior, inferior, and transverse portions (Fig. 23-2). The superior and inferior portions of this ligament attach to the posterior aspect of the body of the dens and the anterior rim of the foramen magnum. The transverse portion, which stretches between tubercles on the medial aspects of the lateral masses of the atlas, connects the atlas with the dens of the axis. The transverse portion of the ligament is so distinct and important that it is often considered a separate ligament (Fig. 23-2). The major responsibility of the transverse ligament is to counteract anterior translation of the atlas relative to the axis, thereby maintaining the position of the dens relative to the anterior arch of the atlas.[12]

The transverse ligament also limits the amount of flexion between the atlas and axis.[20] These limiting functions are of extreme importance because excessive movement of either type could result in the dens compressing the spinal cord, epipharynx, vertebral artery, or superior cervical ganglion. The integrity of the transverse ligament is also essential to the stability of atlas fractures; degenerative, inflammatory, and congenital disorders; and other abnormalities that affect the craniovertebral region.

The importance of the ligament is reflected in its physical properties. Spontaneous or isolated traumatic tears of this ligament are extremely rare events. The ligament is comprised almost entirely of collagen, with a parallel orientation close to the atlas and the dens, but with an approximately 30-degree obliquity at other points in the ligament. Dvorak and colleagues[21] found the transverse ligament to be almost twice as strong as the alar ligaments and to have a tensile strength of 330 Newtons (N) (33 kg/73 lb).

Craniovertebral Muscles

Anterior Suboccipital Muscles

Rectus Capitis Anterior. The rectus capitis anterior (RCA) runs vertically. It travels deep to the longus capitis from the anterior aspect of the lateral mass of the atlas to the inferior surface of the base of the occiput, anterior to the occipital condyle. The RCA flexes and minimally rotates the head. Thus, an adaptively shortened RCA on the right could feasibly produce a decreased left translation in extension during mobility testing of the O-A joint. The muscle is supplied by the anterior (ventral) rami of C1 and C2.

Rectus Capitis Lateralis. This muscle arises from the superior surface of the C1 transverse process and inserts into the inferior surface of the jugular process of the occiput. It is homologous to the posterior intertransverse muscle of the spine. The rectus capitis lateralis side bends the head ipsilaterally. It is supplied by the anterior (ventral) rami of C1 and C2.

Posterior Suboccipital Muscles. The posterior suboccipitals lie beneath the splenius capitis and trapezius muscles. These muscles function in the control of segmental sliding between C1 and C2[22] and may have an important role in proprioception, having more muscle spindles than any other muscle for their size.[22] All of the posterior suboccipital muscles are innervated by the posterior ramus of C1 and also are strongly linked with the trigeminal nerve.[23,24] The suboccipitals receive their blood supply from the vertebral artery.

Rectus Capitis Posterior Major. The rectus capitis posterior major is the largest of the posterior suboccipitals. It runs from the C2 spinous process, widening as it runs cranially to attach to the lateral part of inferior nuchal line (Fig. 23-3). Located inferior and lateral to the occipital

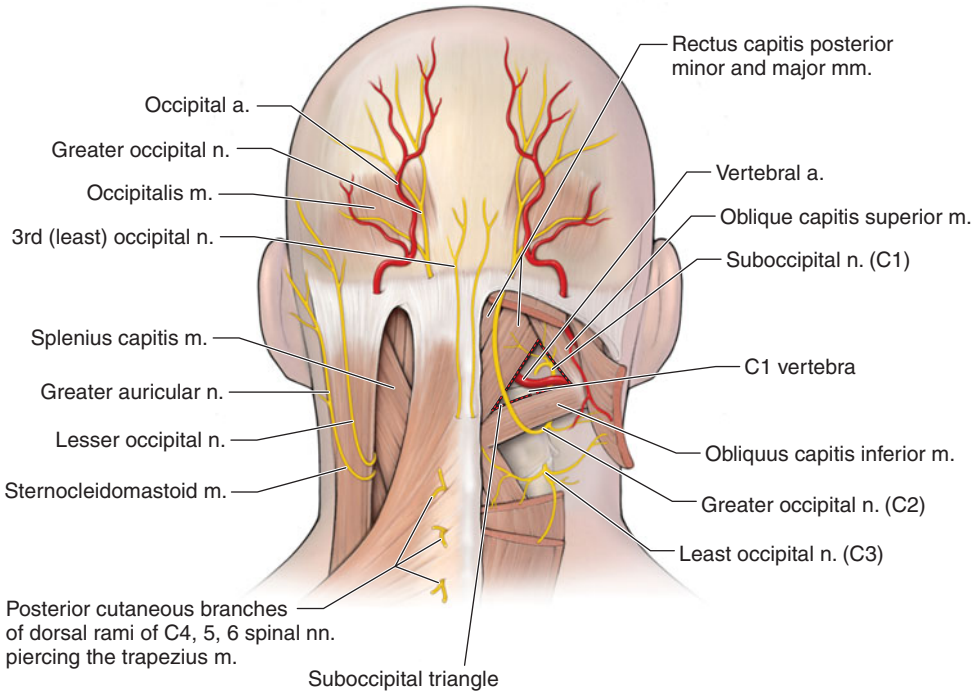

FIGURE 23-3 Muscles of the craniovertebral joints.

protuberances, the rectus capitis posterior major muscles, when working together, extend the head. When working individually, the muscles produce ipsilateral side bending and rotation of the head.

Rectus Capitis Posterior Minor. The rectus capitis posterior minor is a small unisegmental muscle that runs from the posterior arch tubercle of the atlas to the medial part of the inferior nuchal line (see Fig. 23-3). Because of the shortness of the atlantean tubercle, the muscle is very horizontal, running almost parallel with the occiput. The muscle functions to extend the head and provides minimal support during ipsilateral side bending of the head.

CLINICAL PEARL

Connective tissue attachments between the rectus capitis posterior minor and dura mater recently have been identified.[25] This finding has led to the use of cervical flexion with neurodynamic mobility tests (see Chap. 11). The differentiation between adverse neural tension and adaptive shortening of the muscle can be made by performing short neck flexion, with the neural system pretensioned and then relaxed.

Obliquus Capitis Inferior. This is the larger of the two oblique muscles and runs from the spinous process and lamina of the axis superolaterally to the transverse process of the atlas (see Fig. 23-3).

The inferior oblique muscle works to produce ipsilateral rotation of the atlas and skull and to control anterior translation and rotation of C1 (atlas). An adaptively shortened right inferior oblique may exert an inferior and posterior pull on the right transverse process of the atlas, producing a right rotated A-A joint.[26,27] This results in a gross limitation of left rotation of the head while in cervical flexion, but a minimal limitation of left rotation of the head in extension.

Obliquus Capitis Superior. The superior oblique arises from the transverse process of the atlas and runs superoposterior and medially to the bone between the superior and inferior nuchal lines, lateral to the attachment of rectus capitis posterior major (see Fig. 23-3). Because of its posteromedial orientation, the superior oblique functions to provide contralateral rotation and ipsilateral side bending of the O-A joint, when acting unilaterally. When working together, the two superior obliques can produce head extension. Dysfunction of this muscle has been implicated as a common cause of chronic headaches.[28–32]

The posterior sub-occipital muscles can work concentrically with the larger extensors and rotators of the cervical spine, or eccentrically, controlling the action of the flexors. Because two of these muscles parallel the occiput, their controlling influence may be more linear than angular, producing or guiding the arthrokinematic, rather than the osteokinematic, motion.[22]

Nerve Supply

The posterior (dorsal) ramus of spinal nerve C1 is larger than the anterior (ventral) ramus. It exits from the spinal canal by passing posteriorly between the posterior arch of the atlas and the rim of the foramen magnum, along with the vertebral artery. It then enters the suboccipital triangle and supplies most of the muscles that form that triangle. It usually has no cutaneous distribution.

The posterior (dorsal) ramus of spinal nerve C2 (see Fig. 23-3), also known as the greater occipital nerve, is larger than the anterior (ventral) ramus of C2. It exits from the vertebral canal by passing through the slit between the posterior arch of the atlas and the lamina of the axis. This nerve is the largest of the cervical posterior (dorsal) rami and is primarily a cutaneous nerve. It supplies most of the posterior aspect of the scalp, extending anteriorly to a line across the scalp that runs from one external auditory meatus to the other. Because this nerve has an extensive cutaneous distribution, it has a very large posterior (dorsal) root ganglion. This ganglion is commonly located in a vulnerable location, almost directly between the posterior arch of C1 and the lamina of C2 (see Fig. 23-3). The interval between these two bony structures is small, and it is reduced with extension of the upper cervical spine. Given the sensitivity of the posterior (dorsal) root ganglion to compression, the possible relationship between the forward head position and occipital headaches is apparent.[28–32] The O-A joints,[33] A-A joints,[34] and the C2 spinal nerve[35] have all been implicated as primary nociceptors in cervicogenic headaches (CHs). Among individuals with chronic neck pain, 58–88% describe associated headaches.[36,37] The prevalence of C2–3 zygapophyseal joint pain has been estimated at 50–53% in those patients with a chief complaint of headaches after whiplash injury.[36,37]

Blood Supply

The intradural vertebral artery supplies the most superior segments of the cervical spinal cord (see Chap. 24). The cervical cord is supplied by two arterial systems, central and peripheral, which overlap but are discrete. The first is dependent entirely on the single anterior spinal artery (ASA). The second, without clear-cut boundaries, receives supplies from the ASA and both posterior spinal arteries.[38] Because the ASA is medial and dominant, unilateral spinal cord infarctions are very rare. However, they may occur in the perfusion territory supplied by the ASA.[39,40] This is a result of obstruction of either a duplicated ASA[40] or one of the sulcal arteries, which arise from the ASA and turn alternatively left or right to supply one side of the central cord. [41] Peripheral hemicord infarction may result from ischemia, in the territory of the ASA[39] or posterior spinal artery.[42]

Biomechanics

The upper cervical spine is responsible for approximately 50% of the motion that occurs throughout the entire cervical spine. Motions at the O-A and A-A joints occur relatively independently, while below C2, normal motion is a combination of motion at other levels.

Articular facet asymmetry of the human upper cervical spine has been recognized for more than 30 years.[43,44] The implications of this anatomic observation in the human spine has been considered in relation to joint disease, specifically, facet tropism (the phenomenon observed in living tissue, of moving toward or away from a focus of

stimulus), which is associated with subsequent degenerative joint disease.[45,46]

CLINICAL PEARL

Due to the proximity of vital structures, joint disease in this region can have severe consequences. These consequences can include

- vertebral artery compromise;
- compression of the spinal cord;
- brainstem lesions.

O-A Joint

The deep atlantal sockets of the atlas facilitate flexion–extension but impede other movements. In living individuals the average mean motion of flexion and extension at this joint is a combined range of 15–20 degrees.[47] However, the variability in range of motion in normal subject is large. Lind et al.[48] reported a mean of 14 degrees with a standard deviation of 15 degrees in normal subjects. Side bending motion occurs at an average of a little over 9 degrees to both sides,[49–51] with an axial rotation range of 0 degrees (8 degrees when the movement was forced).[50,51]

Although it is generally agreed that rotation and side bending at this joint occur to opposite sides when they are combined, particular rules for patterns of defined coupled motion are not supported by the current literature.[52]

CLINICAL PEARL

Clinical studies suggest that hypermobility of this joint should only be considered as a diagnosis if the range of axial rotation exceeds 8 degrees, making rotational mobility and stability testing necessary at this articulation.

A-A Joint

The design of the ligamentous and bony structures at the A-A joint allow for a large arc of rotation.

CLINICAL PEARL

Within the spine, only two articulations permit pure axial rotation:

- The A-A joint
- The thoracolumbar junction

The major motion that occurs at all three of the A-A articulations is axial rotation. Werne[49] reported 47 degrees to each side in cadavers. A more recent study using CT scanning observed 32 degrees (SD, 10) of axial rotation to either side.[51] This amount of rotation has the potential to cause compression of the vertebral artery (see Chap. 24).[53,54] To help prevent this compression, as the atlas rotates, the ipsilateral facet moves posteriorly while the contralateral facet moves anteriorly, so that each facet of the atlas slides inferiorly along the convex surface of the axial facet, telescoping the head downward.

The first 25 degrees of head rotation (approximately 60%) occur primarily at the A-A articulations.[55] However, the axial rotation of the atlas is not a pure motion, because it is coupled with a significant degree of extension (14 degrees) and, in some cases, flexion.[56]

In living individuals, the reported range of flexion–extension motion at this joint is highly variable, averaging 10 degrees.[57] Flexion at the A-A joint is limited by the tectorial membrane. Extension is limited by the anterior arch of C1, as it makes contact with the odontoid process. The flexion and extension motions are associated with small anteroposterior translational movements, which can create a small space between the back of the anterior arch of the atlas and the odontoid. This space is called the atlanto-odontoid interval (ADI). Because of the arthrokinematics of the joint, flexion increases the ADI, whereas extension decreases it. Excessive gapping of the ADI can have serious consequences, as it can lead to a compression of the spinal cord by the atlas.[58] An ADI of more than 3 mm in adults, and 4.5 mm in children younger than 12 years of age, detected on radiographs is indicative of gross instability and is strongly suggestive of a compromise of the transverse ligament.[58] An increased ADI can be associated with a history of trauma but also may be associated with severe ligamentous laxity in patients with rheumatoid arthritis (RA), neoplastic disease, Down's syndrome, and aplasia or dysplasia of the dens.[19]

Side bending at this joint is approximately 5 degrees. Although coupling at this joint is commonly cited as contralateral side bending during rotation, it is highly variable because of the passive nature of the kinematics of the atlas.[59] Whether the atlas flexes or extends during axial rotation depends on the geometry of the A-A joint and the precise direction of any forces acting through the atlas from the head.[59] The direction of the conjunct rotation appears to be dependent on the initiating movement.[60,61] If the initiating movement is side bending (latexion), the conjunct rotation of the joint is to the opposite side. If the initiating movement is rotation (rotexion), the conjunct motion (side bending) is to the same side.[60,61] If correct, this principle can be exploited in the assessment of the craniovertebral joints:

1. ***Rotexion.*** During rotation of the head to the right (rotexion):
   a. Left side bending and right rotation occur at the O-A joint, accompanied by a translation to the right.
   b. Right side bending and right rotation occur at the A-A joint and at C2–3.

   In other words, if the head motion is initiated with rotation, ipsilateral side bending of the A-A joint and C2–3 occurs, whereas at the O-A joint, contralateral side bending occurs.
2. ***Latexion.*** Side bending of the head to the right produces
   a. left rotation of the O-A joint, accompanied by a translation of the occiput to the left;
   b. left rotation of the A-A joint;
   c. right rotation of C2–3.

In other words, if head motion is initiated with side bending, contralateral rotation of both the O-A and the A-A joints occurs, but ipsilateral rotation occurs at C2–3.

EXAMINATION

The primary objective of the examination of this region is to rule out any serious injury, especially if the patient reports any recent trauma to the head or neck. The pain distribution from cervical structures is outlined in Table 23-1 and the differential diagnoses are described in Chapter 5. The initial examination should focus on the general appearance of the patient (including skin lesions such as rashes), vital signs (pulse, blood pressure, and temperature), and the presence of any upper motor neuron signs or symptoms.[62] Once serious injury has been ruled out, a biomechanical assessment of the craniovertebral joints can be performed. In addition, because of their close relationship with the craniovertebral joints, the cervical spine (see Chap. 25) and temporomandibular joint (see Chap. 26) should be assessed as part of a comprehensive examination of this region.

The biomechanical examination of the craniovertebral joints is best performed in a sequential manner (Fig. 23-4). In general, the O-A joint is examined and treated before the A-A joint to avoid confusion between findings from the combined testing of both joints. The examination and any intervention are terminated if any serious signs and/or symptoms are produced. In these instances, an appropriate referral is made.

History

The craniovertebral region, as with the rest of the neck, is a common area for myofascial pain syndromes. These syndromes are frequently associated with complaints of local muscle soreness, and muscle spasm.[63] Pain may also be referred to this region from trigger points in the upper trapezius muscle, splenius capitis, sternocleidomastoid (SCM) muscle, digastric muscle, cervicis muscles, posterior cervical muscles (semispinalis capitis, semispinalis cervicis, multifidus, and rotators), and sub-occipital muscles (rectus capitis posterior major and minor and inferior and superior obliques) (refer to "Intervention" section).[63]

TABLE 23-1 Pain Distribution from Cervical Structures

Structure	Pain Area
Occipital condyles	Frontal
Occipitocervical tissues	Frontal
C1 posterior (dorsal) ramus	Orbit, frontal, and vertex
C1—2	Temporal and suboccipital
C3 posterior (dorsal) ramus	Occiput, mastoid, and frontal

Data from Meadows J: *A Rationale and Complete Approach to the Sub-Acute Post-MVA Cervical Patient.* Calgary, AB: Swodeam Consulting, 1995.

Complaints of headaches are also common in patients with craniovertebral joint dysfunction.[33-35] Some of the more common types of headaches are described in Chapter 5. In all patients presenting with an unexplained or unusual headache, a full neurologic and general physical examination is required.[62] This examination should focus on the patient's mental status and speech, gait, balance and coordination, a cranial nerve and long tract examination, and an examination of visual fields, and acuity (see Chap. 3).[62]

Patients who complain of headaches should be asked to describe the headache. The clinician must always be alert to the potential coincidental occurrence of secondary headache syndromes. These include headache associated with trauma, vascular disease, nonvascular intracranial disorders, substance abuse or withdrawal, noncephalic infections, metabolic disorders, disorders of facial or cranial structures, and cranial neuralgia.[64] Several conditions may mimic episodic or chronic tension-type headache (see Chap. 5), including muscle tension. Chronic tension-type headaches are often erroneously attributed to chronic sinusitis, but clinical and radiologic evidence must be obtained before making this diagnosis. A causal relationship between tension-type headache and oromandibular dysfunction is controversial, but the two conditions often coexist.[65] The most important structures that register pain within the skull are the blood vessels, particularly the proximal part of the cerebral arteries, as well as the large veins and venous sinuses.[66] The chronic headache of intracranial hypotension is most often distinguished by an increase of pain on standing. Descriptions such as throbbing and pounding are suggestive of a vascular origin but can also inculpate migraine, fever, neuralgia, or hypertension. Chronic, recurrent headaches can be associated with eyestrain, excessive eating or drinking, or smoking.

Intrinsic to the understanding of the relationship of headache to the craniovertebral region are the intracranial pain pathways and their interconnections, especially the trigeminocervical pathway (see Chap. 3).

The location of the headache can provide the clinician with useful information as to the source.

- Forehead pain may be caused by sinusitis or a muscle spasm of the occipital or sub-occipital region.
- Occipital pain can be caused by eyestrain, herniated cervical disk, hypertension, neuralgia, or an ear or eye disorder.
- Parietal pain may be indicative of meningitis or a tumor.
- Facial pain can be caused by sinusitis, trigeminal neuralgia, dental problems, or a tumor.

Dizziness (vertigo) and nystagmus are nonspecific neurologic signs that require a careful diagnostic workup (see Chap. 3). A report of vertigo, although potentially problematic, is not a contraindication to the continuation of the examination.

CLINICAL PEARL

Dizziness associated with disorders of motor function, such as clumsiness, weakness, or paralysis, could suggest compromise of the vertebrobasilar system.

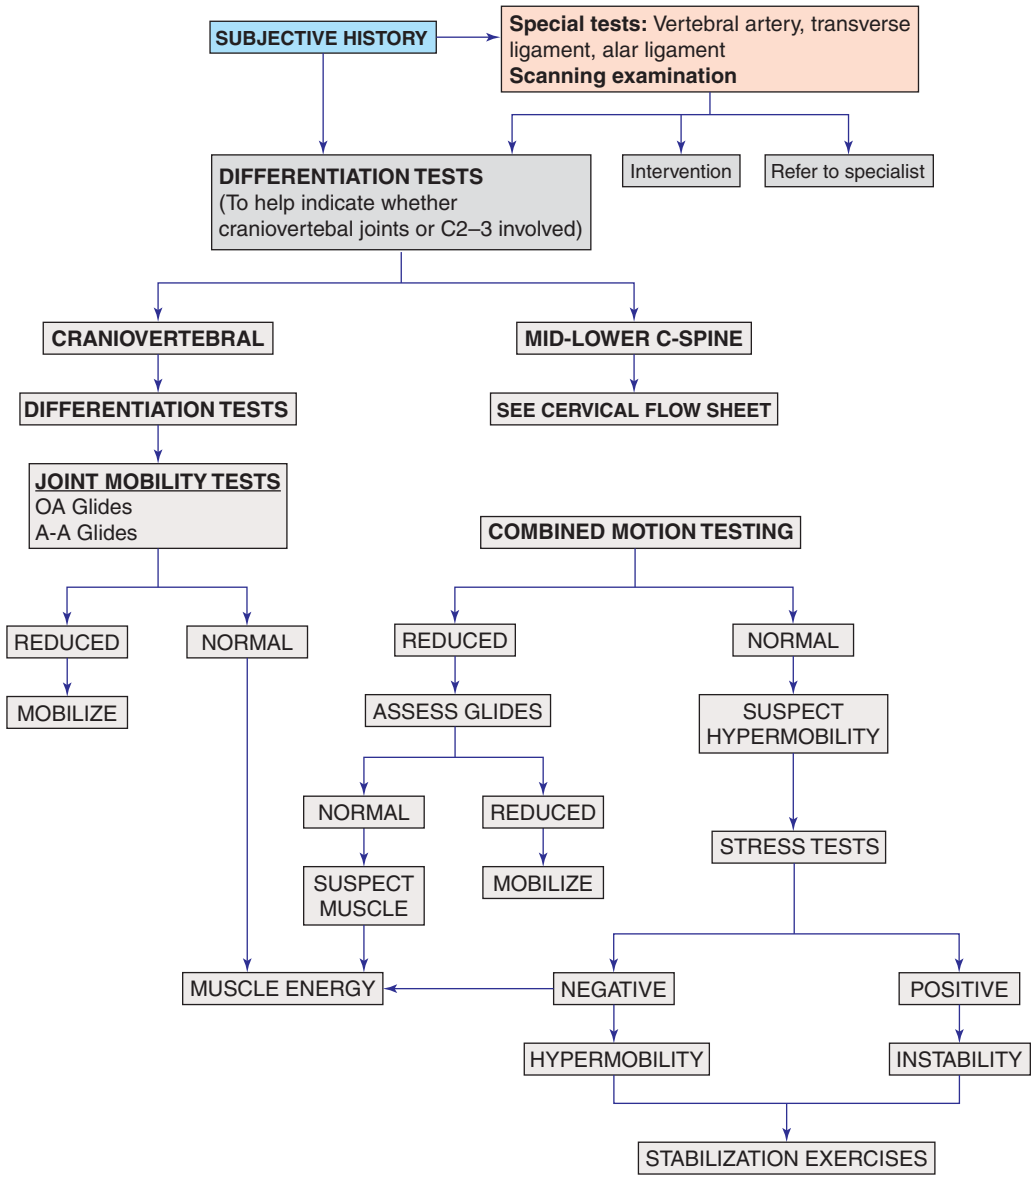

FIGURE 23-4 Craniovertebral examination algorithm.

Systems Review

The craniovertebral region houses many vital structures. These include the spinal cord, the vertebral artery, and the brain stem. It is extremely important for the clinician to approach this area with caution and to rule out the presence of serious pathology. Craniovertebral and cranial dysfunction can be responsible for a number of signs and symptoms that may be benign or may indicate the presence of serious pathology (Table 23-2).

Due to the proximity of the cranial structures, the clinician should develop the habit of quickly screening patients with neck and head pain for their ability to orient to time, place, and name; concentrate; reason and process information; make judgments; communicate effectively; and recall information. Obtaining this information needs to be done in a sensitive manner. Asking questions as to whether the patients know their own name and what day it is may be considered inappropriate by some patients. Most of the concerns about the patient's mental status can be addressed through general conversation, or as part of the history. Perhaps surprisingly, the incidence of neurologic involvement in upper cervical spine injury is relatively low (18–26%).[67] This may be because, significant cord damage in the upper cervical spine is usually fatal secondary to respiratory arrest.[7]

When compression of the spinal cord is suspected, a thorough neurologic examination should be performed. If confirmed, the appropriate medical services should be contacted. The cranial nerves should be assessed, particularly if there are complaints about vision or the patient appears to have problems with speech or swallowing. Patients with referred pain in the region of the trigeminal nerve commonly have an underlying disorder of the upper cervical spine, such as A-A instability caused by RA.[63,68] As described in Chapter 3, the various cranial nerve tests can be performed in approximately 5 minutes with practice.

Tests and Measures

The examination is terminated if any serious signs and symptoms are produced.

TABLE 23-2 Examination Findings and the Possible Conditions Causing Them

Findings	Possible Condition
Dizziness	Upper cervical impairment, vertebrobasilar ischemia, and craniovertebral ligament tear; also may be relatively benign
Quadrilateral paresthesia	Cord compression and vertebrobasilar ischemia
Bilateral upper limb paresthesia	Cord compression and vertebrobasilar ischemia
Hyperreflexia	Cord compression and vertebrobasilar ischemia
Babinski or clonus sign	Cord compression and vertebrobasilar ischemia
Consistent swallow on transverse ligament stress tests	Instability, retropharyngeal hematoma, and rheumatoid arthritis
Nontraumatic capsular pattern	Rheumatoid arthritis, ankylosing spondylitis, and neoplasm
Arm pain lasting >6–9 mo	Neoplasm
Persistent root pain <30 y	Neoplasm
Radicular pain with coughing	Neoplasm
Pain worsening after 1 mo	Neoplasm
>1 level involved	Neoplasm
Paralysis	Neoplasm or neurologic disease
Trunk and limb paresthesia	Neoplasm
Bilateral root signs and symptoms	Neoplasm
Nontraumatic strong spasm	Neoplasm
Nontraumatic strong pain in elderly patient	Neoplasm
Signs worse than symptoms	Neoplasm
Radial deviator weakness	Neoplasm
Thumb flexor weakness	Neoplasm
Hand intrinsic weakness or atrophy	Neoplasm, thoracic outlet syndrome, and carpal tunnel syndrome
Horner's syndrome	Superior sulcus tumor, breast cancer, cervical ganglion damage, and brain stem damage
Empty end-feel	Neoplasm
Severe post-traumatic capsular pattern	Fracture
Severe post-traumatic spasm	Fracture
Loss of ROM post-trauma	Fracture
Post-traumatic painful weakness	Fracture

Data from Meadows J. *Orthopaedic Differential Diagnosis in Physical Therapy*. New York: McGraw-Hill; 1999.
ROM, range of motion.

Observation

The patient is observed in the sagittal, coronal, and transverse planes.

Sagittal Plane. Observing the status of the cervical curve and the relative position of the patient's chin to the chest helps the clinician to assess postural alignment in the sagittal plane. A popular view among clinicians is that habitual adoption of extreme cervical posture may account for symptoms of pain and dysfunction arising from the head and neck area.[69] The argument is that alterations in spinal alignment may lead to changes in muscle activity and loading on the surrounding soft tissue and articular structures, which then predisposes patients to such complaints.[70,71] This argument has been supported in several studies, which have found a statistically significant correlation between the tendency to hold the head forward, relative to the true vertical in the so-called *forward head posture*, and symptoms of pain.[71,72] However, in other investigations, no such correlation has been confirmed.[73,74]

Tucking or elevation of the chin in the presence of a normal cervical curve may indicate craniovertebral dysfunction.[75]

The ears are observed for the presence of asymmetry in size, shape, or color. The top of the ear is normally in line with the eyebrow.

Coronal Plane. Alignment in the coronal plane is assessed by observing the orientation of the head relative to the trunk and shoulders, the leveling of the mastoid processes, and the symmetry of the cervical soft tissues. The face is observed for any asymmetry or indications of bruising, puffiness, prominence, swelling, perspiration, or abnormal skin color. Any asymmetry in the relative size of the pupils of the eyes and the distance between the upper and lower lids is noted. Pupillary size differences can occur in normal individuals but initially should arouse concern, because an abnormal unilateral change in size may be caused by an autonomic dysfunction or a central nervous system lesion.[76] The superior lid should cover a portion of the iris but not the pupil itself, unless ptosis or drooping of the eyelid is present[76] (see Chap. 3).

Missing teeth should be accounted for as a loss of teeth may be a result of trauma, avulsion, or loosening.

Transverse Plane. Alignment in the transverse plane is assessed by observing the patient from behind and noting the orientation of the head. The orientation of the head is best observed by noting any asymmetry in the position of the mastoids, which can indicate whether the head is more rotated or tilted to one side, both of which may indicate a positional fault of the craniovertebral joints. Bruising around the mastoids or around the crown of the head (Battle's sign), with a history of trauma, may indicate the presence of a cranial vault injury, such as a basilar fracture. A low hairline may indicate a condition such as Klippel–Feil syndrome,[77] defined as a short neck with decreased cervical movement and low posterior hairline. Radiologically, patients with Klippel–Feil syndrome show a failure of cervical segmentation. The etiology is unclear, but the syndrome is believed to be caused by faulty segmentation of the mesodermal somites.[78] The syndrome appears to be heterogeneous, with environmental factors possibly contributing.[79] Autosomal dominant and recessive patterns of inheritance also have been reported.[80]

Active Range of Motion, Passive Overpressure, and Resistance

Short Neck Flexion. The clinician instructs the patient to place his or her chin on the surface of the throat. This motion simulates flexion at the craniovertebral joints. If this maneuver produces tingling in the feet or electric shock sensations down the neck (Lhermitte's sign), it is highly indicative of serious pathology. Although Lhermitte's sign is not a specific symptom, it is commonly encountered in patients with meningitis (see Chap. 5) and cervical spinal cord demyelination caused by multiple sclerosis.[81] The sign also has been found in many other conditions that cause a traumatic or compressive cervical myelopathy, such as cervical spondylosis, cervical instability, and epidural or subdural tumors.[82,83]

If the patient reports a pulling sensation during short neck flexion, the cervicothoracic junction may be at fault. Active short neck flexion tests cranial nerve XI and the C1 and C2 myotomes, as well as the patient's willingness to move. Placing the neck in short neck flexion places the short neck extensors (C1), which are innervated by the spinal accessory nerve, on stretch. The clinician applies overpressure and tests the short neck extensors by asking the patient to resist (Fig. 23-5). Positive findings with this test are severe pain, nausea, muscle spasm, or cord signs, the latter of which may indicate a dens fracture or a tumor and cause the examination to be terminated.[82] Thus, if a patient is able to perform short neck flexion, a cervical fracture or a transverse ligament compromise can be provisionally ruled out.

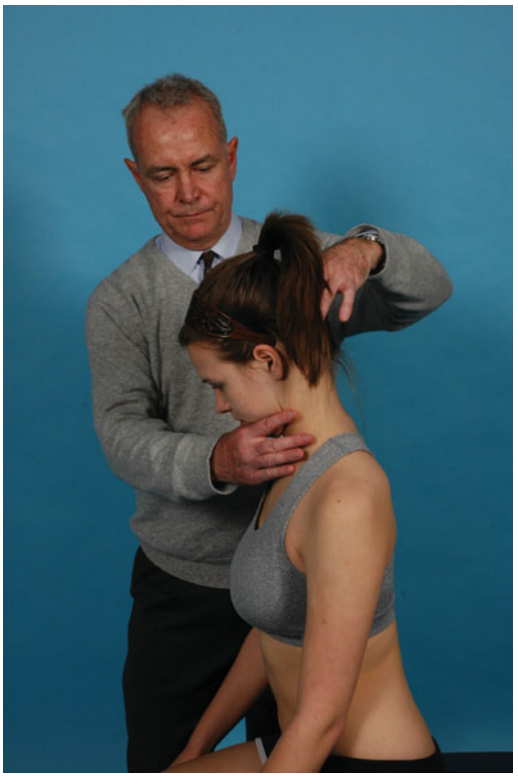

FIGURE 23-5 Short neck flexion with overpressure and resistance.

Short Neck Extension. The clinician instructs the patient to look upward by only lifting the chin. The patient extends the head on the neck and the clinician attempts to lift the occiput in the direction of the ceiling (Fig. 23-6). An inability to perform, or pain during, this motion (in the presence of normal motion in the other planes) may indicate significant tearing of the anterior cervical structures. If this test produces tingling in the feet, it is highly suggestive of compression to the spinal cord. This compression may occur because of "buckling" or ossification of the ligamentum flavum, with resultant loss of its elasticity.[84] A loss of balance or a drop attack with this maneuver would strongly suggest compromise of the vertebrobasilar system. A drop attack is defined as a loss of balance without a loss of consciousness (see Chap. 24). The short neck flexors (C1), which are innervated by the spinal accessory nerve, can be tested in this position by applying overpressure as though lifting the patient's chin toward the ceiling while the patient resists (see Fig. 23-6).

FIGURE 23-6 Short neck extension with overpressure and resistance.

CLINICAL PEARL

If the neck is unstable secondary to a dens fracture or a transverse ligament tear, the patient will be unable or unwilling to flex or extend the neck in the traditional manner, often because of severe muscle spasm.

Side Bending. The patient is asked to side bend their head around the appropriate axis (through the patient's nose). Side bending is included here for completeness. Much more a function of the lower cervical spine, side bending of the neck is nonetheless significantly decreased in cases of craniovertebral instability or articular fixation. It could be argued that, in the presence of serious ligamentous disruption due to a subluxation of the atlas under the occiput, this motion may provoke symptoms, but it is likely that such a significant incidence of instability would be detected earlier in the examination.[85] The side-bending motions that do occur in the craniovertebral joints are essentially conjunct motions, so the results from this test are unlikely to provide much in the way of additional information.

Rotation. Neck and head rotation could be considered as the functional motion of the craniovertebral joints. Thus, if the patient's symptoms and loss of motion are not reproduced with active rotation, it is doubtful that damage to tissues making up the craniovertebral joints is significant or even present. The patient is asked to perform active neck rotation. An inability to move any amount in either direction is potentially a very serious sign, as it could indicate the presence of a dens fracture or a C1–2 dislocation–fracture. Every measure must be taken to determine the cause of this inability to move. In cases of a suspected fracture or severe instability, the patient should be placed in a cervical collar and the physician immediately notified. In addition to the presence of a fracture, some of the other serious conditions that can be provoked by cervical rotation include vertebral artery compromise—cervical rotation is the most likely (single) motion to reproduce signs or symptoms of vertebral artery compromise (see Chap. 24).[82,86–88]

The findings from the cervical rotation tests may also afford the clinician some information with regard to a biomechanical lesion of the craniovertebral joints:

- A loss of rotation associated with pain and a history of recent trauma. This could indicate the presence of an acute/subacute, posttraumatic arthritis of the craniovertebral joints. Since it may also indicate a soft tissue injury, further testing would be required.
- A loss of rotation associated with pain and a history of chronic trauma. This finding could indicate a chronic painless hypomobility with an adaptive but painful ipsilateral hypermobility involving the craniovertebral joints (e.g., pain with right rotation could occur if the right O-A joint cannot flex and there is a hypermobility of the right A-A joint). It may also occur if the left O-A joint cannot extend. Again, further testing is needed to confirm this hypothesis.
- A loss of rotation range of motion associated with no pain, but with a history of chronic trauma. This finding, which could indicate a chronic, posttraumatic arthritis, is likely to be an incidental finding, since most patients seek help because of pain. However, depending on the extent of the loss of rotation, the patient may have become aware of a loss of function.
- Full rotation range of motion associated with pain and a history of chronic trauma. This could indicate a chronic fibrotic (painless) hypomobility with an adaptive but painful contralateral hypermobility (e.g., pain with right rotation could occur if the left O-A joint cannot flex and the right O-A joint develops a compensatory hypermobility).

Palpation

Objective palpation of this area is guided by a sound anatomic knowledge. Palpation usually proceeds layer by layer. It should be noted that asymmetric joint geometry is common in this region.[89] For spine palpation to be a valid indicator for manual techniques, the clinician applying it must first be able to differentiate between asymmetric motion caused by vertebral dysfunction and that caused by asymmetric joint anatomy.[89] However, examination of the skin overlying the spine has been found to be very helpful, because certain skin changes in a particular location may point in the direction of a dysfunctional spinal area.[90] The skin is assessed for its thickness, moisture, and ease of displacement in all directions. Abnormal autonomic skin reactions, such as erythematous changes, increased sweat production, and pain that can be induced with minimal palpatory pressure, may indicate a segmental dysfunction.[91]

Palpation may be started at that area indicated by the patient as painful. These painful sites must be correctly localized. The bony landmarks of this region that should be routinely palpated include the occiput, mastoid, atlas, and axis.

Occiput. The clinician locates the external occipital protuberance, which is the most prominent bony structure at the occiput in the midline. By following the external occipital protuberance laterally, the clinician can locate the superior nuchal line. The semispinalis capitis muscle is located about $1^1/_2$ fingerbreadths below the superior nuchal line.[91]

Mastoid. The mastoid processes are located behind each ear. Once this structure is located, the clinician moves the fingers inferiorly toward the tip of the mastoid process. Starting from the medial tip of the mastoid process, the palpating finger is moved superiorly to the upper pole of the mastoid sulcus, an important area in the examination of the irritation zones of the occiput and C1.[91]

Atlas. By placing the palpating fingers between the mastoid process and the descending ramus of the mandible, the clinician can locate the transverse process of the atlas. The inferior oblique and the superior oblique both have attachments to this site.

Axis. The spinous process of C2 is the first prominent bony landmark that is accessible to palpation below the external occipital protuberance of the occiput. The spinous process of C2 serves as the origin of the inferior oblique muscle and the rectus capitis posterior major muscle.

Passive Physiologic Mobility Testing of the Occiput, Atlas, and Axis

O-A Joint. When mobility testing this joint, the first point to remember is that the joint is capable of both flexion and extension, and that side bending and rotation also can occur, albeit slight. The second point to keep in mind is that the arthrokinematics of this joint are the reverse of those occurring in the other zygapophyseal joints and that they occur in a different plane (horizontal). The joint mobility of the O-A joint can be assessed in sitting **VIDEO** or in supine.

With the patient supine, the head is extended around the axis for the O-A joint **VIDEO**. The head is then side bent left and right. As the side bending is performed, a gradual translational force is applied in the direction opposite to the side bending. The range of movement of the side bending is assessed from side to side as is the end-feel of the translation. This procedure is then repeated for flexion.

During extension of the O-A joint (Fig. 23-7), the occipital condyles glide anteriorly to the limit of their symmetric extension range. During left side bending and right translation in extension, the coupled right rotation is produced. This rotation causes the right occipital condyle to return toward a neutral position, while the left condyle advances toward the extension barrier. If left side bending in extension is limited, then the limiting factor is on the left joint of the segment (ipsilateral to the side bending), which is preventing the advance of the condyle into its normal position. Thus, extension and right translation test the anterior glide of the left O-A joint, whereas extension and left translation stress the anterior glide of the right O-A joint (Table 23-3).

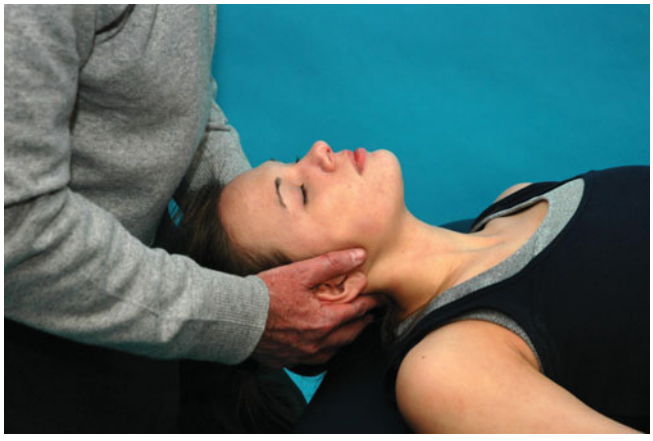

FIGURE 23-7 Passive mobility testing of O-A in extension.

TABLE 23-3 Movement Restrictions of the Craniovertebral Joints and Their Probable Causes

Movement Restriction	Probable Causes
Flexion and right side bending	Left flexion hypomobility Extensor muscle tightness Posterior capsular adhesions Left subluxation (into extension)
Extension and right side bending	Right extension hypomobility Left flexor muscle tightness Anterior capsular adhesions Right subluxation (into flexion)
Flexion and right side-bending motion greater than extension and left side bending	Left capsular pattern (arthritis and arthrosis)
Flexion and right side bending equal to extension and left side bending	Left arthrofibrosis (very hard capsular end-feel)
Right-side flexion in flexion and extension	Probably an anomaly

During flexion of the O-A joint, the occipital condyles glide posteriorly (Fig. 23-8). The right rotation associated with left side bending causes the left condyle to move away from the flexion barrier toward the neutral position, while the right condyle is moved posteriorly further into the flexion barrier. Thus, flexion and translation to the right tests the posterior glide of the right O-A joint, whereas flexion and left rotation tests the posterior glide of the left O-A joint (see Table 23-3).

It is apparent that during these tests, the arthrokinematic and osteokinematic movements are tested simultaneously; thus, the end-feel must be used to determine the cause of the restriction. The following patterns of impairment are more or less commonly seen, and the causes of the impairments can be deduced. However, it must be remembered that deductions are only of value if the resultant intervention is successful.[60]

- A patient who has a subluxation into flexion (loss of anterior glide) on the right O-A joint should demonstrate decreased extension, decreased right side bending and left rotation, and a jammed end-feel with translation to the left.
- A patient with a periarticular restriction of the left O-A joint into flexion (loss of posterior glide) should demonstrate decreased flexion, decreased right side bending and left rotation, and a capsular end-feel with translation to the left.

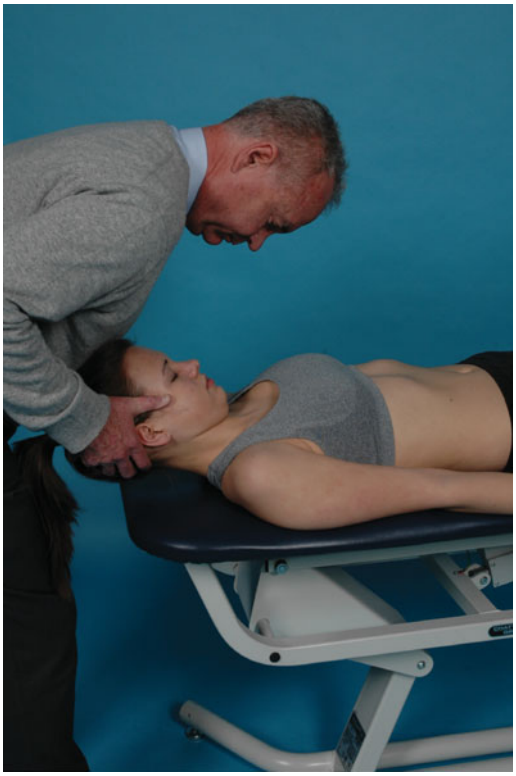

FIGURE 23-8 Passive mobility testing of O-A in flexion.

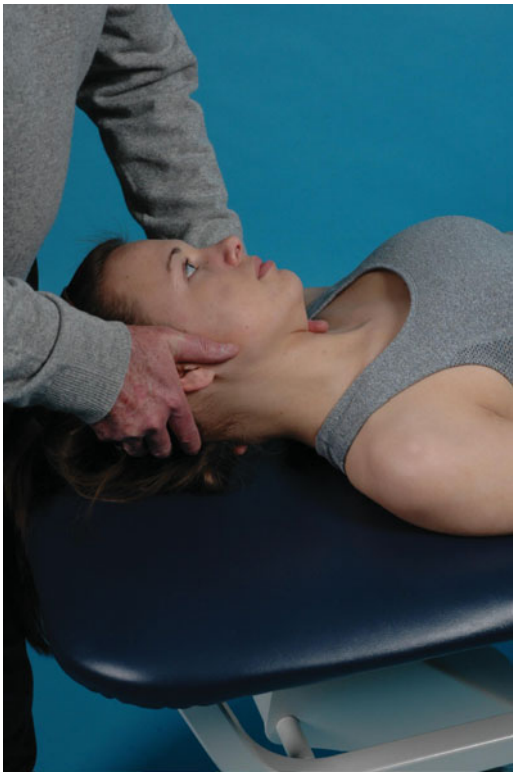

FIGURE 23-9 Passive mobility testing of A-A rotation in supine.

- A patient with a fibrous adhesion of the right O-A joint (loss of anterior and posterior guide) should demonstrate decreased extension and right side bending and decreased flexion and left side bending, with a hard capsular end-feel at both extremes.
- With motion testing, a decreased flexion and right side bending with a pathomechanic end-feel indicates a left O-A joint being subluxed into extension.
- With motion testing, a decreased extension and right side-bending limitation indicates a capsular pattern of the right O-A joint. A decreased extension and left side-bending limitation, with a spasmodic end-feel (flexion with greater range), indicates traumatic arthritis of the left O-A joint.
- A decreased right translation of the O-A in flexion may indicate a right posterior O-A joint dysfunction or an impaired or adaptively shortened right superior oblique muscle.

A-A Joint. There are a number of methods to assess the passive physiologic mobility of the A-A joint **VIDEO**. The most common method described in many texts involves the patient lying supine and the clinician passively applying full cervical flexion, and then introducing cervical rotation. The problem with this technique is that it relies on the fact that the mid-to-lower cervical spine will be locked with the flexion. Because the neck is often prevented from further flexion when the chin meets the sternum, the clinician has no way of knowing whether full cervical flexion has occurred. Thus, some of the subsequent rotation may be attributed to a combination of cervical spine and A-A motion. This assumption may not be important with asymmetric lesions but can result in false-negative findings with symmetric lesions.

A better method of assessment involves the use of cervical side bending. With the patient positioned in supine, the clinician side bends the head and neck around the craniovertebral axis and then rotates the head in the direction opposite to the side bending (Fig. 23-9). The clinician assesses the amount of range available and then assesses the other side.

CLINICAL PEARL

In a study by Smedmark and colleagues,[92] passive intervertebral motion of the cervical spine was assessed independently by two physical therapists. The therapists had equal backgrounds concerning education and clinical experience. Sixty-one patients seeking care for cervical problems at a private clinic were included in the study where three segments of the cervical spine and the mobility of the first rib were graded as stiff or not stiff. Data were analyzed by percentage agreement and kappa coefficient. Results demonstrated interexaminer reliability of between 70 and 87% and kappa coefficients ranging between 0.28 and 0.43 considered to be only "fair to moderate."

In a similar study by Pool and colleagues,[93] which assessed the interexaminer reproducibility of physical examination of the cervical spine, two physical therapists independently judged the general mobility and intersegmental mobility (segments C0–T2) of the neck and the pain that was provoked. Agreement for general mobility showed kappa between 0.05 and 0.61, and for the intersegmental mobility, it showed kappa values between −0.09 and 0.63. Agreement for provoked neck pain within one point of an 11-point numerical rating scale varied between 46.9 and 65.7% for general mobility and between 40.7 and 75.0% for

intersegmental mobility. The ICCs varied between 0.36 and 0.71 for general mobility and between 0.22 and 0.80 for intersegmental mobility. The study concluded that despite the use of a standardized protocol to assess general mobility and intersegmental mobility of the cervical spine, it is difficult to achieve reasonable agreement and reliability between two examiners. Likewise, the patients were not able to score the same level of provoked pain in two assessments with an interval of 15 minutes.

Combined Motion Testing

Flexion and extension at the O-A joints involve a posterior and anterior gliding of the occipital condyles, respectively. The same gliding (although reciprocal in opposing facets) is utilized in rotation. At the A-A joint, flexion and extension primarily involve a "rolling" action of the condyles, with an insignificant amount of gliding. Therefore, craniovertebral flexion and extension will have a minimal effect on A-A rotation.[94] Thus, if a symptom or range of motion is drastically altered by craniovertebral flexion or extension, an assumption could be made that the dysfunction is at the O-A joint.[94] For example, if the right occipital condyle cannot glide posteriorly, the right joint will be unable to flex or to permit rotation to the right, as both of these motions involve a posterior glide at the right O-A joint. In the combined motion tests, the right rotation restriction will be more evident when combined with craniovertebral flexion but will be less evident when combined with craniovertebral extension.

The findings from the combined motion tests can be used to determine which joint glide is to be assessed. For example, if it was determined in the combined motion testing that the right O-A joint is restricted or painful with flexion (implicating the posterior glide), the O-A joint is positioned and assessed in its extreme of flexion and right rotation (the two motions associated with a posterior glide of the right O-A joint).

Linear Segmental Stress Testing

The craniovertebral region demonstrates a high degree of mobility, but little stability, with the ligaments affording little protection during a high-velocity injury. Instability of this region can result from a number of causes:

- Trauma (especially a hyperflexion injury to the neck).
- RA, psoriatic arthritis, or ankylosing spondylitis. Nontraumatic hypermobility or frank instability of the O-A joint has been reported in association with RA.[95]
- Corticosteroid use. Prolonged exposure to this class of drug can produce a softening of the dens and transverse ligament by deteriorating the Sharpey fibers, which attach the ligament to the bone. Steroid use also promotes osteoporosis, predisposing bones to fracture.
- Recurrent upper respiratory tract infections or chronic sore throats in children. Grisel's syndrome[96] is a spontaneous A-A dislocation, affecting children between the ages of 6 and 12 years. The outstanding symptom is a spontaneously arising torticollis. The most likely etiology seems to be an inflammation of the retropharyngeal space caused by upper respiratory tract infections or by adenotonsillectomy and producing pharyngeal hyperemia and bone absorption.
- Congenital malformation. Nontraumatic hypermobility or frank instability of the O-A joint has been reported in association with congenital bony malformations.[97]
- Down's syndrome. Nontraumatic hypermobility or frank instability of the O-A joint has been reported in children and adolescents with Down's syndrome.[98,99]
- Immature development. Patients younger than 12 years of age often have an immature or absent dens (see later).
- Osteoporosis.

It must be remembered that the A-A joint complex consists of three joints. The median joint, although it has no weight-bearing function, is extremely important in maintaining stability, while at the same time facilitating motion within this joint complex. Fielding and colleagues[100] found that the stability of the A-A joint depends greatly on the ligamentous structures and on a normal and intact dens. Occasionally, the integrity of the dens can be compromised because of:

1. Anomalies of the dens, including:
   a. Os odontoideum. This is a condition in which the IVD between the developing bodies of axis and atlas does not ossify.
   b. Congenital absence of the dens.
   c. An underdeveloped dens whose lack of height renders it unchecked by the transverse ligament. The body of the dens is not of sufficient size to be retained in the osseoligamentous ring of the atlas until a child is approximately 12 years old. Great care and justification are needed with any craniovertebral mobilization or manipulative technique with this age group.
2. Pathologies affecting the dens, including:
   a. Demineralization or resorption of the dens, such as occurs with Grisel's syndrome[96] or RA.
   b. An old, undisplaced fracture (especially of the dens), which originally escaped diagnosis and subsequently formed a pseudoarthrosis.

Indications for Stability Testing. The following findings are considered to be indications to perform stability or stress tests of the craniovertebral region[82]:

- History of neck trauma or any of the causes of instability listed previously.
- Patient report of neck instability usually described as the head feeling heavy.
- Presence of the following signs and symptoms:
  - A lump in the throat
  - Lip paresthesia
  - Nausea or vomiting
  - Severe headache and muscle spasm
  - Dizziness

The patient is positioned in supine to remove any muscular influences. If the patient is unable to lie down, the clinician may need to reconsider the appropriateness of performing these tests.

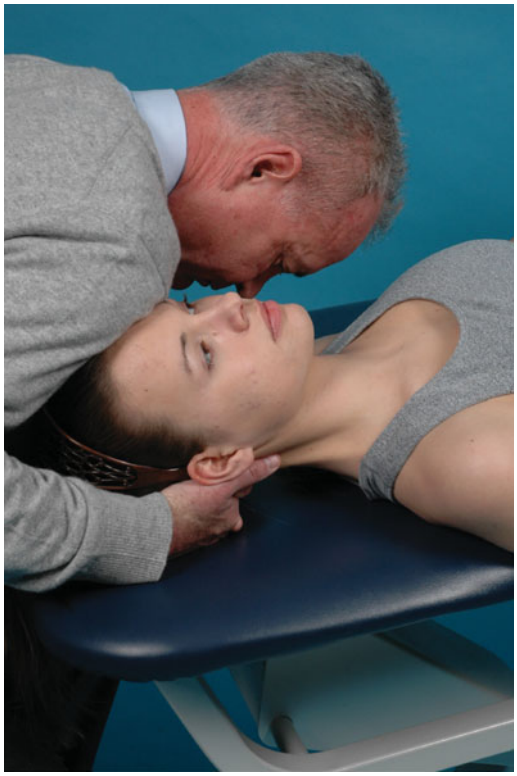

FIGURE 23-10 Longitudinal stability testing.

Longitudinal Stability. General traction is applied to the entire cervical region. If this maneuver does not reproduce the signs or symptoms, C2 is stabilized so that the traction force may be directed at the craniovertebral region (Fig. 23-10). The diagnostic value of this test is as yet unknown.

Anterior Shear: Transverse Ligament. The patient is positioned in supine, with his or her head cradled in the clinician's hands. The clinician locates the anterior arches of C2 by moving around the vertebra from the back to the front using the thumbs. Once the arches are located, the clinician pushes down on the anterior arches of C2 with the thumbs toward the table, while the patient's occiput and C1, cupped in the clinician's hands, is lifted, keeping the head parallel to the ceiling but in slight flexion[82] (Fig. 23-11) **VIDEO**. The patient is instructed to count backward aloud. The position is held for approximately 15 seconds or until an end-feel is perceived. The diagnostic value of this test is as yet unknown.

Sharp–Purser Test. This test was designed originally to test the sagittal stability of the A-A segment in patients with RA, because a number of pathologic conditions can affect the stability of the osseoligamentous ring of the median joints of this segment in this patient population. These changes result in degeneration and thinning of the articular cartilage between the odontoid process and the anterior arch of the atlas, or, occasionally, in a softening of the dens.

The aim of the test was to determine whether the instability was significant enough to provoke central nervous system's signs or symptoms. Uitvlugt and Indenbaum[101] assessed the validity of the Sharp–Purser test in 123 outpatients with RA. The study findings indicated a predictive value of 85% and a high specificity of 96%. The sensitivity was 88% when subluxation was greater than 4 mm.[101] The authors concluded that the Sharp–Purser test is a useful clinical examination to diagnose A-A instability in the RA population.[101]

However, the original test was poorly defined and only involved upper cervical flexion. Hence, a modified version was introduced which is described.

The patient is positioned in sitting. The patient is asked to segmentally flex the head around a craniovertebral axis (short neck flexion) and relate any signs or symptoms that this might evoke to the clinician. In addition, a positive test may be indicated by the patient hearing or feeling a clunk. Local symptoms, such as soreness, are ignored for the purposes of evaluating the test. If no serious signs or symptoms are provoked, the clinician stabilizes C2 posteriorly with one hand and applies a posteriorly oriented force to the forehead of the patient (Fig. 23-12) **VIDEO**.

In the presence of a positive test, a provisional assumption is made that the symptoms are caused by excessive translation of the atlas, compromising one or more of the sensitive structures listed previously, and the physical examination is terminated. No intervention should be attempted other than the issuing of a cervical collar to prevent craniovertebral flexion and an immediate referral to the patient's physician.

Coronal Stability: Alar Ligament. Rotation and side bending tighten the contralateral alar (e.g., rotation or side bending to the right tightens the left alar), whereas flexion typically tightens both alar ligaments.

FIGURE 23-11 Transverse ligament test.

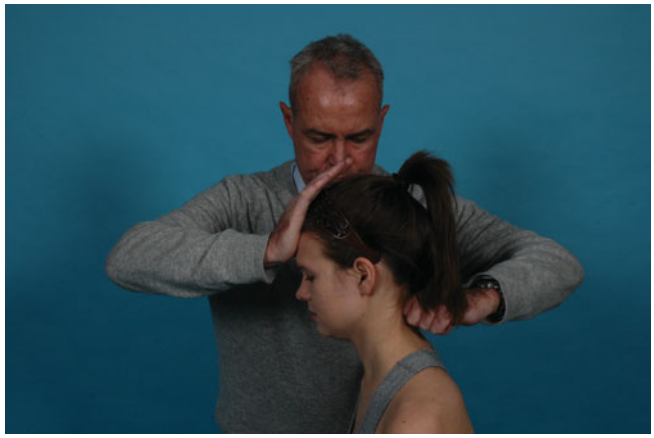

FIGURE 23-12 Modified Sharp–Purser test.

FIGURE 23-13 Alar ligament test in sitting.

The posterior aspect of the transverse process of C2 is palpated with one hand, while the patient's head is side bent or rotated (Fig. 23-13). **VIDEO**. This is a test of immediacy. If the C2 transverse process does not move as soon as the head begins to rotate, laxity of the alar ligament should be suspected. To confirm the findings in this test, the point of rotation is maintained, as the patient's head is cradled by the clinician (Fig. 23-14), and while monitoring the motion at the C2 segment, the clinician introduces side bending through the craniovertebral joints to slacken the alar ligament. Further rotation should now be possible. The diagnostic value of this test is as yet unknown.

Transverse Shear.[82] Transverse shearing of the craniovertebral joints is performed with the patient supine. The clinician stabilizes the mastoid, and C1 is moved in a transverse direction, using the soft part of the metacarpophalangeal joint of the index finger (Fig. 23-15). The test is repeated by stabilizing C1 and translating the mastoid.

C1 and C2 can be tested similarly. The soft aspect of each second metacarpal head is placed on the opposite transverse processes and laminae of C1 and C2, with the palms facing each other. The clinician stabilizes C1 and then attempts to move C2 transversely using the soft part of metacarpals (Fig. 23-16). No movement should be felt. The diagnostic value of this test is as yet unknown.

FIGURE 23-16 Transverse shear of A-A joint.

Neurologic Examination

The neurologic examination is performed to assess the normal conduction of the central and peripheral nervous systems. The presence of neurologic symptoms deserves special attention. Many of the symptoms that occur in the upper limb have their origins in the neck. The patient with neck trauma can report seemingly bizarre symptoms, but these need to be heeded until the clinician can rule out serious pathology. Cervical myelopathy, involving an injury to the spinal cord itself, is associated with multisegmental paresthesias, upper motor neuron (UMN) signs and symptoms such as spasticity, hyperreflexia, visual and balance disturbances, ataxia, and sudden changes in bowel and bladder function. The presence of any UMN sign or symptom requires an immediate medical referral.

In addition to the muscle stretch (deep tendon) reflexes and sensory tests outlined in Chapter 25, the clinician should perform the spinal cord reflexes of Babinski and Hoffman (see Chap. 3). Studies by Boden and colleagues[102] and Sung and Wang have demonstrated that the Hoffman test is the most sensitive reflex test in the detection of cervical myelopathy.[103]

Imaging Studies

The standard, initial cervical spine radiographic series in trauma patients includes a cross-table lateral view, an

anteroposterior view, and an open-mouth view, the latter of which is used to help rule out a fracture of the dens (see Chap. 7).[7] The usefulness of the anteroposterior view has been questioned because it provides little additional information.[104] Although this three-view screening series can detect 65–95% of axis injuries,[105,106] the C2 vertebra often is obscured by overlying bony maxillary, mandibular, and dental structures; therefore, C2 fractures may be missed.[7] The clinician needs to be aware of the limitations of plain radiographs, as problems exist with both specificity and sensitivity. However, radiographs can provide a gross assessment of the severity of the degenerative changes of the spine.

Thin-section CT is the best study for evaluating C2 bony fractures.[107] Sagittal reconstruction of CT images is important because axial images may not detect a transverse odontoid fracture.[7] Although CT is excellent in evaluating bony injuries, it can miss soft tissue and significant ligamentous injuries.[7] Recently, therefore, dynamic flexion/extension lateral fluoroscopic evaluation has been advocated in polytrauma patients to identify occult ligamentous instabilities and confirm that the cervical spine is uninjured.[108] As with any diagnostic study, the findings must be correlated with the history and physical examination.

INTERVENTION STRATEGIES

The gamut of musculoskeletal injury to the craniovertebral region of the spine ranges from a simple strain (muscle) or sprain (ligament) to injuries of the bone and neurovascular injuries. The most common injuries seen clinically are muscle strains and postural dysfunctions.

Muscle strains are common in the cervical spine because most of the cervical muscles attach via myofascial tissue inserting into the periosteum rather than by the more resilient tendon.[109] The severity of the strain is dependent on the magnitude of forces involved. If the force is sufficient, both the muscle and the associated joint become involved. In an abnormal spine, the forces needed to cause injury are reduced. Repetitive microtrauma is a common cause of craniovertebral dysfunction.

Postural dysfunctions of this region, particularly the forward head posture (see Chap. 25), usually manifest themselves at the O-A joint, resulting in fixed capital extension and a loss of O-A flexion. Patients with postural dysfunctions may develop secondary myofascial trigger points (MTrPs) and myofascial pain syndromes. In postural dysfunctions and trauma-related injuries, other joints and regions may be involved and require further investigation.

Pain, tenderness, active range of motion restrictions, muscle imbalances, and segmental motion restrictions are common findings with craniovertebral dysfunction.

The structure at fault should determine the intervention[110]:

- If ligamentous tissue damage or an intra-articular lesion is suspected, the safest initial approach would be to help in unloading the joint and controlling the extremes of motion with a soft collar for a 7–10-day period.
- Within the patient's pain tolerance, contractile lesions should be treated aggressively once the acute phase has subsided, with the emphasis on regaining maximal muscle length.[110]

The techniques to increase joint mobility and soft tissue extensibility are described later, under "Therapeutic Techniques" section.

A correct diagnosis can usually be accomplished through detailed history and a comprehensive examination. Confirmation of the correct diagnosis can be made with an assessment of the response of the patient to the initial rehabilitation program. The intervention for the craniovertebral region may commence when the possibility of serious injury including fracture, dislocation, or injury to the spinal cord and vertebral artery have been ruled out.

Acute Phase

The goals of this phase include

- reducing pain, inflammation, and muscle spasm;
- reestablishing a nonpainful range of motion;
- improving neuromuscular postural control;
- retarding muscle atrophy;
- promotion of healing.

Various electrotherapeutic modalities and physical agents may be used during the acute phase to modulate pain and to decrease inflammation and muscle spasm (see Chap. 8). Therapeutic cold and electrical stimulation may be used for 48–72 hours. The cryotherapy is continued at home. A transcutaneous electrical nerve stimulation (TENS) unit may be prescribed to help control pain and encourage range of motion. Joint protection may be appropriate. In such cases, a soft or semirigid cervical collar may be prescribed for 7–10 days to reduce muscle guarding (see Chap. 25). Nonsteroidal anti-inflammatory drugs (NSAIDs) often are prescribed for 2–3 weeks to help decrease inflammation and to control pain, thereby increasing the potential for an early return to function. Bed rest, along with analgesics and muscle relaxants for no more than 2–3 days, is prescribed for patients with a severe injury. However, in less severe cases, bed rest has not been shown to improve recovery and, compared with mobilization or patient education, rest tends to prolong symptoms.[111,112]

The patient also is taught how to find the neutral position for the upper cervical spine. The neutral position is defined as the least painful position that minimizes mechanical stresses.

Range of motion exercises are initiated as early as possible, based on patient tolerance, to prevent hypomobility. Neck flexion and rotation exercises usually are performed first. Extension and side-bending exercises are introduced based on the response of the patient to the flexion and rotation exercises. The rotation and side-bending exercises are performed in the supine position and then progressed to weight bearing. All of the exercises should be performed in the pain-free range.

Upper extremity range of motion and strengthening exercises should also be introduced to promote early integration of the entire upper kinetic chain. Important muscles to include are the rhomboids, middle and lower

trapezius, latissimus dorsi, serratus anterior, and deltoid. In addition, the muscles of the rotator cuff should be strengthened.

Gentle manual techniques (see "Therapeutic Techniques" section later), such as sustained or rhythmic specific traction (grade I or II) mobilizations and massage, may also be used. As the patient progresses, muscle stretching may be introduced. Manual techniques can have a mechanical effect on joint mobility and soft tissue extensibility. In addition, these techniques can have beneficial neurophysiologic effects, which can help alleviate pain and muscle spasm. Self-stretching and self-mobilization techniques are taught to the patient at the earliest and appropriate opportunity (see "Therapeutic Techniques" section later).

Active joint protection techniques may be part of the acute phase. Joint protection exercises work by supporting the joint and reducing the applied stresses. Joint protection exercises include cervical stabilization exercises. These exercises initially are performed in single planes and in the neutral position, using submaximal isometric contractions. As with the range of motion exercises, it is recommended that these exercises be performed initially in the supine position, and later, in sitting, as tolerance increases. As the pain-free ranges increase, the exercises are performed throughout the newly attained pain-free ranges.

Aerobic conditioning must also be included as part of the comprehensive rehabilitation program. A stationary bike, tread-mill, or a stair-stepping machine can be used.

The patient is advanced to the functional phase when

- the pain has significantly decreased so that there is minimal pain with activities of daily living;
- there is significant improvement in the pain-free ranges of motion.

Functional Phase

The duration of this phase can vary tremendously and depends on several factors:

- Severity of the injury.
- Healing capacity of the patient.
- How the condition was managed during the acute phase.
- Level of patient involvement in the rehabilitation program.

The goals of this phase are to

- significantly reduce or completely resolve the patient's pain;
- restore full and pain-free range of motion;
- fully integrate the entire upper kinetic chain;
- restore full cervical and upper quadrant strength and neuromuscular control.

During this phase, the range of motion exercises are continued until maximum range of motion is attained. The strengthening program is progressed from submaximal isometrics in single planes to maximal isometrics in single planes. Then the patient is progressed to isometrics in combined motions (flexion and side bending and extension and side bending). The strength training is then progressed to concentric and eccentric exercises in single planes, using elastic tubing, pulleys, or isolation exercises. Proprioceptive neuromuscular facilitation patterns are introduced when appropriate. Elastic tubing is issued to the patient to allow training at home.

For progression to return to play, the athlete should demonstrate

- normal and pain-free single-plane and multiplane range of motion;
- normal cervical, cervicothoracic, glenohumeral, and scapulothoracic strength;
- normal flexibility of cervical, cervicoscapular, and cervicothoracic musculature.

Return to sport activities should be designed to mimic the sport as closely as possible. The goal should be to improve the balance, power, and endurance of the cervical, cervicothoracic, glenohumeral, and scapulothoracic muscle groups and force couples.

Pattern 4D: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Connective Tissue Dysfunction

Transverse Ligament Injuries

Injuries to the transverse ligament are classified as follows[49,58]:

- ***Type I injuries.*** Disruptions of the substance of the transverse ligament, without an osseous component.
- ***Type II injuries.*** Fractures or avulsions involving the tubercle for insertion of the transverse ligament on the C1 lateral mass, without disruption of the ligament substance.

The medical literature supports the conclusion that a type I injury is incapable of healing without surgery for internal fixation but that most type II injuries heal when treated with an orthosis.[113]

Integration of Patterns 4B and 4D: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Secondary to Impaired Posture and Connective Tissue Dysfunction

Myofascial Pain Patterns

Myofascial pain syndromes are closely associated with tender areas that have come to be known as MTrPs (see Chap. 10). The term *myofascial trigger point* is a bit of a misnomer, because trigger points may also be cutaneous, ligamentous, periosteal, and fascial.[114] Dysfunctional joints also are associated with trigger points and tender attachment points.[115]

For a more detailed description of myofascial pain patterns in the upper quadrants, including their causes, signs and symptoms, and interventions, the reader is referred to the excellent book by Travell and Simons, *Myofascial Pain and Dysfunction: The Trigger Point Manual* (Volume 1, *The Upper Extremities*).[63]

The interventions for MTrPs are outlined in Chapter 10. These include stretch and spray, muscle stripping, massage therapy, myofascial release, ischemic compression, stretching, postural correction and education to eliminate any causative or perpetuating factors, electrotherapeutic and thermal modalities, cryotherapy, injections, and joint mobilizations.

Integration of Patterns 4D and 4E: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Secondary to Connective Tissue Dysfunction and Localized Inflammation

Osteoarthritis

Osteoarthrosis of the A-A joints, unrelated to trauma, is a rare cause of pain in the craniovertebral region and an even more uncommon cause of A-A instability. It could be argued that if osteoarthrosis of the lateral mass articulations progresses, the synovitis may gradually involve the ligamentous structures, thereby weakening them and rendering them prone to rupture.[116]

Inflammatory Arthritis

The greatest risk for complications with the spondyloarthropathies in the craniovertebral region occurs at the A-A joint, where there are two different synovial articulations: the two lateral facet joints and the articulation between the odontoid process of C2 and the anterior part of C1.[86] The transverse ligament is typically the weakest part of the complex in the presence of spondyloarthropathy.

Rheumatoid Arthritis. The most common inflammatory lesion found in the retro-odontoid space is RA, which induces abnormal proliferation of the synovial soft tissue (pannus) and frequently causes the destruction of the bony structure[117] (see Chap. 5).

Ankylosing Spondylitis. See Chapter 5.

Gout. See Chapter 5.

Craniovertebral Instability

There has been much controversy about defining and diagnosing spinal instability. Segmental spinal instability generally is defined as a greater displacement between vertebrae than that which occurs under physiologic load. Therefore, maximum flexion and extension radiographs usually are used to determine hypermobility between vertebrae. Craniovertebral instability frequently is encountered in inflammatory, neoplastic, degenerative, and traumatic disorders, in addition to congenital and developmental abnormalities. Clinically, instability appears as a subluxation or spinal deformity accompanied by severe pain or neurologic deficits. Several types of craniovertebral instability are recognized; among them are the following:

- ***Translational or rotary instability of C1.*** Translational anterior A-A instability is detected on lateral cervical radiographs as a widened, mobile atlantodental interval (ADI) of greater than 3 mm, caused by laxity or rupture of the transverse ligament or from an odontoid fracture.[118] Patients with congenital abnormalities of the odontoid process may develop chronic A-A subluxation. This leads to the formation of fibrous granulation tissue or a hypertrophic scar in the peri- or retro-odontoid epidural space, which is known as a "pseudotumor."[119] Chronic mechanical irritation associated with neck movement is speculated to be one of the causes of fibrous scar formation.[120] Posterior translation of C1 is also possible, but for this to occur, the dens or anterior arch of the atlas must be fractured or incompetent. Rotational A-A instability appears as asymmetric rotation of the C1 lateral masses on plain radiographs. Rotational subluxations that are irreducible, recurrent, or associated with transverse ligament disruption require surgery.[118] Patients with A-A subluxations exceeding 6 mm are at high risk for neurologic injury and sudden death and are, therefore, immediately considered for fusion.[121]
- ***O-A instability.*** O-A instability is demonstrated radiographically by movement between the dens and basion (the middle point on the anterior margin of the foramen magnum), by distraction or translation of the occipital condyles, or by vertical migration.[122]

Surgical stabilization is required to correct instability when conservative intervention has failed or when spontaneous healing with an orthosis, such as a halo brace, is unlikely.

Pattern 4F: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion, or Reflex Integrity, Secondary to Spinal Disorders

Peripheral Vertigo

Dizziness is the third most common complaint among outpatients, after chest pain and fatigue.[123] There are several types of dizziness, some benign and some serious, and it is important that the clinician be able to make the distinction. Among the causes of dizziness that must be carefully considered by the clinician examining the cervical spine are the central and peripheral (Table 23-4) causes of vertigo or dizziness (see Chap. 3).[124]

TABLE 23-4 Peripheral Vestibular Disorders

Vestibular neuritis
Ramsay Hunt syndrome
Labyrinthitis
Benign proximal positional vertigo
Ménière's disease
Acute peripheral vestibulopathy
Otosclerosis
Head trauma
Cerebellopontine angle tumor
Toxic vestibulopathies
Acoustic neuropathy
Perilymphatic fistula
Autoimmune disease of the inner ear

Data from Huijbregts P, Vidal P: Dizziness in orthopaedic physical therapy practice: classification and pathophysiology. *J Man Manip Ther* 12:199–214, 2004.

Vestibular Neuritis. Vestibular neuritis is thought to represent a reactivated dormant herpes infection in Scarpa's ganglion, within the superior division of the vestibular nerve, which innervates the anterior and horizontal SCC.[125,126]

Ramsay Hunt Syndrome. Ramsay Hunt syndrome is caused by varicella zoster and is a variant of vestibular neuritis, with multiple cranial nerves involved. This involvement results in facial paresis, tinnitus, hearing loss, and a vestibular defect.[127,128] It may also involve cranial nerves V, IX, and X.

Labyrinthitis. Infection of the labyrinth can be viral or bacterial. Acute labyrinthitis usually presents with severe vertigo, sudden or progressive hearing loss, nausea, vomiting, and fever. The condition lasts for 1–5 days, with subsequent resolution of complaints over a 2–3-week period.

Benign Paroxysmal Positional Vertigo. Benign paroxysmal positional vertigo (BPPV) is the most common peripheral vestibular disorder and the most common cause of dizziness in the elderly, with the incidence increasing with age.[127] Causes of BPPV (see also Chap. 3) include head trauma, vestibular neuritis, insult to the labyrinth, surgical stapedectomy, degeneration of the inner ear, and vestibular artery compromise. Two pathophysiological theories have been proposed to explain the etiology of BPPV: cupulolithiasis, and canalithiasis[129]:

- ***Cupulolithiasis.*** Sedimentous material, possibly macular otoconia, is released into the endolymphatic fluid in the SCC. This release of sedimentous material is hypothesized to result from trauma or degenerative changes. When the head is upright, this material will settle on the SCC cupula. Fixed deposits on the cupula increased density at the structure making the cupula, which previously had the same density as the surrounding endolymphatic fluid now sensitive to gravity and, therefore, head position.
- ***Canalithiasis.*** An accumulation of utricle debris (otoconia), which can move within the posterior SCC and stimulate the vestibular sense organ (cupula), causing vertigo and nystagmus.[127]

The name BPPV implies that this type of vertigo is positional in nature. However, it may be more correct to call BPPV a positioning-type vertigo[129] Symptom duration is brief: 30–60 seconds; hence, it is a positioning-type vertigo rather than positional-type vertigo, as occurs in vertebrobasilar insufficiency.[129]

The diagnosis usually is made solely on the basis of the history, although it is possible to confuse BPPV with orthostatic hypotension, another common cause of dizziness in the elderly. Whereas orthostatic hypotension causes dizziness when the patient sits up or stands, BPPV can occur in all positions, especially with changes in head position.

The side of the lesion is diagnosed with a maneuver similar to the Dix–Hallpike test (see Fig. 3-26 in Chap. 3). The intervention for posterior canal BPPV involves performing a canalith-repositioning maneuver, which is designed to return the otoconia from the SCC back to the macule of the utricle, from whence it can be reabsorbed.

Canalith-Repositioning Procedure.[127] The patient is seated on the end of the bed with his or her feet dangling. The clinician stands to the side of the patient, supporting the patient's head. The patient is moved into the Dix–Hallpike position, toward the side of the involved ear and maintained there for 20 seconds. Then the head is slowly rotated through moderate extension of the cervical spine toward the uninvolved side and maintained in the new position for 20 seconds. The patient is then rolled to a side-lying position, with the head being turned 45 degrees down (toward the floor) and maintained there for 20 seconds. While keeping the head turned toward the uninvolved side and the head pitched down, the patient slowly sits up.

To maintain the otoconia in the utricle following the maneuver, the patient is fitted with a soft collar and is instructed not to bend over, lie back, move the head up or down, or tilt the head to either side for the remainder of the day.

Ménière's Disease. This condition is characterized by paroxysmal vertigo, lasting minutes to days, accompanied by tinnitus, fluctuating low-frequency hearing loss, and a sensation of fullness in the ear.[129,130] Attacks are often associated with nausea and vomiting. Age at onset is usually between the ages of 20 and 50 years, and men are more often affected than women.[130] The underlying cause is thought to be an increase in the volume of the endolymphatic fluid in the membranous labyrinth, which displaces the inner ear structures with resultant signs and symptoms of horizontal or rotary nystagmus.[130]

Acute Peripheral Vestibulopathy. This condition is characterized by a sudden onset of vertigo, nausea, and vomiting, which last for up to 2 weeks and is not associated with hearing loss. Differential diagnosis from central disorders characterized by acute vertigo is imperative.[130]

Otosclerosis. The pathophysiologic mechanism behind otosclerosis is immobility of the stapes and resultant conductive hearing loss. Associated signs and symptoms include vertigo and nystagmus.

Head Trauma. Head trauma may result in labyrinth damage and subsequent vertigo.

Cerebellopontine Angle Tumor. This is a benign acoustic neuroma that can produce insidious unilateral sensorineural hearing loss, vertigo, and tinnitus.[130]

Toxic Vestibulopathies. Ingested alcohol differentially distributes between the cupula and the endolymphatic fluid: It initially diffuses preferentially into the cupula, decreasing its density relative to that of the endolymphatic fluid, thus rendering the peripheral vestibular apparatus unusually sensitive to gravity.[129] The vertigo and nystagmus are evident in the lateral recumbent position and are accentuated when the eyes are closed.[129,130] Aminoglycosides (streptomycin, gentamicin, and tobramycin), salicylates (aspirin and derivatives) quinine and quinidine, and various chemotherapeutic drugs have all been associated with producing vertigo, nausea, and vomiting, and occasionally nystagmus.

Acoustic Neuropathy. Conditions such as basilar meningitis, hypothyroidism, diabetes mellitus, and Paget's disease can lead to compression of the vestibulocochlear nerve.[129,130]

Perilymphatic Fistula. A rare cause of vertigo, which can result from head injury, barotrauma due to diving or flying, or a very forceful Valsalva maneuver, which results in a rapid loss of perilymphatic fluid.[129,130]

Autoimmune Disease of the Inner Ear. Diseases such as RA, Crohn's disease, or polyarthritis are often concurrently present with fluctuating deafness and recurrent vertigo.[129,130]

Vestibular Rehabilitation. The use of a custom-designed physical therapy program in the rehabilitation of patients with unilateral peripheral vestibular hypofunction is aimed at promoting vestibular compensation, promoting central habituation, and readjusting the vestibulo-ocular and vestibulospinal reflexes (see Chap. 3).[131,132]

Repetition of movements and positions that provoke dizziness and vertigo form the basic premise of habituation training, even though many of the exercises may initially increase the patient's symptoms. Several progressions have been devised (Table 23-5 and Box 23-1). Brown and colleagues, in a retrospective case series of 48 patients with central vestibular dysfunction noted improvement in both subjective and objective measures of balance after physical therapy intervention.[134] The treatment consisted of one or more of the following: balance and gait training, general strengthening and flexibility exercises, vestibular adaptation exercises, education in the use of assistive devices and safety awareness techniques to avoid falls, and utilization of varied senses, particularly somatosensation and vision, to aid in maintaining balance.[134]

Cervical Vertigo

Cervical vertigo is a diagnosis and a disorder that seems to be poorly understood, and yet dizziness is a common clinical symptom in patients with cervical and upper quadrant syndromes.[124] Cervical or reflex vertigo is thought to originate from a disturbance of the tonic neck reflex input from the neck to the vestibular nucleus. This disturbance can be caused by a dysfunction in the cervical joints[135] or the SCM.[136] As early as 1926, Barré[137] described a syndrome involving sub-occipital pain and vertigo, which was usually precipitated by turning the head. Ryan and Cope[138] coined the term "cervical vertigo" in 1955 for this syndrome.

Cervical vertigo symptoms appear to result from an alteration to proprioceptive spinal afferents from the mechanoreceptors of the neck, usually, but not always, resulting from trauma.[139] Macnab[133] thought that the 575 patients he studied exhibited little evidence of overt neck damage, or of neurologic damage. He thought areas other than the neck itself, such as the brain, brain stem, cranial nerves, cervical nerve roots, or inner ear, might be responsible for the symptoms.

TABLE 23-5 Cawthorne–Cooksey Exercises for Patients with Vestibular Hypofunction

A. In bed
   1. Eye movements—at first slow, then quick
      a. Up and down
      b. From side to side
      c. Focusing on a finger moving from 3 to 1 ft away from face
   2. Head movements—at first slow, then quick; later with eyes closed
      a. Bending forward and backward
      b. Turning from side to side

B. Sitting
   1. Same as A1 and A2, above
   2. Shoulder shrugging and circling
   3. Bending forward and picking up objects from ground

C. Standing
   1. Same as A1 and A2 and B3, above
   2. Changing from sitting to standing position with eyes open and shut
   3. Throwing a small ball from hand to hand (above eye level).
   4. Throwing ball from hand to hand under knee
   5. Changing from sitting to standing and turning round in between

D. Moving about (in class)
   1. Circle around center person who will throw a large ball and to whom it will be returned
   2. Walk across room with eyes open and then closed
   3. Walk up and down slope with eyes open and then closed
   4. Walk up and down steps with eyes open and then closed
   5. Any game involving stooping and stretching and aiming, such as skittles, bowls, or basketball

Diligence and perseverance are required, but the earlier and more regularly the exercise regimen is carried out, the faster and more complete will be the return to normal activity.

Data from Dix MR: The rationale and technique of head exercises in the treatment of vertigo. *Acta Oto-Rhino-Laryngol Belg* 33:370, 1979.

Box 23-1 Exercises to Improve Postural Stability[133]

These exercises are devised to incorporate head movement (vestibular stimulation) or to foster use of different sensory cues for balance.

1. The patient stands with his or her feet as close together as possible, with both or one hand helping maintain balance by touching a wall if needed. The patient then turns his or her head to the right and to the left horizontally, while looking straight ahead at the wall for 1 minute without stopping. The patient takes his or her hand or hands off the wall for longer and longer periods of the time while maintaining balance. The patient then tries moving his or her feet even closer together.
2. The patient walks, with someone for assistance if needed, as often as possible (acute disorders).
3. The patient begins to practice turning his or her head while walking. This will make the patient less stable, so the patient should stay near a wall as he or she walks.
4. The patient stands with his or her feet shoulder-width apart with eyes open, looking straight ahead at a target on the wall. He or she progressively narrows the base of support from feet apart to feet together to a semi-heel-to-toe position. The exercise is performed first with arms outstretched, then with arms close to the body, and then with arms folded across the chest. Each position is held for 15 seconds, before the patient does the next-most-difficult exercise. The patient practices for a total of 5–15 minutes.
5. The patent stands with his or her feet shoulder-width apart with eyes open, looking straight ahead at a target on the wall. The patient progressively narrows his or her base of support from feet apart to feet together to a semi-heel-to-toe position. The exercise is performed with eyes closed, at first intermittently and then for longer and longer periods of time. The exercise is performed first with arms outstretched, then with arms close to the body, and then with arms folded across the chest. Each position is held for 15 seconds, and then the patient tries the next position. The patient practices for a total of 5–15 minutes.
6. A headlamp can be attached to the patient's waist or shoulders, and the patient can practice shifting weight to place the light into targets marked on the wall. This home "biofeedback" exercise can be used, with the feet in different positions and the patient standing on surfaces of different densities.
7. The patient practices standing on a cushioned surface. Progressively more difficult tasks might be standing on hard floor (linoleum, wood), thin carpet, shag carpet, thin pillow, and sofa cushion. Graded-density foam can also be purchased.
8. The patient practices walking with a more narrow base of support. The patient can do this first, touching the wall for support or for tactile cues and then gradually touching only intermittently and then not at all.
9. The patient practices turning around while walking, at first making a large circle but gradually making smaller and smaller turns. The patient must be sure to practice turning in both directions.
10. The patient can practice standing and then walking on ramps, either with a firm surface or with more cushioned surface.
11. The patient can practice maintaining balance while sitting and bouncing on a Swiss ball or while bouncing on a trampoline. This exercise can be incorporated with attempting to maintain visual fixation of a stationary target, thus facilitating adaptation of the otolith-ocular reflexes.
12. Out in the community, the patient can practice walking in a mall before it is open and, therefore, while it is quiet; can practice walking in the mall while walking in the same direction as the flow of traffic; and can then walk against the flow of traffic.

Biesinger,[140] on the other hand, proposed two possible neurologic origins:

1. A contributor from the sympathetic plexus surrounding the vertebral arteries.
2. Functional disorders of proprioception in segments C1–2.

It would seem likely that direct damage to the vestibular apparatus, or severe damage to the vertebral artery, will produce immediate dizziness, whereas dizziness arising from the cervical joints or a less severely injured vertebral artery may not occur until the joints themselves became abnormal, or until the ischemia has had time to make itself felt (Table 23-6).[110] Because cervical pain also frequently is delayed, it is at least arguable that delayed dizziness commonly originates from injured cervical joints and less commonly from ischemia.[110]

The intervention for cervical vertigo generally begins with conservative physical therapy and anti-inflammatory medications, once testing rules out other causes. With time and therapy, most patients with abnormal electroneurograms end up having normal results at follow-up testing.[110]

Cervicogenic Headache

CHs, also known as cervical headaches, are loosely defined as "any headache beginning in the neck."[30] These types of headaches are difficult to define and classify because of their variable distribution and character of symptoms. Neck pain can arise from injuries of the cervical muscles, ligaments, disks, and joints. From lower cervical segments, the pain may be referred to the shoulder and upper limb (see Table 22-1). From upper segments, neck pain may be referred to the head and manifested as headache.[141] The World Cervicogenic Headache Society has defined CH as "referred pain perceived in any part of the head and caused by a primary nociceptive source in musculoskeletal tissues that are innervated by

TABLE 23-6 Differential Diagnostic Characteristics of Cervicogenic Dizziness, BPPV, and VBI

	Vertigo Type	Nystagmus Characteristics	Associated Signs and Symptoms
Cervicogenic dizziness	Positioning type	No latency period	Nystagmus
		Brief duration Fatigable with repeated motion	Neck pain Suboccipital headaches Cervical motion abnormality
BPPV	Positioning type	Short latency: 1–5 s Brief duration: <30 s Fatigable with repeated motion	Nystagmus
VBI	Positional type	Long latency: 55 ± 18 s Increasing symptomatology with maintained head position Not fatigable with repeated motion	Dizziness Drop attacks Diplopia Dysarthria Dysphagia Ataxia of gait Nausea Numbness Nystagmus

BPPV, benign paroxysmal positional vertigo; VBI, vertebrobasilar insufficiency.
Data from Huijbregts P, Vidal P: Dizziness in orthopaedic physical therapy practice: classification and pathophysiology. *J Man Manip Ther* 12:199–214, 2004; Terrett AGJ: *Current Concepts in Vertebrobasilar Complications Following Spinal Manipulation,* 2nd edn. Norwalk, IA: Foundation for Chiropractic Education and Research, 2001.

cervical nerves." According to the International Headache Society (IHS),[142] a CH is defined as one that meets the following criteria: (1) pain localized to the neck and occipital region that may project to the forehead, orbital region, temples, vertex, or ears; (2) pain precipitated or aggravated by specific neck movements or sustained neck posture; and (3) resistance to or limitation of active or passive physiologic and accessory neck movements or abnormal tenderness of neck muscles, or both. In addition, the IHS guidelines require radiographic examination to diagnose CHs. According to the IHS, radiologic examination must reveal at least one of the following: (1) movement abnormalities during flexion–extension, (2) abnormal posture, or (3) fractures, bone tumors, RA, congenital abnormalities, or other distinct pathology other than spondylosis or osteochondrosis.[142] To help in the determination when examining a patient complaining of headache, the clinician is advised to follow the simple diagnostic clinical algorithm set out below:[62]

- Exclude possible intracranial causes on history and physical examination. If intracranial pathology is suspected, then an urgent workup is required, which may include neuroimaging studies and laboratory investigations.
- Exclude headaches associated with viral or other infective illness.
- Exclude a drug-induced headache or headache related to alcohol or substance abuse.
- Consider an exercise-related (or sex-related) headache syndrome (see Chap. 5).
- Differentiate between vascular, tension, cervicogenic, or other causes of headache.

With CHs, pain is precipitated or aggravated by specific neck movements or sustained neck posture.

CLINICAL PEARL

CHs tend to be unilateral and accompanied by tenderness of the C2–3 articular pillars on the affected side.[143] The patient with a CH usually reports a dull aching pain of moderate intensity, which begins in the neck or occipital region and then spreads to include a greater part of the cranium.[144]

CHs can emerge from a number of sources, including[145]

- irritation of the posterior (dorsal) root ganglia and nerve root components caused by compression of the C2 posterior (dorsal) root ganglia between the C1 posterior arch and the superior C2 articular process[146];
- compression of the C2 anterior (ventral) ramus at the articular process of C1–2[88];
- entrapment of the C2 posterior (dorsal) root ganglia by the C1–2 epistrophic ligament.[147]

Neck pain and headache are also the cardinal features of a whiplash mechanism.[37,148,149] According to the international classification, headache after whiplash is best classified as cervicogenic (group 11.2.1) and thus related to injured structures around the cervical spine.[142] The incidence of headache after whiplash injury is said to decrease during the first 6 months after trauma.[150] Headache after whiplash can be from cervical spine trauma as listed or from a possible coup–contracoup injury from the rapid acceleration–deceleration

of the brain in a closed calverium. Particularly relevant is the relation between a history of headache and the development of a trauma-related headache after whiplash injury. In addition, psychological variables, which may be important in idiopathic headache,[151,152] should be evaluated in relation to the development and recovery from headache after whiplash.

Several interventions have been recommended for CHs, including posture training, manual therapy, exercise, rest, and minor analgesics.[64] Manual therapy studies have demonstrated positive effects at both the impairment (pain and muscle function) and the disability level, with most studies focusing on short-term outcomes.[153,154]

In a single case study, McDonnell and colleagues[153] described an intervention approach for CH, consisting of a specific active exercise program and modification of postural alignment, with good results after seven visits over a 3-month period. The intervention focused on

- increasing the strength and control of the abdominals;
- increasing the length of the anterior thorax muscles;
- increasing the length of the posterior cervical extensor muscles;
- improving the strength and decreasing the length of the posterior scapulothoracic muscles;
- increasing shoulder joint and cervical motion.

Schoensee et al.[155] found that a treatment regimen of joint mobilization to the upper cervical spine in 10 CH patients decreased headache frequency, duration, and intensity.[156] CH frequency remained lower 1 month after the study.[155]

McKenzie[157] recommends a home program of cervical retraction exercises to decrease CH symptoms and maintain correct cervical alignment **VIDEO**. These exercises, which are performed throughout the day, are progressed based on changes in symptom location and intensity. If an exercise fails to reduce CH pain, a new component is added and the prior exercise is discontinued.[156]

For the prevention of chronic tension-type headaches, behavioral approaches commonly involve regular sleep and meals, stress coping, meditation, or relaxation strategies, and avoidance of initiating or trigger factors, including work-related or family stress and emotional problems.[64]

Hammill and colleagues[158] conducted a study, in which 20 subjects with tension-type headaches were treated with posture training, massage, and stretches. The results showed a significant decrease in headache frequency and in sickness impact profile scores at the end of the 6-week treatment period and again 12 months after the treatment concluded.[156]

Bronfort and colleagues[159] performed a systematic review of randomized controlled trials to include nine trials of 683 subjects with chronic headaches. They found that spinal mobilization treatment had a better effect than massage for CH and that it had a comparable effect to commonly used prophylactic prescription medications for tension-type and migraine headaches.[156,159]

Chiari Malformations

Chiari malformations are a group of disorders that manifest varying degrees of inferior displacement of the cerebellum and brain stem through the foramen magnum. Four types are recognized[160]:

- ***Chiari type I malformation.*** This type consists of the inferior displacement of the cerebellar hemispheres (cerebellar tonsils) through the foramen magnum. This tongue-like projection of the medial inferior cerebellum envelops the medulla. The fourth ventricle is in a normal position. As the degree of descent increases, the outflow of cerebrospinal fluid decreases, and a tubular cavitation of the upper spinal cord, called syringomyelia, then occurs. Syringomyelia is distinct from hydromyelia, which is an enlargement of the central canal of the spinal cord.
- ***Chiari type II malformation.*** Chiari type II malformation is associated with inferior displacement of the brainstem and fourth ventricle through the foramen magnum into the vertebral canal, often with hydrocephalus and meningomyelocele.
- ***Chiari type III malformation.*** This type is associated with a herniation of the cerebellum into a high cervical meningocele.
- ***Chiari type IV malformation.*** In Chiari type IV malformation, the cerebellum is generally hypoplastic.

Chiari types II–IV typically present with florid symptoms and are usually diagnosed in infancy or childhood.[160] In contrast, in Chiari type I malformation, the signs of brainstem dysfunction evolve slowly over years and are, thus, more likely than the other types to be encountered in physical therapy.

The clinical manifestations of Chiari I malformation are among the most protean in clinical medicine, which can lead to a delay in diagnosis. The most common presenting symptoms are upper extremity weakness and various pain syndromes that often include neck and arm pain.[161] Occipital headaches, which are exacerbated by coughing, sneezing, stooping, or lifting, are also frequent.[161] Clumsiness, upper extremity sensory changes ataxia, vertigo, hearing loss, tinnitus, dysphagia, hiccups, dysarthria, and hoarseness of voice are some of the other reported symptoms.[161]

The diagnosis of Chiari malformation is most commonly made with MRI. If surgical intervention is necessary, it involves decompression of the Chiari malformation with or without drainage of the syringomyelia.[160]

Pattern 4G: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Fracture

Although the intervention for fractures is beyond the scope of practice for a physical therapist, being able to detect their presence, especially in this region, is critical. Clinical findings that could suggest the possibility of a craniovertebral fracture include[162,163]:

- painful neck muscle splinting;
- neck and occipital numbness;
- pain and stiffness in the neck, with a reluctance to move the head;
- presence or absence of neurological signs and symptoms.

Fractures of the Axis

There are three types of fractures of the C2 (axis) vertebra: odontoid fractures involving the dens, bilateral traumatic spondylolisthesis of the pars interarticularis ("hangman's" fracture), and nonodontoid/nonhangman's (miscellaneous) fractures.[164]

Odontoid Fractures

Odontoid fractures are a relatively common upper cervical spine injury, comprising nearly 60% of all fractures of the axis and 10–18% of all cervical spine fractures.[67,165–168] Although odontoid fractures occur in all age groups, the mean age is approximately 47 years with a bimodal distribution.[7] In younger patients, who comprise the first peak, these fractures are usually secondary to high-energy trauma; motor vehicle accidents are responsible for the majority of the odontoid injuries.[169] The second peak in the incidence of odontoid fractures is in the elderly.[106] In fact, odontoid fractures are the most common cervical spine fracture in patients older than age 70.[7] These fractures, unlike those in the younger patients, tend to result from low-energy injuries, such as falls from a standing height.[7] The mechanism of injury often is hyperextension resulting in posterior displacement of the odontoid.[7]

Described in 1974, the Anderson and D'Alonzo system divides fractures into three types based on anatomic location[166]:

- ***Type I.*** Type I is an oblique avulsion fracture from the tip of the odontoid above the transverse ligament, attached to the alar ligament. This fracture is clinically rare, accounting for 1–5% of odontoid fractures, and may be associated with O-A dislocation.[167]
- ***Type II.*** Type II fractures occur through the neck of the odontoid. They are the most common type of odontoid fracture (38–80%).
- ***Type III.*** Type III fractures extend into the body of C2. They account for 15–40% of all odontoid fractures.

Current management of odontoid fractures is based on three principles: timely diagnosis, reduction of the fracture, and sufficient immobilization to permit healing.[168] Numerous treatment methods have been developed to achieve anatomic alignment and optimal stability, including cervical orthoses, Minerva jackets, halo-thoracic vests, posterior cervical fusion, and direct anterior dens screw fixation.[170]

Jefferson Fracture. Jefferson fracture was defined as the association of a lateral mass fracture of C1 and the disruption of the C1 ring (either on the posterior or on the anterior arch).[171] Jefferson fractures now represent a spectrum of injuries from bilateral ring fractures, to lateral mass fracture, to the pathognomonic four-point fracture (both anterior and posterior arches) of the C1 ring that the fracture was originally named for.[172] Jefferson fracture classically results from axial loading on the atlas and is generally associated with minimal neurologic deficit and good prognosis for neurologic recovery.[173] Presently, three general types of Jefferson fractures are described[174]:

- ***Type I.*** Type I involves bilateral single-arch (anterior or posterior, but not both) fractures.
- ***Type II.*** Type II is the concurrent anterior and posterior arch fractures, which include the classic four-point break Jefferson fracture.
- ***Type III.*** Type III is the lateral mass fracture of C1, which may extend into the anterior or the posterior osseous arch.

No prognostic significance has been attached to the different types of Jefferson fracture.[174] Isolated Jefferson fracture can be treated effectively with external immobilization. The traditional mode of cervical immobilization is the halo vest.[172]

THERAPEUTIC TECHNIQUES

Techniques to Increase Soft Tissue Extensibility

Soft tissue techniques generally are applied before performing the local segmental examination and in preparation for a mobilization or manipulation intervention. Soft tissue techniques are capable of producing a strong analgesic, and relaxing, effect. With a reduction in cervical muscle tension, or spasm, it becomes much easier for the clinician to palpate and register movement.

General Kneading

General kneading techniques can be applied to the soft tissues of the craniovertebral region. These techniques are especially useful before performing a specific mobilization or manipulation VIDEO.

Suboccipital Massage

Soft tissue techniques can be performed at several sites in the cervical region. In principle, every tender site can be treated, even though it usually involves areas of referred pain or tenderness.[175]

The patient is positioned prone or sitting, and the head is positioned in slight flexion, without rotation. The clinician stands on the uninvolved side. The SCM may need to be displaced laterally, in order to palpate the muscles attaching to the transverse process of C1. The clinician locates the most tender area and places the thumb directly lateral to the tender spot (Fig. 23-17). During the massage, the thumb moves from laterally to medially and slightly cranially, while at the same

FIGURE 23-17 Suboccipital massage.

time, pressure is exerted in an anteromedial and superior direction.

A similar technique is used in a combination of upper cervical traction and soft tissue mobilization of the suboccipital muscles. This technique is best performed with the patient supine, because the neck is unloaded and the patient can relax more in the supine versus seated position. While one hand grasps the patient's head, the clinician uses the fingers of the other hand to press gently into the muscles between two vertebrae. While maintaining the pressure on the muscles, a slight traction force is applied and sustained for several seconds before being released. The procedure is repeated in a rhythmic manner.

The paravertebral muscles can be treated in a similar fashion. With one hand, the clinician stabilizes the patient's head at the forehead. With the index or middle finger of the left hand, or both fingers, the clinician pulls the musculature in a lateral and anterior direction. At the same time, the hand on the patient's forehead rotates the patient's head away from the side being treated. The end position is held for 2–3 seconds, before returning to the initial position. The clinician repeats this technique for several seconds or minutes in a rhythmic manner.

Muscle Stretching of the Suboccipital Muscles

Rectus Capitis Posterior Major and Minor. To stretch these muscles, the patient is positioned in supine or sitting. The clinician fixes C2 into craniovertebral flexion (see Fig. 23-18). To stretch the left muscle, a right side bending and right rotation motion is added, and the patient is instructed to not let the head drop back. Hold–relax or contract–relax techniques can be used.

Inferior Oblique. To stretch the left muscle, the patient's head and neck are positioned into flexion (see Fig. 23-19), left side bending, and right rotation. A massage to the muscle can be applied by stroking the muscle from the C1 transverse process to the C2 spinous process, applying a force in the direction of less pain.

Superior Oblique. The patient is positioned in sitting. The clinician places the index finger over the posterior aspect of the transverse process of C1, and the other hand wraps around the patient's head. To stretch the right superior oblique, the patient's head and neck must be placed in flexion, left side bending, and right rotation (see Fig. 23-20). Hold–relax or contract–relax techniques can be used.

FIGURE 23-18 Stretch for rectus capitis posterior major and minor.

FIGURE 23-19 Stretch for inferior oblique.

Self-Stretching

The following exercises should be performed at an intensity level that achieves an improvement without a regression of status.

Chin Retraction. The patient is seated in the correct posture. The patient is instructed to attempt to move the head, as a unit, in a posterior direction, while maintaining eye level **VIDEO**. The clinician should limit the number of chin tucks the patient performs, to remove any potential for harm to the cervical structures from overuse.

C2–3 Side Bending and Rotation. The pattern of limitation for this area is usually one of a closing restriction. The patient is seated in the correct posture. The patient places both hands behind the neck, with the ulnar border of the little finger being just below the C2 spinous process and the rest of the hand covering as much of the midcervical region as possible. The

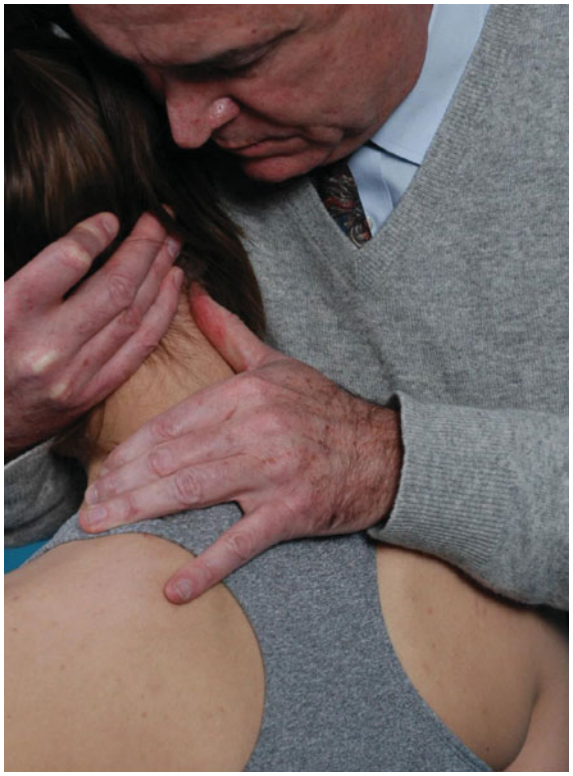

FIGURE 23-20 Stretch for superior oblique.

FIGURE 23-21 C2–3 side-bending and rotation exercise.

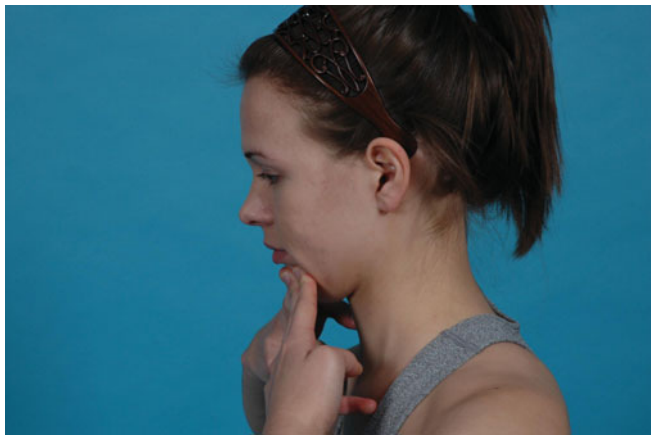

FIGURE 23-23 Home exercise for O-A flexion.

patient then simultaneously side flexes and rotates the neck and head in the direction of the restriction (Fig. 23-21), by attempting to look downward and backward (for a closing restriction).

A-A Rotation. The patient is seated in the correct posture. The patient places both hands behind the neck, with the ulnar border of the little finger being at the level of the C2 spinous process and the rest of the hand covering as much of the midcervical region as possible. The patient then gently turns the head in the direction of the restriction (Fig. 23-22) **VIDEO**. Coupled motions should be encouraged. For example, if the patient has a restriction with right rotation, right rotation and left side bending are emphasized.

O-A Flexion. The patient is seated in the correct posture. The patient performs a chin tuck. From the chin-tucked position, the patient is instructed to place the tips of the index and middle fingers of both hands over the anterior aspect of the chin (Fig. 23-23). The fingertips provide resistance for an attempted extension movement of the head on the neck. The patient then attempts to look upward, while resisting the motion with the fingertips. This is followed by relaxation and then another chin tuck. An alternative method involves asking the patient to clasp their figures behind the neck so that the little fingers are placed at the base of the skull **VIDEO**.

O-A Extension. The patient is seated in the correct posture. The patient places both hands behind the neck, with the ulnar border of the little finger being at the level of the C1 spinous process and the rest of the hand covering as much of the midcervical region as possible. The patient then gently lifts the chin around the appropriate axis (Fig. 23-24).

Techniques to Increase Joint Mobility

A series of studies that have investigated the efficacy of manual therapy in the treatment of upper cervical dysfunction and headache are outlined in Table 23-7.

Joint Mobilization Techniques

O-A Joint. ***Specific Traction***.[175] Specific traction is used here, as elsewhere in the spine, to apply a gentle degree of distraction and mechanical stimulation. It typically is used with acute conditions.

The patient is positioned in supine. The clinician stabilizes the C1 vertebra using a wide pinch grip, and the patient's forehead is stabilized against the clinician's shoulder (see Fig. 23-25). A traction force is then applied, a graded cranial force (I to II) by the occipital hand and the chest **VIDEO**.

Supine Technique for a Symmetrical Loss of O-A Extension. The patient is positioned in supine, head on a pillow, and knees flexed over a pillow. The clinician is positioned at the head of the table. The clinician cradles the patient's head in

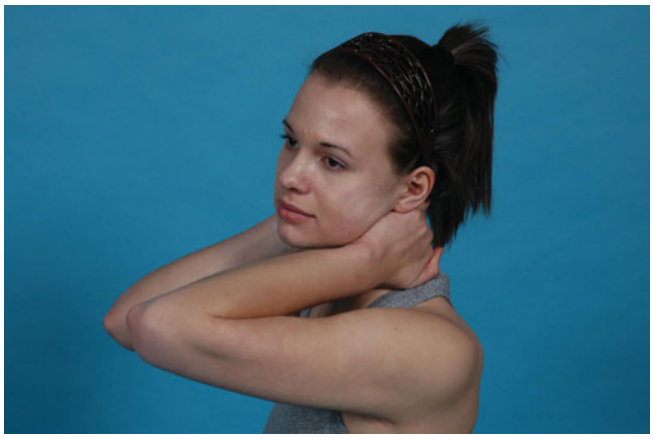

FIGURE 23-22 Exercise to increase right rotation at the A-A.

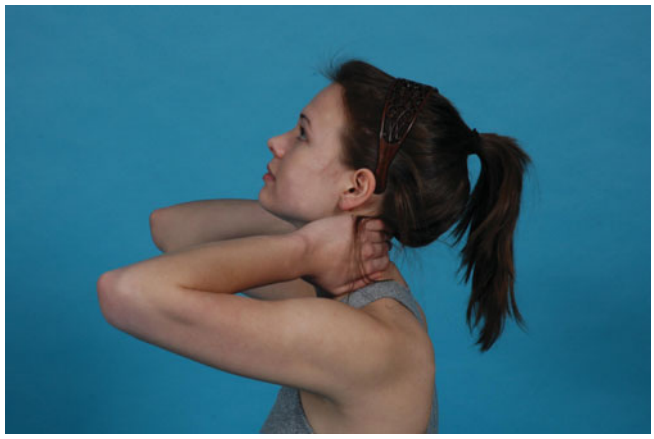

FIGURE 23-24 Home exercise for O-A extension.

TABLE 23-7 Summary of Published Studies Investigating Manual Therapy Treatment for Upper Cervical Dysfunction and Headache

Author	Sample Size	Intervention Group	Control Group	Outcome Measured	Number of Visits and Duration of Care
Boline et al.[a]	150	Manipulation	Medication	Headache frequency and intensity. Number of medications. SF-36 score	12 visits 6 wks
Howe et al.[b]	52	Manipulation ± Injection + Medication	Medication only	Cervical range of motion. Neck, scapular, arm, and hand pain. Neck stiffness. Headache intensity	1 visit only
Jensen et al.[c]	19	Mobilization Muscle energy	Cold packs	Frequency of medications. Pain intensity, dizziness, visual, and hearing	6 visits 12 wks
Nilsson[d]	39	Manipulation	Laser Friction massage	Headache duration and intensity. The number of nonsteroidal anti-inflammatory drugs	6 visits 3 wks
Nilsson et al.[e]	39	Manipulation	Laser Friction massage	Cervical passive range of motion	6 visits 3 wks
Osterbauer et al.[f]	20	Manipulation Electrical ± stimulation ± Medication	No treatment (10 nonimpaired)	Pain intensity. Cervical range of motion. Kinesthesia	2–3 visits per wk 6 wks
Parker et al.[g]	85	Manipulation by Chiropractor Manipulation by physical therapist	Mobilization by a physical therapist	Migraine frequency, intensity, and duration. Disability	Up to 16 visits 8 wks
Rogers[h]	20	Manipulation	Stretching	Pain. Kinesthesia	6 visits
Schoensee et al.[156,i]	10	Mobilization	None	Headache frequency, duration, and intensity	3–4 wks 9–12 visits 3–4 wks
Vernon[j]	33	Manipulation	None	Headache frequency, duration, and intensity	9 visits Unspecified
Whittingham et al.[k]	26	Manipulation at C1 and C2	None	Headache frequency, duration, and intensity	4 visits 2 wks
Yeomans[l]	58	Manipulation	None	Cervical intersegmental range of motion	3 visits per wk 2–6 wks

both hands with the finger pads under the occiput and places each thumb over the zygomatic arches of the patient. Using thumb pressure, the clinician tilts the patient's head into craniovertebral flexion, while the finger pads produce a posterior glide of the occipital condyles (see Fig. 23-26) **VIDEO**.

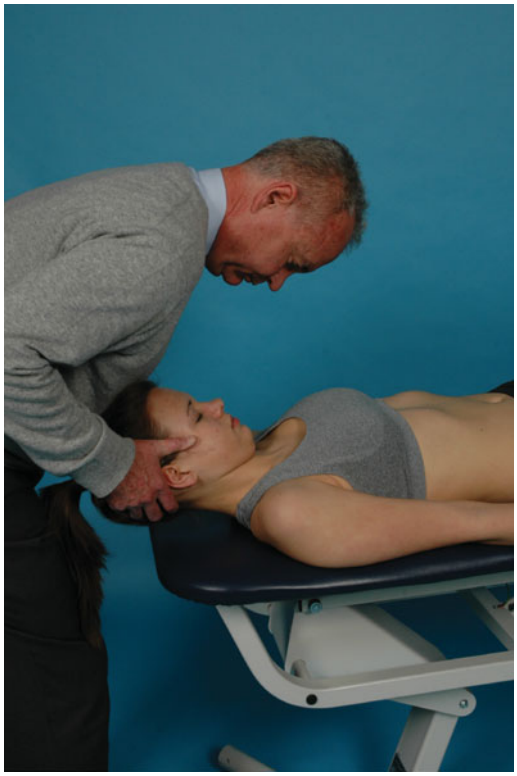

FIGURE 23-26 Supine technique for a symmetrical loss of O-A extension.

The joint slack is taken up. The patient is instructed to attempt to place the chin on their throat. After an isometric contraction of 3–5 seconds, the patient is instructed to relax, and the resultant joint slack is taken up by the clinician. When, following repeated muscle-assisted mobilizations, no further increased motion is apparent, it can be assumed that the inert barrier to motion has been reached. Passive soft tissue mobilization is then performed. This combination of muscle-assisted and passive mobilizations is continued until no further soft-tissue slack is appreciated.

Seated Technique for a Loss of Extension at the Left O-A Joint.[175] The following mobilization techniques can be used for a restriction of the anterior glide of the left O-A joint. The reader is expected to extrapolate the information to produce the necessary technique for a restriction of the anterior glide of the right joint.

The patient is seated with the clinician standing on the right side. C1 is stabilized anteriorly, using a wide pinch grip by the left hand and wrapping the pads of the index finger and thumbs around the front of the transverse process (Fig. 23-27). The right arm stabilizes the patient's head against the clinician's chest, and the right hand grasps the occiput. The patient's head is then extended and left side flexed around the appropriate axes, with right translation being produced by means of the side bending until the extension barrier is reached. The mobilization is then performed by applying a graded force against the translation barrier.

Active participation from the patient can be introduced. From the motion barrier, the patient is asked to gently meet the clinician's resistance. The direction of resistance is that which facilitates further extension, left side bending, and right rotation. The isometric contraction is held for up to 5 seconds and followed by a period of complete relaxation. The joint is then passively taken to the new motion barrier. The technique is repeated three times and followed by a reexamination.

Supine Technique for an Asymmetrical Loss of O-A Extension (e.g., Loss of Left O-A Joint Extension).[94] The patient is positioned in supine, head on a pillow, and knees flexed over a pillow. The clinician is positioned at the head of the table. The clinician cradles the patient's head in both hands. The left index and middle finger pads are placed just medial to the patient's left mastoid process, with the palm supporting

FIGURE 23-27 Seated technique for a loss of extension at the left O-A joint.

the occiput. The clinician's right hand is placed over the right side of the patient's head VIDEO.

Using both hands, the clinician passively moves the patient's head into craniovertebral extension and right translation, until the extension motion barrier of the left O-A joint is reached. The joint slack is taken up by the clinician using their left fingers to push upward toward the patient's lips and the clinician's right hand, thereby inducing side flexion of the patient's head to the left.

The patient is instructed to resist left side flexion of the O-A joint using the command "Don't let me pull your left ear upwards." The contraction is held for 3–5 seconds, and the patient is asked to relax. As the patient relaxes, the new joint slack is taken up by the clinician pushing further toward the patient's lips with the left finger pads and side flexing the patient's head to the left with clinician's right hand. To ensure that the extension is occurring around a craniovertebral axis, the clinician looks at the patient's face. As slack is taken up, flexion of the right O-A joint should simultaneously produce chin movement toward the ceiling, while the forehead moves toward the bed. To ensure that the left side flexion is occurring around the correct axis, the clinician should note the chin movement occurring to the right, while the forehead moves to the left. During the conjunct right rotation, the chin and forehead should both be seen to rotate to the right.

As with the technique to increase unilateral flexion, once the inert barrier is reached, the combined passive motion into the barrier is stressed with oscillatory passive stretch, and then muscle-assisted mobilizations are repeated. This is continued until there is no further "give" to the motion barrier.

Supine Technique for an Asymmetrical Loss of O-A Flexion (e.g., Loss of Left O-A Joint Flexion).[94] The patient is positioned in supine, head on a pillow, and knees flexed over a pillow. The clinician is positioned at the head of the table. The clinician cradles the patient's head in both hands, so that the right hand is placed over the right side of the patient's head and the clinician's left index and middle finger pads are placed just medial to the patient's left mastoid processes, with the palm supporting the patient's occiput VIDEO.

Using both hands, the clinician produces craniovertebral flexion to the barrier. At this point, the patient's head is translated to the left until a firm end-feel is encountered. This maneuver induces a right side bending and a left rotation at the O-A joints. The barrier to flexion of the left O-A joint is thus achieved.

Joint slack is taken up as the clinician uses a lumbrical action to pull on the patient's left mastoid process, in the direction toward the bed surface, with the left index and middle fingers. Simultaneously, the patient's head is side flexed to the right by the clinician's right hand. Using fingertip pressure through the right hand, the clinician instructs the patient: "Don't let me lift your right ear upwards." The clinician then attempts to draw the patient's right mastoid process superiorly. This produces an isometric resistance of right side flexion of the O-A joint (and, therefore, left rotation).

After an isometric contraction of 3–5 seconds, the patient is instructed to relax, and as the relaxation is felt by the clinician, the resultant joint slack is taken up by the clinician by simultaneously pulling the patient's left mastoid process toward the bed (with the left hand) and side bending the head to the right (with the right hand). When, following repeated muscle-assisted mobilizations, no further increased motion is apparent, it can be assumed that the inert barrier to motion has been reached. Passive soft tissue mobilization is then achieved by pushing further into the left O-A joint flexion barrier by simultaneously pulling the left mastoid process toward the bed (left hand) and right side bending of the head (right hand). This combination of muscle-assisted and passive mobilizations is continued until no further soft tissue slack is appreciated. To ensure that the flexion is occurring around a craniovertebral axis, the clinician looks at the patient's face. As slack is taken up, flexion of the left O-A joint should simultaneously produce

- a downward motion of the patient's chin and an upward motion of the patient's forehead (flexion);
- a left-sided motion of the patient's chin with a left-sided motion of the forehead (right side flexion);
- a rotation of chin and forehead to the left (left rotation).

If these facial movements are not seen, then the right hand is used to ensure that these motions are occurring, thus maintaining a craniovertebral axis.

A-A Joint. ***Loss of the Anterior-Inferior Glide of the Left A-A Joint (e.g., Loss of Right Rotation in A-A Joint—Loss of Left Anterior/Inferior Glide).***[94] The patient is positioned in supine, head on a pillow, and knees flexed over a pillow. The clinician is positioned at the head of the table. The clinician cradles the patient's head in both hands. The clinician's right index and middle finger pads are placed around the *left* side of the patient's C2 neural arch, making firm contact with the left side of the C2 spinous process VIDEO. The clinician's left hand supports the left side of the patient's head. The patient's head is side flexed by clinician's left hand. Using the fingers of the right hand, the clinician feels for the C2 spinous process to move to the right. At this point, the C2 spinous process is pulled by the index and middle fingers of the right hand until the motion barrier is detected. The patient is instructed to push their head into clinician's left hand, i.e., resisted left side flexion. The C2 spinous process should be felt to move to the right, and the clinician's right fingers move to fix it, as the patient is instructed to relax. As patient relaxes, the slack in left side bending of the head is taken up. This is repeated until no further motion of C2 spinous process is detected.

A similar technique can be performed with the patient in sitting (Fig. 23-28). Using one hand (left, in the photo), the clinician stabilizes the C2 segment and the inferior vertebral segments using a lumbrical grip. The fifth digit of the other hand wraps around the neural arch of C1 and supports the head. The patient's head is side flexed by clinician's shoulder and rotated by the clinician's right hand until the rotation barrier is reached. The mobilization is then performed by applying a graded force against the barrier. Active participation from the patient can be introduced. From the motion barrier, the patient is asked to gently meet the clinician's resistance. The direction of resistance is that which facilitates further rotation. The isometric contraction is held up to 5 seconds and followed by a period of complete relaxation.

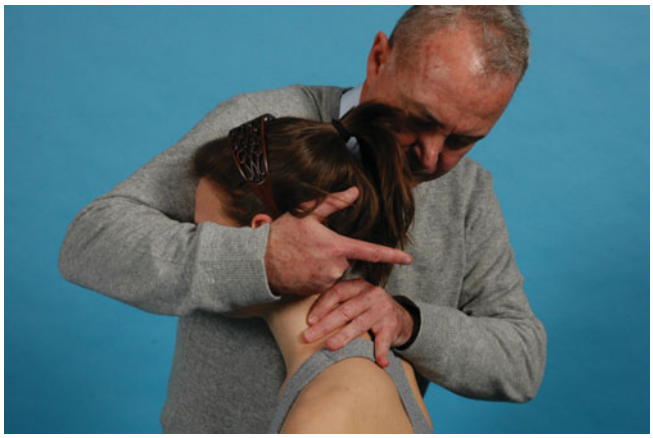

FIGURE 23-28 Seated technique for loss of right rotation in A-A joint—loss of left anterior/inferior glide.

FIGURE 23-30 Mobilization to increase right rotation of the A-A.

The joint is then passively taken to the new motion barrier. The technique is repeated three times and followed by a reexamination.

Mobilizations with Movement[176]

Upper Cervical Traction. This is an excellent technique for the intervention of upper cervical headaches. The patient is positioned in sitting, with the clinician standing in front, facing the patient. The patient's head against the clinician's chest, and the fingers wrap around the patient's head to provide firm support (Fig. 23-29). The clinician's other hand is used to stabilize the inferior segment (see Fig. 23-29).

FIGURE 23-29 Upper cervical traction.

The clinician applies pressure on the inferior segment while preventing motion of the head and applying a longitudinal force through the head. The end-feel is obtained and is maintained for 10–20 seconds.

To Improve Right Rotation of the A-A Joint. The patient is positioned in sitting, with the clinician sitting behind. The clinician places the thumb of one hand over the left aspect of the transverse process of C2, and the other thumb over the first thumb to help reinforce it. The remaining fingers of the hands are placed around the patient's neck and upper back, or to the side of the head (Fig. 23-30).

The patient is asked to rotate the head and neck slowly to the right, while the clinician simultaneously assists the movement using pressure from both thumbs, rotating C2 to the left.

This technique can be taught as part of the patient's home exercise program, using a to wel, belt, or a strap (Fig. 23-31). The same technique can be used to improve cervical rotation to the left by altering the position of the thumbs.

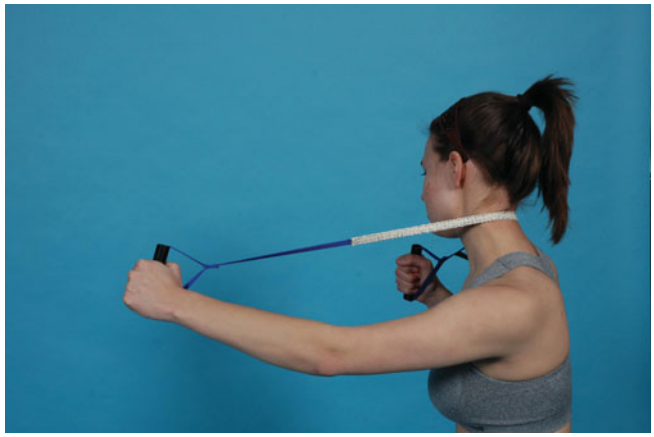

FIGURE 23-31 Home exercise to increase right rotation of the A-A.

CASE STUDY

HEADACHE AND NECK PAIN

HISTORY

A self-employed 42-year-old man presented to the clinic complaining of posterior upper neck pain and right suboccipital and occipital headache, which began 2 months earlier after a diving accident. He denied being knocked unconscious and could remember everything about the accident except for the period a few minutes after it. The posterior neck pain was felt immediately but was much worse the next morning upon waking. The occipital headaches started a few days later and became worse with fatigue or exertion. The patient also reported difficulty concentrating and sleeping and had occasional bouts of dizziness, especially when turning his head to the left, during which he would become unsteady, but denied vertigo. When the neck and occipital pain flared up, it spread from the occipital region over the head to the right eye. Previous interventions included physical therapy in the form of ultrasound, massage, spray and stretch, myofascial release, and cranial sacral therapy, which had provided no relief.

The patient had no history of back or neck pain, apart from the occasional ache, and his medical history was unremarkable.

Questions

1. List the concerns the clinician should have following this history.
2. Using a flow diagram describe how you would proceed with this patient following the history.
3. What special tests should be considered at this point?
4. Are additional questions needed with regard to the history?

REVIEW QUESTIONS*

1. Describe the anatomy of the craniovertebral region.
2. What structures provide stability in the craniovertebral region?
3. Which of the following is not a suboccipital muscle: rectus capitis lateralis, rectus capitis posterior major, rectus capitis posterior minor, obliquus capitis inferior, and obliquus capitis superior?
4. What is the extension of the posterior longitudinal ligament called?
5. Which muscle produces side bending of the O-A joint to the same side, as well as extension and contralateral rotation of the O-A?

*Additional questions to test your understanding of this chapter can be found in the Online Learning Center for *Orthopaedic Assessment, Evaluation, and Intervention* at www.duttononline.net.

Vertebral Artery

CHAPTER 24

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy and distribution of the vertebral artery.
2. Describe the four commonly recognized portions of the vertebral artery.
3. Outline the causes of vertebral artery occlusion or compromise.
4. Recognize the characteristics of vertebral artery occlusion or insufficiency.
5. Describe various special tests used to assess the patency of the vertebrobasilar system and their diagnostic value.

OVERVIEW

The vertebral artery (VA), a component of the vertebrobasilar artery (VBA) system, supplies 20% of the blood to the brain (primarily the posterior cranial fossa), with the remaining 80% being supplied by the carotid system.[1] The first studies of the VA were recorded as far back as 1844.[2] Since that time, recognition of the importance of the VA has continued to grow, and it is now discussed in more detail than any other artery by physical therapists. For this reason, the VA is afforded its own chapter. To fully comprehend its significance, a review of its anatomy and function is in order.

ANATOMY

The VBA system consists of three key vessels: two VAs and one basilar artery. The basilar artery is formed by the two VAs joining each other at the midline (Fig. 24-1).

Along its course, the artery can be viewed as having four portions: proximal, transverse, suboccipital, and intracranial.[3,4]

Proximal Portion

This portion runs from the origin of the artery to its point of entry to the cervical spine. The VA usually originates from the posterior surface of the subclavian artery, but it can also originate from the aortic arch and common carotid artery.[5]

The VA runs vertically, slightly medial, and posteriorly lateral to the longus colli and medial to the anterior scalene muscles to reach the transverse foramen of the lower cervical spine, although its exact direction is dependent on its exact point of origin. Its anomalous origin in this region has been suggested as a potential factor increasing the chance of blood flow compromise due to compression by the longus colli or scalene muscles.

In approximately 88% of individuals, the artery enters the transverse foramen of C6, but it has been shown to enter as far superior as the transverse foramen of C4.[6]

CLINICAL PEARL

Tortuosity and compression of this portion of the artery are common. The reasons for this can be congenital or muscular (resulting from compression by the longus colli and medial aspect of the anterior scalene), or a consequence of advancing years.

Transverse Portion

The second portion of the VA runs from the point of entry at the spinal column to the transverse foramen of C2 (Fig. 24-2). As already described, the origin of this part of the artery is typically at the C6 level, but this may vary between individuals and even from side to side in the same individual.

Throughout this section of the spinal column, the artery travels vertically in a true canal called the transverse canal (TC). The TC is formed by the bony transverse foramina at each spinal level and the overlying anterior and posterior intertransverse muscles, the scaleni, and the longus colli muscle. The dimension of the TC is proportionate to the diameter of the artery which itself is variable. Within the TC, the artery is surrounded by a periosteal sheath that is adherent to the boundaries of the canal and affords protection for the artery. However, the artery is in close proximity to the uncinate processes of each vertebral body on its medial aspect

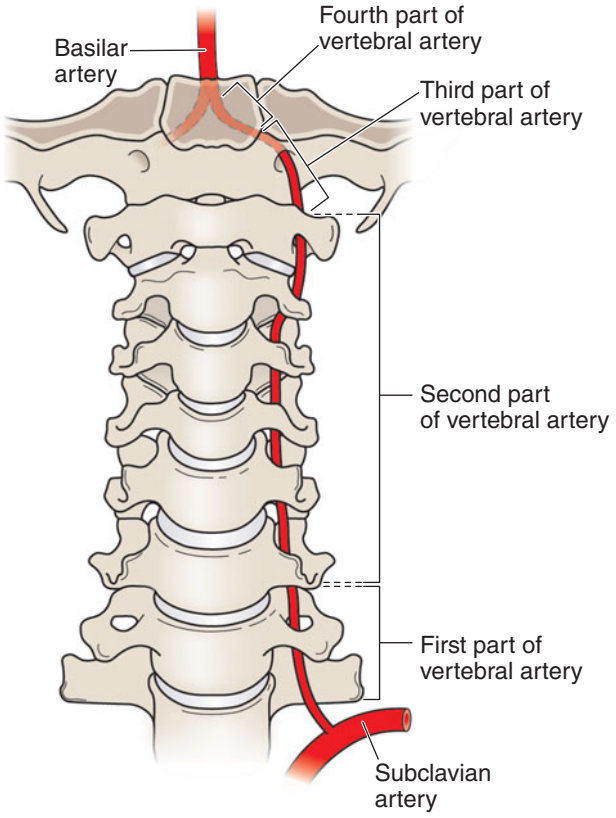

FIGURE 24-2 The left vertebral artery showing the four parts of its route.

and is prone to compression from osteophyte formation or subluxation from the zygapophyseal joint.[4,7] The VA in the transverse foramen is also adjacent to the anterior spinal roots. Arterial enlargement by an intramural hematoma or a dissecting aneurysm may cause radiculopathy by compressing or stretching the spinal root.[8]

Anomalies in this portion of the artery, which can include looping within the intervertebral foramina, can occur because of an abnormal origin of the artery from the aorta.[9]

The proximal and suboccipital portions of the artery are more elastic and less muscular than the transverse part.[10] This variation is believed to be an adaptation to the greater mobility required in the proximal and transverse portions of the artery.

Suboccipital Portion

This portion of the artery extends from its exit at the axis (C2) to its point of penetration into the spinal canal. This portion can be further subdivided into four parts:

1. Within the transverse foramen of C2 (see Fig. 24-2). This portion lies in a complete bony canal formed by the two curves of the transverse foramen of C2. The inferior curve is almost vertical, whereas the superior curve is more horizontal and orientated laterally.
2. Between C2 and C1 (see Fig. 24-2). The second part runs vertically upward to the transverse foramen of C2. Throughout its journey, it is covered by the intertransversarii, the levator scapulae muscle, and the inferior oblique capitis muscle. Compression of the VA may occur in conditions in which these muscles have increased tone or loss of flexibility.[11] It is also at this level that the VA is subjected to the most mechanical stress, as more than 50% of cervical spine rotation occurs here.
3. In the transverse foramen of C1 (see Fig. 24-2). In its third part, the suboccipital portion of the VA bends posteriorly and medially in the transverse foramen of C1 in which it is completely enclosed.
4. Between the posterior arch of the atlas and its entry into the foramen magnum (see Fig. 24-2). On exiting from the transverse foramen of C1, the artery and the nerve of C1 wind behind the mass of the superior articular process of the atlas (C1) to cross the posterior arch of the atlas in a groove in which the artery is held by a restraining ligament. Anomalies in this portion of the artery include ossification of the restraining ligament of the atlantal groove, turning this into a complete bony tunnel. From the medial end of this groove, the artery runs forward, inward, and upward to pierce the posterior atlantooccipital membrane. The artery penetrates the dura mater on the lateral aspect of the foramen magnum about 1.5 cm lateral to the midline of the neck. This upper portion of the extracranial VA is relatively superficial and covered only by the trapezius, semispinalis capitis, and rectus capitis muscles. Having unyielding bone beneath it, and only muscles above, the artery is vulnerable to direct blunt trauma at this part of its course, whereas in the remainder of its course, it is threatened more by penetrating trauma or disease processes such as osteophytosis or atherosclerosis.[12,13]

Although the artery is affected by cervical motion in the lower cervical region, it is affected even more between C2 and the occipital bone.[14]

CLINICAL PEARL

The VA is most vulnerable to compression and stretching at the level of C1–2 because of the amount of cervical rotation that can occur at the atlantoaxial joint.[15]

In addition, because the transverse foramen of C1 is more lateral than that of C2, the artery must incline laterally between the two vertebrae. At this point, the artery is vulnerable to impingement from the following:

- Cervical extension at the craniovertebral joints, such as that which occurs with a forward head posture.[11]
- Excursion of the transverse mass of C1 during rotation. Approximately 50% of the cervical axial rotation occurs between C1 and C2; hence, there is a large excursion of the transverse mass of C1 with rotation. The artery is stretched during this process and the size of the lumen can be reduced.[14,16] Any reduction in the size of the lumina is more profound in the presence of arterial disease.
- The atlantoaxial membrane. Ossification of this membrane can occur.

Intracranial Portion

This portion of the VA that runs from its penetration of the dura mater into the arachnoid space at the level of the foramen magnum to the formation of the basilar artery by the midline union of the two arteries at the lower border of the pons (Fig. 24-1).

CLINICAL PEARL

The VA that is most vulnerable to a stretch injury during neck rotation is usually the one that is contralateral to the side of the rotation.[17,18] For example, the left VA is more vulnerable with rotation to the right. During right rotation, the left transverse foramen of C1 moves anteriorly and slightly to the right. This movement imparts a marked stretch on the left VA, and it increases the acuteness of the angle formed between its ascending and posteromedial courses.

After its penetration of the cranium, the VA inclines medially toward the medulla oblongata. It courses up the front of the medulla to reach the lower border of the pons, where the artery from each side unites with its partner to form the basilar artery. A major change in the structure of the VA occurs as it becomes intracranial.[4] The tunica adventitia and tunica media become thinner, and there is a gross reduction in the number of elastic fibers in these coats.[10] This decrease in elasticity can result in the distortion of the VA during cervical extension and rotation.[14,16,19]

CLINICAL PEARL

The intracranial portion of the artery is prone to mechanical obstructions including atherosclerotic plaques and stenosis.[11]

Branches

Intracranially, the VA first generates small meningeal branches that supply the bone and dura mater of the cerebellar fossa. It is possible that ischemia of these tissues, which occurs with VA occlusion, could be responsible for the suboccipital pain that often accompanies damage to the artery.[15]

Spinal Branches[8]

Each of the vertebral arteries gives off single branches (Fig. 24-1), which fuse to form the anterior spinal artery (ASA) that descends in the median anterior fissure and is additionally supplied by anterior radicular arteries (typically two to four). While the ASA is bilaterally derived, the anterior radicular arteries may arise exclusively or predominately from one VA. This helps to explain how a unilateral insufficiency of the VA may cause bilateral spinal cord infarction.

The paired posterior spinal arteries (PSAs) originate superiorly from the vertebral arteries or posterior inferior cerebellar arteries (PICAs). The PSAs are also supplied by posterior radicular arteries (usually two or three), which themselves arise exclusively or predominately from one VA, again demonstrating how a unilateral VA dissection can lead to bilateral spinal cord infarction. The PSAs supply the posterior one-fifth to one-quarter of the spinal cord including the posterior columns, the posterior (dorsal) horns, and parts of the corticospinal and spinothalamic tracts. The ASA is the exclusive arterial supply to the gray matter of the cord. The watershed area between the PSA and ASA encompasses the anterior (ventral) horns and part of the corticospinal and spinothalamic tracts.

Muscular Branches

The muscular branches arise from the suboccipital part of the artery as it winds around the superior articular process of the atlas. They supply the deep suboccipital muscles and anastomose with the occipital and cervical arteries.

Posterior Inferior Cerebellar Artery

The PICA (see Fig. 24-1) is the largest branch of the VA, usually being formed opposite to the medulla oblongata about 1 cm below the formation of the basilar artery. It supplies, either directly or indirectly, the medulla and the cerebellum and, via the PSAs, the posterior (dorsal) portion of the spinal cord.

CLINICAL PEARL

The term cervical arterial dysfunction has been suggested for use when referring to arterial problems of the cervical spine, as the term embraces both the completeness of the arterial anatomy (i.e., the vertebrobasilar system, internal carotid arteries, and the Circle of Willis) and the range of pathologies that the clinician may encounter.[20]

Basilar Artery

The formation of the basilar artery at the lower border of the pons marks the termination of the VA. The basilar artery runs in a fissure on the anterior surface of the pons (see Fig. 24-1). Directly and indirectly, the basilar artery supplies the pons, the visual area of the occipital lobe, the membranous labyrinth, the medulla, the temporal lobe, the posterior thalamus, and the cerebellum.

Collateral Circulation

Fortunately, there is an inherent redundancy in the vascular supply to the brain. The posterior and anterior vessels, and the vessels stemming from the internal carotid arteries, form an anastomotic network via the circle of Willis. Thus, occlusion of the left VA may be compensated for by perfusion of the right VA, the occipital artery, the ascending and deep cervical arteries, and the internal carotid arteries.[21,22] In fact, there is evidence that suggests that blood flow velocity and blood flow volume can increase in the arteries to compensate for occlusion in another vessel.[23] It is worth considering that palpation of the carotid pulse would give the clinician information regarding the ability of the carotid to perform its normal function, and if the pulse appears excessively strong, this could be an indication that the carotid artery is compensating for loss of VA flow.[24,25]

VERTEBROBASILAR INSUFFICIENCY

Damage and occlusion of the vertebral arteries are felt to occur because of the close proximity of the VA and the bony and ligamentous structures of the cervical spine.[26] Trauma to this area may lead to thrombosis, dissection, transection, transmural hematoma, pseudoaneurysm, and spasm of the VA. VA insufficiency may also occur because of atherosclerotic involvement of the artery, sickle cell disease (see Chapter 5), rheumatoid arthritis, arterial fibroplasias, an arteriovenous fistula, and a number of congenital syndromes.

Whatever the cause of VA compromise, the diagnosis requires a high index of suspicion for prompt recognition and intervention. Vertebrobasilar insufficiency (VBI) is associated with signs and symptoms of focal neurologic compromise that are of sudden onset and brief duration and relate to the specific areas that are normally supplied by the vessels.

Occlusion

The VA is subject to occlusion from external and internal causes.

External Causes

Extracranial Compression

Extracranial compression of the VA may cause neurologic symptoms depending on the acuteness of the occlusion or the presence of underlying pathologic conditions such as atherosclerosis, sickle cell disease, fibromuscular dysplasia, rheumatoid arthritis, or osteogenesis imperfecta.

Many blood flow studies have demonstrated a change (reduction) in blood flow in the contralateral VA during cervical rotation.[27–30] Other studies, however, have found no change in blood flow.[31,32]

What is known is that the greatest mechanical stress affecting the contralateral artery occurs at a position of cervical rotation and extension. Furthermore, if this position is sustained, the arterial flow takes longer to return to normal.[32]

In addition to the C1–2 portion, the VA is vulnerable to compression in the portion that courses through the transverse foramen from C6 to C1. Because of its fixation to the spine in this segment, subluxations of one vertebral body on another may exert undue tension and traction on the artery. Positions of the cervical spine can cause compression of the VA.[19,33] Rotation–extension–traction appears to be the most stressful, followed by rotation–extension, rotation alone, side flexion alone, extension alone, and then flexion.[19,33,34]

If the main restraint to atlantoaxial rotation, the alar ligament, is ruptured, then the degree of C1–2 rotation has been shown to increase by 30%.[35] Insufficiency of the alar ligament has been shown to follow a rear-end collision in motor vehicle accidents, and it may also exist because of a congenital defect of the dens.[36] Other contributing factors to the preponderance of lesions occurring at the second cervical joint level are the fixation of the periosteal sheath of the artery to the dura mater, the superficiality of the artery in this region, and the hard neural arch beneath the artery.

Unilateral occlusion of the VA rarely results in a neurologic deficit because of the collateral supply through the contralateral vertebral and PICAs.[37]

CLINICAL PEARL

The most common mechanism for a nonpenetrating trauma injury to the VA is hyperextension of the neck, with or without rotation, or cervical side flexion.[38,39] These motions can result in stretching and tearing of the intima and media, especially at the points where the artery is tethered to a bone.[40,41]

After the primary tear of the intima, blood flows into the arterial wall between the intima and the media causing intramural hematoma and thickening of the vessel wall. Subintimal hemorrhage can produce various degrees of stenosis; subadventitial hemorrhage can cause a pseudoaneurysm. Tearing of the artery is not always related to remarkable trauma, and so this aspect may not appear in the history unless the symptoms appear immediately following the injury. The presence of a pseudoaneurysm has been a commonly noted angiographic feature following sudden head and neck movements. In this injury, the two internal coats of the VA are torn from the tunica adventitia, which under the influence of arterial pressure slowly balloons out and sometimes ruptures.

CLINICAL PEARL

Even in the absence of underlying trauma, cervical rotation (approximately 20 degrees) and extension (approximately 20 degrees) have been shown to reduce the lumen of the VA to the point where blood flow is compromised to the point of almost nonexistence.[42] An underlying pathology may therefore be quiescent, and the patient may not complain of vascular-like symptoms prior to an infarction except with specific movements.[43]

Extracranial Dissection

Extracranial VA dissection (vertebrobasilar infarction) is recognized with increasing frequency as a cause of stroke, and spontaneous dissections of the carotid and vertebral arteries are well-recognized causes of stroke in young and middle-aged adults.[44–47] Traumatic dissection can also occur in the extracranial part of the internal carotid arteries, often after only moderate blunt trauma.[48]

Postmortem studies have shown that neurologic deficits, or even death, have followed posterior neck injuries by up to 8 days after the accident.[49,50] The most common clinical findings are brain stem or cerebellar ischemic symptoms preceded by severe neck pain, occipital headache, or both. Occasionally, these patients report radicular symptoms.[45]

Spinal manipulation, in particular manipulation of the upper spine, has been associated with serious adverse occurrences, including dissection of the vertebral[51] and internal carotid artery,[52] resulting in strokes[53] and death.[54] However, the evidence implicating cervical manipulations with these serious consequences is conflicting, especially in light of the

fact that even normal neck movements have been associated with spontaneous dissections. The reciprocal finding of increased blood flow through the carotid artery during VA occlusion was made by Stern,[55] who demonstrated that the flow rate in the contralateral carotid artery increased by one and a half to two times with experimental occlusion of the VA. These alterations in the flow rates following an occlusion of the parallel artery serve as an apparent safety mechanism and may explain why more patients are not injured during cervical manipulation.

CLINICAL PEARL

The potential risk of a VBA dissection after manipulation is reported to be somewhere between 1 in 1.3 million treatment sessions[56] and 1 in 400,000 manipulations.[57] The clinicians involved in such instances have stated that the patient's prognosis is greatly enhanced if they can be treated by anticoagulant therapy quickly enough.[24] This requires that the manipulative clinician is totally familiar with the signs and symptoms of VBA damage.

Frisoni and Anzola[58] concluded that VA dissection at the atlantoaxial joint with intimal tear, intramural bleeding, or pseudoaneurysm leading to thrombosis or embolism is the mechanism for VBI when associated with chiropractic manipulation. The same study found that possible risk factors for VBI after neck motion are VA size asymmetry, anomalous course of VA, atherosclerosis, osteoarthritis, and vertebral ligament laxity.[58] However, despite the reports of 115 cases of cerebrovascular accidents after manipulation in English language publications during the period of 1966–1998 (198 articles), there is virtually no detailed information on the magnitude of forces that were exerted or the type of procedure used. It has even been suggested that, in many cases, cervical manipulation may have been administered to patients who already had a spontaneous dissection in progress.[59]

CLINICAL PEARL

It is the responsibility of all health care providers who use cervical manipulation to be cognizant of the potential adverse consequences.

Internal Causes

Atherosclerosis and Thrombosis

Atherosclerosis of the extracranial part of the VA primarily affects the proximal and transverse portions, leaving the suboccipital part relatively free. Atherosclerosis in the transverse portion of the artery occurs at any level between C2 and C6 and tends to occur at levels of the artery opposite osteophytic spurs. Castaigne et al.[60] investigated 44 patients with VBA occlusions and found that the cause in almost 90% of cases was atherosclerosis, mostly affecting the proximal and intracranial portions of the artery. Approximately 40% of the patients in this study had concomitant carotid stenosis.

Atherosclerosis may, as with any other artery, produce signs and symptoms resulting from ischemia of the tissues supplied by the artery distal to the occlusion. However, if the contralateral artery is not occluded, and is of good caliber, the condition may be asymptomatic.

Thrombosis can occur at any level of the VA but is more common in the suboccipital and intracranial portions than in the transverse part.[61]

Arterial Fibrodysplasia

This condition is a nonatheromatous, noninflammatory segmental angiopathy of unknown etiology. It occurs in less than 1% of all patients receiving cerebral angiograms, but it is the third most frequent structural lesion affecting the VA following atherosclerosis and dissection.[62] Arterial fibrodysplasia is believed to be hereditary, affecting mainly young and middle-aged female patients.

Klippel–Trenaunay Syndrome

Klippel–Trenaunay syndrome consists of a constellation of anomalies including capillary malformation, varicose veins or venous malformations, and hypertrophy of both bony and soft tissues primarily involving limbs and to a much lesser degree, intra-abdominal, thoracic, or facial structures.[63,64] The vascular abnormalities commonly occur in the lower extremity but have been observed in other areas as well (head, neck, buttocks, abdomen, chest, and oral cavity). Klippel–Trenaunay syndrome is theorized to result from a mesodermal abnormality.[65] The syndrome is diagnosed on the basis of presence of any two of the three aforementioned features and any intervention is based on the severity of these features.

Arteriovenous Fistulas

An arteriovenous fistula is an abnormal communication between the extracranial VA, or one of its muscular or radicular branches, and an adjacent vein. It has variable causes, including traumatic dissections or dissecting aneurysms, and may occur spontaneously as a result of the existing disease, such as fibromuscular dysplasia, or as a congenital condition. Most spontaneous arteriovenous fistulas occur at the level of C2–3 and come directly from the VA through what is believed to be a tiny rupture in the wall of the artery.[66,67] Although rare, progressive myelopathy from an intracranial arteriovenous fistula can occur.[68] In these cases, endovascular embolization, either alone or followed by surgery, is the intervention of choice.

The Clinical Manifestations of Vertebrobasilar Insufficiency

The clinical manifestations of VBI are difficult to distinguish from other causes of brainstem ischemia (see later) and can include any or all of the following: dizziness, visual disturbance, drop attacks (a sudden loss of postural tone without loss of consciousness), ataxia, dysarthria, dysphagia, hemiplegia, hemianesthesia, nausea, and ringing in the ears. Indeed, no single consistent pattern of neurologic signs and symptoms is pathognomonic for VA insufficiency. The most common presenting symptoms are vertigo, nausea, and headache that can be subtle, intermittent, and even chronic in nature.[11,69–71]

CLINICAL PEARL

Terret[72] proposed the following pneumonic for the signs and symptoms associated with VBI: five D's and 3 N's:

- Dizziness
- Drop attacks
- Diplopia
- Dysarthria
- Dysphagia
- Nausea
- Numbness
- Nystagmus

Vertigo

Vertigo or dizziness is a commonly reported symptom in the physical therapy clinic.[11,70,71] Owing to the different areas of the brain that the VA and its branching arteries supply, dizziness, although the most common and usual symptom of VBI, is rarely an isolated symptom, especially in advanced stages of the condition. Tatlow and Bammer[16] proved that the cause of the vertigo in patients with VBI was cervical rather than vestibular. This was accomplished by placing symptomatic patients into a Stryker bed to determine whether the vertigo symptoms were being elicited by the movement of the entire body or by the movement of the head relative to the torso. Each patient who was secured within the Stryker bed had the entire body rotated up to a full 360 degrees en bloc (without movement of the head and neck relative to the torso), and the patients reported no symptoms. However, when the torso was fixed in a still position but the head and neck was moved relative to the torso, symptoms were reproduced.

Nausea

Nausea is the accompanying symptom for many different conditions including VBI.

Headache

The headache associated with VBI is typically a unilateral occipital headache with associated vertigo and nausea.[40] The pain is usually sharp and acute in its onset located on the same side as the insufficiency.

In addition to those signs and symptoms already mentioned, the following have also been linked, both directly and indirectly, to VBI[40,73,74]:

- Wallenberg, Horner, and similar syndromes
- Bilateral or quadrilateral paresthesia
- Hemiparesthesia
- Scotoma (a permanent or temporary area of depressed or absent vision)
- Periodic loss of consciousness
- Lip/perioral anesthesia
- Hemifacial paralysis/anesthesia
- Hyperreflexia
- Positive Babinski, Hoffman, or Oppenheim signs
- Clonus
- Gait ataxia
- Dysphasia

Clinicians need to be aware of these signs and symptoms and consider VA dissection early in the differential diagnosis because of the potential devastating neurological consequences and to decrease morbidity and mortality.[40]

Subclavian Steal Syndrome

The subclavian steal syndrome involves a proximal subclavian artery obstruction and reversed vertebral flow with resultant siphoning of blood from the brain and cerebrovascular symptoms.[75–77]

The subclavian steal syndrome can produce cerebral symptoms such as a "drop attack."[78] Headache, dizziness, and vertigo can occur while walking and turning the neck to look to the side or up.[79]

Imaging Studies

Conventional angiography has long been the gold standard in the diagnosis of arterial and venous pathology in the neck. Angiography can show the arterial lumen and allows extensive characterization of dissections of the carotid and vertebral arteries.[80] VA angiography is not, however, without risk. Magnetic resonance angiographic (MRA) techniques are less invasive and are replacing conventional angiography as the gold standard in the diagnosis of dissections of the carotid and vertebral arteries. MRA is highly sensitive and specific in identifying stenoses and occlusions and can show the intramural hematoma itself.[81]

Ultrasonographic techniques are useful in the initial assessment of patients who are thought to have a dissection of the carotid artery.[82] Doppler sonography allows a direct visualization of the vascular tree while assessing blood flow velocity and pressure waveforms. Although the site of dissection generally is not seen, an abnormal pattern of flow is identified in more than 90% of patients.[82]

Physical Therapy Examination of the Vertebral Artery

Screening procedures to identify patients at risk for VBI prior to manual therapy interventions have been widely advocated and routinely used by physical therapists for many years, being first described by Maitland in 1968.[83] It is widely recognized that passive therapeutic maneuvers applied to the cervical spine carry a small risk of developing iatrogenic stroke. This is especially pertinent with regard to cervical manipulations (high-velocity thrust or grade V techniques). It is therefore generally advised that all patients with neck pain receive a subjective screening examination for VBI and be evaluated for their ability to perform active neck movements.[84] The initial test consists of having the patient rotate the head to each side while in the sitting position. The longus colli and scalene muscles rotate the cervical spine and can squeeze the VA on the side contralateral to the rotation.[11]

The presence of muscular compression of the artery can be further tested by combining cervical flexion with rotation to place the inferior oblique capitis on stretch.[11] If dizziness is provoked with rotation, it is sometimes possible to implicate or exclude the vestibular apparatus of the inner ear as the source of dizziness.[85] In a standing position, the clinician holds the patient's head steady as the patient turns the trunk while keeping the feet fixed, thus producing sustained end-range cervical spine rotation.[86] Because the semicircular canal fluid is not disturbed by this test, a positive response theoretically excludes the labyrinth of the inner ear.[85]

CLINICAL PEARL

Following positive responses in the history or initial test, the patient must be handled very carefully and further intervention, particularly manipulation of the cervical spine, should not be delivered. The patient should not, under any circumstance, be allowed to leave the clinic until his or her physician has been contacted and until the necessary arrangements have been made for the safe transport of the patient to an appropriate facility.

Theoretically, patients with a negative subjective history and negative findings with the initial test should undergo additional passive physical examination procedures in the form of stress tests for the vertebrobasilar system to further assess the potential for VBI.[87] Traditionally, this has involved the use of manual premanipulative tests to determine the appropriateness of a grade V technique.

In those cases in which the clinician is to perform cervical mobilizations of grade I–IV rather than a grade V thrust technique, the Australian Physiotherapy Association's Protocol for Premanipulative Testing of the Cervical Spine continues to be recommended, although this cannot be viewed as a prescriptive guideline.[84] The protocol recommends that the clinician should maintain the immediate premobilization position for a minimum of 10 seconds to test the patency of the vertebrobasilar system. Others recommend assessing the patient's responses for a further 10 seconds to note any latent response.[17,37] Clinical testing of the VA should stop once positive signs or symptoms are noted. Throughout the tests, the clinician should observe the patient's eyes for possible nystagmus or changes in pupil size and should have the patient count backward to assess his or her quality of speech. The patient is asked to report any changes in symptoms however insignificant he or she may feel the changes to be.

Unfortunately, it is not clear how sensitive these premanipulative protocols are.[85,88] For example, studies by Haynes[89] and Cote et al.,[90] found these protocols to have poor predictiver value. Other studies have shown that the results of these tests are inconsistent[91] and inaccurate, [92] suggesting that the VA tests have very little, if any, diagnostic value. In addition, many of these premanipulative screening protocols involve the same combination of positions that have been suspected of causing spontaneous arterial dissections (cervical extension and rotation).

CLINICAL PEARL

A positive VA test is one in which signs or symptoms change, especially if the changes evoked include those previously mentioned. More subtle examination findings can include a significant delay in verbal responses to questions of orientation with some inconsistency of answers, changes in pupil size, and nystagmus.[15]

Although one could argue that if the VA was damaged or compromised, the patient would surely have signs and/or symptoms indicating this, the logical question still becomes, "How does one proceed in the absence of certainty?"[87] It would seem extremely prudent to avoid cervical thrust techniques on a patient with any degree of uncertainty. Even in the absence of any symptoms, it would be wise to either introduce the application of incrementally greater movements and loads or investigate VA flow using Doppler sonography or an MRA scan before performing a grade V technique in the cervical spine.[93] In addition to the specific tests of blood flow, the clinician should use a combination of the patient's description of the symptoms and medical history, and those considerations in Table 24-1, before reaching a conclusion.[94] Alternatively, the clinician should consider avoiding placing the patient's cervical spine in the extremes of rotation and side bending in both the examination and the subsequent intervention, which would obviate the need for these tests.

CLINICAL PEARL

Grade V techniques should never be performed when slow blood flow of the VA is displayed on neck Doppler sonography or MRA scan.[93]

The following case study[42] illustrates the problems associated when encountering a patient with a VBA insufficiency.

TABLE 24-1 Nine Factors to Consider with Vertebral Artery Testing

1. Inherent redundancy of blood supply—collateral circulation
2. Morphology of the vertebral artery at the atlantoaxial level
3. Biomechanics of upper cervical spine—concurrent contralateral side bending with cervical rotation
4. The nonvascular causes of dizziness (cervicogenic dizziness and benign paroxysmal positional vertigo)
5. The amount of cervical rotation to be used
6. Medical history (transient ischemic attack, cerebrovascular accident, cardiac risk factors, cervical spondylosis)
7. Psychometric properties of vertebral artery testing (0% sensitivity)
8. Force to be applied
9. Potential risk of injury with manipulation (thrust, rotational techniques vs nonthrust, nonrotational techniques)

Data from Vidal PG: Vertebral artery testing as a clinical screen for vertebrobasilar insufficiency: Is there any diagnostic value? *Orthop Pract* 16:7–12, 2004.

CASE STUDY

HISTORY

A 62-year-old woman with no history of vertigo or dizziness reported to the clinic for her scheduled physical therapy session for cervical degenerative joint disease. During the course of conversation, the patient reported experiencing dizziness after a shampoo treatment of her hair at a hairdressing salon. She had visited her hairdresser earlier that day and reported severe vertigo, occipital pain, difficulty in standing, and a periodic numbness of the right arm and leg. The patient also reported hypesthesia in a glove-and-stocking type of distribution.

Tests and Measures

Most of the findings of the physical therapy examination were negative. Although muscle stretch reflexes and muscle power were normal, disturbances of equilibrium were noted and nystagmus was present.[95] Given the presence of the nystagmus, the patient was referred back to her physician for further testing.

Following MRA, a diagnosis was made of VBA insufficiency with cerebellar infarction caused by neck hyperextension in the hairdressing salon. The patient was treated conservatively with rest and medication, and the vertigo improved 1 week after injury, enabling the patient to walk without assistance.

DISCUSSION

Beauty parlor stroke syndrome was first described by Weintraub[96] in 1993. Since then, various authors have reported similar cases.[97,98] Because this syndrome is not recognized widely, a careful history is necessary in the presence of symptoms such as those described. Such symptoms are often thought to be nonspecific and might be attributed to neurosis, psychogenic headache, or menopause, particularly when imaging studies do not show specific findings. Routine radiography, computed tomography, and magnetic resonance imaging studies usually do not help to identify lesions in this syndrome. Special care is therefore necessary to evaluate the clinical findings during examination of the nervous and auditory systems. The most likely pathophysiologic mechanism of the beauty parlor stroke syndrome is stenosis of the VA caused by compression at the atlantooccipital junction. This compression leads to damage of the intima, thrombus formation, stenosis of the artery by fibrosis, or embolism followed by infarction of the brain stem or cerebellum.

REVIEW QUESTIONS

1. From which artery does the VA normally arise?
2. What is the most common variation in the origin of the VA?
3. Describe the course of the third part of the artery (suboccipital).
4. List the branches generated directly by the basilar artery.
5. Which of the cranial nerves is (are) not vascularized by the VA?

CHAPTER 25 The Cervical Spine

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the vertebrae, ligaments, muscles, and blood and nerve supply that comprise the cervical intervertebral segment.
2. Describe the biomechanics of the cervical spine, including coupled movements, normal and abnormal joint barriers, kinesiology, and reactions to various stresses.
3. Perform a detailed objective examination of the cervical musculoskeletal system, including palpation of the articular and soft tissue structures, specific passive mobility tests, passive articular mobility tests, and stability tests.
4. Perform and interpret the results from combined motion testing.
5. Assess the static and dynamic postures of the cervical spine and implement the appropriate intervention.
6. Apply manual therapy techniques using the correct grade, intensity, direction, and duration.
7. Evaluate intervention effectiveness in order to progress or modify the intervention.
8. Plan an effective home program, including spinal care, and instruct the patient in this program.
9. Help the patient to develop self-reliant intervention strategies.

OVERVIEW

The cervical spine, (Fig. 25-1) which consists of 37 joints, permits more motion than any other region of the spine. The majority of the anatomy of the cervical spine can be explained in reference to the functions that the head and neck perform on a daily basis. To carry out these various tasks, the head has to be provided with the ability to perform extensive, detailed, and, at times, very quick motions. These motions allow for precise positioning of the eyes and the ability to respond to a host of postural changes that result from stimulation of the vestibular system (see Chap. 3).[1] In addition to providing this amount of mobility, the cervical spine has to afford some protection to several vital structures, including the spinal cord and the vertebral and carotid arteries. However, with stability being sacrificed for mobility, the cervical spine is rendered more vulnerable to both direct and indirect trauma.[2] Neck and upper extremity pain are common in the general population, with surveys finding the 1-year prevalence rate for neck and shoulder pain to be 16–18%.[2,3] This frequency is also reflected in the prevalence of neck pain in the outpatient physical therapy setting, which has been found to be between 15% and 34%.[3,4] In the younger population, cervical pathology is most commonly due to a ligament sprain or muscle strain, whereas in the older population cervical injuries are more commonly due to cervical spondylosis and/or spinal stenosis. Due to the complexity of this area, sufficient time must be allowed for a comprehensive examination to ensure that all causes of the signs and symptoms are determined.

ANATOMY

Bogduk and Mercer[5] divide the cervical spine into four anatomical units: the atlas, the axis, the C2–3 junction, and the remaining cervical vertebrae. For the sake of simplicity, these units are described in separate chapters. The atlas, axis, and C2–3 junction are described in Chapter 23. The remaining cervical vertebrae are described in this chapter.

Vertebrae

Compared with the rest of the spine, the vertebral bodies of the cervical spine are small and consist predominantly of trabecular (cancellous) bone.[1] The third to sixth cervical vertebrae can be considered typical, whereas the seventh is atypical. The third, fourth, and fifth vertebrae are almost identical, whereas the sixth has enough minor differences to distinguish it from the others.

The typical cervical vertebra has a larger transverse than anteroposterior dimension. The superior aspect of the centrum is concave transversely and convex anteroposteriorly, forming a sellar surface that reciprocates with the inferior surface of the centrum, superior to it.[1] The superior surface of

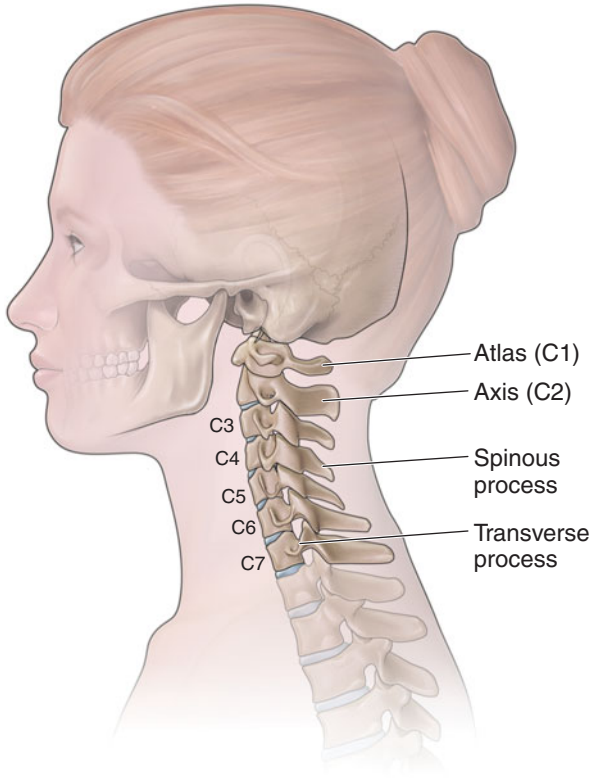

FIGURE 25-1 Cervical vertebra only.

the vertebral body is characterized by superiorly projecting processes on their superolateral aspects. Each of these hook-shaped processes is called an uncinate process and is composed of the raised lip of the superolateral aspect of the body, which articulates with a reciprocally curved surface at the synovial uncovertebral joint.

Variations in the lower cervical vertebrae are most commonly found in the spinous and transverse processes. The transverse processes are short and project anterolaterally and slightly inferiorly and are typified by a foramen in each. The transverse processes of vertebrae C3–6 are posterior and lateral to the transverse foramina, through which the vertebral artery, accessory vertebral vein, and the vertebral nerve all pass.

With the exception of the C2 vertebra (see Chap. 23), the superior aspect of the transverse process has a deep groove that mimics the orientation of the transverse process and the spinal nerve, both of which are parallel with the intervertebral foramen. The inferolateral orientation of the transverse process, and the fact that the spinal nerves are firmly anchored in the groove, makes the nerves vulnerable to a stretch injury around the distal end of the transverse process.[1]

The articular pillars and zygapophyseal (facet) joints of vertebrae C2–7 are located approximately 1 inch lateral to the spinous processes. The articular pillar is formed by the superior and inferior articular processes of the zygapophyseal joint, which bulge laterally at the pedicle–lamina junction. The articular facets on the superior articular process are concave and face superolaterally to articulate with the reciprocally curved and orientated facet on the inferior articular process of the vertebra above. The articular pillars bear a significant proportion of axial loading.[6]

As in the rest of the spine, the pedicles and laminae form the neural arch, which encloses the vertebral foramen. The pedicles project backward and laterally, whereas the long, narrow laminae run posteriorly and medially, to terminate in a short bifid spinous process, which projects slightly inferiorly.[1] The seventh cervical vertebra varies from the typical cervical vertebra. In addition to possessing a much longer and monoid spinous process to which the ligamentum nuchae attaches, the seventh vertebra has wider transverse processes, no inferior uncinate facet, and no transverse foramen.

Intervertebral Disk

In the cervical spine, there are five disks, with the first disk being located between C2 and C3. The cervical disks (Fig. 25-2) are named after the vertebra above (C4 disk lies between C4 and C5). The anatomy of the cervical disk is distinctly different from that of the lumbar intervertebral disk (IVD). The cervical nucleus pulposus (NP) at birth constitutes no more than 25% of the entire disk, not 50% as in lumbar disks.[7]

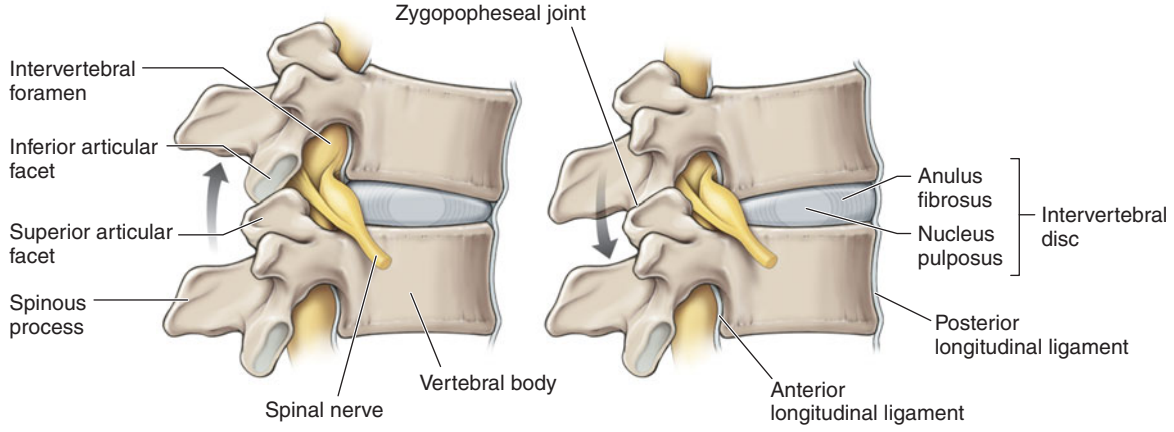

FIGURE 25-2 The intervertebral disk, articulations, ligaments, and neurologic structures. (Reproduced, with permission, from Morton, DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

The IVD height-to-vertebral body height ratio (2:5) is the greatest in the cervical spine, and the IVDs make up approximately 25% of the superior-to-inferior height of the cervical spine.[8] This increase in height ratio allows for the greatest possible range of motion. The NP sits in, or near, the center of the disk, lying slightly more posteriorly than anteriorly. The inferior surface of the cervical IVD is concave, and the inferior–anterior surface of the centrum projects downward to partly cover the anterior aspect. The anterior margin of the IVD is attached to the anterior longitudinal ligament (ALL). This surface can be palpated by the clinician and is often tender in the presence of intervertebral instability. The diskal margins of the posterior surface of the vertebral body give rise to the posterior longitudinal ligament (PLL).

CLINICAL PEARL

The cervical IVD, and its development, is distinctly different from that of the lumbar disk.

A number of features distinguish the cervical disk from the lumbar disk[9]:

- Anteriorly, the cervical annulus fibrosis (AF) consists of interwoven alar fibers, whereas posteriorly, the AF lacks any oblique fibers and consists exclusively of vertically orientated fibers.
- Essentially, the cervical AF has the structure of a dense anterior interosseous ligament, with few fibers to contain the NP posteriorly.
- In no region of the cervical AF do successive lamellae exhibit alternating orientations. In fact, only in the anterior portion of the AF—where obliquely orientated fibers, upward and medially, interweave with one another—does a cruciate pattern occur.
- Posterolaterally, the NP is contained only by the alar fibers of the PLL, under or through which the nuclear material must pass if it is to herniate. Further protection against disk herniation is afforded by the uncovertebral joints, which reinforce the posterolateral aspect of the IVD.
- The absence of an AF over the uncovertebral region. In this region, collagen fibers are torn during the first 7–15 years of life, leaving clefts that progressively extend across the back of the disk. Rather than an incidental age change, this disruption has been interpreted either as enabling[10] or resulting from[11] rotatory movements of the cervical vertebrae (see next section).
- Axial rotation of a typical cervical vertebra occurs around an oblique axis perpendicular to the plane of its facets.[11]

As in the rest of the spine, the cervical IVD functions as a closed but dynamic system, distributing the changes in pressure equally to all components of the container (i.e., the end plates and the AF) and across the surface of the vertebral body. It has been observed that in the first and second decades of life, before complete ossification occurs, lateral tears occur in the AF, most probably induced by motion of the cervical spine in the bipedal posture.[12] The tears in the lateral part of the disk tend to enlarge toward the medial aspect of the IVD. The development of such tears through both sides may result in a complete transverse splitting of the disk. Such a process can be observed in the second and third decades of life in the lower cervical spine when the IVD is split in the middle into equal halves.[12] With this aging process, the NP rapidly undergoes fibrosis such that, by the third decade, it is fibrocartilaginous in nature.[13] Almost everyone older than 40 years of age has evidence of cervical disk degeneration.[14] According to Töndury and Theiler,[15] in the fourth and fifth decades of life, the NP usually dries out, and acute extrusion is not expected then. This development can be visualized on conventional radiographs as a flattening of the uncovertebral processes and a narrowing of the IVD space.[16] This may lead to a loss of elasticity and increased stresses on the vertebral end plates.

These age-related changes are evident chemically and morphologically and are much more evident in the NP than in the AF. Degenerative disk disease in this region results in diminished disk height, subjecting the bony elements to increased load.[8] The splitting of the IVD in the second and third decades of life may result in segmental instability.[12] Also, such splitting of the IVD can allow the NP to move toward the spinal canal, ultimately causing disk protrusion or extrusion and resulting in nerve root compression.[12]

In general, compression of the cervical nerve roots occurs at the entrance zone of the intervertebral foramina.[17] Anteriorly, compression of the nerve roots is likely caused by protruding disks and osteophytes of the uncovertebral region, whereas the superior articular process, the ligamentum flavum, and the periradicular fibrous tissues often affect the nerve posteriorly.[17–20] Osteophytes develop in response to this increased stress and from degenerative changes of the zygapophyseal and uncovertebral joints. The osteophytes effectively increase the available surface area and decrease the overall force on the end plates.[21] Radicular arteries within the dural root sleeves may become compressed by osteophytes, leading to spasm and decreased vascular perfusion.[21] In addition, venous obstruction may occur, resulting in edema and additional reduction in nerve root perfusion.[21]

The nerve root is divided into the anterior (ventral) and posterior (dorsal) roots (Fig. 25-2), which are responsible for motor and sensory functions, respectively. Ebraheim and colleagues[22] described the quantitative anatomy of the cervical nerve root groove and divided it into three zones: medial zone (pedicle), middle zone (vertebral artery foramen), and lateral zone. The medial zone of the cervical nerve root groove corresponds to the intervertebral foramen, and this zone is believed to play an important role in the etiology of cervical radiculopathy.[17] The intervertebral foramen, which can be further divided into an entrance zone (medial) and an exit zone (lateral), resembles a funnel in shape. The entrance zone corresponds to the narrow part of the funnel, and the shape of the radicular sheath is conical, with its takeoff points from the central dural sac being the largest part.[17] Consequently, nerve root compression occurs mostly in the entrance zone of the intervertebral foramina. Whether compression of the anterior (ventral) roots, posterior (dorsal) roots, or both occurs depends on various anatomic structures around the nerve roots. Anteriorly, compression of the nerve roots is likely caused by protruding disks and osteophytes of the uncovertebral region, whereas the superior articular process, the

ligamentum flavum, and the periradicular fibrous tissues often affect the nerve posteriorly.[17–20] Osteophytes may develop in response to this increased stress and form degenerative changes of the zygapophyseal and uncovertebral joints. The osteophytes effectively increase the available surface area and decrease the overall force on the end plates.[21] Radicular arteries within the dural root sleeves may become compressed by osteophytes, leading to spasm and decreased vascular perfusion.[21] In addition, venous obstruction may occur, resulting in edema and additional reduction in nerve root perfusion.[21]

Articulations

The structure of the cervical vertebrae, combined with the orientation of the zygapophyseal facets, provides very little bony stability, and the lax soft tissue restraints permit large excursions of motion.[1] A narrow space exists between the spinal cord and the vertebral canal walls in this region. There also is a very small amount of extra space in the intervertebral foramina. Thus, a relatively small change to either the vertebral canal or the dimensions of the intervertebral foramen can result in significant compression of the spinal cord or the spinal nerve, respectively.[23]

Each pair of vertebrae in this region is connected by a number of articulations: a pair of zygapophyseal joints, two uncovertebral joints, and the IVD.

Zygapophyseal Joints

There are 14 zygapophyseal joints (Fig. 25-2) from the occiput to the first thoracic vertebra (C1–7). These joints are typical synovial joints and are covered with hyaline cartilage. The articular facets are teardrop shaped, with the superior facet facing up and posteriorly, while the inferior one faces down and anteriorly. In the middle to lower cervical regions, the dual requirements of stability and mobility are provisioned through zygapophyseal joints, with C5–6 contributing the greatest segmental mobility. The average horizontal angle of the joint planes of the middle segments is approximately 45 degrees between the frontal and transverse planes[24,25] with the upper cervical levels being closer to 35 degrees, and the lower levels at approximately 65 degrees.

CLINICAL PEARL

Clinically, the orientation of the zygapophyseal joint planes can be thought of as passing through a patient's nose.

The orientation of the zygapophyseal joint planes in the midcervical spine permits considerable flexibility in the motions of flexion and extension and encourages the coupling motions of rotation and side bending to the same side in the upper segments (see Chap. 22). However, the more caudal segments approaching the cervicothoracic junction show a tendency for a smaller range of motion—it is here that axial loading is higher and the segmental mobility becomes markedly diminished as the thoracic cage commences.[26]

The anterior joint capsule is strong, but it is lax in neutral and extension.[27] The posterior capsule is thin and weak. This laxity allows for translation between facets. The major constraints and supports of these joints are the ligaments of the vertebral column and the IVD.

Vascular, fat-filled, synovial intra-articular inclusions[5] have been observed in these joints. These structures have been described as fibroadipose meniscoids, synovial folds, and capsular rims. The meniscoids consist of connective and fatty tissue that is highly vascularized and innervated.[12] In the cervical spine, the meniscoids function as space fillers for the uneven articular surfaces, especially in regions where the elasticity of the relatively thin cartilage is not sufficient.[12] These inclusions, which are theorized to play some role in protecting the articular surfaces as they are sucked in or expelled during movements, are prone to entrapment and can play a potential role in intra-articular fibrosis and cervical spine pain.[28] Töndury and Theiler[15] have observed that the meniscoids atrophy and virtually disappear with increasing age.

The zygapophyseal joint receives its nerve supply from the medial branches of the cervical posterior rami from C2 to C8 and the recurrent meningeal (sinuvertebral) nerve. The recurrent meningeal (sinuvertebral) nerve also innervates the anterior dural sac, the posterior AF, and the PLL. The capsular pattern of the zygapophyseal joint is a limitation of extension and equal loss of rotation and side bending, with flexion being unaffected.

Uncovertebral Joints

From C3 to T1, there usually are a total of 10 saddle-shaped, diarthrodial articulations. These articulations, known as *joints of Luschka*, *uncinate processes*, or *uncovertebral joints*, are formed between the uncinate process found on the lateral aspect of the superior surface of the inferior vertebra and the beveled inferolateral aspect of the superior vertebra.[29] The uncovertebral joints develop within the first 12 years of life, as a result of loading from the head, and become fully developed by about 33 years of age.[30,31] Two of these uncovertebral joints are found between each pair of adjacent vertebrae in the cervical spine proper (C2–3 to C6–7). The uncovertebral joint maintains a synovial compartment and creates the posterior lateral border of the IVD.[32]

The biomechanical role of the uncovertebral joint is thought to be that of a sagittally oriented guiding rail during cervical flexion and extension that acts to transfer rotation forces into side bending and posterior translation motions.[29,33,34] This function is accomplished while simultaneously ensuring that the translation and, to some extent, the side bending (lateral flexion) between adjacent vertebral bodies are limited to the sagittal plane.[29,33,34] This stabilizing feature develops and changes with age and is based on alterations in the uncinate processes.[35]

CLINICAL PEARL

The uncovertebral joints serve to

- guide cervical flexion and extension;
- reduce side bending of the cervical spine;
- prevent posterior translation of neighboring vertebrae;
- reinforce the posterolateral aspect of the IVD.[36]

Penning and Wilmink[37] highlighted a possible correlation between uncovertebral joint configuration and the coupled cervical segmental motion of side bending and axial rotation. A more recent study of the C5–6 segment level by Clausen and colleagues[38] found that both the zygapophyseal joints and the uncovertebral joints are the major contributors to coupled motion in the lower cervical spine and that the uncinate processes effectively reduce motion coupling and primary cervical motion (motion in the same direction as load application), especially in response to axial rotation and side-bending loads. [38]

The onset of degenerative changes in the cervical spine has been shown to occur more commonly at the midcervical level than at the lower cervical level.[39] The reasons for the different degrees of involvement are not clear. The degenerative changes result in the substitution of a hinge-like motion, with the pivot point on the contralateral side, in place of the normal gliding motion at the uncovertebral joints.[1] This alteration effectively transforms the cervical segment into a sellar joint.[15,37,40]

CLINICAL PEARL

With a loss of disk height as a result of degeneration or degradation of the IVD, the potential for repeated contact between the bony surfaces of the uncovertebral joint increases. This repetitive contact may result in hypertrophic changes in the bone in the form of osteophytes.[1]

The nerve roots in the midcervical level are more predisposed to osteophytic compression because of a combination of

- higher uncinate process;
- smaller anteroposterior diameter of the intervertebral foramina;
- longer course of nerve roots in close proximity to the uncovertebral joints at C4–6 levels;
- greatest segmental mobility at C5 and C6.

The vertebral artery may also be compromised in the degenerative cervical spondylotic process. When involved, the vertebral artery (see Chap. 24) usually is compromised at the level of the inferior aspect of the superior vertebra, where the apical posterolateral uncovertebral osteophytes are present.

Intervertebral Foramina

The intervertebral foramina are found between all vertebrae of the spine, except in the upper cervical spine. Although there are seven cervical vertebrae, there are eight intervertebral foramina. This difference occurs because there is a nerve root existing between the occiput and the atlas (C1) that is designated to the C1 nerve root. The cervical intervertebral foramina are 4–5 mm long and 8–9 mm high. They extend obliquely anteriorly and inferiorly from the spinal canal at an angle of 45 degrees in the coronal plane.[41] The anterior boundary of the foramen is formed by the IVD and by portions of both vertebral bodies, with the zygapophyseal joints serving as the posterior boundaries. The pedicles form the superior and inferior boundaries. The medial to lateral depth of the posterior wall is formed by the lateral aspect of the ligamentum flavum.

The intervertebral foramina serve as the principal routes of entry and exit for the neurovascular systems to and from the vertebral canal. Within each foramen are

- a segmental mixed spinal nerve;
- from two to four recurrent meningeal nerves or sinuvertebral nerves;
- various spinal arteries;
- plexiform venous connections.

Because they contribute to the innervation of the upper limb, the lower cervical spinal nerves are quite large in diameter and nearly fill the foramina. This region is vulnerable to narrowing with certain motions, or with osteophyte growth. The dimensions of the intervertebral foramina decrease with full extension and ipsilateral side bending of the cervical spine such that uncovertebral osteophytes may compress the nerve root and cervical cord posteriorly.

The spinal nerves also are in close proximity to both the ligamentum flavum and the zygapophyseal joint. Thus, zygapophyseal joint arthritis or a hypertrophic ligamentum flavum can cause posterior impingement of these nerves.

Vertebral Canal

In the cervical region, the vertebral canal contains the entire cervical part of the spinal cord, as well as the upper part of the first thoracic spinal cord segment. There are eight cervical spinal cord segments, and thus eight cervical spinal nerves (see Chap. 3) on each side, but only seven cervical vertebrae.

Ligaments

Both the function and the location of the ligaments in this region are similar to that of the rest of the spine. For the purposes of these descriptions, the short ligaments that interconnect the adjacent vertebrae are classified as segmental, whereas those that attach to the peripheral aspects of all of the vertebrae are classified as continuous.

Continuous Ligaments

Anterior Longitudinal Ligament. The ALL (Fig. 25-1) is a strong band, extending along the anterior surfaces of the vertebral bodies and IVDs, from the front of the sacrum to the anterior aspect of C2. The ALL is narrower in the upper cervical spine but is wider in the lower cervical spine than it is in the thoracic region. It is firmly attached to the superior and inferior end plates of the cervical vertebrae, but not to the cervical disks. At the waist of the centrum, the ligament thickens to fill in the concavity of the body. The ALL functions to restrict spinal extension and is thus vulnerable to hyperextension trauma.

Posterior Longitudinal Ligament

Lying on the anterior aspect of the vertebral canal, the PLL extends from the sacrum to the body of the axis (C2), where it is continuous with the tectorial membrane (Fig. 25-1). The

PLL travels over the posterior aspect of the centrum, attaching to the superior and inferior margins of the body, but is separated from the waist of the body by a fat pad and the basivertebral veins. In addition, this ligament attaches firmly to the posterior aspect of the IVDs, laminae of hyaline cartilage, and adjacent margins of vertebral bodies. The PLL is broader and considerably thicker in the cervical region than in the thoracic and lumbar regions.[42] The PLL functions to prevent disk protrusions and also acts as a restraint to segmental flexion of the vertebral column.

The dura mater is strongly adherent to the PLL at the level of C3 and higher, but this attachment diminishes at lower levels.

Ligamentum Nuchae (Nuchal Ligament)

This bilaminar fibroelastic intermuscular septum spans the entire cervical spine, extending from the external occipital protuberance to the spinous process of the seventh cervical vertebra.[43] Some consider the ligament to be an extension or a replacement of the supraspinous and interspinous ligaments.[44,45] However, an observational study by Allia and Gorniak[46] suggest that it is a distinct ligamentous structure comprised of four portions formed by aponeurotic fibers from the trapezius, splenius capitis, rhomboid minor, and the serratus posterior superior.[45] The ligament is described as being a strong, thick band of elastic tissue that aids in the suspension of the head, neck.[45] However, the function of the nuchal ligament is controversial. While Mercer[47] suggests that the only contribution of the ligament to stability is at C7 and the occiput, others have proposed that the ligament may play a more important role in cervical stability,[46,48] while still others have proposed that it many play a role in posterior dural stretching and cervicogenic headaches. Studies[45–47] have shown that when the occipitoatlantal joint is flexed, the superficial fibers of the ligament tighten and pull on the deep laminae and muscular attachments, which, in turn, pull the vertebrae posteriorly, limiting the anterior translation of flexion and, therefore, flexion itself.

Segmental Ligaments

The interspinous ligaments are thin and almost membranous, interconnecting the spinous processes. The ligament is poorly developed in the upper cervical spine but well developed in the lower.[42]

The ligamentum flavum runs perpendicularly to the spine from C1 and C2, where it is referred to as the *posterior atlantoaxial ligament*, to L5 and S1. This ligament connects the laminae of successive vertebrae, from the zygapophyseal joint to the root of the spinous process. It is formed by collagen and yellow elastic tissue and, therefore, differs from all other ligaments of the cervical spine. The ligamentum flavum of the cervical spine is fairly long, allowing an appreciable amount of flexion to occur, while maintaining tension when the head and neck are in neutral. Scarring or fatty infiltration to the ligament in this region can compromise the degree of elasticity, making the ligament lax, particularly with cervical extension. This laxity increases the potential for the contents of the vertebral canal to be compressed by the buckling ligament.[49] Any enlargement of the ligament increases the likelihood that a spinal nerve or its posterior root will become impinged.[9] The ligament appears to function as a restrictor of flexion of the neck.

Muscles

The neck muscles are characteristically grouped in layers[50]:

- The superficial layer consists of muscles that connect the skull and shoulder girdle and include the trapezius (Fig. 25-3) and sternocleidomastoid (SCM) (Fig. 25-3). Other superficial muscles, which connect the scapula with the vertebral column, include the levator scapulae and the rhomboids. The scalene muscle group (Fig. 25-4) provides a relationship between the cervical spine and the first and second ribs.
- A deeper layer links the skull and vertebral column and includes long posterior (dorsal) (splenius capitis (Fig. 25-5), semispinalis capitis, and longissimus capitis).
- The deepest layers consist of muscles that link the cervical and thoracic vertebrae, splenius cervicis, semispinalis cervicis, and longissimus cervicis.

For the most part, the muscles of the neck function to support and move the head. Given the number of degrees of freedom available at the neck, it is likely that the muscles are organized as functional synergies. Muscle synergies are conceptualized as units of control, incorporating the muscles around the joint that will act together in a functional fashion.[50] Under this concept, the central nervous system (CNS) needs only trigger a synergic unit to produce a specific movement, instead of communicating with each individual muscle.[50] Synergistic movements incorporate both agonist and antagonist muscle groups, which results in a greater level of control.

Superficial Muscles

Trapezius

The trapezius muscle (Fig. 25-3) is the most superficial back muscle. It is a flat triangular muscle that runs from the superior nuchal line and external occipital protuberance of the occipital bone to the spinous process of T12 and is the largest muscle attachment in the body. Its insertion can be traced from the entire superior aspect of the spine of the scapula, the medial aspect of the acromion, and the posterior aspect of the lateral third of the clavicle.

This muscle traditionally is divided into middle, upper, and lower parts, according to anatomy and function.

- The middle part originates from C7 and forms the cervicothoracic part of the muscle.
- The lower part, attaching to the apex of the scapular spine, is relatively thin.
- The upper part (Table 25-1) is very thin, and yet it has the most mechanical and clinical importance to the cervical spine.[51]

The innervation for the trapezius comes from the accessory nerve (CN XI) and fibers from the anterior (ventral) rami of the third and fourth cervical spinal nerves, with the former being speculated to provide the motor innervation and the latter supplying the sensory information.[52–56] The greater

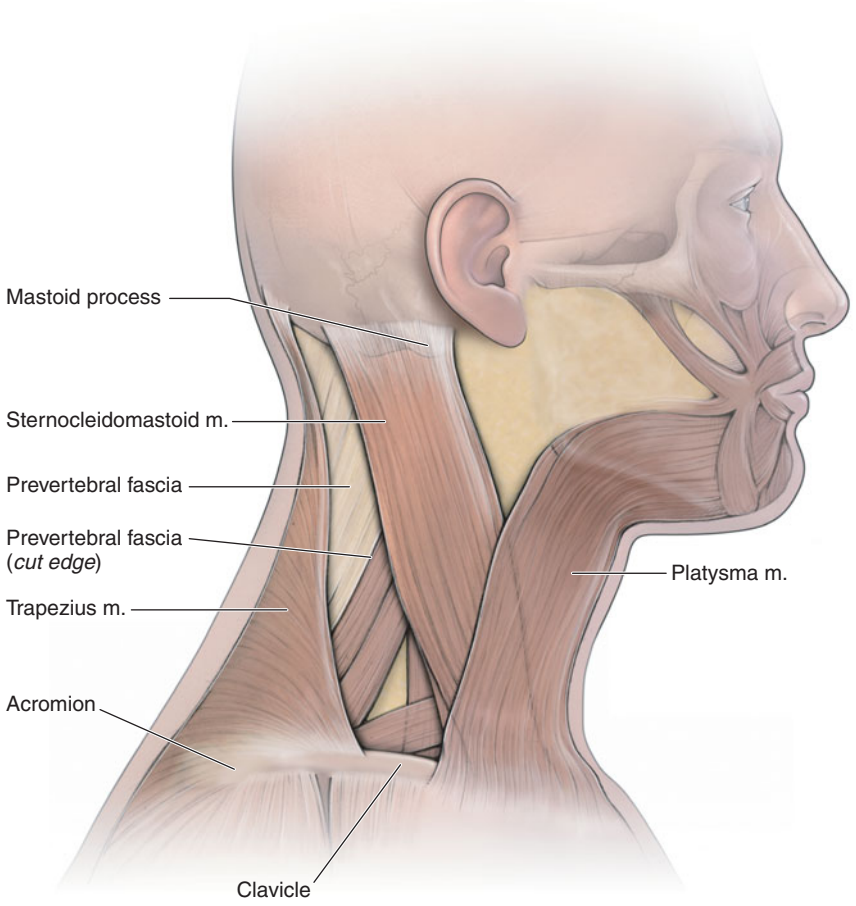

FIGURE 25-3 Muscles of the lateral and posterior cervical spine. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

occipital nerve occasionally travels through the trapezius near its superior border to reach the scalp and can become entrapped by an adaptive shortening of the upper trapezius muscle or be traumatized by a blunt force.[56–58]

The different parts of this muscle provide a variety of actions on the shoulder girdle, including elevation and retraction of the scapula. When the shoulder girdle is fixed, the trapezius can produce ipsilateral side bending and contralateral rotation of the head and neck. Working together, the trapezius muscles can produce symmetric extension of the neck and head.[59] In addition, the trapezius muscle can produce scapular adduction (all three parts), and upward rotation of the scapula (primarily the superior and inferior parts). The importance of the trapezius to the shoulder joint is discussed in Chapter 16.

Sternocleidomastoid

The SCM (Fig. 25-3) is a fusiform muscle that descends obliquely across the side of the neck, forming a distinct landmark for palpatory purposes. It is the largest muscle in the anterior neck. It is attached inferiorly by two heads, arising from the posterior aspect of the medial third of the clavicle and the manubrium of the sternum. From here, it passes superiorly and posteriorly to attach on the mastoid process of the temporal bone. The motor supply for this muscle is from the accessory nerve (CN XI), whereas the sensory innervation is supplied from the anterior (ventral) rami of C2 and C3.[60] This muscle can provide the clinician with information regarding the severity of symptoms, and postural impairments, because of its tendency to become prominent when hypertonic. The SCM also is involved with a condition called torticollis, a postural deformity of the neck (see Chap. 5 and later).

In broad terms, the actions of this muscle are flexion, side bending, and contralateral rotation of the head and neck.[59] Acting together, the two muscles draw the head forward and can also raise the head when the body is supine. This head-raising action is a combination of upper cervical extension and lower cervical flexion. The muscle is also active on resisted neck flexion. With the head fixed, it is also an accessory muscle of forced inspiration.

Levator Scapulae

The levator scapulae (Fig. 16-5), is a slender muscle attached by tendinous slips to the posterior tubercles of the transverse processes of the upper cervical vertebrae (C1–4). The levator, located deep to both the upper and the middle parts of the trapezius, can be palpated just deep to the superior border of the trapezius. It descends posteriorly, inferiorly, and laterally to the superior angle and medial border of the scapula, between the superior angle and the base of the spine (Table

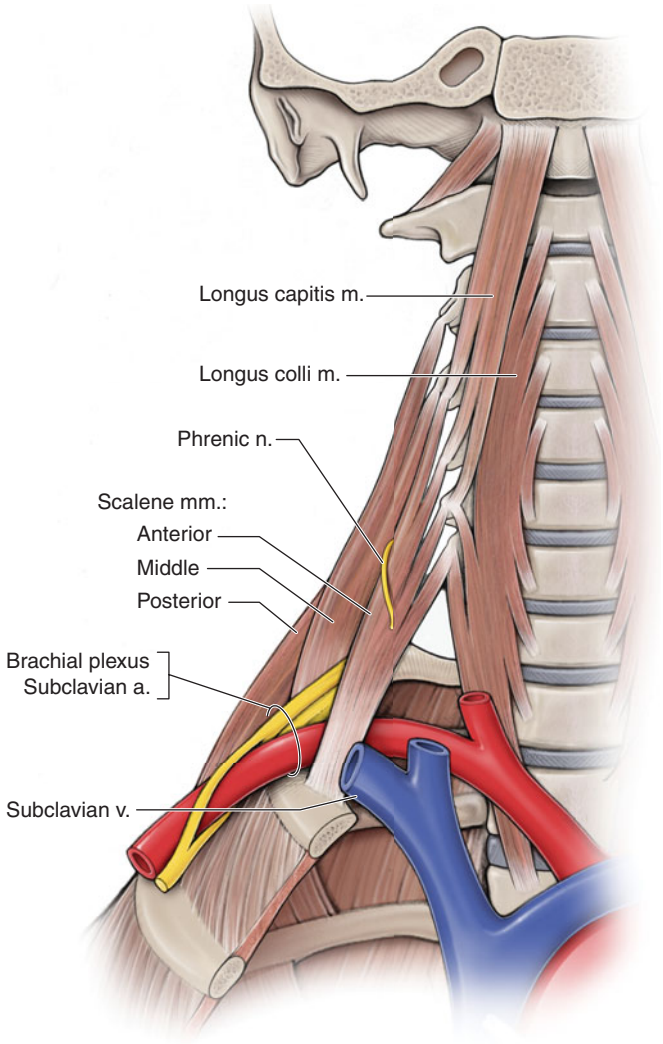

FIGURE 25-4 Muscles of the anterior cervical spine. (Reproduced, with permission, from Morton, DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

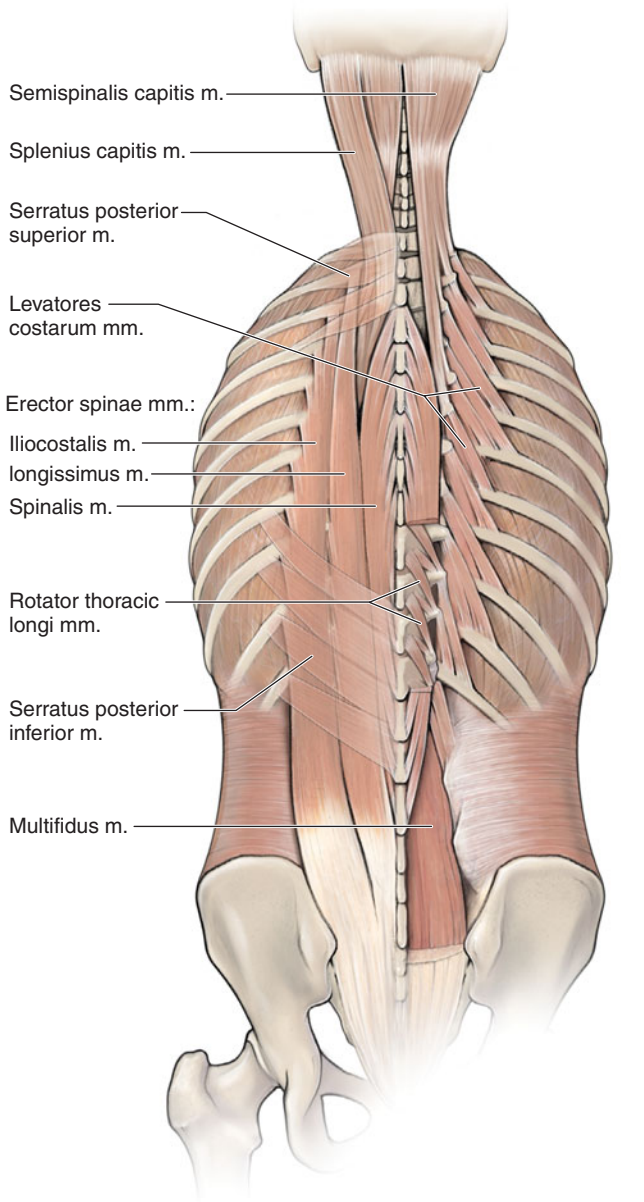

FIGURE 25-5 Deep cervical muscles. (Reproduced, with permission, from Morton, DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

25-1). The levator is the major stabilizer and elevator of the superior angle of the scapula. With the scapula stabilized, the levator produces rotation and side bending of the neck to the same side; when acting bilaterally, cervical extension is produced. With a forward head posture, the potential for this extension moment increases.[1] This abnormal anterior translation is resisted by tension within the levator scapulae and the ligamentum nuchae.[61]

CLINICAL PEARL

If the levator scapulae is shorter on one side, it may provoke contralateral suboccipital muscle spasms and subsequent headaches.[1]

The levator is supplied by direct branches of the C3 and C4 cervical spinal nerves and from C5 through the posterior (dorsal) scapular nerve. It is heavily innervated with muscle spindles.

TABLE 25-1 Attachments of Upper Trapezius and Levator Scapulae Muscles

Muscle	Proximal	Distal	Innervation
Upper trapezius	Superior nuchal line Ligamentum nuchae	Lateral third of clavicle and the acromion process	Spinal accessory
Levator scapulae	Transverse processes of upper four cervical vertebrae	Medial border of scapula at level of scapular superior angle	Posterior (dorsal) scapular C5 (C3 and C4)

Rhomboids

The rhomboid major is a quadrilateral sheet of muscle, and the rhomboid minor muscle is small and cylindrical (see Chap. 16). Together they form a thin sheet of muscle that fills much of the interval between the medial border of the scapula and the midline. Although the rhomboid minor, with its attachment to the spinous processes of C7 and T1, has a slight association with the cervical spine, the rhomboid major, arising from the spinous processes of T1–5, is inactive during isolated head and neck movements. The two muscles descend from their points of origin, passing laterally to the posterior aspect of the vertebral border of the scapula, from the base of the spine to the inferior angle. Both of these muscles receive their nerve supply from the posterior (dorsal) scapular nerve (anterior (ventral) ramus of C4–5). The principal action of these muscles is to work with the levator scapulae to control the position and movement of the scapula. Both of the muscles are involved with concentric contractions during rowing exercises or other activities involving scapular retraction.

Scalenes

The scalenes (Fig. 25-4) extend obliquely like ladders (*scala* means ladder in Latin) and share a critical relationship with the subclavian artery. Tightness of these muscles will affect the mobility of the upper cervical spine. In addition, because of their distal attachments to the first and second ribs (Table 25-2), they can, if in spasm, elevate the ribs and be implicated in thoracic outlet syndrome (TOS).[62,63]

Scalenus Anterior. The scalenus anterior (see Fig. 25-4) runs vertically, behind the SCM on the lateral aspect of the neck. Arising from the anterior tubercles of the C3–6 transverse processes, it travels to the scalene tubercle on the inner border of the first rib. The osteal portion of the vertebral artery and the stellate ganglion are located lateral to the scalenus anterior. Acting from above, the scalenus anterior, like the rest of the scalenes, is an inspiratory muscle, even with quiet breathing.[64] Working bilaterally from below, it flexes the spine. Unilaterally, it side bends the spine ipsilaterally and rotates the spine contralaterally. It is supplied by the anterior (ventral) rami of C4, C5, and C6.

Scalenus Medius. The scalenus medius (see Fig. 25-4) is the largest and longest of the group, attaching to the transverse processes of all cervical vertebrae except the atlas (although it often attaches to this) and running to the upper border of the first rib. It is separated from the anterior scalene by the carotid artery, and cervical nerve, and is pierced by the nerve to the rhomboids (posterior (dorsal) scapular) and the upper two roots of the nerve to the serratus anterior (long thoracic). Working unilaterally on the cervical spine, the scalenus medius is an ipsilateral side bender of the neck. Working bilaterally, it is a cervical flexor.

Scalenus Posterior. The scalenus posterior (Fig. 25-4) is the smallest and deepest of the group, running from the posterior tubercles of the C4–6 transverse processes to attach to the outer aspect of the second rib. It functions to elevate or fix the second rib and side bends the neck ipsilaterally. It is innervated by the anterior (ventral) rami of C5, C6, and C7.

Scalenus Minimus (Pleuralis). The scalenus minimus is a small muscle slip, running from the transverse process of C7 to the inner aspect of the first rib and the dome of the pleura. It is a suprapleural membrane that is often considered to be the expansion of the tendon of this muscle. The muscle functions to elevate the dome of the pleura during inspiration, and is innervated by the anterior (ventral) ramus of C7.[65]

Platysma. The broad sheet of the platysma muscle is the most superficial muscle in the cervical region (Fig. 25-3). The platysma covers most of the anterolateral aspect of the neck, the upper parts of the pectoralis major, and deltoid, extending superiorly to the inferior margin of the body of the mandible. As a muscle of facial expression, it cannot affect bony motion, except perhaps as a passive restraint to head extension. It is supplied by the cervical branch of CN VII (facial).

Deeper Muscles of the Back

The deep or intrinsic muscles of the back are the primary movers of the vertebral column and head and are located deep

TABLE 25-2 Attachments of Scalene, Longus Colli, and Longus Capitis Muscles

Muscle	Proximal	Distal	Innervation
Scalenus			
Anterior	Anterior tubercles of C3–6	Superior crest of first rib	Anterior (ventral) primary rami of cervical spinal nerves
Middle	Posterior tubercles of C2–7	Superior crest of first rib	
Posterior	Posterior tubercles of C5–7	Outer surface of second rib	
Longus colli	Anterior tubercles of C3–5 Anterior surface of C5–7, T1–3	Tubercle of the atlas, anterior tubercles of C5 and C6, and anterior surface of C2–4	Anterior (ventral) primary rami of cervical spinal nerves
Longus capitis	Anterior tubercles of C3–6	Inferior occipital bone and basilar portion	Anterior (ventral) primary rami of cervical spine nerves

to the thoracolumbar fascia. The muscles in all of these groups are segmentally innervated by the lateral branches of the posterior (dorsal) rami of the spinal nerves.

Splenius Capitis

The splenius capitis (Fig. 25-5) extends upward and laterally, from the posterior (dorsal) edge of the nuchal ligament and the spinous processes of the lower cervical and upper thoracic vertebrae (T4–C7) to the mastoid process of the occipital bone just inferior to the superior nuchal line and deep to the SCM muscle.

Splenius Cervicis

The splenius cervicis is just inferior and appears continuous with the capitis, extending from the spines of the third to the sixth thoracic vertebrae to the posterior tubercles of the transverse processes of the upper cervical vertebrae.

The splenius capitis and splenius cervicis muscles are two important head and neck rotators. From their attachments (Table 25-3), it is clear that these two muscles are capable of producing ipsilateral rotation, side bending, and extension at the spinal joints they cross.

Cervical Erector Spinae

The erector spinae complex spans multiple segments, forming a large musculotendonous mass (Fig. 25-6) consisting of the iliocostalis, longissimus, and spinalis muscles (Tables 25-4 and 25-5).

- The iliocostalis cervicis appears to function as a stabilizer of the cervicothoracic junction and lower cervical spine.
- The semispinalis has thoracis, cervicis, and capitis divisions. The obliquus capitis superior (superior oblique) and inferior (inferior oblique) and the rectus capitis posterior major and minor (see Chap. 23) lie underneath the semispinalis capitis and splenius capitis muscles.[66] The semispinalis cervicis is a stout muscle that extends superiorly to the spinous process of vertebra C2, functioning as a strong extensor of the lower cervical spine.[1]

- The interspinales and intertransversarii, which interconnect the processes for which they are named, produce only minimal motion because they can influence only one motion segment and are more likely to function as sensory organs for reflexes and proprioception.[67]

Deep Neck Flexors

The prevertebral muscles of the neck consist of:

- ***Longus colli.*** The longus colli (Fig. 25-4) consists of a vertical portion that originates from the bodies of the first three thoracic and last three cervical vertebrae, an inferior oblique portion that originates from the bodies of the first three thoracic vertebrae, and the superior oblique portion that originates from anterior tubercles of the transverse processes of C3–5. The various portions of the longus colli insert into the bodies of C2–4, the anterior tubercles of the transverse processes of C5–6, and the anterior tubercle of the atlas. The longus colli functions to flex (and assists in rotating) the cervical vertebrae and head. Acting singly, the longus colli side bends the vertebral column. The longus colli is innervated by branches of the anterior primary rami of C2–8.
- ***Longus capitis.*** The longus capitis (Fig. 25-4) originates from the anterior tubercles of the transverse processes of C3–6 and inserts onto the inferior surface of the basilar part of the occipital bone. The longus capitis functions to flex (and assists in rotating) the cervical vertebrae and head. It is innervated by the muscular branches of C1–4.
- ***Rectus capitis anterior.*** The rectus capitis anterior (RCA) originates from the lateral mass of the atlas and inserts onto the base of the occipital bone in front of the foramen magnum. The RCA flexes and rotates the head and is innervated by the muscular branches of C1–2.
- ***Rectus capitis lateralis.*** The rectus capitis lateralis (RCL) originates from the upper surface of the transverse process of the atlas and inserts onto the inferior surface of the jugular process of the occipital bone. The RCL side bends the head to the ipsilateral side and is innervated by branches of the anterior rami of C1–2.

CLINICAL PEARL

The longus colli and longus capitis play an important role in cervical stabilization (see "Muscle Control" section).

Neurology

The nerve supply to the cervical structures is rather unique because of the association that some of the muscles have with the cranial nerves. The cervical spine is the only region that has more nerve roots than vertebral levels.[8]

In general, structures supplied by the upper three cervical nerves can cause neck and head pain (see Table 23-1), whereas the mid to lower cervical nerves can refer symptoms to the shoulder, anterior chest, upper limb, and scapular area.[68]

Cervical proprioceptive input has considerable influence on posture through the tonic neck reflex and on eye movement and accommodation through the cervico-ocular and vestibulo-ocular reflexes (see Chap. 3).[68–70] It is probably no accident that the two largest postural muscles of the head and neck, the trapezius and the SCM muscles, are partly innervated by the accessory nerve (CN XI).

Vascular Supply

The middle cervical segments are supplied by radicular branches off the extradural vertebral artery and are the most common segments to be affected in vertebral artery disease.[71] The vertebral artery is detailed in Chapter 24.

The common carotid artery bifurcates at the middle to upper cervical level into the internal and external carotid arteries. The carotid body, a specialized structure that senses oxygen and carbon dioxide levels in the blood, is located at this bifurcation.[8] The carotid sinus, which contains baroreceptors that monitor blood pressure, is located at a point before the bifurcation.[8]

Cervical Lordosis

The amount of cervical lordosis is a factor of the zygapophyseal joint planes and the cervical IVDs. Under normal conditions, the C4–5 interspace is considered the midpoint of the curve, and the center of gravity (COG) for the skull lies anterior to the foramen magnum. The longus colli has been shown to have an important supporting role on the cervical curve.[72]

A reduction in the cervical lordotic curve because of injury or abnormal posture results in more weight being borne by the vertebral bodies and IVDs, whereas an increase in the lordosis increases the compressive load on the zygapophyseal joints and posterior elements. Watson and Trout[73] have demonstrated a link between a lack of endurance capacity of the upper cervical and deep neck flexors and the forward head posture (see later).

Cervicothoracic Junction

The cervicothoracic junction comprises the C7–T1 segment, although functionally it includes the seventh cervical vertebra, the first two thoracic vertebrae, the first and second ribs, and the manubrium. In addition, the cervicothoracic junction forms the thoracic outlet, through which the neurovascular structures of the upper extremities pass. Lewit[74] considers the cervicothoracic junction to be the third major area of the spine for musculoskeletal problems, with the craniovertebral area and the lumbosacral junction being first and second, respectively.

BIOMECHANICS

The motions that occur at the cervical spine correspond to motions of the head, although the range of head movement bears little relation to the range of neck movement and that the total range is the sum of both the head and the neck motions.[75]

The cervical spine is a complex mechanical linkage composed of multiple degrees of freedom of movement about each of its joints and at least 20 pairs of muscles, many of which are capable of performing similar actions.[50] It is estimated that the osseoligamentous system contributes 20% to the mechanical stability of the cervical spine while 80% is provided by the surrounding neck musculature.[76] The role of the ligaments in stabilization occurs mainly at end of range postures,[77] while the muscles supply dynamic support in activities around neutral- and mid-range postures.[78]

At the zygapophyseal joints, there is a sagittal range of 50–80 degrees in each direction of flexion and extension.[79] The only significant arthrokinematic motions available to the zygapophyseal joint are an inferior, medial glide of the inferior articular process of the superior facet during extension and a superior, lateral glide during flexion. Segmental side bending is, therefore, extension of the ipsilateral joint and flexion of the contralateral joint. Rotation, coupled with ipsilateral side bending, also involves extension of the ipsilateral joint and flexion of the contralateral. Because of their multiple insertions, many of the neck muscles have multiple functions or can change their function depending on the initial position of each vertebral joint and the degree to which the joints are free to move in each of the planes of motion.[50] Thus, a voluntary motor task in the head and neck can be accomplished through a variety of combinations of kinematic and muscle actions. Considering that most functional daily tasks are performed in and around midrange postures, the muscles controlling the cervical spine are subject to constant external and internal forces.[78]

Flexion

Flexion may be divided into three sequential phases.[80,81] The initial phase begins in the lower cervical spine (C4–7) where C6–7 makes its maximum contribution followed by the C5–6 segment and then by C4–5. Motion in the second phase occurs initially at C0–2 followed by C2–3 and C3–4. The first phase of motion occurs again at the lower cervical spine (C4–7) initially, with the C4–5segment followed by C5–6 then the C6–7 segment.[80,81]

At the segmental level, flexion is described as an anterior osteokinematic rock tilt of the superior vertebra in the sagittal plane, a superoanterior glide of both superior facets of the zygapophyseal joints, and an anterior translation slide of the superior vertebra on the IVD (see Fig. 25-7). This produces an anterior (ventral) compression and a posterior (dorsal) distraction of the cervical disk. The uncovertebral joint lies on, or very near to, the axis of rotation for flexion and extension. Consequently, the main arthrokinematic motion that seems likely to be occurring here is an anterior spin (or very near spin).[82] This arthrokinematic spin appears especially probable, as impairments of the uncovertebral joint seem to be unaffected by flexion or extension. Thus, uncovertebral restrictions may be detected in all cervical positions, although flexion partly disengages the joint because of its posterior position on the vertebra.[82]

Although all of the following anatomic movement restrictors act to some degree on most of the components of flexion, they act particularly on the associated movement component.

- Anterior osteokinematic motion is restrained by the extensor muscles and the posterior ligaments (posterior longitudinal, interspinous, and ligamentum flavum).
- Superoanterior arthrokinematic is restrained by the joint capsule, whereas translation is restrained by the disk and the nuchal ligament.

Extension

Extension is described as a posterior osteokinematic sagittal rock, an inferoposterior glide and approximation of the superior facets of the zygapophyseal joints, and a posterior translation of the vertebra on the disk (see Fig. 25-8). The uncovertebral joint undergoes a posterior arthrokinematic spin. The osteokinematic motion of extension is restricted by the anterior prevertebral muscles and the ALL. The arthrokinematic motion is restricted by the zygapophyseal joint capsule.[82] The IVD restrains the posterior translation.

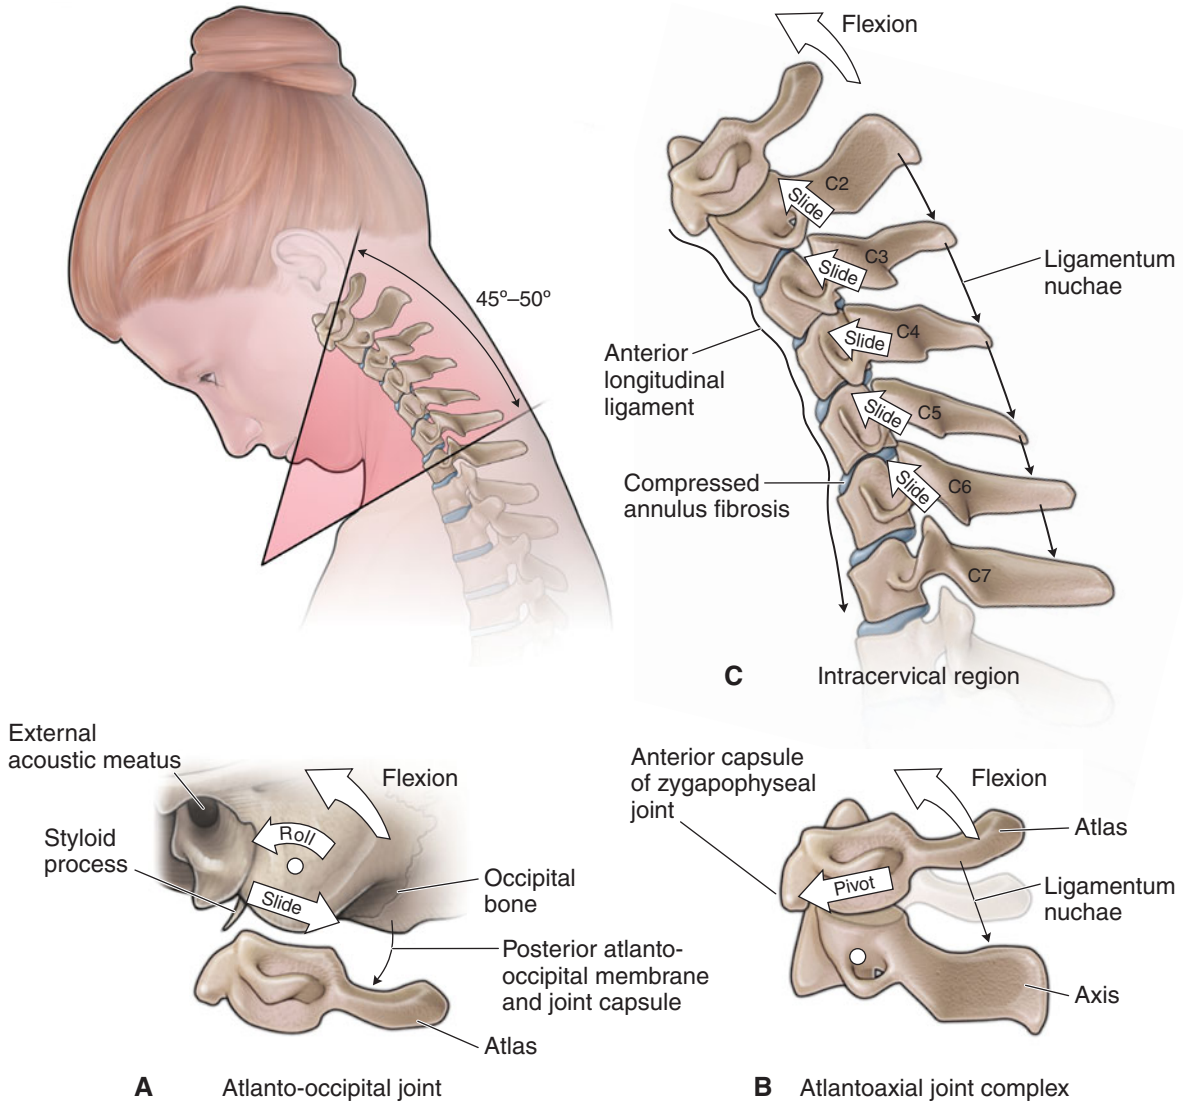

FIGURE 25-7 Kinematics of craniocervical flexion.

CLINICAL PEARL

Forward flexion occurs with rotation below the C5–6 level, and extension occurs with rotation above the C4–5 level. The net result is that whenever cervical spine rotation occurs, the greatest degree of weight bearing is on the anterior edge of the vertebral bodies below the C5 to C6 segments and on the posterior edge above C4 to C5 (this factor has been implicated in the cause of spondylosis in these areas).[1]

The greatest amount of cervical motion occurs at the C5 to C6 segment, with the C4 to C5 and C6 to C7 segments a close second.[79] Significant flexion occurs at C5 to C6, and extension around C6 to C7.[83] A coupled translation of between 2 and 3.5 mm occurs with flexion and extension. Side bending averages about 10 degrees to each side in the midcervical segments, decreasing in the caudal segments.[83]

Side Bending

Side bending (lateral flexion) is an ipsilateral osteokinematic rock, a superoanterior glide of the contralateral superior facet, and a posteroinferior glide of the ipsilateral facet (see Fig. 25-9). In addition, there is a contralateral translation of the vertebra on the disk, an inferomedial glide of the ipsilateral uncovertebral joint, and a superolateral glide of the contralateral uncovertebral joint. A composite curved translation results. This curve is formed by the superoinferior linear glides of the zygapophyseal joints, the oblique inferomedial and superomedial glides of the uncovertebral joints, and the linear translation across the disk.[82]

The osteokinematic rock can be limited by the contralateral scalenes and intertransverse ligaments. The uncovertebral and zygapophyseal arthrokinematic motions can be limited by the joint capsule, and the translation is limited by the IVD. If the side bending is limited but the translation is okay, it is unlikely

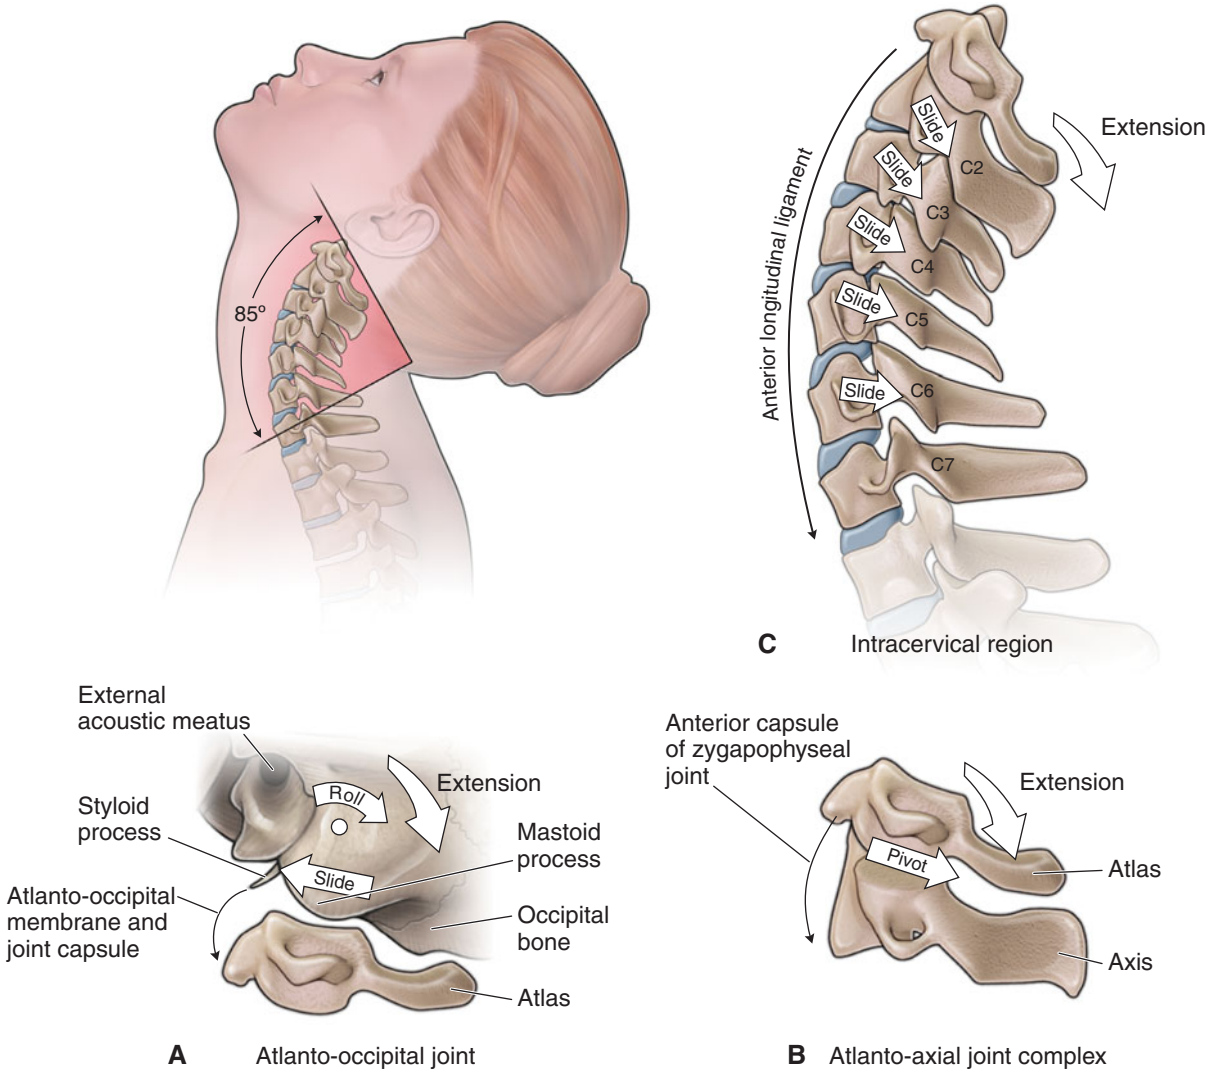

FIGURE 25-8 Kinematics of craniocervical extension.

that the joint complex (the zygapophyseal joint, disk, or uncovertebral joint) is impaired; instead, these findings may implicate adaptive shortening of the soft tissues.[82] However, if the translation is also limited, a problem with the joint complex also probably exists.

Rotation

Rotation is chiefly an osteokinematic motion of the vertebra about a vertical axis that is coupled with ipsilateral side bending (see Fig. 25-10). Presumably, the translation follows the side bending (i.e., contralateral), resulting in the same uncovertebral and zygapophyseal arthrokinematic motions as does side bending.[82]

Muscle Control

The control of head and neck postures and movements is a complex task, especially in the presence of pain or dysfunction. The muscle groups of the cervical region may be divided into those that sustain postures or stabilize the segments and those that produce movement.[84–86] Considerable biomechanical, physiological and clinical research in both the cervical and lumbar regions has been undertaken which supports Bergmark's[86,87] model for a functional division between the deep and more superficial muscles in their relative contributions to spinal support and control.[78] According to this model, the more superficial multisegmental (global) muscles have the responsibility for maintaining equilibrium of external forces (torque production and control of the head) so that the load transmitted to the spinal segments can be controlled efficiently by the deep intersegmental (local) muscle system.[68,78,86]

The SCM (anteriorly) and the semispinalis capitis and splenius capitis (posteriorly) are thought to be the global muscles of the neck, whereas the local system is thought to comprise the longus capitis and colli (Table 25-2),[72] semispinalis cervicis, and multifidus.[88] The longus colli and posterior (dorsal) neck muscles form a muscle sleeve that surrounds the cervical column to support the cervical spinal segments in functional movements.[72]

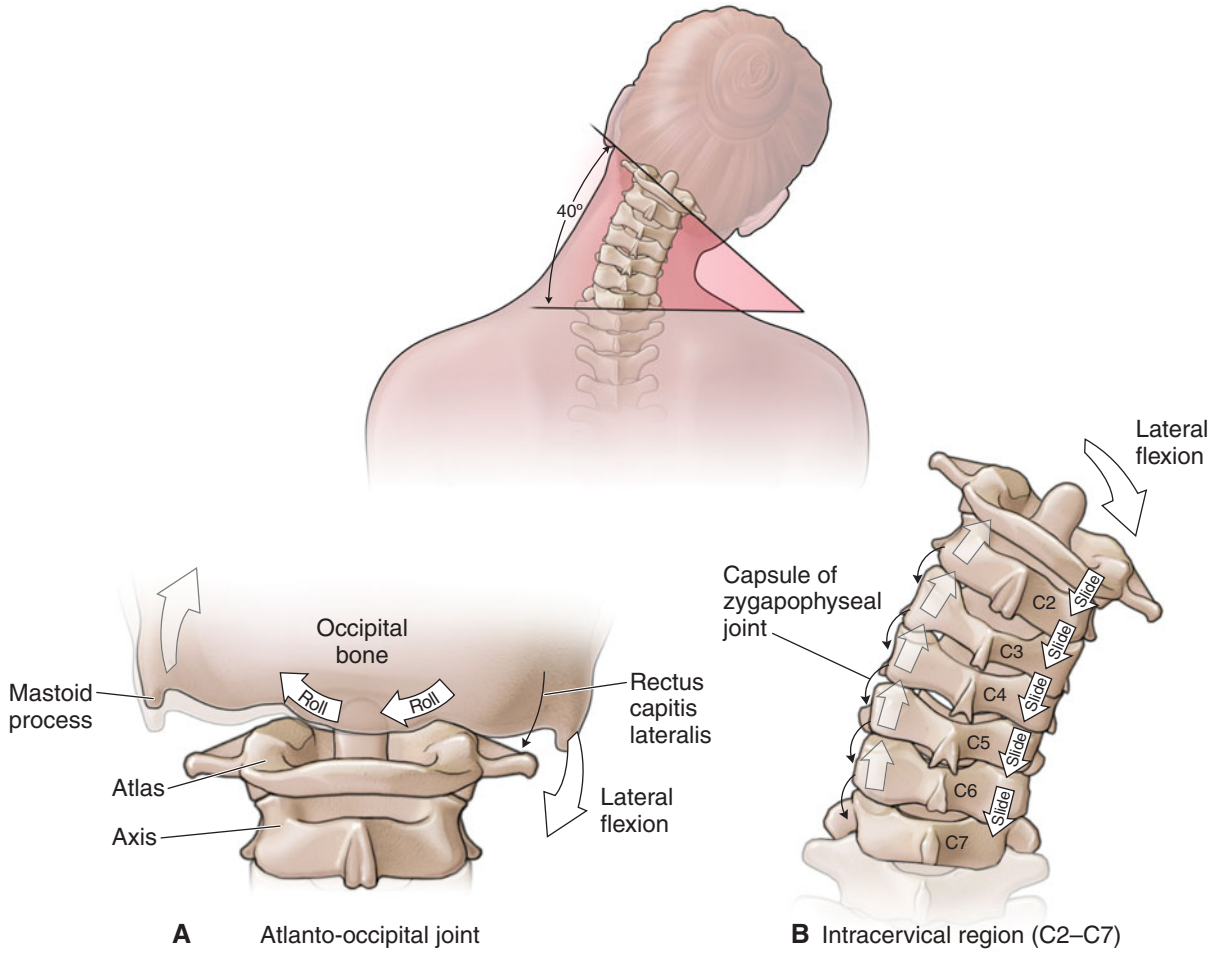

FIGURE 25-9 Kinematics of craniocervical side bending.

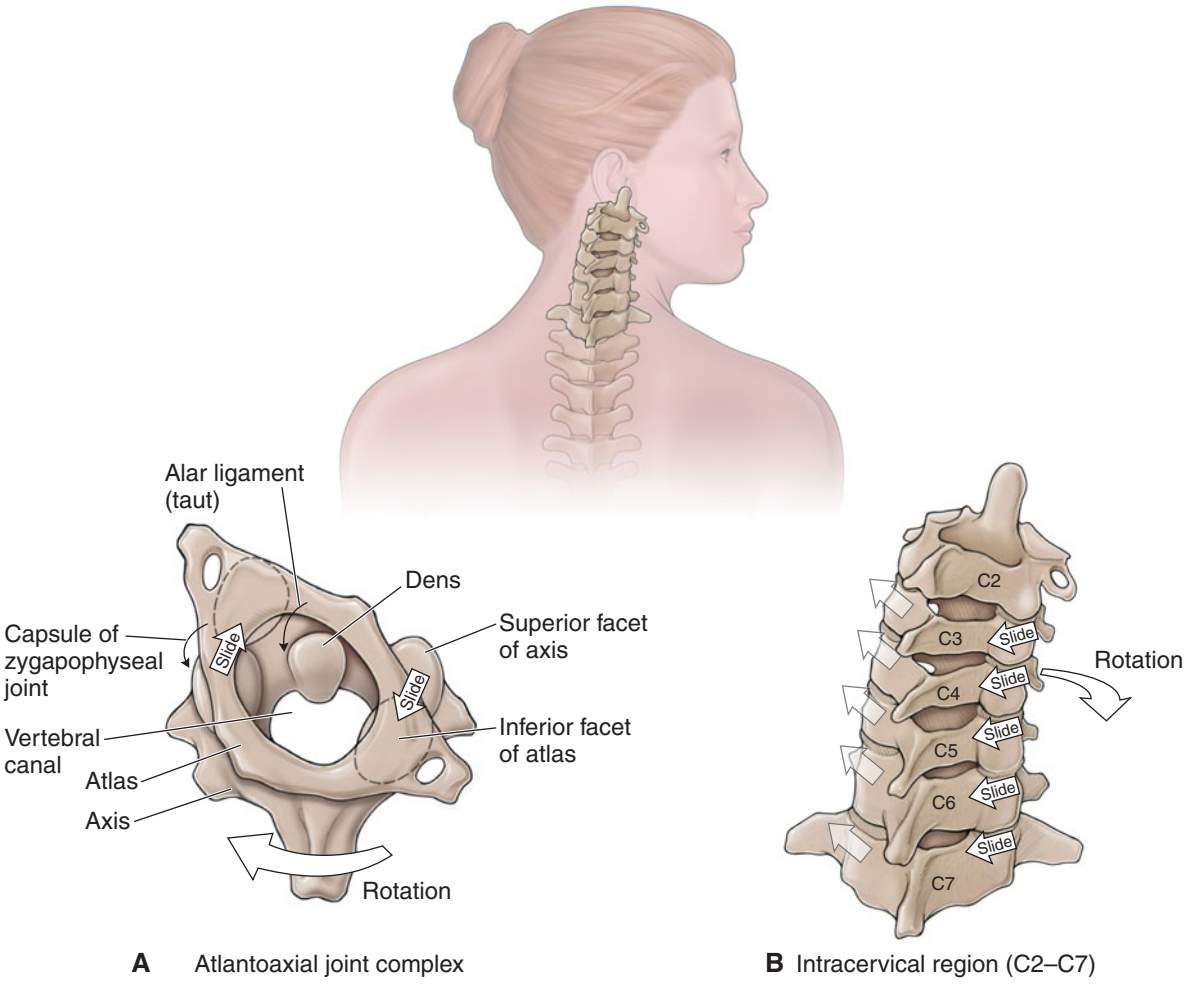
Patients with neck pain have been found to demonstrate generally less torque production (strength and endurance) in all planes, with a greater loss in the cervical flexors than extensors.[89] However, addressing strength alone in research and exercise programs may oversimplify the problems in the neuromuscular system associated with neck pain.[78] Recent research has recognized the vital role that activation of the deep neck flexor muscles plays in supporting the cervical segments and the cervical curve (see "Muscle Function Testing: Deep Neck Flexors" section later).[72,88,90] Indeed, impairment in the axioscapular-girdle muscles has been linked clinically to cervical pain syndromes.[84,91–95] The nature of the impairment in the cervical and cervicobrachial muscle systems indicates the need for careful and precise movement analysis and muscle testing to appreciate and accurately define the problem.[78]

EXAMINATION

The cervical spine is an area with a high potential for serious injury, which makes this a region of the body that needs to be examined with caution, especially when there is a history of acute and recent trauma of the neck, because of the potential for the examination itself to be harmful.[96] Although most conditions involving neck and upper limb symptoms can be diagnosed after a careful history and physical examination, in cases of significant trauma, imaging studies may be required to exclude a fracture or instability. Where possible, the patient should be examined for central and/or peripheral neurologic deficit, neurovascular compromise, and serious skeletal injury, such as fractures or craniovertebral ligamentous instability.

Winkel and colleagues[97] clinically categorize cervical disorders by the location of symptoms and the etiology of each condition:

- ***Local cervical syndrome (LCS).*** This syndrome manifests with local neck complaints, resulting from cervical muscle strain, ligament sprain, or a primary or secondary disk-related condition.
  - A primary disk-related LCS is characterized by symptoms that may result from a protrusion, prolapse, or extrusion of the disk.
  - A secondary disk-related LCS is characterized by symptoms resulting from gradual changes in the cervical spine that have been generated by previous degradation of



A Atlantoaxial joint complex **B** Intracervical region (C2–C7)

FIGURE 25-10 Kinematics of craniocervical rotation.

the IVD. These changes include internal disk disruption and synovitis or irritation of the zygapophyseal and uncovertebral joints. In the cervical spine, myofascial pain may be a secondary tissue response to an IVD or zygapophyseal joint injury.[98] The cervical zygapophyseal (facet) joints can be responsible for a significant portion of chronic neck pain. Established referral zones for the cervical zygapophyseal joint[99,100] overlap both myofascial and dermatomal pain patterns. Cervical zygapophyseal joint pain is typically unilateral and is described by the patient as a dull ache. Occasionally, the pain can be referred into the craniovertebral or interscapular regions.

- ***Cervicobrachial syndrome.*** This syndrome includes symptoms in the local cervical region, as well as in one or both upper extremities, as a result of nerve root irritation through compression or tension of the nerve root.
- ***Cervicocephalic syndrome.*** This syndrome is characterized by complaints in both the neck and the head and includes symptoms such as dizziness, tinnitus, and headache. These symptoms may result from articular, ligamentous, neurologic, organic, or vascular sources.
- ***Cervicomedullary syndrome.*** This syndrome is characterized by spinal cord symptoms associated with cord compression at the cervical spine (cervical myelopathy).

Clearing tests for the cervical spine include

- vertebral artery tests;
- Sharp–Purser test;
- articular stability tests;
- transverse ligament test;
- alar ligament test;
- temporomandibular joint (TMJ) assessment.

Once damage to the vertebral artery (see Chap. 24) and transverse ligament (see Chap. 23) has been ruled out, the most likely pain candidates are assessed first. These include the bone, muscles, ligaments, zygapophyseal joints, and IVD. In addition, because of its close proximity, a quick examination of the TMJ should be performed to rule out pain referral from this joint (see Chap. 26). The examination must be graduated and progressive so that the testing can be discontinued at the

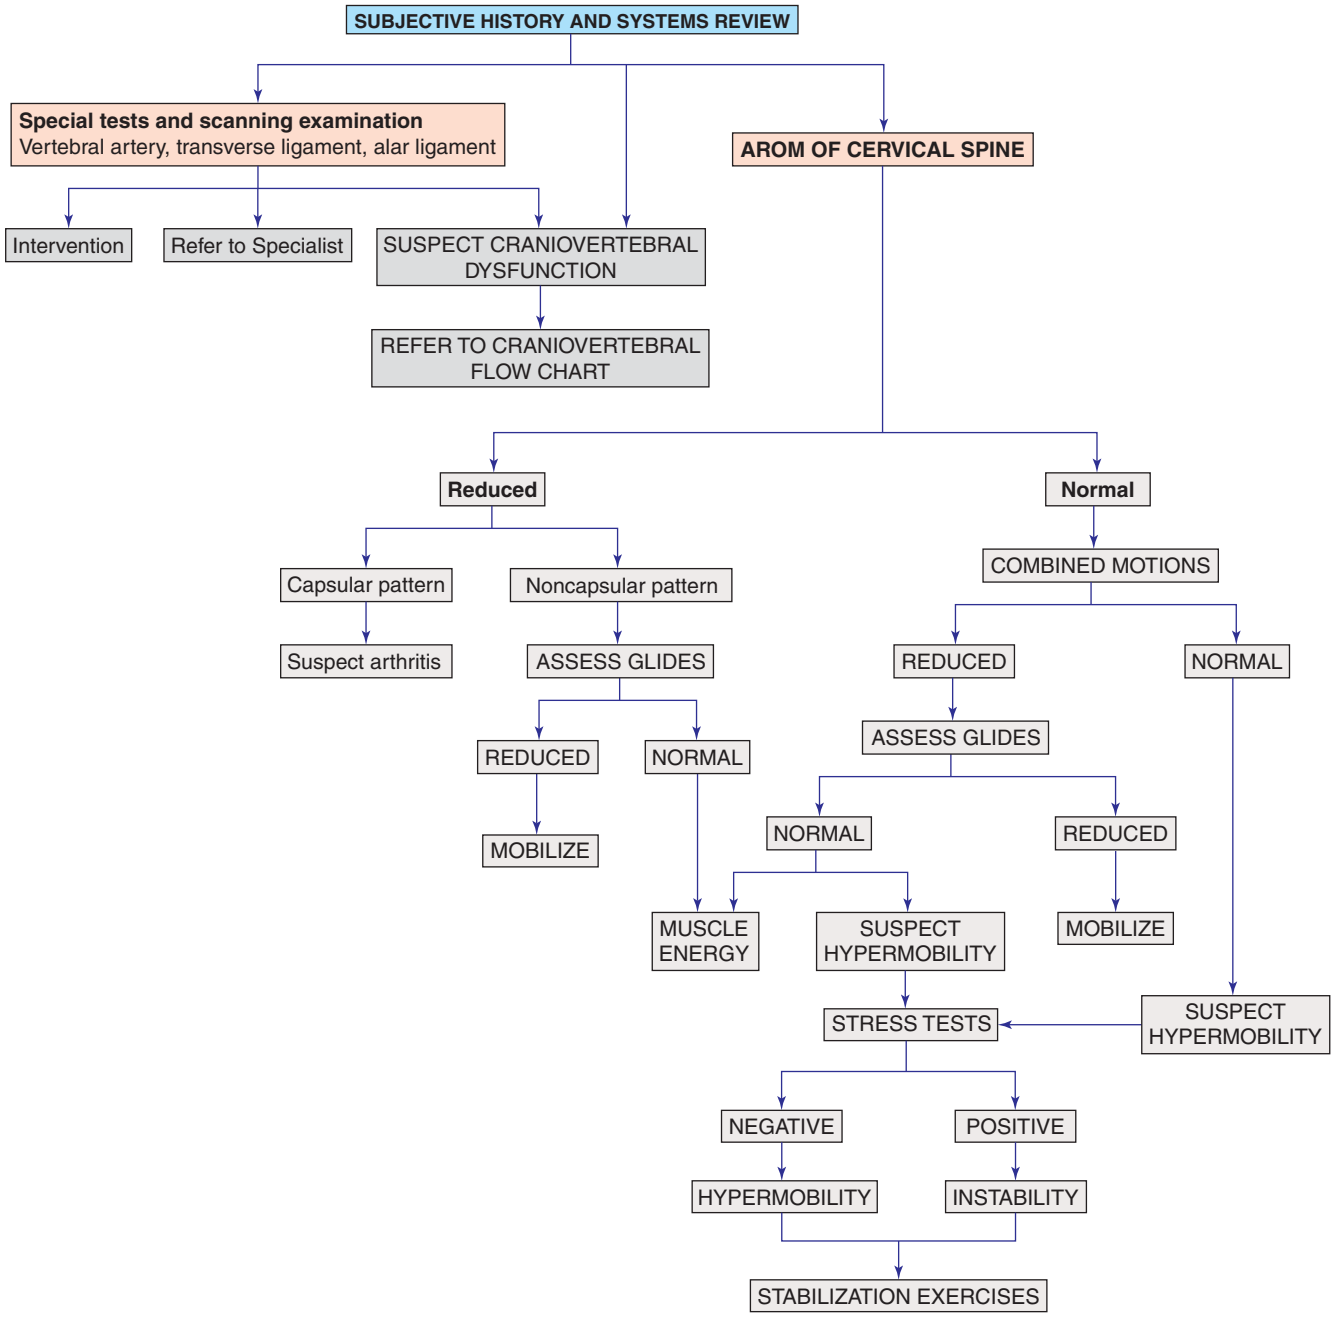


FIGURE 25-11 An examination and treatment algorithm for the mid-lower cervical spine.

first signs of serious pathology.[96] An examination and treatment algorithm for the mid-lower cervical spine is outlined in Figure 25-11.

History

The most common symptoms of cervical disorders are ongoing or motion-induced neck or arm pain, or both, and suboccipital headache.[12] In addition to the questions listed under History in Chapter 4, the clinician should obtain the following information.

The clinician must determine whether the trauma occurred and the exact mechanism. In acute sprains and strains, patients typically relate an activity that precipitated the onset of their symptoms. This may be lifting or pulling a heavy object, an awkward sleeping position, a hyperextension injury, or prolonged static postures. In whiplash-associated disorders (WADs), patients generally describe an accident in which they were unexpectedly struck from the rear, front, or side. Rotational injuries may also occur. If there were neurologic symptoms following the trauma (paresthesias, dizziness, tinnitus, visual disturbances, or loss of consciousness), more severe damage should be suspected.[101] If the patient reports electric shock-like symptoms down the spine with neck flexion (Lhermitte's sign), the clinician should consider the possibility of inflammation or irritation of the meninges.[102–104] A traumatic mechanism of injury with complaints of nonspecific cervical symptoms that are exacerbated in the vertical position,

and relieved with the head supported in the supine position, is suggestive of cervical instability, especially if the patient reports that dysthesias of the face occur with neck movement.[105–107]

For the purposes of the examination, it is important to establish a baseline of symptoms so that the clinician is able to determine whether a particular movement aggravates or lessens the patient's symptoms. The history can provide the clinician with information as to the location of the patient's symptoms (head, neck, shoulder, arm, and hand), the nature of the symptoms (constant, intermittent, or variable), the type of symptoms (pain, paresthesia, numbness, weakness, and stiffness), the severity of the condition, and the activities or positions that appear to aggravate or improve the patient's condition. It is also important to determine the type of work the patient does and whether that work involves sustained postures, the potential for eye strain, repetitive motions of the head, neck and upper extremity, or heavy lifting. Symptoms associated with coughing and sneezing are often associated with disk pathology. Radicular pain may be accompanied by sensorimotor symptoms.[12]

The patient's chief complaint should be determined. The clinician should determine the location and boundaries of the symptoms. All symptoms present should be recorded on a body diagram, even those that may initially appear unrelated. If pain is the major symptom, the clinician should attempt to quantify the pain using a pain rating scale. It is also appropriate at this time to establish the patient's goals.

Asking the patient to describe his or her symptoms over a 24-hour period can provide the clinician with valuable information about the severity, the positions and activities that aggravate or relieve the symptoms, and the duration of the symptoms. Patients who report difficulty in sleeping because of pain may have an inflammatory condition, but the more insidious causes of night pain, such as malignancy, must be ruled out. The patient's sleeping position and habits should be investigated. Cervical symptoms often are increased when a foam or very firm pillow is used.[108] Sleeping in the prone position requires adequate cervical and upper thoracic rotation. Some degree of cervical extension also is required, depending on the number and type of pillow used. The onset of symptoms may also provide clues as to the type of tissue involved. Muscle or ligamentous pain may either occur immediately following trauma or be delayed for several hours or days. Bone pain usually occurs immediately.

The reports of headaches or facial pain, depending on frequency and severity warrant special attention (see Systems Review).

It is important for the clinician to determine whether the patient has had successive onsets of similar symptoms in the past, because recurrent injury tends to have a detrimental effect on the potential for recovery. If the patient has had a recurrent injury, the clinician should note how often, and how easily, the injury has recurred and the success or failure of previous interventions.

The clinician must determine whether there are musculoskeletal symptoms elsewhere. It is well established that the head, neck, upper thoracic regions, and upper extremities can be sites of referred pain. Thoracic interscapular pain, at a point level with T4–5, is a very common complaint, especially in women.[2] This pain is thought to be posture related.

CLINICAL PEARL

Referred symptoms that are cervical in origin can occur in the upper extremities, thoracic spine, scapula, and, occasionally, the upper chest. Pain may be referred to the tip of the acromion or scapular region via the cutaneous branches of the upper thoracic posterior (dorsal) rami.[109] The rib articulations of cervicothoracic region may produce local pain, or refer pain to the suprascapular fossa or shoulder.[110]

Neck pain accompanied by widespread musculoskeletal pain raises the strong possibility of fibromyalgia, whereas neck pain with synovitis of peripheral joints suggests an inflammatory arthropathy, such as rheumatoid arthritis.[111] Myofascial pain syndromes are characterized by generalized aching and the presence of trigger points (see Chap. 10). The basic pathologic impairment in myofascial pain has yet to be substantiated.[112,113] Pain that is constant in nature and unrelated to rest or activity may be inflammatory in origin, in which case physical therapy and, specifically, manual therapy may be inappropriate.[114]

A report of diffuse nonspecific neck pain that is exacerbated by neck movements is suggestive of mechanical neck pain, cervical facet syndrome,[115] or a cervical strain/sprain.[116] Conditions that have a mechanical origin usually are improved with rest, although they may worsen initially on retiring.[117] Pain caused by sustained positions and postures, such as the upper crossed postural syndrome,[84] may awaken the patient at night but usually is relieved with a change of position.

CLINICAL PEARL

An insidious onset of symptoms could suggest postural (e.g., TOS), degenerative, or myofascial origins; or a disease process, such as ankylosing spondylitis, cervical spondylosis, or facet syndrome. An insidious onset may also indicate the presence of a serious pathology such as a tumor.

Systems Review

General health questions provide information about the status of the cardiopulmonary system, the presence or absence of systemic disease, and medications the patient may be taking that might affect the examination or intervention. Warning signs in the cervical region include

- unexplained weight loss;
- evidence of compromise to two or three spinal nerve roots;
- gradual increase in pain;
- expansion of pain in terms of the regions involved;
- spasm with passive range of motion of the neck;
- visual disturbances;
- painful and weak resistive testing;

- hoarseness;
- limited scapular elevation;
- Horner's syndrome;
- T1 palsy (weakness and atrophy of the intrinsic muscles of the hand);
- arm pain in a patient who is younger than 35 years or in a patient for more than 6 months;
- side bending away from the painful side that causes pain (if this is the only motion that causes pain).

It must also be remembered that all cervical patients, especially the ones with a history of a hyperextension mechanism, are at potential risk of serious head and neck injuries, including vertebrobasilar injury (Chap. 24) and cervical myelopathy. Cervical myelopathy (Table 25-6), involving an injury to the spinal cord itself, is associated with multisegmental paresthesias and upper motor neuron (UMN) signs and symptoms such as spasticity, hyperreflexia, visual and balance disturbances, ataxia, and sudden changes in bowel and bladder function. Early indicators of this condition include reports of symptoms in multiple extremities and clumsiness when performing fine motor skills. Myelopathy may occur with compression of the spinal cord and is more likely to occur at the C5–6 level, because in this region the spinal cord is at its widest and the spinal canal, at its narrowest.[118] Usually, narrowing of the spinal canal occurs during the end stages of degenerative disease, although structural anomalies, such as a narrowed trefoil canal or shortened pedicles, can result in congenital stenosis.[8] Depending on the cause, the onset of myelopathy can be sudden or gradual.

TABLE 25-6 The Differential Diagnosis of Myelopathy

Compressive myelopathy
Cervical spondylosis with stenosis
Cervical disk herniation fracture
Spondylolisthesis
Tumor
▸ Vertebral column primary tumor
▸ Metastatic tumor infection
▸ Epidural abscess
▸ Discitis or osteomyelitis with epidural extension
Epidural hematoma syringomyelia
Medical myelopathy
Idiopathic acute or subacute transverse myelitis
Postinfectious and postvaccination myelitis
Multiple sclerosis
Amyotrophic lateral sclerosis
Infectious myelitis: viral, bacterial, fungal, and parasitic
Arachnoiditis
Vascular disease of the spinal cord
▸ Atherosclerosis
▸ Epidural arteriovenous malformation
Connective tissue disease
Paraneoplastic myelopathy
Metabolic and nutritional disease of the spinal cord
▸ Vitamin B_{12} deficiency
▸ Chronic liver disease
Toxins
Decompression illness (Caisson's disease)
Electrical injury
Radiation injury (postradiation therapy)
Necrotic myelopathy of unknown cause

Data from Spivak JM, et al.: *Orthopaedics: A Study Guide*. New York: McGraw-Hill, 1999:349.

The following signs and symptoms demand a cautious approach or an appropriate referral:

- recent trauma (occurring up to 6 weeks earlier);
- an acute capsular pattern;
- severe movement loss, whether capsular or noncapsular;
- strong spasm;
- paresthesia
- segmental paresis;
- segmental or multisegmental hyporeflexia or areflexia;
- UMN signs and symptoms (see Chap. 3). These can include reports of neck pain with bilateral upper extremity symptoms and occasional reports of loss of balance or lack of coordination of the lower extremities.
- Constant or continuous pain;
- moderate-to-severe radiating pain;
- moderate-to-severe headaches;
- tinnitus;
- history of loss of consciousness;
- memory loss or forgetfulness;
- difficulties with problem solving;
- reduced motivation;
- irritability;
- anxiety or depression;
- insomnia.

CLINICAL PEARL

Symptoms that respond to mechanical stimuli in a predictable manner are usually considered to have a mechanical source. Symptoms that show no predictable response to mechanical stimuli are unlikely to be mechanical in origin, and their presence should alert the clinician to the possibility of a more sinister disorder or one of central initiation, autonomic, or affective in nature.[114]

Neurologic Symptoms

The presence of neurologic symptoms, including sympathetic symptoms (e.g., blurred vision, sweating, tinnitus), deserves special attention. Many of the symptoms that occur in an upper limb have their origins in the neck. The patient with neck trauma can report seemingly bizarre symptoms, but these

need to be heeded until the clinician can rule out serious pathology. Cervical radiculitis is most commonly associated with spinal nerve root irritation. Peripheral symptoms can also be caused by a host of other conditions, including TOS or an isolated peripheral nerve lesion.[119]

The systems review must include questions that will elicit any symptoms that might suggest a CNS condition or a vascular compromise to the brain. For example, lower limb symptoms associated with neck motions, difficulty walking, poor balance, or bowel or bladder dysfunction. One of the earlier indications of a balance disturbance can be elicited during the history or systems review with correct questioning. A simple question such as "Do you have difficulty with walking or with balance?" can provide the clinician with valuable information. Positive responses may indicate a cervical myelopathy or systemic neurologic impairment.[120] The neurologic examination, if appropriate, attempts to differentiate between nerve root and spinal cord compression. The presence of any UMN sign or symptom requires an immediate medical referral.

Vascular Compromise

A history of dizziness, falling, faintness, or seizures always warrants further investigation. It is not always an easy task for the clinician to determine whether the presenting dizziness is the result of a disturbed afferent input from the cervical spine, which can be extremely rewarding to treat, or has a more serious cause.[96] For example, dizziness provoked by head movements may indicate an inner ear or vertebral artery problem. A history of falling without loss of consciousness (drop attack) is strongly suggestive of vertebral artery compromise.[121] Testing of the vertebral artery (see Chap. 24) should be considered if the observation and history reveal any of the signs and symptoms that have been linked, directly or indirectly, to vertebral artery insufficiency. These include

- Wallenberg's, Horner's, and similar syndromes;
- bilateral or quadrilateral paresthesia;
- hemiparesthesia;
- ataxia;
- nystagmus;
- drop attacks;
- periodic loss of consciousness;
- lip anesthesia;
- hemifacial paresthesia or anesthesia;
- dysphasia;
- dysarthria.

Headache or Facial Pain

Does the patient have headaches and, if so, where? What is their frequency and intensity? Does a position alter the headache? If the patient reports relief of pain and referred symptoms with the placement of the hand or arm of the affected side on top of the head (Shoulder abduction/Bakody's sign), this usually is indicative of a disk lesion of the C4 or C5 level.[122]

A history of headaches may or may not be benign, depending on the frequency and severity. Differential diagnosis is important, especially in light of the fact that there is considerable overlap in symptoms among tension headaches; cervicogenic headaches (see Chap. 23); cervical, trigeminal, and glossopharyngeal neuralgia (see Chap. 5); the headache associated with Lyme disease (see Chap. 5); migraines without aura (see Chap. 5); and TMJ dysfunction (see Chap. 26).[123] Cervicogenic headaches, which can be mild, moderate, or severe, tend to be unilateral and located in the suboccipital region, with referral to the frontal, retro-orbital, and temporal areas.[69,124] The more serious causes of headache without a history of trauma include spontaneous subarachnoid hemorrhage, vertebral artery compromise, meningitis, pituitary tumor, brain tumor, and encephalitis (see Chap. 5).

Facial pain can be the consequence of temporomandibular dysfunction, temporal arteritis, acute sinusitis, orbital disease, glaucoma, trigeminal neuralgia, referred pain, and herpes zoster (see Chap. 5).

TESTS AND MEASURES

Observation

Static observation of general posture, as well as the relationship of the neck on the trunk, and the head on the neck, is carried out while the patient is standing and sitting, both in the waiting area and in the examination room (see Chap. 6). Once in the examination room, the patient is asked to assume an upright neutral postural position from a relaxed sitting position. This can help the clinician to gain an idea of which muscle strategy the patient is using to support the natural spinal curves.[78] A major contributor to cervicogenic pain is a lack of postural control resulting from poor neuromuscular function.[85,123,125,126] Sustained postures, or fatigue overloading of the deep spinal and postural muscles, can result in increased joint compressive forces and inefficient movement strategies.[112,113,127,128] A good pattern when assuming an upright neutral postural position would involve the pelvis being brought into an upright neutral position, with the formation of a low lumbar lordosis (lumbar multifidus) rather than with thoracolumbar extension (thoracopelvic extensors).[78] Postural misalignment of the head on the trunk is associated with complaints of pain in the neck and shoulder region and TMJ dysfunction, but is also observed in asymptomatic individuals.

The clinician should look for:

- Hair quality (i.e., brittle hair due to thyroid problems).
- The position of the patient's head. If it is shifted to one side, a disk protrusion may be present; if deviated, acute arthritis may be the cause. Severe or constant pain usually is manifested by the patient constantly changing his or her posture or remaining very still.
- Evidence of the patient being a mouth breather. Mouth breathing encourages forward head posture.
- Evidence of skin cancer, such as unusual looking moles.
- Torticollis.

- Sprengel's deformity, a congenital elevation and medial rotation of the scapula, which gives the patient the appearance of having no neck on one side, secondary to a high-riding scapula.
- Scars (long, transverse scars indicative of cervical surgery), lumps, rashes, thyroid enlargement (goiter), skin discoloration, or other lesions.
- Scoliosis in the thoracic spine.
- Soft tissue contours that can highlight swelling, muscle atrophy or hypertrophy.
- The position of the thoracic and cervical curves as well as the craniocervical posture.
- Scapular position in association with muscle bulk/tone of the axioscapular-girdle muscles both anteriorly and posteriorly.[78] Ideally, the resting scapulae should sit such that the superior angle lies level with the T2 or T3 spinous process, the root of the spine of the scapula level with the T3 or T4 spinous process, and the inferior angle level with the T7–9 spinous process.[129] Common "abnormal" postural positions of the scapula include a downwardly rotated and protracted scapula, which is often associated with a dominant action of the levator scapular and an increase resting length of the trapezius.[78,93,128] Conversely the scapula may appear slightly elevated, indicating an adaptively shortened upper trapezius, protective positioning, or neural tissue mechanosensitivity.[78]
- Bone deformities (i.e., endocrine disorders). Conditions include abnormal bony enlargement of the face, jaw, hands, and feet (acromegaly); a "moon-faced," buffalo hump (fatty deposits) at the neck, axial obesity, generalized atrophy of muscles, and kyphotic posture due to excess cortisol production (Cushing's syndrome) or bulging eyes due to excess thyroid hormone (Graves disease).[130]
- Autonomic skin changes (increased sweating, trophic changes, and texture changes).
- Birthmarks.
- Changes in the patient's facial expression suggesting pain with transitional movements.

SIDE VIEW

- The forehead should be vertical.
- The tip of the chin should be in line with the manubrium. If the chin is anterior to the manubrium, a forward head is present (see later discussion). The amount of forward head can be measured in two ways. The simplest method is to measure the distance between the tip of the chin and the manubrium. The more complex and expensive methods involve the use of computer-assisted digitizing systems.
- The clinician should observe the cervical lordosis. A flattened lordosis may be associated with stretched posterior cervical ligaments and extensor muscles, and adaptively shortened cervical flexors. An excessive lordosis is associated with a forward head and an adaptive shortening of the posterior ligaments and neck extensor muscles.
- The ears are inspected for signs of asymmetry, inflammation, rashes, lumps, scars, or other lesions. Discharge from within the external ear canal may indicate infection (i.e., otitis externa).[130]

POSTERIOR VIEW

- The clinician should assess muscular asymmetry, especially in the upper trapezius and SCM (see also Chap. 16).
- The spinous process of the axis should be in the midline.
- Usually the shoulder on the dominant side is slightly lower than that on the nondominant side.
- Is there any atrophy of the deltoid suggesting axillary nerve palsy?
- As the patient rotates the head to each side, the tips of the transverse processes of the atlas should be felt to rotate anteriorly and then posteriorly. Both sides are compared. The procedure is repeated for side bending. The transverse process should become less prominent and should approximate the mastoid process, on the side of the side bending.

ANTERIOR VIEW

- The clinician should assess whether the patient's head is shifted to one side. A cervical disk protrusion (C3–4 or C4–5) can produce a horizontal side shift of the head.[82] This side shift allows the patient to maintain eye level.
- A slight tilt of the head is normal but may indicate an upper cervical joint dysfunction.
- The eyes should be inspected for ptosis (droopy eyelid). The patient should be instructed to look up, while the clinician gently pulls down both lower eyelids to inspect the conjunctiva (for signs of anemia—bluish appearance and conjunctivitis—redness) and sclera (for jaundice—yellowish appearance).[130] The eyes should also be observed for other signs of discoloration, discharge, and any deformity of the iris. The clinician should also note any evidence of nystagmus (see Chap. 3), which may be positional and fatigable and which may be caused by a lesion anywhere from the eyes to the midbrain.[131] A Dix–Hallpike test (see Chap. 3) should be carried out in patients suspected of having a vestibular disorder.[131]
- Facial symmetry. The clinician visually splits the mass of the head into two vertical halves. Cerebral asymmetries in form and volume, associated with cranial asymmetries, are a common feature of the human race and are often associated with facial asymmetries.[132,133] This asymmetry is, in many cases, related to asymmetric cerebral growth, which is mostly accomplished in utero,[134,135] although it may also have a local origin, for instance, in the case of mandibular asymmetry. Facial asymmetry can also be due to facial nerve (CN VII) paralysis or partial weakness. The trigeminal nerve (CN V) may be involved if asymmetry (deviation) is observed in the mouth due to muscle weakness or atrophy on one side of the jaw.[130]

TABLE 25-7 Potential Consequences of the Forward Head

Deficit	Impairment	Effect
Cervical hyperlordosis	Overclosing of TMJ	Trigeminal facilitation
	Posterior compression	Suboccipital hypertonicity
	Capsular ligament injury	Scalene hypertonicity with first rib impairment
	Meniscal derangement	
	Craniovertebral hyperextension	Trigeminal facilitation
	O-A flexion hypomobility	Masticator hypertonicity
	A-A rotation hypomobility	TMJ impairment
	O-A extension hypermobility	
	Craniovertebral instability	
	Midcervical hyperextension	C4 facilitation
	Flexion hypomobility	Levator scapulae hypertonicity with adduction of scapula and overuse of supraspinatus
	Extension hypermobility	
	Anterior instabilities	C5 facilitation
		Rotator cuff hypertonicity
		Tennis elbow
Shoulder protraction	Glenohumeral instability	Supraspinatus tendonitis
	Acromioclavicular instability	Infraspinatus tendonitis
		Acromioclavicular sprain
Cervicothoracic hyperkyphosis	Extension hypomobilities	Shoulder girdle hypomobility
		Glenohumeral instability
		Acromioclavicular instability
		Supraspinatus tendonitis

A-A, atlantoaxial; O-A, occipitoatlantal; TMJ, temporomandibular joint.

Forward Head

The cervical and upper thoracic regions are highly prone to postural and degenerative dysfunctions. Poor posture and dysfunctional movement patterns may alter the normal segmental motion of the neighboring regions (Table 25-7). A forwardly inclined head increases the stresses at the cervicothoracic junction and increases the craniovertebral lordosis, producing compensatory occipitoatlantal extension.

In the forward head posture, the upper trapezius can be maintained in a constant state of contraction[33] (Table 25-7). This constant state of contraction can also occur as a result of a protective mechanism for the cervical joints, ligaments, or IVD.[136]

This hypertonicity of the upper trapezius produces a paravertebral area that is broader and more prominent than normal. Tightness or adaptive shortening of the levator scapulae results in the contour of the neckline appearing as a double line (wave) where the muscle inserts into the scapula.[84] This is described as Gothic shoulders, because it is reminiscent of the form of a Gothic church tower.

Movement patterns performed on a poor postural base contribute to repetitive microtrauma of cervical structures. These structures include the zygapophyseal facets, IVD, ligaments, joint capsules, and muscles, all of which are capable of propagating the cycle of pain and dysfunction.[137,138]

Active Range of Motion

The clinical examination of the mobility of the cervical spine should consist of a comparison between active and passive ranges and coupled movements of the cervical spine. Knowledge of cervical anatomy and kinematics should assist the clinician in determining the structure responsible, based on the pattern of movement restriction noted in the physical examination (Table 25-8). The range of motion assessment of the craniovertebral region is described in Chapter 23.

The range of motion available at the cervical spine is the result of such factors as the motion available at each segment, the shape and orientation of the zygapophyseal joint surfaces, the inherent flexibility of the restraining ligaments and joint capsules, the height and pliability of the IVD, and the range available in the craniovertebral and

TABLE 25-8 Movement Restriction and Possible Causes

Movement Restriction	Possible Causes
Extension and right side bending	Right extension hypomobility Left flexor muscle tightness Anterior capsular adhesions Right subluxation Right small disk protrusion
Flexion and right side bending	Left flexion hypomobility Left extensor muscle tightness Left posterior capsular adhesions Left subluxation
Extension and right side bending restriction greater than extension and left side bending	Left capsular pattern (arthritis and arthrosis)
Flexion and right side bending restriction equal to extension and left side flexion	Left arthrofibrosis (very hard capsular end-feel)
Side bending in neutral, flexion, and extension	Uncovertebral hypomobility or anomaly

upper thoracic joints. A movement restriction is a loss of movement in a specific direction, and one in which a movement toward or away from the restriction may alter the degree and location of those symptoms. When cervical range of motion (CROM) is painful or restricted, muscle pathology is suggested if the restricted motion exists in the direction opposite to the action of the involved muscles. The clinician can apply resistance to the indicated muscle group(s) to verify this hypothesis.

CLINICAL PEARL

A motion that is restricted but painless, or normal but painful, could indicate a hypomobility. Pain that is produced by the motion that is restricted indicates an acute or subacute injury, whereas pain that is produced by the motion that is not restricted, or excessive, could indicate a hypermobility.

Because of the close relationship of the shoulder to the cervical spine, active elevation of each upper extremity should be assessed to rule out symptom reproduction from the shoulder movements. If there is a loss of one of the cervical motions, the restricted motion should be examined more closely by separating the motion into its various components. For example, full cervical rotation requires motion at the craniovertebral joints, particularly the atlantoaxial joint, as well as segmental rotation at each of the cervical segments.

CLINICAL PEARL

Radiographic evaluation has long been considered the "gold standard" for studying CROM.[139–143] However, this method is invasive and is generally not feasible or practical. However, in situations in which an accurate and reliable cervical ROM evaluation is needed, radiographic evaluation is the method of choice because of its greater sensitivity.[143]

The major movements that are assessed clinically are rotations out of neutral position **VIDEO** flexion–extension, and side bending (Fig. 25-12A–D). The most painful movements are performed last so that no residual pain is carried over from the previous movement. The dual inclinometer method recommended in the American Medical Association's *Guides to the Evaluation of Permanent Impairment*[144] is often considered the clinical standard for assessing cervical ROM in the clinic.[145,146] This method requires accurate identification of anatomic landmarks (Table 25-9). Both inter- and intra-rater reliability studies have shown the inclinometry method to be reliable.[147–150] Others dispute this conclusion and contend that the inclinometer method is flawed and should not be used in clinical settings.[151,152] Using the inclinometer technique, the normal active ranges of motion for the cervical spine are as follows:

- forward flexion: 45–50 degrees;
- extension: 85 degrees;
- side bending: 40 degrees;
- rotation: 70–90 degrees.

The CROM instrument, introduced on the market by Performance Attainment Associates (Roseville, MN), measures the cervical range of motion for flexion, extension, side bending, and rotation using separate inclinometers. These inclinometers are attached to a frame similar to that for eyeglasses: one in the sagittal plane for flexion–extension, a second in the frontal plane for side bending, and a third in the horizontal plane for rotation.[141] Two of these inclinometers have a gravity-dependent needle (in the sagittal and frontal planes), and the other has a magnetic needle (in the horizontal plane).[141] A magnetic neck brace is worn by the patient. Several researchers have studied the instrument to investigate its intrarater and interrater reliability. Youdas and colleagues[151] reported and intraclass correlation coefficient (ICC) varying from 0.73 to 0.95 and an interrater reliability of 0.73 to 0.92 for six cervical movements assessed in 20 patients with orthopaedic disorders.[141] Capuano-Pucci and colleagues[147] obtain similar results with 20 healthy subjects.[141] In a study by Tousignant and colleagues,[141] which attempted to estimate the criterion validity of the CROM goniometer using a healthy population found the device to be valid for measurements of cervical flexion and extension. In a more recent study, which compared range of motion measurements using a CROM goniometer and an optoelectronic system (OPTOTRAK), Tousignant et al.[142] reported that the CROM device showed excellent criterion validity for measurements of cervical rotation. Wainner et al.[153] used an inclinometer and a goniometer in 50 patients with suspected cervical radiculopathy or carpal tunnel syndrome. The results of this study are summarized in Table 25-10.

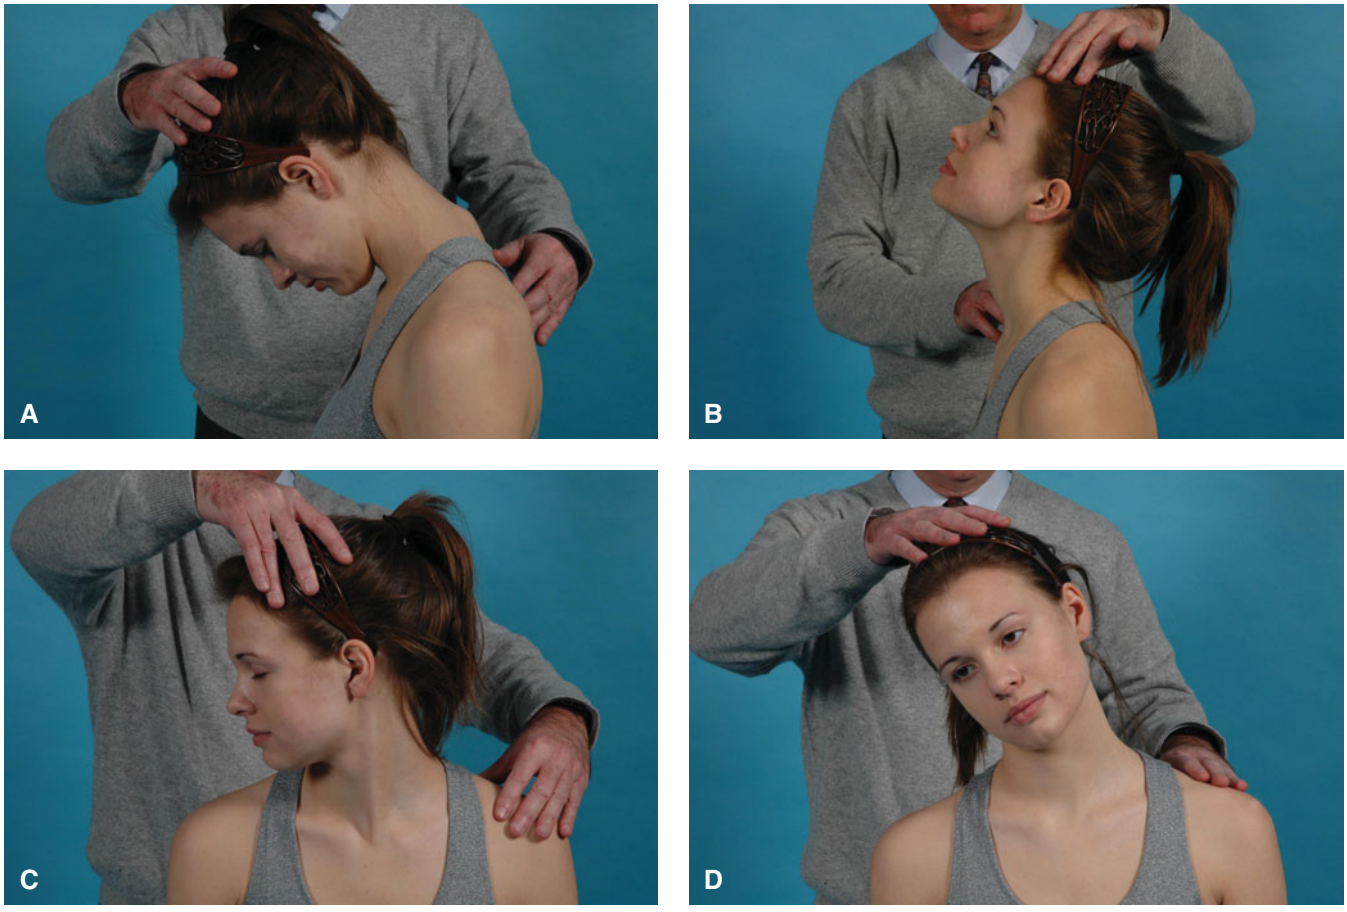

FIGURE 25-12 Cervical active range of motion with passive overpressure and resistance. **A** flexion. **B** extension. **C** rotation. **D** side bending.

Whichever method is chosen, it is important remember that, as with other joints in the body, the range of motion in the cervical spine may vary according to a number of factors including the structural ones already mentioned. The available range of motion may be reduced based on the individual's age, neck girth and length, body habitus, diurnal changes,[154] neurologic disease, or other factors unrelated to the disability for which the exam is being performed. Without taking body size into account, measurements may underestimate or overestimate range of motion.[155] The decrease due to age is probably because of the development of degenerative changes, the only exception being the rotation available at C1-2, which may increase.[156] Gender influences on cervical mobility are somewhat more controversial. Dvorak and colleagues[156] reported women having greater cervical range of motion compared with men, whereas other studies have shown men have greater available flexion,[157,158] women have a greater range in cervical extension only,[146] or that that gender is not a variable in cervical range of motion.[159]

Biomechanical studies have shown that during flexion of the cervical spine, the segments below the second vertebra are blocked.[12] Therefore, rotation out of maximum flexion of the cervical spine occurs in the atlantoaxial joint. However, rotation out of maximum extension occurs predominantly in the middle and lower cervical spine but includes the atlantoaxial joint, as well.[160]

Each of the active motions is tested with a gentle overpressure applied at the end of range if the active range appears to be full and pain free. With the exception of rotation, the weight of the head usually provides sufficient overpressure. It is necessary to apply overpressure even in the presence of pain, in order to achieve an end-feel. If the application of overpressure produces pain, the presence of an acute muscle spasm is possible. Caution must be taken when using overpressure in the direction of rotation, especially if the rotation is combined with ipsilateral side bending and extension, because this can compromise the vertebral artery.[161] Given the variability in CROM in the literature even with "normal" patients, recording absolute ranges of motion are perhaps not as important in the presence of pain and dysfunction as the assessment of:

- ***Quality and quantity of the motion.*** Quantity and quality of movement refers to the ability to achieve end range with curve reversal and without deviation from the intended movement plane.[162]
- ***Symptoms provoked.*** According to McKenzie, the use of repeated movements to provoke symptoms helps to differentiate between the postural, dysfunction, and derangement syndromes (see Chap. 22). For example, pain of postural origin does not occur with repeated movements and does not limit movement in any direction but is felt only when the patient is stationary or when static loading has been prolonged. In contrast, the pain experienced in the dysfunction syndrome is felt immediately when movement reaches the end of the limited range but stops immediately when the end range position is released. In addition, the pain

TABLE 25-9 The American Medical Association Inclinometer Technique for Measuring Cervical ROM

Range	Method
Flexion	Two inclinometers are used, which are aligned in the sagittal plane. The center of the first inclinometer is placed over the T1 spinous process. The center of the second one is placed on top of the head, parallel to a line drawn from the corner of the eye to the ear, where the temple of eyeglasses would sit. The patient is asked to flex the neck, and both inclinometer angles are recorded. The cervical flexion angle is calculated by subtracting the T1 from the calvarium inclinometer angle.
Extension	Two inclinometers can be used, which are aligned as for measuring cervical flexion. The patient is asked to extend the neck, and both inclinometer angles are recorded. The cervical extension angle is calculated by subtracting the T1 from the calvarium inclinometer angle.
Rotation	The patient is positioned supine. One inclinometer is used, and it is aligned in the transverse plane. The base of the inclinometer is placed over the forehead. The patient is asked to rotate the neck, and the inclinometer angle is recorded. The test is repeated on the other side.
Side bending	Two inclinometers are used, which are aligned in the coronal plane. The center of the first inclinometer is placed over the T1 spinous process. The center of the second one is placed on top of the head, over the calvarium. The patient is asked to side bend the neck, and both inclinometer angles are recorded. The cervical side-bending angle is calculated by subtracting the T1 from the calvarium inclinometer angle.

ROM, range of motion.

TABLE 25-10 Reliability of Cervical ROM Testing Using a Goniometer and Inclinometer

Motion	Instrumentation	Interexaminer Reliability ICC (95% CI)
Flexion	Inclinometer	0.79 (0.65, 0.88)
Extension	Inclinometer	0.84 (0.70, 0.95)
Left rotation	Goniometer	0.75 (0.59, 0.85)
Right rotation	Goniometer	0.63 (0.22, 0.82)
Left side bending	Inclinometer	0.63 (0.40, 0.78)
Right side bending	Inclinometer	0.68 (0.62, 0.87)

ROM, range of motion.
Data from Wainner RS, Fritz JM, Irrgang JJ, et al.: Reliability and diagnostic accuracy of the clinical examination and patient self-report measures for cervical radiculopathy. *Spine* 28:52–62, 2003; Cleland J: Cervical Spine, *Orthopaedic Clinical Examination: An Evidence-Based Approach for Physical Therapists*. Carlstadt, NJ: Icon Learning Systems, LLC, 2005:92–140.

felt by the patient with a dysfunction syndrome is always intermittent and is the same each day, provided that their activity levels are consistent. In the derangement syndromes, the symptoms can be produced or abolished, increased or decreased, or centralized or peripheralized in response to repeated movements or sustained positions.

- ***Willingness of the patient to move.***
- ***Presence of specific patterns of restriction.*** According to Cyriax,[163] the capsular pattern of the cervical spine is full flexion in the presence of limited extension, and symmetric limitation of rotation and side bending.

When interpreting the motion findings, the position of the joint at the beginning of the test should be correlated with the subsequent mobility noted, because alterations in joint mobility may merely reflect an altered starting position.

Flexion

An assessment of gross range of motion of cervical flexion is performed (Fig. 25-12A), and the clinician makes note of any motion that reproduces or enhances the symptoms and the location of the symptoms. Considerable emphasis should be placed on the amount and quality of flexion available, and the symptoms it provokes, because flexion is the only motion normally tolerated well by the cervical spine. If the patient has poor concentric control of the deep neck flexors, the SCM will initiate the flexion movement, which will result in the jaw leading the movement instead of the nose (the SCM initially protrudes the chin before flexion occurs). The extreme of cervical flexion is normally found when the chin is able to reach the chest with the mouth closed, although a gap of up to two finger widths is also considered normal.

If end-range flexion is immediately painful, meningitis or acute radicular pain should be ruled out. If the pain is felt after a 15–20-second delay, ligament pain should be suspected. The most common restrictions to cervical flexion are an upper thoracic or cervicothoracic restriction or an occipitoatlantal joint restriction. If, during flexion, the patient pivots the head and neck over a hypomobile and fixed cervicothoracic region, excessive motion will be noted at the levels of C4–6.

Flexion may also be limited by acute or severe trauma (muscle spasms straighten the lordosis), fracture dislocations, or IVD dysfunction.

Extension

The patient is asked to extend the neck (Fig. 25-12B). Normal extension motion allows the face to be parallel with the ceiling. The deep cervical flexors with their extensive longitudinal intersegmental attachments from the upper thoracic spine to the skull are best suited to control extension.[78] If the patient has poor eccentric control of the deep neck flexors, two characteristic patterns of movement are evident[78]:

- There is minimal, if any, movement of the head posteriorly during extension.
- At some point during the extension, the head appears to drop or translate backward.

The return from a fully extended position to a neutral upright position requires a coordinated concentric contraction of the cranial cervical flexors.

Cervical flexion or cervical extension can provoke dizziness. This finding is thought to result from an osteophytic compression on the posterolateral aspect of the transverse foramen by the inferior articulating surface of the zygapophyseal joint.[164] Cervical distraction can be applied at the point of symptom provocation. If this maneuver increases the symptoms, manual or mechanical traction should not be part of the intervention plan.

Rotation

With rotation, the chin should be in line with the acromioclavicular joint at the end of rotation (see Fig. 25-12C).

Limitation of or pain on cervical rotation usually suggests pathology at the C1–2 (atlantoaxial) segment, because most rotation occurs at this joint.[111] However, if a patient is able to achieve 40–50 degrees of cervical rotation while maintaining eye level, atlantoaxial involvement is unlikely. If, on the other hand, the neck has to side bend early in the active rotation range in order to achieve full motion, the atlantoaxial joint is likely to be involved. If full rotation is limited and cannot be achieved even with the substitution of neck side bending, the problem is likely with the mid-to-low cervical spine segments.

Two screening tests can be used to highlight the level of a rotation restriction. Both of the tests utilize rotation of the neck, with the neck in various amounts of flexion.

1. Rotation with the neck in full side bending is reported to test the C1–2 level.
2. Rotation with the neck in a chin tuck tests the C2–3 level.

Side Bending

Side bending is performed to the left and right, while the ipsilateral and contralateral shoulder are monitored for movement by the clinician as stabilization of the ipsilateral shoulder merely tests the length of the upper trapezius, Fig. 25-12D.) The range of side bending is always greater in the supine than in the sitting position. Active side bending is typically the first motion to demonstrate problems of the cervical spine.[165] Restricted cervical side bending could be the result of joint restriction, muscle tightness, or lack of pain-free movement or extensibility of the neural tissues.[68]

Finally, if in the history, the patient has reported that repetitive movements or sustained postures have caused problems, these should be reproduced in an attempt to provoke the symptoms.

PASSIVE RANGE OF MOTION

In those situations where the patient does not have full active range of motion and even in those situations when overpressure has been applied at the end of active range of motion to determine the end-feel, passive range of motion must be assessed. This is best performed with the patient in supine to relax the muscles. Due to this muscle relaxation, passive range of motion in supine is greater than in sitting, particularly with side bending (approximately 45 degrees in sitting but 75 to 80 degrees in supine), so an assessment of the end-feel in sitting can often be misleading. With each of the cervical motions, the end-feel should be a solid tissue stretch. As with the active motions, the most painful movements are performed last. Further assessment of passive movements can include position testing, and passive physiological intervertebral motion testing (see Differing Philosophies).

Combined Motion Testing

Because normal cervical function involves complex and combined motions, and because symptoms may only occur with these combined motions, combined motion testing may need to be assessed. Combined motion testing typically occurs when the testing of single plane motions (flexion, extension, side bending, and rotation) and end-feels were found to be normal and pain-free.

Using a biomechanical model, a restriction of cervical extension, side bending, and rotation (Fig. 25-13) to the same side as the pain is termed a *closing* restriction. This restriction is the most common pattern producing distal symptoms. However, a limitation in cervical flexion accompanied by the production of distal symptoms can also occur.[165] Side bending toward or away from the side of the pain can also reproduce upper extremity symptoms, depending on the cause. Pain caused by intervertebral foraminal narrowing may be increased with ipsilateral side bending. Pain caused by an IVD protrusion may be increased with contralateral side bending.

A restriction of the opposite motions (cervical flexion, side bending, and rotation to the opposite side of the pain) is termed an *opening* restriction. Opening restrictions are slightly more difficult to identify in the cervical spine because, frequently, there is no actual restriction of cervical flexion, but rather a restriction of rotation and side bending, along with reproduction of pain on the contralateral side.[165]

McKenzie[117] advocates using neck retraction and protrusion, with other motions and positions being superimposed. Neck protrusion produces an extension of the upper cervical

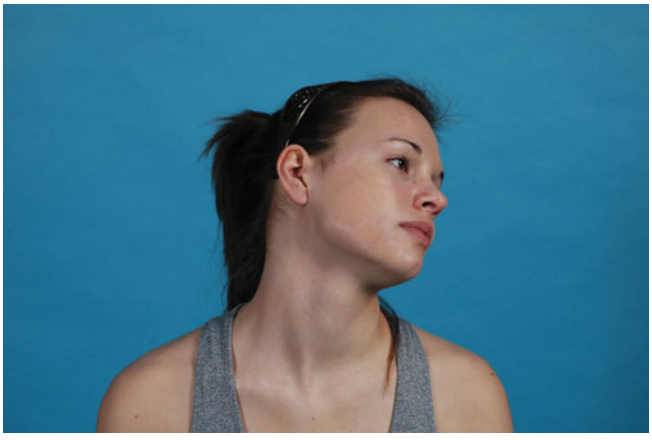

FIGURE 25-13 Cervical extension, side bending and rotation.

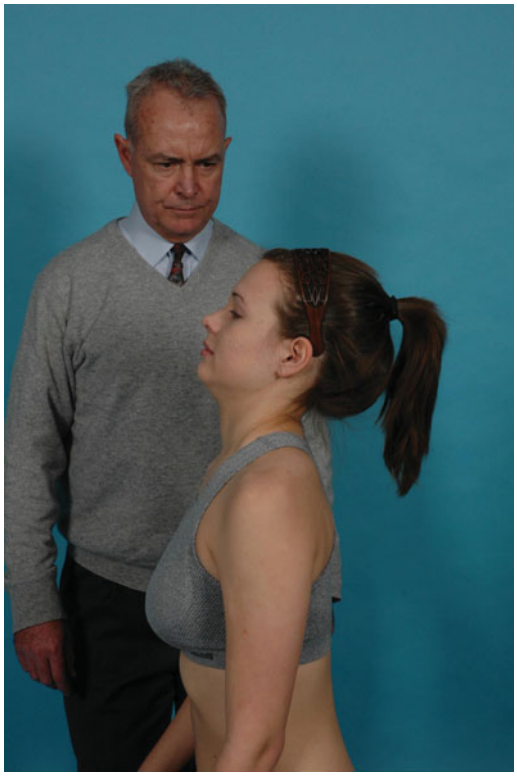

FIGURE 25-14 Neck retraction in extension.

spine and flexion of the mid and lower cervical spine, whereas neck retraction produces a flexion of the upper cervical spine and an extension of the mid and lower cervical spine. Neck retraction is performed with extension (Fig. 25-14), side bending (Fig. 25-15), and rotation to both sides in sitting

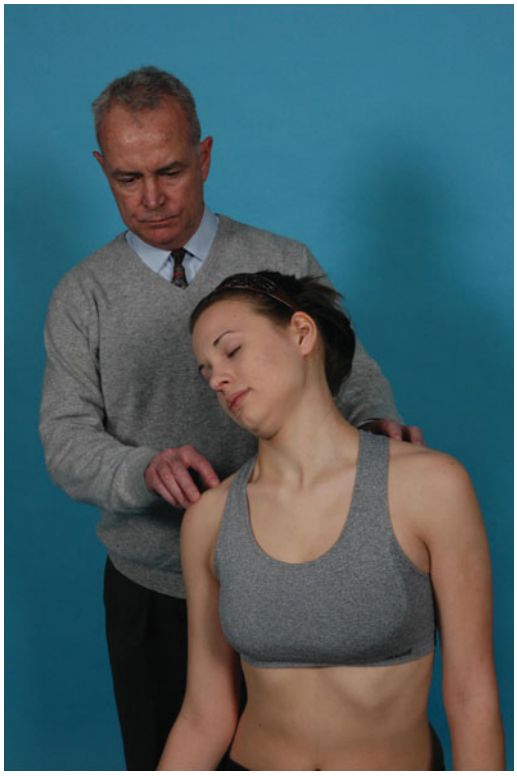

FIGURE 25-15 Neck retraction in side bending.

FIGURE 25-16 Neck retraction in prone—start position.

position and then prone, with the head off the end of the table (Figs. 25-16 and 25-17). The results from these motions are combined with the findings from the history and the single-plane motions to categorize the symptomatic responses into one of three syndromes: postural, dysfunction, or derangement. This information can guide the clinician as to which motions to use in the intervention.

Key Muscle Testing

The purpose of resisted testing is outlined in Chapters 3 and 4. There are numerous smaller muscles throughout this area, so resistance needs to be applied gradually. The same movements that were done actively are tested isometrically. Some of these muscles are also tested as part of the Cyriax upper quarter scanning examination (see Chap. 4) and are used as a peripheral joint scanning examination to determine muscle power and possible neurological weakness. Ideally, the clinician should place the joint in its resting position before testing each muscle and the contraction should be held for at least 5 seconds.

Resisted Cervical Flexion

Resisted cervical flexion tests the key muscle of C1–2, and cranial nerve XI (spinal accessory).

FIGURE 25-17 Neck retraction in prone—terminal position.

FIGURE 25-18 Resisted cervical rotation.

Resisted Cervical Rotation

Resisted cervical rotation (Fig. 25-18) tests the key muscle of C2.

Resisted Cervical Side Bending

Resisted side bending tests the key muscle of C3, and cranial nerve XI (Fig. 25-19).

Scapular Elevators (C4 and cranial nerve XI)

The clinician asks the patient to elevate the shoulders about one-half of full elevation. The clinician applies a downward force on both shoulders, while the patient resists (Fig. 25-20).

Diaphragm (C4)

Using a tape measure, the clinician measures the amount of rib expansion that occurs with a deep breath (Fig. 25-21). A comparison is made to a similar measurement at rest. Four measurement positions are used:

1. fourth lateral intercostal space;
2. axilla;
3. nipple line;
4. tenth rib.

FIGURE 25-19 Resisted cervical side bending.

FIGURE 25-20 Resisted shoulder elevation.

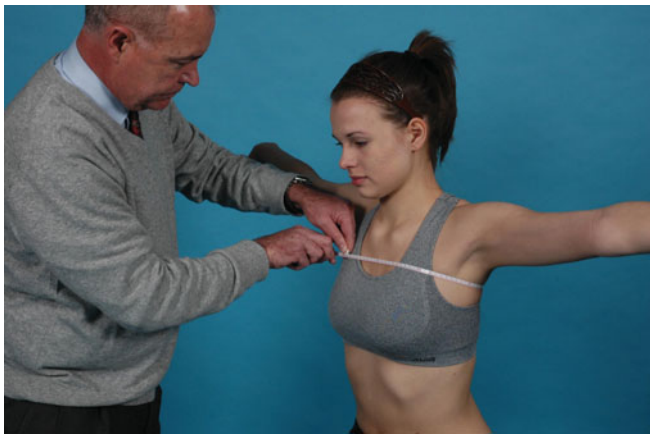

FIGURE 25-21 Chest expansion measurement.

Shoulder Abduction (C5)

The clinician asks the patient to abduct the arms to about 80–90 degrees, with the forearms in neutral. The clinician applies a downward force on the humerus, while the patient resists (Fig. 25-22).

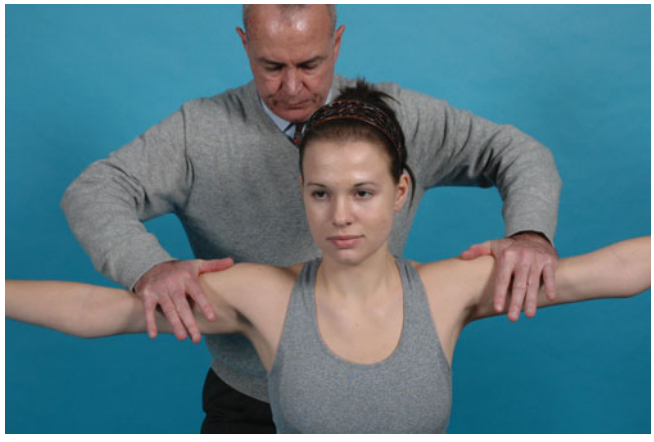

FIGURE 25-22 Resisted shoulder abduction.

FIGURE 25-23 Resisted shoulder external rotation.

FIGURE 25-25 Resisted wrist extension.

Shoulder External Rotation (C5)

The clinician asks the patient to put the arms by the sides, with the elbows flexed to 90 degrees and the forearms in neutral. The clinician applies an inward force to the forearms (Fig. 25-23).

Elbow Flexion (C6)

The clinician asks the patient to position the arms, with the elbows flexed to 90 degrees and the forearms supinated. The clinician applies a downward force to the forearms (Fig. 25-24).

Wrist Extension (C6)

The clinician asks the patient to place the arms by the sides, with the elbows flexed to 90 degrees and the forearms, wrists, and fingers in neutral. The clinician applies a downward force to the back of the patient's hands (Fig. 25-25).

Shoulder Internal Rotation (C6)

The clinician asks the patient to put the arms by the sides, with the elbows flexed to 90 degrees and the forearms in neutral. The clinician applies an outward force to the forearms (Fig. 25-26).

Elbow Extension (C7)

The patient is seated with the arm above the head and the elbow flexed. The clinician stands beside the patient and tests the triceps by grasping the patient's forearm and attempting to flex the elbow (Fig. 25-27).

FIGURE 25-26 Resisted shoulder internal rotation.

Wrist Flexion (C7)

The clinician asks the patient to place the arms out in front, with the elbows flexed slightly and the forearms, wrists, and fingers in neutral. The clinician applies an upward force to the palm of the patient's hands (Fig. 25-28).

FIGURE 25-24 Resisted elbow flexion.

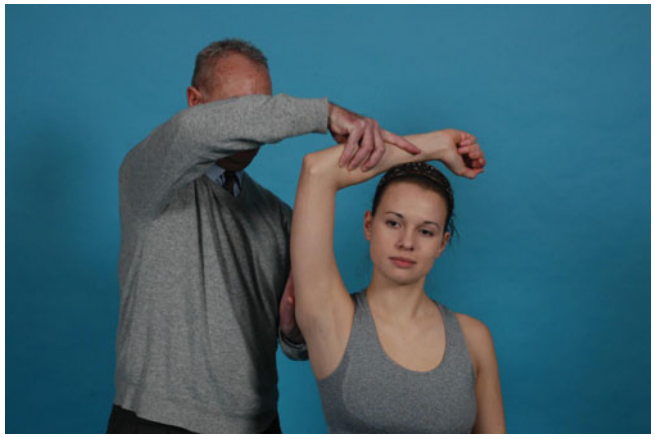

FIGURE 25-27 Resisted elbow extension.

FIGURE 25-28 Resisted wrist flexion.

FIGURE 25-29 Resisted thumb extension.

Thumb Extension (C8)

The patient extends the thumb just short of full range of motion. The clinician stabilizes the patient's wrist with one hand and applies an isometric force into thumb flexion with the other (Fig. 25-29).

Hand Intrinsics (T1)

The patient is asked to squeeze the clinician's fingers between their fingers, while the clinician tries to pull their fingers away (Fig. 25-30).

Based on the findings from the history, systems review, and key muscle testing, a sensory examination may be necessary (see Chap. 3).

Strength Testing of the Deep Segmental and Postural Support Muscles

Deep Neck Flexors

The patient is positioned in supine, with the knees bent and the feet flat on the bed. The patient's head and neck are positioned in the desired midrange neutral position of the craniocervical region—where the line of the forehead and chin is in a horizontal plane and an imaginary line extending from the tragus and bisecting the neck longitudinally is parallel to the bed. If the patient does not adopt this position automatically, padding may be used. Once the correct position is obtained, an inflatable pressure sensor (Stabilizer, Chattanooga, South Pacific) is folded in three and positioned suboccipitally behind the neck (Fig. 25-31), such that it abuts the occiput. The bladder is inflated until the pressure is stabilized on the baseline of 20 mm Hg, a volume sufficient to just fill the space between the bed and the patient's neck, without exerting any pressure on the neck. The patient is instructed to gently nod the head slowly in an arc-like motion as if saying "yes," while

FIGURE 25-30 Strength test for finger adductors (hand intrinsics).

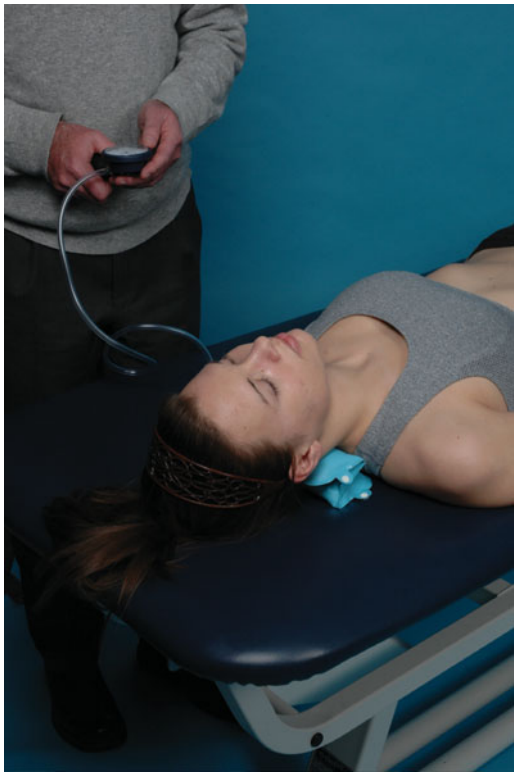

FIGURE 25-31 Muscle function testing of deep neck flexors.

TABLE 25-11 Common Faults in Performance of the Craniocervical Flexion Test and Suggestions for Correction

Common Faults	Correction
The patient performs a neck retraction movement rather than the rotation action of craniocervical flexion	Teach the patient to initiate the movement with their eyes. Look down with the eyes and follow with a slow and controlled chin nod. Look up to the ceiling with the eyes only and follow with the chin to resume the neutral position. Emphasize the sliding of the occiput on the bed to achieve the pure craniocervical flexion. The clinician may guide the movement with fingers placed on either side of the patient's head.
The pressure change is achieved using excessive superficial muscle activity	Palpate the sternocleidomastoid and scalene muscles during the test, to give the patient an awareness of the superficial muscle contraction. Limit the range of craniocervical flexion to the point just short of palpating the dominant superficial muscle activity. Teach the patient self-palpation and an awareness of the correct action. EMG biofeedback may also be beneficial, while the patient practices a slow and controlled craniocervical flexion.
The patient rests in a position of flexion, with associated tension in the scalene muscles	Re-educate the awareness of the neutral position by focusing the eyes on the ceiling above the head, lifting the chin, and palpating the relaxation in the scalenes. Relaxation training may be required in cases of anxiety. Diaphragmatic breathing training can help to relax the respiratory accessory muscles.
There is evident jaw clenching and use of the jaw muscles	Instruct the patient in the relaxed position of the mandible—the anterior one-third of the tongue on the roof of the mouth, lips together, teeth apart.
The patient is holding their breath	Instruct in relaxed nasal breathing while performing the exercise
The patient performs the action quickly and often overshoots the target pressure	Reteach the craniocervical flexion action and emphasize that the movement should be slow and controlled.

Data from Jull GA, Falla D, Treleaven J, et al.: A therapeutic exercise approach or cervical disorders. In: Boyling JD, Jull GA, eds. *Grieve's Modern Manual Therapy: The Vertebral Column*. Philadelphia, PA: Churchill Livingstone, 2004:451–470.

the clinician notes both the quality and the quantity of motion. Ideally, there should be a pattern of progressively increasing craniocervical flexion (Table 25-11). With weak deep neck flexors in the presence of a strong SCM, the jaw juts forward at the beginning of the movement, producing hyperextension of the craniovertebral junction[85] (Fig. 25-32). Confirmation is made by applying a very slight amount of resistance (2–4 g) against the patient's forehead.

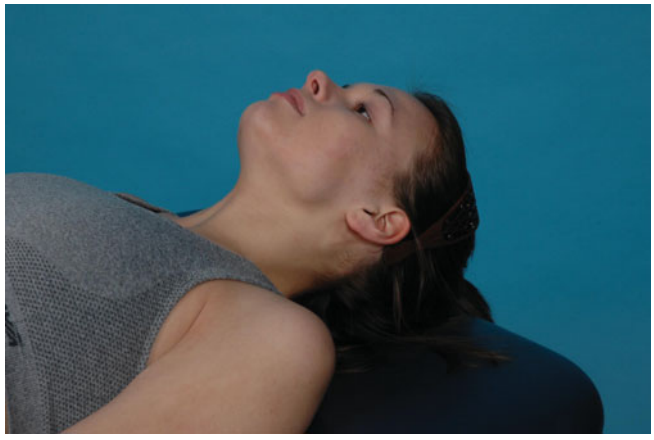

FIGURE 25-32 Patient demonstrating weak neck flexors in the presence of a strong SCM.

Holding Capacity of Deep Segmental and Postural Support Muscles[68]

This test is designed to assess the ability of a muscle group to sustain a low-load isometric contraction and to replicate its function.

Deep Neck Flexors

The deep flexors of the craniovertebral and cervical regions are assessed by testing the patient's ability to sustain a precise inner range upper cervical flexion action.[68]

The patient is positioned in supine, with the head being supported on a folded towel, the knees flexed, and the feet flat on the bed. The inflatable pressure sensor is again positioned suboccipitally behind the neck (Fig. 25-31), and the bladder is inflated to 22 mm Hg to just fill the space between the bed and the patient's neck, without exerting any pressure on the neck.

The patient is asked to bring the chin toward the sternum in a gentle and slow manner. Ideally, the patient should attempt to target five incremental pressure targets (in increments of 2 mm Hg) from the baseline level of 22 mm Hg.[68]

Lower Scapular Stabilizers

The mid and lower trapezius, and serratus anterior muscles, can be assessed with the patient positioned in prone, the arm slightly abducted, and the arms placed by the side of the patient. The patient is asked to sustain the scapula against the chest wall in a position of retraction and depression (Fig. 25-33), while the clinician palpates over the muscles.[68] The end-range position is sustained for 10 seconds, and the test is repeated 10 times.

Retraining the postural support muscles initially involves postural education, an emphasis on the relaxation of unwanted muscle activity, and repeated repetitions of 10-second holds of the corrected scapula position.

FIGURE 25-33 Testing the holding capacity of the lower scapular stabilizers (clinician not shown).

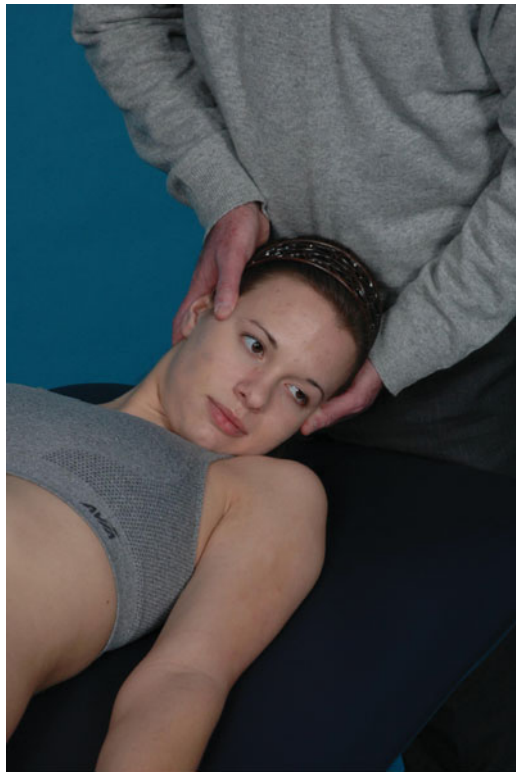

FIGURE 25-34 Cervical flexion, contralateral side flexion and ipsilateral rotation. The amount of available rotation is minimal.

Muscle Length Testing

Upper Trapezius

The upper trapezius has a tendency to become adaptively shortened and overactive, which can have the effect of pulling the head laterally, as well as increasing the craniovertebral and cervical lordosis.[166]

The patient is positioned in supine. The patient's head is maximally flexed, inclined to the contralateral side (Fig. 25-34), and ipsilaterally rotated. While stabilizing the head, the clinician depresses the shoulder distally. A normal finding is free movement of about 45 degrees of rotation, with a soft motion barrier. Tightness of this muscle results in a restriction in the range of motion and a hard barrier.

Levator Scapulae

A quick test to determine the extensibility of the levator involves positioning the patient sitting.[165] The patient is asked to place one hand above the head. For example, the right hand if the length of the right levator is to be tested, the patient's neck and head are positioned in left side flexion, and the patient is asked to abduct the left arm as far as possible. Normal extensibility of the levator and the rhomboids, and the absence of shoulder girdle pathology, should allow the patient to fully abduct the arm, while the head is side bent away (Fig. 25-35). The test is repeated on the other side for comparison.

The more specific test involves positioning the patient in supine. The clinician maximally flexes the patient's head, induces contralateral rotation, and inclines the head toward

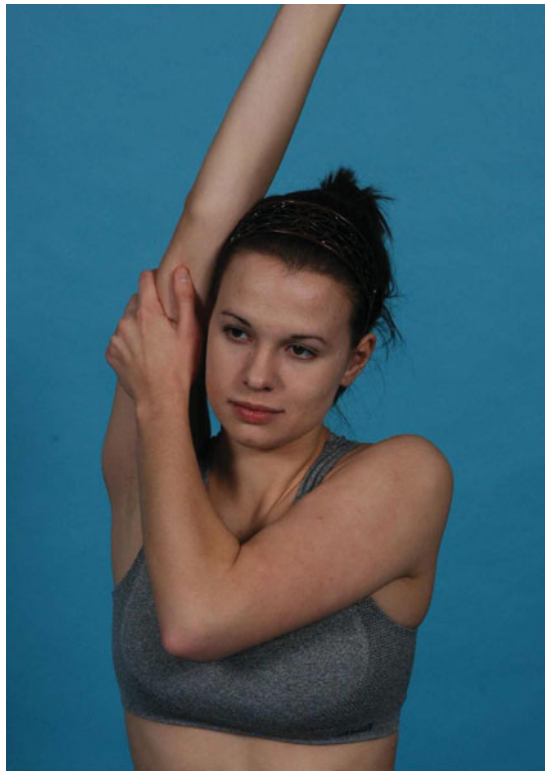

FIGURE 25-35 Muscle length test of levator scapulae.

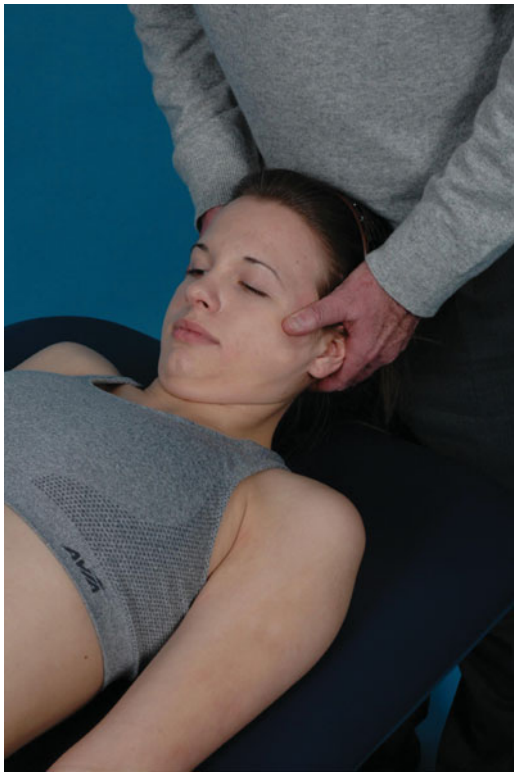

FIGURE 25-36 More specific test to assess the muscle length of the levator scapulae.

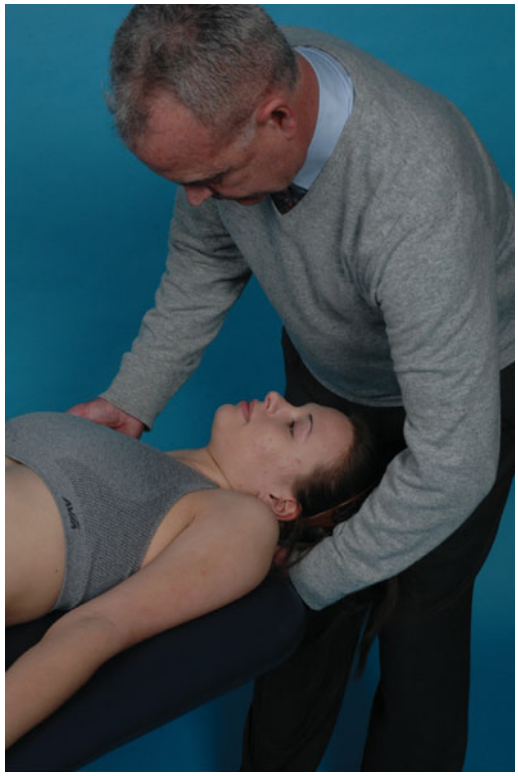

FIGURE 25-37 Muscle length test of the right sternocleidomastoid.

the contralateral side (Fig. 25-36). The clinician then depresses the patient's shoulder distally. If tightness is present, there will be tenderness at the levator insertion and a restriction of movement to less than 45 degrees.

Sternocleidomastoid

The SCM muscle has a tendency to become adaptively shortened and overactive, which can have the effect of altering the relationships between the head, neck, and shoulders and producing restrictions at the craniovertebral and cervicothoracic junctions.[166]

The patient is positioned in supine, with the head being supported. From this position, the clinician induces side bending of the neck to the contralateral side and extension of the neck (Fig. 25-37). The clinician stabilizes the scapula and rotates the patient's head and neck toward the ipsilateral side.

Scalenes

The patient is positioned in supine, with the clinician at the head of the bed. The clinician side flexes and extends the head to the contralateral side, while stabilizing the shoulder (Fig. 25-38). The normal range of motion should be 45 degrees.

Neurologic Examination

The neurologic examination is performed to assess the normal conduction of the central and peripheral nervous systems and to help rule out such conditions as brachial neuritis and TOS. The tests for the TOS are described under "Special Tests" section later. Depending on the results from the history, a cranial nerve examination may be warranted (see Chap. 3).

Sensory (Afferent System)

The clinician instructs the patient to say "yes" each time he or she feels something touching the skin. The clinician notes any hypoesthesia or hyperesthesia within the spinal and peripheral

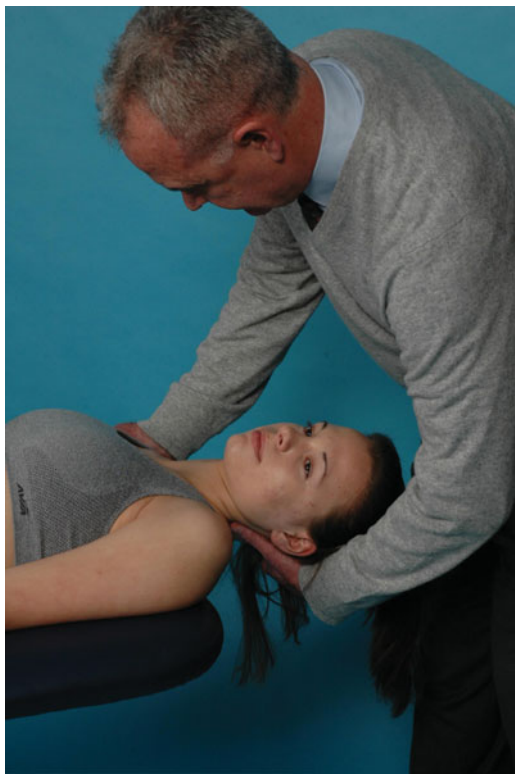

FIGURE 25-38 Muscle length test of scalenes.

FIGURE 25-39 Brachioradialis reflex.

FIGURE 25-41 Triceps reflex.

nerve distributions. Light touch of hair follicles is used throughout the whole dermatome, followed by pinprick in the area of hypoesthesia. Remember that there is normally no C1 dermatome!

Muscle Stretch Reflexes

The following muscle stretch reflexes should be checked for differences between the two sides:

- C5–6: brachioradialis (Fig. 25-39)
- C6: biceps (Fig. 25-40)
- C7: triceps (Fig. 25-41)

Pathological Reflexes

The following reflexes are tested:

- Hoffmann's sign (Fig. 3-36)
- Babinski (Fig. 3-29)
- Lower limb deep tendon reflexes (Achilles and patellar) for hyperreflexia

Palpation

The results from palpation rely on the patient's subjective report; thus, changes in the patient's attention and pain tolerance affect reliability. It is important to place the patient in a position where the neck muscles can relax. Usually, this involves the patient lying supine with their head supported by a pillow and the clinician positioned at the patient's head.

In the neck, the major lymph nodes are located along the anterior and posterior aspects of the neck, which is divided by the SCM muscle.[131] Usually, the closer the lymph node is to the spinal cord, the greater the size of the lymph node.[131] The neck is the exception to the rule. Other lymph nodes are also located on the underside of the jaw and suboccipital areas.[131] The number and size of lymph nodes usually decrease with aging.

The anterior neck can be palpated for the thyroid gland by gently displacing the trachea laterally and palpating each side in turn. Asking the patient to swallow during the palpation can help locate the thyroid gland, as it should be felt to slide under the fingers while it moves upward.

Using the index fingers, the clinician slides the fingers under the SCM and begins to palpate the anterior aspect of the cervical vertebral bodies (from C7 to C3) for tenderness. The posterior aspects, including the facet joints, can be palpated with the other hand. If palpation reveals some tenderness, the clinician can further stress the segment by gently applying a posteroanterior pressure.[167] This is accomplished using the hand under the neck and applying an anterior shear at each segmental level. This pressure should result in a slight increase in the cervical lordosis. If it results in an excessive anterior glide at the segment compared with the segment above or below, the test can be considered positive and a stability test of that segment should be performed.

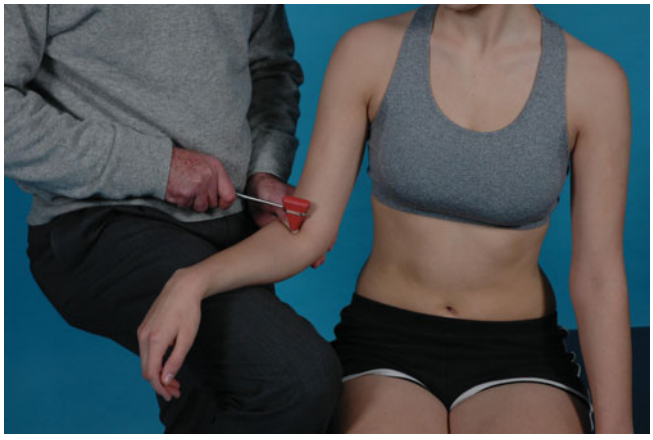

FIGURE 25-40 Biceps reflex.

CLINICAL PEARL

Sandmark and Nisell[168] reported that palpation over the facet joints was the most appropriate screening to corroborate self-reported neck dysfunction.

According to Hoppenfeld,[169] all of the spinous processes lower than C2 are usually palpable. The interval between the external occipital protuberance and the spine of C2 contains the posterior arch of vertebra C1, which is very deeply located and usually not palpable. The C2 spinous process can be

palpated in the midline below the external occipital protuberance, the prominent midline elevation on the posteroinferior aspect of the occipital bone.[1] Occasionally, because of a bifid spine that is not symmetric, the spine may appear to be lateral to the midline, or two bony prominences may be felt at a single level between C3 and C6. C7 is usually the longest spinous process, being referred to as the *vertebra prominens,* although the spinous process of either C6 or T1 might be quite long, as well. The spinous process of C7 is located by either counting down to the correct level or using a motion test. The motion test involves the clinician feeling for the largest spinous process located at the base of the neck and then asking the patient to extend the neck. The C6 spinous process will be felt to move anteriorly with neck extension, whereas the spinous process of C7 does not.

CLINICAL PEARL

Palpation is a key component of the evaluation for cervical myofascial pain.[170]

The following muscles should be palpated for tenderness:

- trapezius;
- sternocleidomastoid;
- splenius;
- semispinalis;
- multifidus;
- suboccipitals (see Chap. 23).

The TMJ can be checked for clicking, limited range of motion, tenderness, or swelling by gently palpating the area immediately anterior of the tragus of each ear while the patient slowly opens and closes the mouth (see Chap. 26).[131]

Differing Philosophies

The next stage in the examination process depends on the clinician's background. Many manual techniques are used to examine the cervical spine, but the reproducibility of these techniques is questionable.[171–175] Clinicians who are heavily influenced by the muscle energy techniques of the osteopaths[176] use position testing to determine the segment on which to focus. Other clinicians omit the position tests and proceed to the combined motion and passive physiologic tests.

Position Testing

The position tests are screening tests that, like all screening tests, are valuable in focusing the attention of the clinician on one segment, but not appropriate for making a definitive statement concerning the movement status of the segment. However, when combined with the results of the active and passive movement testing, they help to form a working hypothesis.

The patient is positioned sitting, and the clinician stands behind the patient. Using the thumbs, the clinician palpates the articular pillars of the cranial vertebra of the segment to be tested (Fig. 25-42). The patient is asked to flex the neck, and the clinician assesses the position of the cranial vertebra relative to its caudal neighbor and notes which articular pillar

FIGURE 25-42 Palpating the articular pillar just lateral to the spinous process.

of the cranial vertebra is the most posterior (dorsal). A posterior (dorsal) left articular pillar of the cranial vertebra relative to the caudal vertebra is indicative of a left-rotated position of the segment in flexion.[176]

In the following example, the C4 and C5 segments are used. The patient is asked to extend the joint complex, while the clinician assesses the position of the C4 vertebra relative to C5 by noting which articular pillar is the most posterior (dorsal). A posterior (dorsal) left articular pillar of C4 relative to C5 is indicative of a left-rotated position of the C4–5 joint complex in extension.[176]

This test may also be performed with the patient supine. However, in the sitting position, one can better observe the effect of the weight of the head on the joint mechanics.

Passive Physiologic Intervertebral Mobility Testing

These screening tests examine intersegmental mobility. As with any other screening test, these tests quickly obviate the need for more exhaustive testing and focus the clinician's attention on a specific level or levels and specific movement(s). Manual examination of the cervical spine by experienced clinicians has shown good sensitivity and specificity to detect cervical zygapophyseal syndromes compared with other medical diagnostic tools, including radiographs, and are sensitive for identifying fused joint levels (Table 25-12).[98,177] However, the protocols used to assess general mobility and intersegmental mobility of the cervical spine have demonstrated difficulty achieving reasonable interexaminer agreement and reliability.[172,175]

To test the intersegmental mobility of the midcervical region, the patient is positioned in supine and the the patient's neck is placed in the neutral position of the head on the neck, and the neck on the trunk. Once in this position, lateral glides are performed, beginning at C2 and progressing inferiorly **VIDEO**. The lateral glides are usually tested in one direction before repeating the process on the other side. The lateral glides result in a relative side bending of the cervical spine in the direction opposite to the glide. Light pressure from the clinician's body can be applied against the top of the patient's skull to hold the head in position. This reinforces the

TABLE 25-12 Usefulness of Passive Physiological Testing in the Cervical Spine

PPM Test Level	Reliability (kappa)	Sensitivity	Specificity	LR+	LR−	DOR	QUADAS Score
C2–3 block[a]	76	98	91	10.9	0.02	495.8	11
C5–6 block[a]	46	78	55	1.7	0.4	4.3	11

[a]Humphreys BK, Delahaye M, Peterson CK: An investigation into the validity of cervical spine motion palpation using subjects with congenital block vertebrae as a 'gold standard'. BMC Musculoskeletal Disorders 5:19, 2004.

stabilization caused by the weight of the patient's thorax against the table. Each spinal level is glided laterally to the left and right, while the clinician palpates for muscle guarding, range of motion, end-feel, and the provocation of symptoms **VIDEO**. Lateral glides are performed as far inferiorly as possible.

Following these procedures, the areas in which a restricted glide was found are targeted, and repetition of the lateral glides is performed in the flexed and then extended positions.

Flexion

The same considerations are pertinent for flexion hypomobilities. To test in flexion, the patient's head and neck are flexed without allowing a chin tuck, which would tighten the nuchal ligament (Fig. 25-43). For example, if left side bending is restricted in flexion, the right side of the segment is not flexing sufficiently (see Table 25-8). The opposite occurs if the restriction occurs with right-side bending (the left side is not flexing sufficiently).

Extension

With the patient supine, and the occiput cupped, the segment is extended by lifting the superior vertebra forward (obviating the need to extend the entire spinal region) and allowing the patient's head and neck to bend over the fulcrum, created by the clinician's fingers. While maintaining the extended position (by pushing the transverse processes of the segment anteriorly), the segment is side bent left and then right around its axis of motion and translated contralaterally (Fig. 25-44). During the translation, very slight head motion should occur. Rather, a slight tilting around each segmental axis occurs, using gentle pressure via the fingertips or the fleshy part of the second metacarpophalangeal joint. The slight side bending before the translation is to fix the axis at that segmental level. During left side bending, the left side of the segment is maximally extended, while the right side is moved toward its neutral position. The opposite occurs with right side bending.

The range of motion of the side bending and the end-feel of the translation is evaluated for normal, excessive, or reduced

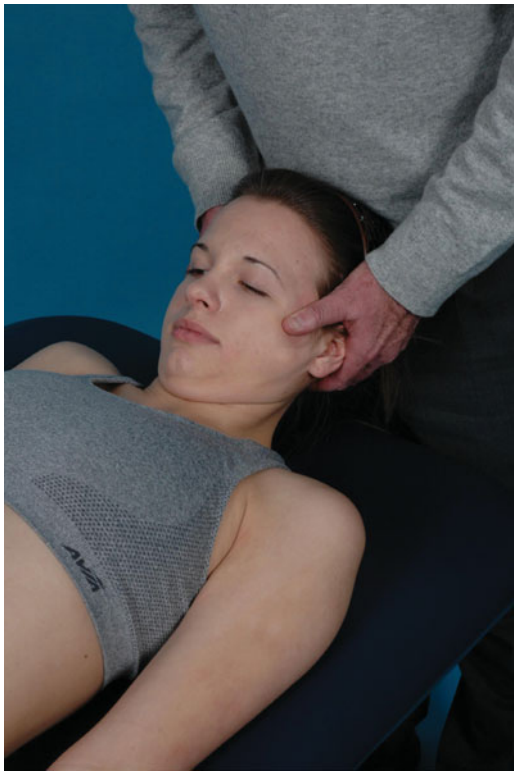

FIGURE 25-43 Translational glides of cervical spine in flexion.

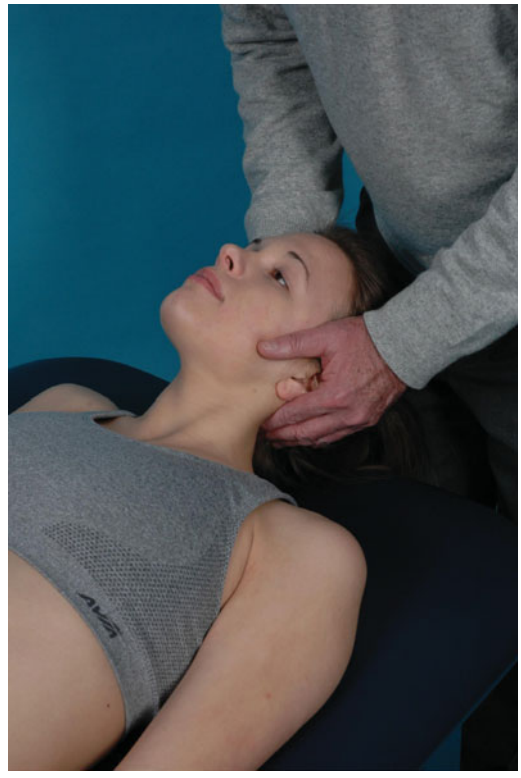

FIGURE 25-44 Translational glides of cervical spine in extension.

FIGURE 25-45 Segmental mobility testing of the cervicothoracic junction.

motion states. If the end-feel of the translation is normal, but the side bending is restricted, the hypomobility is extra-articular (myofascial) (see Table 25-8).

To test the intersegmental mobility of the lower cervical/upper thoracic region, the patient is positioned in side lying with their arm over the end of the table to stabilize the thorax and their head cradled by the clinician (Fig. 25-45). The patient's neck is placed in the neutral position of the head on the neck and the neck on the trunk. Once in this position, the clinician uses the index finger to monitor intersegment motion between the spinous processes, while passively moving the patient's head and neck into flexion, extension, side bending, and then rotation.

Because of the unreliability of mobility testing in extension, the information gleaned from motion testing is more likely to be more reliable in determining the side of the closing restriction.

Clinically, it would appear that the zygapophyseal joints are more involved with the rotational aspect of the coupling, functioning to prevent excessive rotation, whereas the uncovertebral joints appear to be more involved with pure side-bending motions. Although this concept may not hold up to scientific scrutiny, it tends to work well in the clinic. Thus, a glide restriction found in flexion, extension, and neutral would tend to implicate a problem with the uncovertebral joint.

While it is not necessary, or sometimes not possible, to make a diagnosis from these tests, some useful deductions can be made and these will direct the ensuing joint glide tests to the appropriate joint. Remember, that if the end-feel of the glide suggests that motion is still occurring at the end of available range, the joint is *not* the cause of restriction (think *muscle*).

Passive Physiologic Accessory Intervertebral Mobility Tests

The passive physiologic accessory intervertebral mobility (PPAIVM) tests investigate the degree of linear or accessory glide that a joint possesses and are used on segmental levels where there is a possible hypomobility, to help determine if the motion restriction is articular, periarticular, or myofascial in origin. In other words, they assess the amount of arthrokinematic motion, as well as the quality of the end-feel. The motion is assessed in relation to the patient's body type and age and the normal range for that segment, and the end-feel is assessed. A variety of techniques can be used to assess the joint glides in this region. Unless otherwise stated, the patient is positioned in supine with their head resting on the treatment table. The cervical spine is positioned in midrange in relation to flexion, extension, side bending, and rotation. The clinician is positioned at the patient's head. For each of the tests, the clinician assesses the quantity and quality of motion and makes comparisons to the contralateral side, or to the adjacent segment, as appropriate.

Distraction. Using both hands, the clinician wraps around the occiput of the patient using the web space of the hands. The clinician leans backward, and gently applies a force to the chin and occiput to distract the vertebral bodies from one another (Fig. 25-46). Most of the force should be directed to the occiput.

Segmental Translation. In the following example, a left side bending of C3–4 will be described. The patient is positioned in supine, with the clinician at the head of the bed. The clinician cradles the patient's head with both hands and places the pad of the index fingers of each hand across the neural arches of

FIGURE 25-46 General distraction of cervical spine in supine.

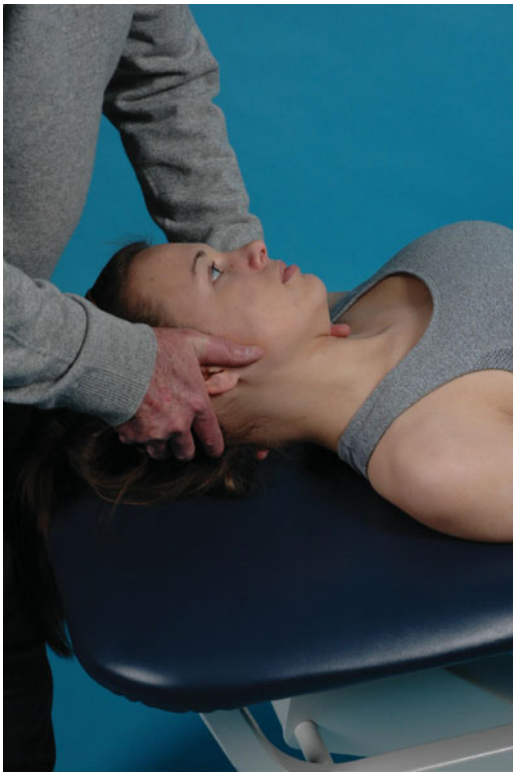

FIGURE 25-47 Left side bending/rotation with right translation at the C3–4 level.

FIGURE 25-48 Rotation of superior segment in supine.

C3. The clinician then applies a right translatory (shearing) force on the C3 neural arch, while keeping the head and upper neck in neutral. A firm end-feel should be achieved as the soft tissue slack is taken up in the joints below as, at the C3–4 level, there is a normal congruent set of motions occurring, e.g., left side bending/rotation with right translation (Fig. 25-47). However, at the levels below there is an incongruent set of motions occurring, e.g., right side bending/rotation with right translation. The diagnostic accuracy for these tests are unknown, but the reliability scores from one study[175] were kappa = 0.03–0.63 (mobility) and ICC = 0.22–0.80 (pain).

Rotation. To test the motions involved with cervical rotation, the patient is positioned in supine and the cervical spine is placed in the range in relation to flexion, extension, side bending, and rotation. The clinician stands at the patient's head. Leaning forward, the clinician rests the abdomen against the top of the patient's head. Using one hand, the clinician grips the inferior segment posteriorly using the web space of the hand, and laterally with the index finger and thumb. Using a similar grip, the clinician uses the other hand to wrap around the superior segment. While stabilizing the inferior segment, the clinician glides the superior segment into rotation (Fig. 25-48).

Combined motions. Leaning forward, the clinician rests the abdomen against the top of the patient's head. Using one hand, the clinician grips the inferior segment posteriorly using the web space, and laterally with the index finger and thumb. Using a similar grip, the clinician uses the other hand to wrap around the superior segment. The patient's head is then guided into the four quadrants: flexion and rotation to the right (Fig. 25-49), flexion and rotation to the left, extension and rotation to the right, and extension and rotation to the left.

Cervical Stress Tests

Depending on the irritability of the segment, a variety of tests can be used to assess for instability. It is worthwhile to start gently with segmental palpation and gentle posteroanterior

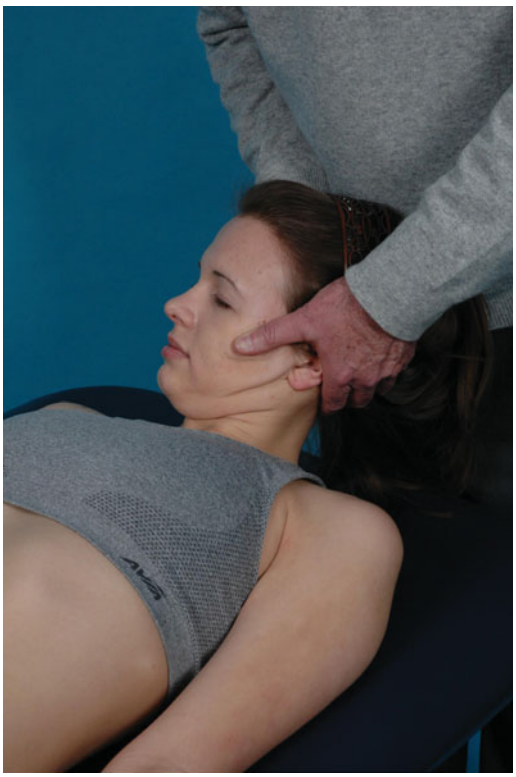

FIGURE 25-49 Flexion and rotation to the right in supine.

pressures before progressing to the other techniques. Unless indicated, the patient is positioned supine. The following tests are performed to examine segmental stability.

Posteroanterior Spring Test

The patient is positioned in prone for anterior stability testing; the clinician places his or her thumbs over the posterior aspects of the transverse processes of the inferior vertebra of the segment being tested. To ensure patient comfort during this test, the thumbs must be placed under (posterior to) the SCM, rather than over it, and must function merely to stabilize the maneuver, exerting no pushing force. The vertebra is then pushed anteriorly (Fig. 25-50), and the clinician feels for the quality and quantity of movement. A rotational component can be added to the test by applying force on only one of the transverse processes.

For posterior stability testing, the thumbs are placed on the anterior aspect of the superior vertebra, and the index fingers are on the posterior aspect (neural arch) of the inferior.[167] The inferior vertebra is then pushed anteriorly on the superior one, producing a relative posterior shear of the superior segment.

It is likely that this test is highly sensitive at implicating the dysfunctional level, but is not specific for the causative pathological process. However, the diagnostic value of this test is as yet unknown.

Transverse Shear

The transverse shear test should not be confused with the lateral glide tests previously mentioned. The lateral glide tests are used to assess joint motion, whereas the transverse shear test assesses the stability of the segment. Although motion is expected to occur in the lateral glide test, no motion should be felt to occur with the transverse shear test.[178]

The inferior segment is stabilized, and the clinician attempts to translate the superior segment transversely using the soft part of the metacarpophalangeal joint of the index finger[167] (Fig. 25-51). The end-feel should be a combination of capsular and slightly springy. The test is then reversed so that the superior segment is stabilized and the inferior segment is translated under it.

The test is repeated at each segmental level and for each side. The diagnostic value of this test is as yet unknown.

FIGURE 25-51 Transverse shear test.

Craniovertebral Ligament Stress Tests

The tests for these ligaments, which include the alar and transverse ligament, are described in Chapter 23.

Distraction and Compression

The patient is supine, and the clinician sits or stands at the patient's head. The clinician cups the patient's occiput in one hand and rests the anterior aspect of the ipsilateral shoulder on the patient's forehead. The other hand stabilizes at a level close to the base of the neck[167] (Fig. 25-46). A traction–compression–traction force is applied. This test can also be performed with the patient in sitting (Figs. 25-52 and 25-53). The clinician notes the quality and quantity of motion.

Pain reproduced with compression suggests the presence of

- disk herniation;
- vertebral end plate fracture;
- vertebral body fracture;
- acute arthritis or joint inflammation of a zygapophyseal joint;
- nerve root irritation, if radicular pain is produced.

Reproduction of pain with cervical distraction suggests the presence of

FIGURE 25-50 P-A pressures of cervical spine.

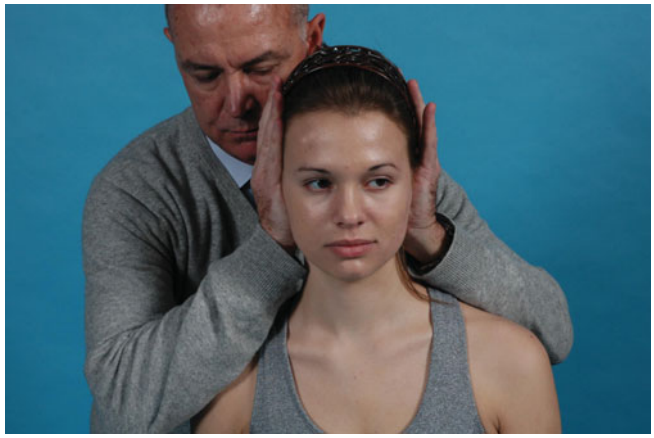

FIGURE 25-52 Cervical distraction in sitting.

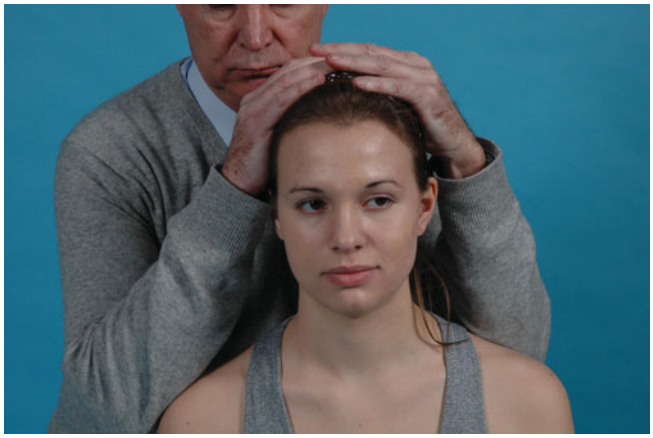

FIGURE 25-53 Cervical compression in sitting.

- spinal ligament tear;
- tear or inflammation of the AF;
- muscle spasm;
- large disk herniation;
- dural irritability (if nonradicular arm or leg pain is produced).

Functional Assessment

A number of formal ways of measuring neck function are available, and include the following:

- The neck disability index (NDI) is a patient survey instrument (see Table 5-3) that contains 10 items, seven related to activities of daily living, two related to pain, and one item related to concentration. The NDI is a revision of the Oswestry index and is designed to measure the level of reduction in activities of daily living in patients with neck pain. The NDI has been widely researched and validated,[179] and its test–retest reliability has been found to be 0.89.[179]
- The Northwick Park Neck Pain Questionnaire (Table 25-13)[180] contains nine sections that cover activities likely to affect neck pain. Each section contains five statements related to the patient's perceived level of difficulty performing the activity of the section. Scores on the questionnaire range from 0 to 100%, with 0% being associated with no disability and 100% with severe disability. The questionnaire has good short-term repeatability and internal consistency.[181]

Special Tests

In most cases, the special tests are only performed if there is some indication that they would be helpful in arriving at a diagnosis. However, in the cervical spine, in addition to the cervical stress tests, the vertebral artery should also be assessed (see Chap. 24), especially if the plan is to place the cervical spine in the extremes of extension, or extension and rotation as part of the examination or treatment.

Temporomandibular Joint Screen

Because the TMJ (see Chap. 26) can refer pain to this region, the clinician is well advised to rule out this joint as the cause for the patient's symptoms.

The patient is asked to open and close the mouth and to laterally deviate the jaw, as the clinician observes the quality and quantity of motion and notes any reproduction of symptoms.

Neurodynamic Mobility Tests

Upper limb tension testing (see Chap. 11) may serve a useful role in differentiating between the involvement of neural and nonneural structures.[8]

Lhermitte's Symptom or "Phenomenon"

This is not so much a test as it is a symptom, described as an electric shock-like sensation that radiates down the spinal column into the upper or lower limbs when flexing the neck (see Chap. 3).

Flexion Rotation Test

This test is used to determine the presence of a cervicogenic headache and is both a range of motion and provocation test. The patient is positioned in supine and resting symptoms are noted. The patient is asked to maximally flex his or her neck and to hold that position. Using both hands, the clinician applies a full rotational force to both sides and notes any changes in symptoms (Fig. 25-54). The test is considerd positive for a cervicogenic headache if a loss of 10 degrees or greater is noted when comparing both sides. Given the testing position, it is likely that C1–2 is the tested level. A single blind, age and gender matched, comparative measurement study by Hall and Robinson[182] found this test to have a sensitivity of 86% and a specificity of 100% (QUADAS score of 12).

Scalene Cramp and Relief Tests

For the scalene cramp test, the patient is positioned in sitting and is asked to turn the head toward the painful side and pull the chin down into the supraclavicular fossa (Fig. 25-55). This position causes contraction of the scalenes and should reproduce distal radiation of pain if the scalenes are involved. The scalene relief test is performed by asking the patient to actively place the forearm against the forehead on the involved side. This position increases the space between the clavicle and the scalenes and is positive for scalene dysfunction if it relieves the patient's pain. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Spurling Test

Provocative tests for cervical radiculopathy include the foraminal compression test or Spurling test.[183] The patient is positioned in sitting. The test is performed by asking the patient to rotate the head to the uninvolved side and then the involved side (Fig. 25-56). The clinician then carefully applies a downward pressure on the head, with the head in neutral. The test is considered positive if pain radiates into the limb ipsilateral to the side at which the head is rotated.[184] Neck pain

TABLE 25-13 The Northwick Park Neck Pain Questionnaire

Parameter	Status	Points
Neck pain intensity	I have no pain at the moment.	0
	The pain is mild at the moment.	1
	The pain is moderate at the moment.	2
	The pain is severe at the moment.	3
	The pain is the worst imaginable at the moment.	4
Neck pain and sleeping	My sleep is never disturbed by pain.	0
	My sleep is occasionally disturbed by pain.	1
	My sleep is regularly disturbed by pain.	2
	Because of pain I have less than 5 hours sleep in total.	3
	Because of pain I have less than 2 hours of sleep in total.	4
Pins and needles or numbness in the arms at night	I have no pins and needles or numbness at night.	0
	I have occasional pins and needles or numbness at night.	1
	My sleep is regularly disturbed by pins and needles or numbness.	2
	Because of pins and needles I have less than 5 hours sleep in total.	3
	Because of pins and needles or numbness I have less than 2 hours of sleep in total.	4
Duration of symptoms	My neck and arms feel normal all day.	0
	I have symptoms in my neck or arms on waking which last less than 1 hour.	1
	Symptoms are present on and off for a total period of 1–4 hours.	2
	Symptoms are present on and off for a total of more than 4 hours.	3
	Symptoms are present continuously all day.	4
Carrying	I can carry heavy objects without extra pain.	0
	I can carry heavy objects but they give me extra pain.	1
	Pain prevents me from carrying heavy objects but I can manage medium weight objects.	2
	I can lift only light-weight objects.	3
	I cannot lift anything at all.	4
Reading and watching TV	I can do this as long as I wish with no problems.	0
	I can do this as long as I wish if I'm in a suitable position.	1
	I can do this as long as I wish but it causes extra pain.	2
	Pain causes me to stop doing this sooner than I would like.	3
	Pain prevents me from doing this at all.	4
Working/housework	I can do my usual work without extra pain.	0
	I can do my usual work but it gives me extra pain.	1
	Pain prevents me from doing my usual work for more than half the usual time.	2
	Pain prevents me from doing my usual work for more than a quarter of the usual time.	3
	Pain prevents me from working at all.	4
Social activities	My social life is normal and causes me no extra pain.	0
	My social life is normal but increases the degree of pain.	1
	Pain has restricted my social life but I am still able to go out.	2
	Pain has restricted my social life to the home.	3
	I have no social life because of pain.	4
Driving[a]	I can drive whenever necessary without discomfort.	0
	I can drive whenever necessary but with discomfort	1
	Neck pain or stiffness limits my driving occasionally.	2
	Neck pain or stiffness limits my driving frequently.	3
	I cannot drive at all due to neck symptoms.	4
	TOTAL SCORE:	

Instructions: The questionnaire has been designed to give us information as to how your NECK PAIN has affected your ability to manage in everyday life. Please answer every question and mark in each section ONLY THE ONE BOX which applies to you. We realize you may consider that two of the statements in any one section relates to you but PLEASE JUST MARK THE BOX WHICH MOST CLOSELY DESCRIBES YOUR PROBLEM.

[a]The question on driving is omitted if the patient did not drive a car when in good health.

FIGURE 25-54 Flexion rotation test.

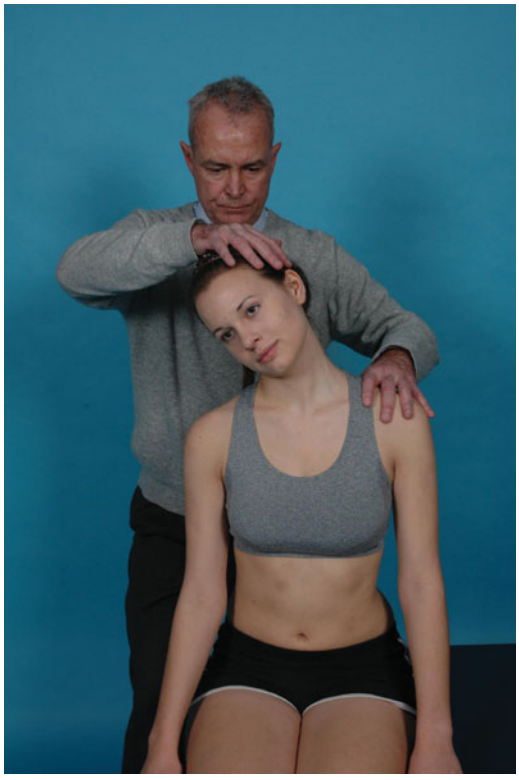

FIGURE 25-56 Spurling Test.

with no radiation into the shoulder or arm does not constitute a positive test. Conditions such as stenosis, cervical spondylosis, osteophytes, or disk herniation are implicated with a positive test. There are few methodologically sound studies that assess the interexaminer reliability, sensitivity, and specificity of this test. The literature appears to indicate high specificity and low sensitivity.[185] Therefore, the test is not useful as a screening test, but it is clinically useful in helping to confirm a cervical radiculopathy.

Modifications to this test have been advocated, which divide the test into three stages, each of which is more provocative.[120] If symptoms are reproduced, the clinician does not progress to the next stage. The first stage involves applying compression to the head in neutral. The second stage involves compression with the head in extension. The final stage involves compression with the head in extension and rotation to the uninvolved side, and then to the involved side. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of these variations.

FIGURE 25-55 Scalene cramp and relief tests.

Valsalva

The patient is positioned in sitting and is instructed to hold his or her breath and then "bear down" as in performing a bowel movement. Reproduction of the consistent pain during bearing down is considered a positive response for a disk herniation (Table 25-14).

Shoulder Abduction Test

This test[186,187] is used to test for the presence of radicular symptoms. The patient is positioned sitting or supine and is asked to elevate the arm through abduction, so that the hand or forearm rests on top of the head (Fig. 25-57). If this position relieves or decreases the patient's symptoms, a cervical extradural compression problem, such as a herniated disk, or nerve root compression should be suspected. The literature seems to indicate high specificity with low sensitivity for this test (Table 25-14). The specific segmental level can be determined by the dermatome distribution of the symptoms. If the symptoms are increased with this maneuver, the implication is that pressure is increasing in the interscalene triangle.[187]

Brachial Plexus Compression Test

The patient is positioned in sitting and is asked to side bend the head to the uninvolved side. The clinician applies firm

FIGURE 25-58 Brachial Plexus Compression Test without the sidebending.

pressure to the brachial plexus by squeezing the plexus lateral to the scalenus between the thumb and fingers (Fig. 25-58). Reproduction of shoulder or upper arm pain is positive for mechanical cervical lesions (Table 25-14), or a thoracic outlet dysfunction.[188]

Cervical Hyperflexion

The patient is positioned in sitting and is asked to flex his or her neck to the first point of pain or toward end range if no pain exists (Fig. 25-59). Reproduction of radicular symptoms during hyperflexion is considered a positive response (Table 25-14).

Cervical Hyperextension (Jackson's Test)

The patient is positioned in sitting and is asked to extend his or her neck to the first point of pain or toward the end range if no

FIGURE 25-59 Cervical hyperflexion.

FIGURE 25-60 Cervical hyperextension (Jackson's test).

pain exists (Fig. 25-60). Reproduction of symptoms is considered a positive response (Table 25-14).

Cervical Distraction

The patient is positioned in supine. Using one hand the clinician uses a lumbrical grip around the occiput. Using the other hand the clinician wraps the hand gently around the patient's chin. A traction force is applied and the patient's symptoms are assessed (Fig. 25-61). A positive test is reduction of symptoms during traction and is indicative of some form of foraminal compression, or zygapophyseal joint irritation. This test appears to have high specificity but low sensitivity (Table 25-14).

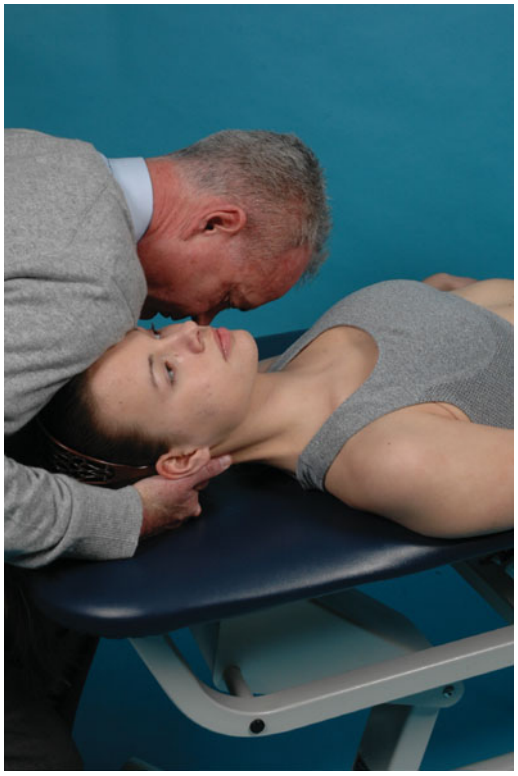

FIGURE 25-61 Cervical distraction.

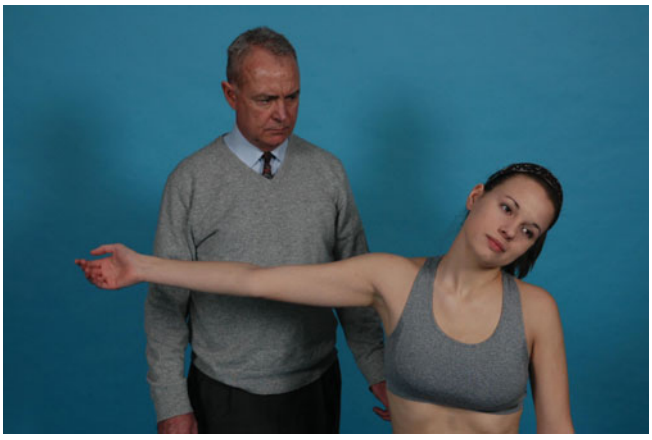

FIGURE 25-62 Stretch Test.

Brachial Plexus Tests

Stretch Test

The patient is positioned sitting or standing and is asked to raise the arm on the involved side (Fig. 25-62) and then to side bend the head to the uninvolved side. Pain and paresthesia along the involved arm are indicative of a brachial plexus irritation.

Cervical Rotation Lateral Flexion Test

This test is used as part of the examination of a patient presenting with brachialgia and thoracic outlet symptoms to assess first rib hypomobility. The motion of cervical rotation combined with lateral flexion (side bending) can be restricted in the presence of a subluxed first rib at the costotransverse joint.[189] The patient is seated and the cervical spine positioned in neutral with regard to flexion–extension. The clinician then passively rotates the cervical spine maximally, away from the side to be tested, and then flexes the neck forward as far as possible, moving the ear toward the chest (Fig. 25-63). The test is then repeated to the other side, and a comparison is made about the quantity and quality of motion. If the first rib is subluxed, the restriction to passive movement is felt abruptly. If restricted motion is found on

FIGURE 25-63 Cervical Rotation Lateral Flexion Test.

FIGURE 25-64 Tinel's Sign.

one side, first-rib mobilizations are performed and then the patient is retested. Lindgren and colleagues found this test to have excellent interobserver repeatability and to have good agreement with a radiologic examination in the detection of a subluxed first rib.[190] However it is worth remembering that a number of additional factors may influence the finding, including TOS, cervical radiculopathy, and upper thoracic pain.

Tinel's Sign

The patient is positioned in sitting and is asked to side bend the head to the uninvolved side. The clinician taps or squeezes along the trunks of the brachial plexus using the fingers (Fig. 25-64). Local pain indicates a cervical plexus lesion. A tingling sensation in the distribution of one of the trunks may indicate a compression or neuroma of one or more trunks of the brachial plexus.[191]

Thoracic Outlet Tests

Despite their widespread use, no studies documenting the reliability of the common thoracic outlet maneuvers of Adson's, Allen's, or the costoclavicular maneuver have been performed.[192] Because TOS is a controversial diagnosis, most of the thoracic outlet tests examine specificity only.

When performing TOS tests, either the diminution or disappearance of pulse or reproduction of neurologic symptoms indicates a positive test. However, the aim of the tests should be to reproduce the patient's symptoms rather than to just obliterate the radial pulse.

Adson's Vascular Test

The patient is positioned in sitting with the arms placed at 15 degrees of abduction. The clinician palpates the radial pulse. The patient is asked to inhale deeply, and to hold his or her breath (Fig. 25-65). The patient is then asked to tilt the head back, and rotate the head, so that the chin is elevated and pointed towards the examined side **VIDEO**. The clinician records the radial pulse as diminished or occluded and asks

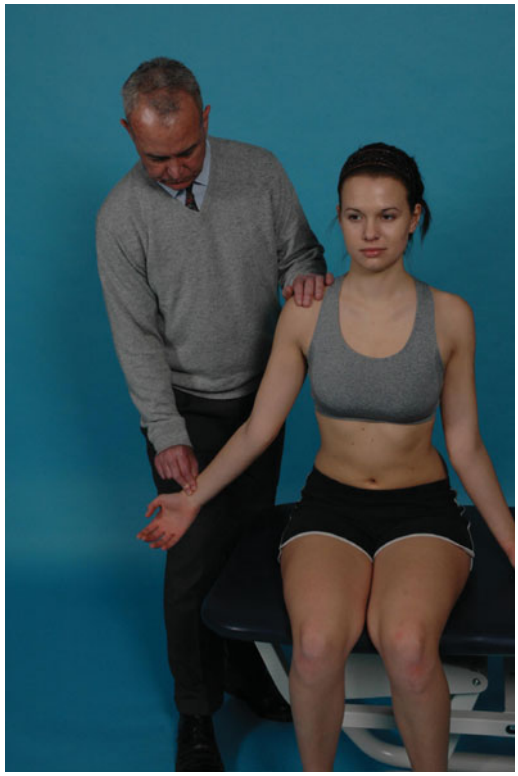

FIGURE 25-65 Adson's test.

the patient about the presence of paresthesia. The test position theoretically increases the scalenus angle and the tension of the anterior and middle scalenes thereby compromising the interscalene triangle.[193] However, biomechanically, the scalene angle actually increases, which should reduce the likelihood of compression. Moreover, to date, no studies have been performed to document the reliability of this test. Plewa and Delinger[194] found the specificity of this test to be 100% when assessing pain, 89% when assessing vascular changes, and 89% when assessing paresthesia.

Costoclavicular Test

The patient is positioned sitting straight in an exaggerated military posture and with both arms at the sides. The clinician assesses the radial pulse in this position. The patient is asked to retract and depress the shoulders while protruding the chest (Fig. 25-66) **VIDEO**. This position is held for 60 seconds. The clinician assesses changes in the radial pulse and asks the patient about the presence of paresthesia. It is likely that this test position reduces the volume of the costoclavicular space. Plewa and Delinger[194] found the specificity of this test to be 100% when assessing pain, 89% when assessing vascular changes, and 85% when assessing paresthesia.

Roos Test[195]

The patient is positioned sitting. The arm is positioned in 90 degrees of shoulder abduction, and 90 degrees of elbow flexion. The patient is asked to perform slow finger clenching for 3 minutes (Fig. 25-67). The radial pulse may be reduced or obliterated during this maneuver, and an infraclavicular bruit

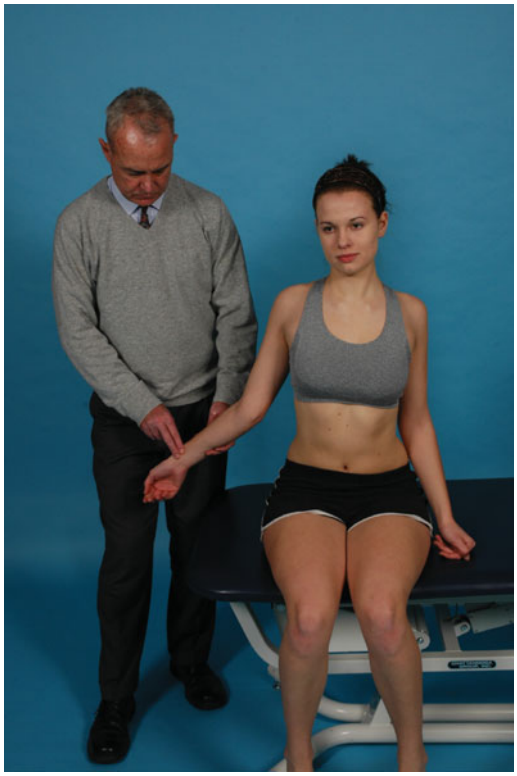

FIGURE 25-66 Costoclavicular test.

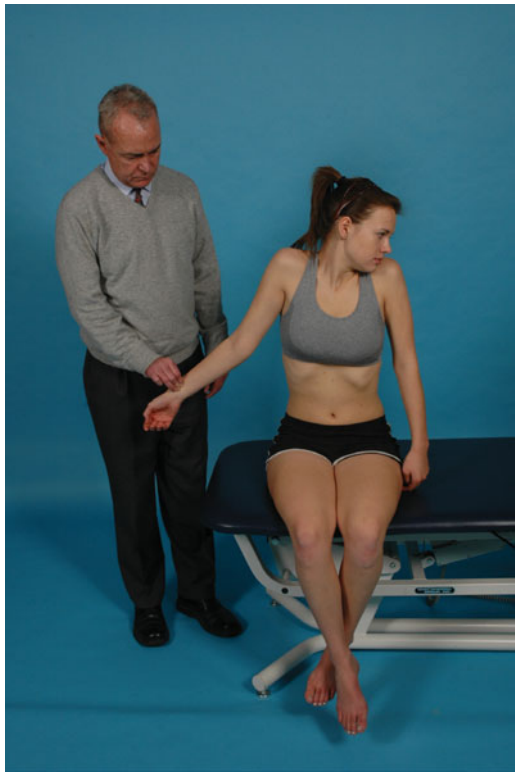

FIGURE 25-68 Hyperabduction Maneuver (Wright Test).

FIGURE 25-67 Roos test.

may be heard. If the patient is unable to maintain the arms in the start position for 3 minutes, or reports pain, heaviness, or numbness and tingling, the test is considered positive for TOS on the involved side. This test is also referred to as the hands-up test, or the elevated arm stress test. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Hyperabduction Maneuver (Wright Test).[196]

The patient is positioned in relaxed sitting. The clinician palpates the radial pulse and then asks the patient to hyperabduct his or her shoulders and to turn the head away from the side being examined (Fig. 25-68). The position is held for 1–2 minutes. A positive test includes reproduction of paresthesia or a decrease in the radial pulse. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test. However, is important to note that a number of studies have found that arm elevation induces radial pulse obliteration in 60–69% of normal subjects.[197,198]

Passive Shoulder Shrug

This simple, but effective, test is used with patients who present with symptoms of TOS to help rule out this syndrome. The patient is seated with the arms folded, and the clinician stands behind. The clinician grasps the patient's elbows and passively elevates the shoulders up and forward (Fig. 25-69). This position is maintained for 30 seconds. Any changes in the patient's symptoms are noted. The maneuver has the effect of slackening the soft tissues and the brachial plexus. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

UPPER LIMB TENSION TESTS

The reader is encouraged to refer to Chapter 11 for the descriptions of these tests. The upper limb tension tests are equivalent to the straight leg raise test and others of the lower extremities and are designed to put stress on the neuromeningeal structures of the upper limb. A negative finding strongly suggests a lack of existence of radiculopathy (Table 25-15). Each test begins by testing the normal side first. Normal responses include

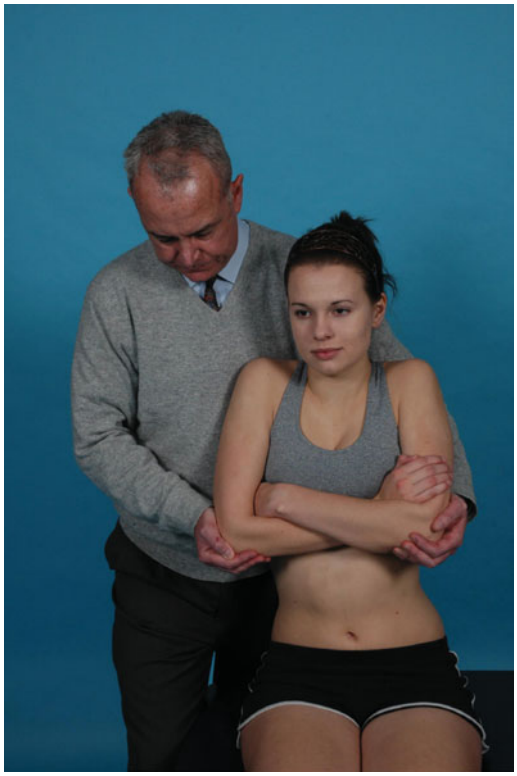

FIGURE 25-69 Passive Shoulder Shrug.

- deep stretch or ache in the cubital fossa;
- deep stretch or ache into the anterior or radial aspect of the forearm and radial aspect of hand;
- deep stretch in the anterior shoulder area;
- sensation felt down the radial aspect of the forearm;
- sensation felt in the median distribution of the hand.

Positive findings include

- reproduction of the patient's symptoms;
- a sensitizing test in the ipsilateral quadrant that alters the symptoms.

IMAGING STUDIES

It is recommended that the results of any imaging studies should be viewed after the clinical examination, so as to remove the potential for bias, especially in light of the fact that degenerative changes and anatomical variations are fairly common in the cervical spine, but that many of these changes have no relationship to the patient's complaints. A description of the various imaging studies and their relevance to a specific region are described in Chapter 7.

INTERVENTION STRATEGIES

Cervical impairments have the same causes as any other areas of the body, that is, a micro- or macrotraumatic impairment of the structures that compose the joint complex.

The clinician must discuss the diagnosis, prognosis, and the intervention with the patient. It is important that the clinician describe the basic anatomy and function of the cervical spine in a way that the patient will understand. Expectations of both the patient and the clinician must be clarified. Patients must realize at the outset that they are responsible for their own recovery and must participate actively in their treatment.

Based on a working hypothesis, the physical therapy intervention needs to be precise, and guided by the impairments, functional limitations, and disability found during the examination. The intervention should aim to reverse the dysfunction and to prevent the recurrence of future episodes. A study by Saturno and colleagues,[199] which assessed the reliability and validity of existing clinical guidelines on neck physiotherapy treatment and follow-up in Spain, determined the eight evidence-based recommendations listed in Table 25-16. Other studies have reported that physical therapy interventions that have included manual therapy, postural reeducation, neck-specific strengthening and stretching exercises, and ergonomic changes at work have been shown to be beneficial in reducing neck pain and improving mobility.[200–202] A pragmatic randomized clinical trial by Hoving et al.,[203] that compared the effectiveness of manual therapy (mainly spinal mobilizations), physical therapy (mainly exercise therapy), and continued care by the general practitioner (analgesics, counseling, and education) for cervical pain over a period of 1 year, found high improvement scores for the manual therapy group for all of the outcomes, followed by physical therapy and general practitioner care.

The joint mobilization techniques for the cervical spine and the manual techniques to increase soft tissue extensibility are described later, under "Therapeutic Techniques" section.

Systematic reviews of physical therapy modalities for neck pain report a lack of high-quality evidence of their efficacy and highlight poor methodologic quality in many studies.[204] Electrotherapy has a long history of use in physical therapy interventions and two high-quality trials reported that pulsed shortwave diathermy delivered by small portable units

TABLE 25-15 Clinical Usefulness of Upper Limb Tension Tests

TABLE 25-16 Evidence-Based Recommendations for Cervical Intervention

Every patient with neck pain must receive ergonomic advice on the reduction of repetitive movements and/or postures. As a basic treatment for all patients, an active physical therapy program will be useful in neck and shoulder muscles. This will include

1. active stretching exercises;
2. dynamic muscular strengthening exercises;
3. exercises to do at home.

As a basic treatment for all patients with chronic neck pain (>3 months) a program of oculocervicokinetic reeducation (exercises to address eye–head coordination to improve cervicocephalic anesthesia—the ability to relocate accurately the head on the trunk after an active movement in the horizontal plane) will be used.

If trigger points are identified in some muscles, transcutaneous electrostimulation will be used.

If there is a dysfunction of the analytic joint passive mobility, joint mobilization/manipulative treatment will be used, which includes structural techniques of vertebral mobilization/manipulation, or contract–relax techniques, or both.

If there is pain radiating to the upper limb, mechanical intermittent cervical traction will be used.

inserted into cervical collars significantly reduced pain in patients with mechanical neck pain.[205,206]

Acute Phase

During the acute phase, the patient should be encouraged to perform as many activities of daily living as possible. The return to activities should be encouraged and begin within 2–4 days after a cervical injury, depending on severity. Rest is usually advocated in the first 24–72 hours, depending on the severity of the injury, to give healing a chance. Indications for rest include pain reported with all neck and head motions, however, slight, and high irritability of the symptoms. Ignoring the need for rest in these situations increases the risk of delaying the recovery from the acute phase. In those situations where absolute rest is warranted, the patient is told that rest means just that. Pillows should be adjusted so that the head remains in neutral when sleeping in side-lying or supine position. The patient should be cautioned about prone lying.

Patients are encouraged to take up or resume a regular activity such as walking or, later in this phase, swimming and perhaps running, or anything else that will get them back to a normal mind set about their function, without reinjuring the area.

In general, two basic approaches are used to treat neck pain with exercises:

- General strengthening and endurance exercises for the neck flexor muscles.[207,208]
- Specific exercises designed to improve coordination and control of the muscles.[78]

Appropriate exercises must ensure proper motor control, performance, and endurance of a specific part of the body. When prescribing exercises to the patient, the clinician must decide on the type of muscle contraction, the patient's body position, the level of resistance or load, and the number of repetitions, and method of progression.[209,210] Gentle exercises are prescribed in the first part of the healing phase. The main reasons for these early exercises are

- to encourage patient involvement;
- to provide mechanoreceptor stimulation;
- to control pain and inflammation;
- to promote healing;
- to maintain the newly attained ranges;
- to provide neuromuscular feedback.

AAROM/AROM[211]

The patient is positioned in supine with the head supported on a pillow or a towel roll. Usually, the easiest and most comfortable exercise is rotation. The patient is asked to perform gentle, active, small-range, and amplitude rotational movements of the neck, initially in one direction, and then the other up to a maximum range of comfort. Care must be taken with these exercises to ensure that the normal movement pattern is performed and that the pattern is reinforced with repetition. The movements are repeated 10 times in each direction. According to Bird and colleagues,[212] to improve endurance, a repetition of 4–6 sets per exercise, with rest periods of 30–60 seconds between sets, is appropriate. To help relieve muscle tension, the exercises can be done in conjunction with breathing.[96] When the patient reaches the end of the comfortable range (at the point where some tissue resistance is first being felt), the patient takes a moderate breath in and then releases it. At the end of the release, a relaxation of the muscles allows a slight increase in range without stressing any tissues, and without causing pain. The focus of these exercises is on motor control rather the muscle strength.

Once these non–weight-bearing active assisted range of motion exercises can be performed without an exacerbation or recurrence of symptoms, active cervical range-of-motion exercises can be initiated in the sitting, and then standing positions.

Retraining of Craniovertebral Flexion

The patient is positioned in supine and is instructed by the clinician on how to perform correct craniovertebral flexion (CVF) using gentle nodding movements while eliminating any compensation strategies, such as neck retraction, excessive cervical flexion, and/or jaw clenching.[78]

FIGURE 25-70 Head nod.

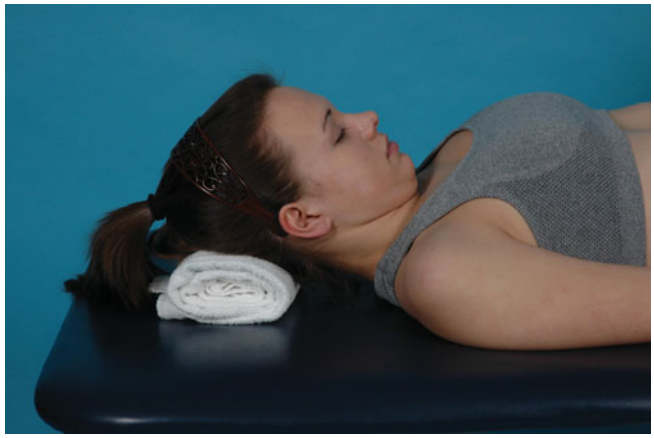

FIGURE 25-72 Head nod with towel roll in supine.

Head Nod.[211] The key exercise to recruit the deep cervical flexors, which are the most common muscles to become weak with neck dysfunction, is the head nod exercise (Fig. 25-70). Correct performance of the exercise ensures that the flexion only occurs at the junction between the head and neck (at the O-A joint) before continuing segmentally into midcervical flexion. The exercise is initially performed in sitting (gravity assisted) while ensuring that no forward movement of the head occurs (which would change the exercise into one of eccentric contraction of the cervical extensors), and to reduce the potential of using the SCM muscle. The patient can be taught to palpate the SCM and scalene muscles during the exercise for any unwanted contractions. As the patient gradually nods the chin down, the back of the head should be seen to move up toward the ceiling. The nod is stopped at the point in the range that can be achieved without superficial muscle activity, held for 10 seconds to promote the endurance function of the muscles, and is repeated 10 times. Once the patient is able to tolerate the exercise in the upright position, they are asked to perform the exercise in supine on an inclined board (Fig. 25-71). As the inclined board is tilted progressively backward toward horizontal the assistance from gravity is gradually reduced. Once in supine, the head is positioned in neutral, either resting on a pillow, or on a small folded towel placed under the occiput so that the normal cervical lordosis is supported (Fig. 25-72). In this position, the head nod exercise is performed with no lifting of the head off the surface, while the patient palpates anteriorly to ensure no superficial muscle activity. Once this is mastered, the exercise is progressed so that the head nod uses the towel roll as a fulcrum (making sure that the neck does not lose contact with the towel) and the back of the head may lift just off the bed during the motion, while preventing the chin from poking forward (this is a sign of excessive anterior translation caused by a relative dominance of the SCM and scalenes). At this time, it is no longer necessary to palpate the anterior structures as the superficial muscles must now be active to lift the head off the bed (Fig. 25-73). To highlight contraction of the flexors more unilaterally in cases of asymmetric weakness, a head nod into a flexion quadrant (e.g., flexion, side bending, rotation to the same side) can be used. The exercise can also be performed in prone over an exercise ball or in the quadruped position (Fig. 25-74). In the prone position, gravity draws the head forward into a position of upper cervical extension, which is opposed by the head nod motion into upper cervical flexion.

FIGURE 25-71 Head nod on incline.

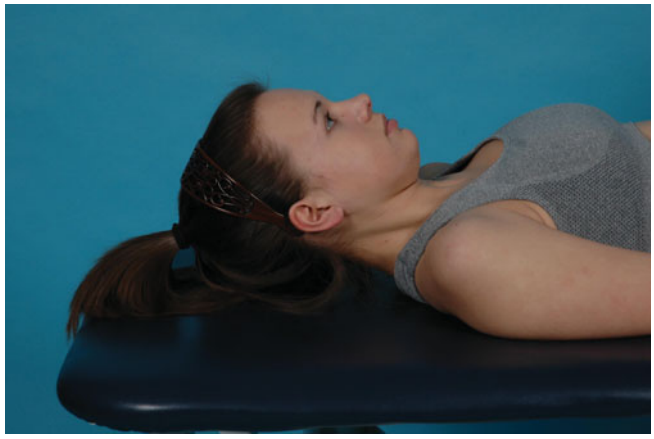

FIGURE 25-73 Head nod with head lift.

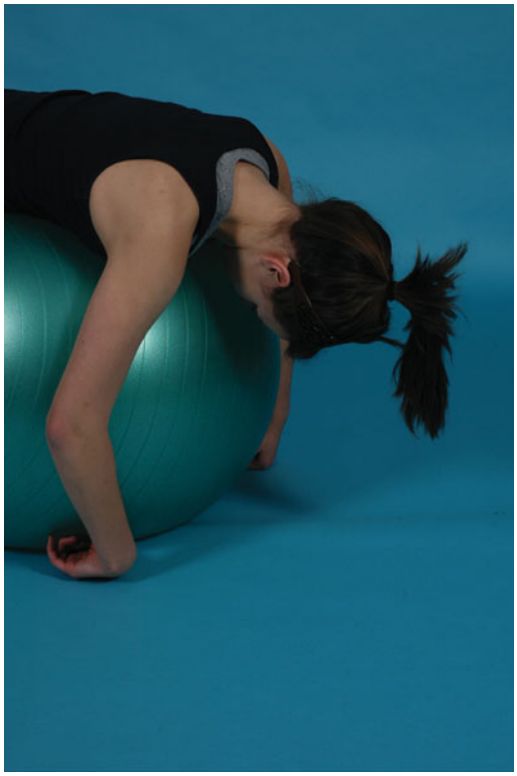

FIGURE 25-74 Head nod prone on Swissball.

Return to Neutral[211]

The return to neutral exercise is intended to recruit the deep cervical segmental extensors. The deep cervical extensor muscles include the semispinalis cervicalis and the multifidus. The craniovertebral extensor muscles include the rectus capitis and the suboccipital muscles. While in the sitting position, and starting from a position at the end of the head nod exercise, the patient is asked to gradually lift the chin and then look up toward the ceiling (eccentric contraction of the cervical flexor muscles), while preventing any chin retraction or cervical retraction, and to continue this movement, trying to look farther along the ceiling, until the end of the comfortable range is reached. At this point, the patient then returns to the start position (concentric contraction of the cervical flexor muscles). Once the patient is able to perform this exercise correctly, the start position is initiated from a position of CVF (Fig. 25-75). If the CV region can be sustained in flexion until the end of the motion, the capitis group of the erector spinae muscles will tend to be inhibited. The exercise is progressed by having the patient perform it on all fours (Fig. 25-76). Finally, isometric hold exercises in different parts of the range can be initiated and progressed based on patient tolerance. In cases of asymmetric weakness, the exercise can be made more specific by working into an extension quadrant (e.g., combined extension, side bending, and rotation to the same side).

Coupling Activation[211]

The primary side benders and rotators can be recruited by exercising into a quadrant position. For both of the following exercises, the patient is told to perform a preset nod to activate the deep stabilizing muscles before performing any motion of the head. These muscles can be trained more specifically and intensely in the sidelying position, with the head supported on a wedge (Fig. 25-77). As the head is lifted off the wedge, the muscles opposite to the side the patient is lying on contract

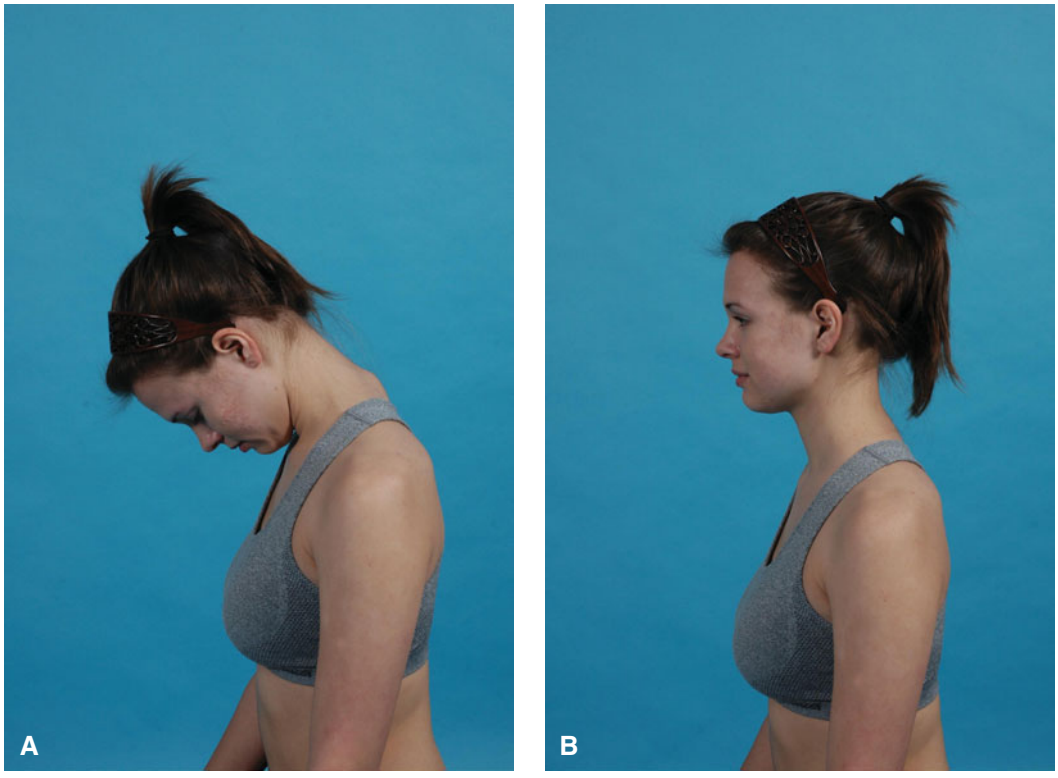

FIGURE 25-75 Seated head nod with return to neutral. **A** Start position. **B** End position

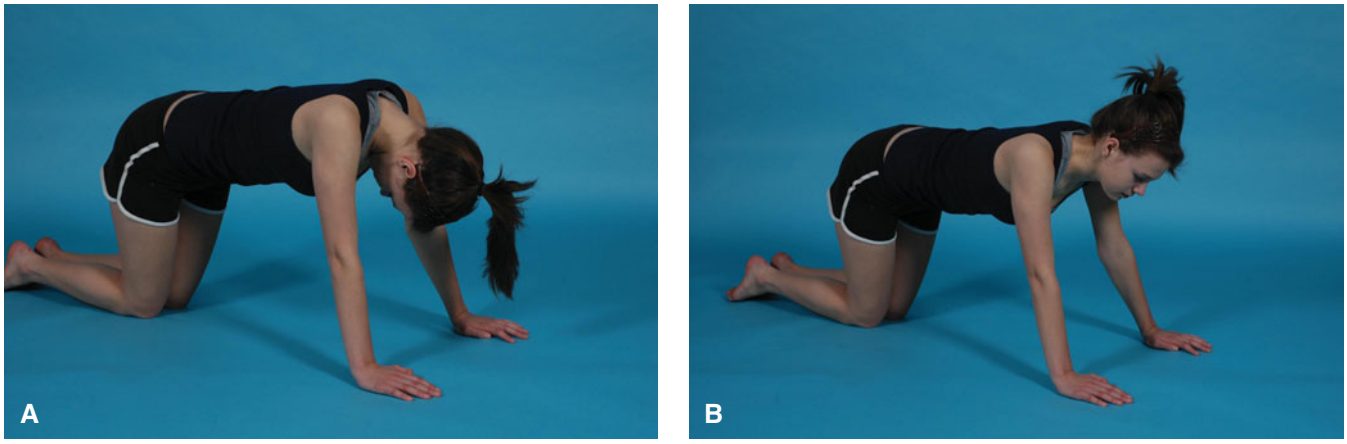

FIGURE 25-76 Return to neutral on all fours. **A** Start position. **B** End position.

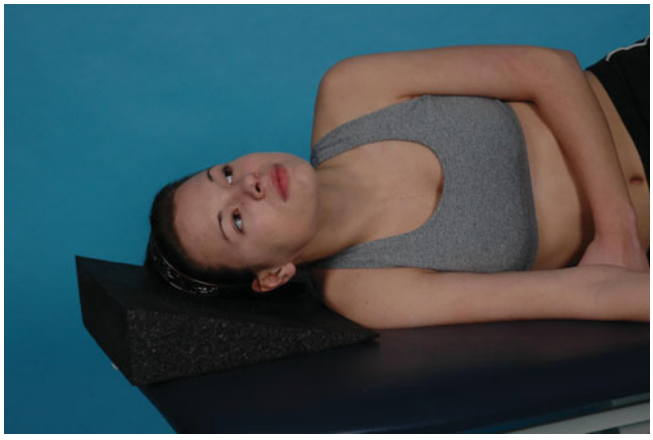

FIGURE 25-77 Combined flexion, side bending, and rotation on wedge in sidelying.

against gravity. The deeper muscles can be emphasized by ensuring that the neck remains in contact with the wedge, thereby decreasing the amount of translation.

Global Strengthening

The global strengthening exercises are initiated with submaximal isometric contractions throughout the single planes using multi-angle submaximal isometric contractions, including flexion VIDEO, extension VIDEO, side bending VIDEO, and rotation VIDEO (Fig. 25-78A–D). The manual resistance is initially applied by the clinician and then by the patient. Although these exercises should not cause sharp pain, they may produce mild delayed-onset muscle soreness. Minimal resistance is used in the neutral position to aid in venous return, stimulate the mechanoreceptors in the muscle, and allay any concerns regarding weakening of the neck from disuse or a cervical collar.[96]

The exercise progression proceeds using the following principles[213]:

- The hold time of the isometric contraction is increased.
- The number of repetitions of this holding activity is increased.
- Progression to the next level is based on the ability of the patient to stabilize and isolate the correct muscle action in the exercise positions.

Increasing the Holding Capacity of the Deep Neck Flexors

Once the patient is able to perform a correct CVF movement, the emphasis switches to increasing the endurance capacity of the involved muscles (deep neck flexors). It is recommended that a preinflated, air-filled pressure sensor is used to help guide and control the training of these muscles so as to provide visual feedback and motivation to the patient.[78] The starting point for the training is the pressure level the patient has reached and can hold without compensation for at least 10 seconds (typically at 22 or 24 mmHg). The patient is instructed on how to achieve the determined pressure level and then to hold it for a time without evidence of compensation or poor motor patterns. The aim is to the patient to hold the position for 10 seconds and then to repeat this 10 times. Practice should occur at least twice a day. The goal is for the patient to perform this exercise with a pressure level between 28 and 30 mmHg. Depending on the patient, achievement of this goal can take anywhere from 4 to 6 weeks to 12 weeks.[78]

Co-contraction of the Neck Flexors and Extensors

These exercises are initially performed with the patient positioned in sitting, and consist of a series of gentle, alternating self-resisted isometric rotation contractions, similar to those used with rhythmic stabilization protocols. A typical progression for training the cervical flexors and extensors to enhance dynamic stability is outlined in Table 25-17.

The other exercises prescribed early in the intervention include:

- exercises designed to regain correct scapular positioning. In patients with cervical problems, the scapula is typically protracted and downwardly rotated. Exercises are prescribed in an attempt to bring the coracoid upward and the acromion backward incorporating a slight retraction

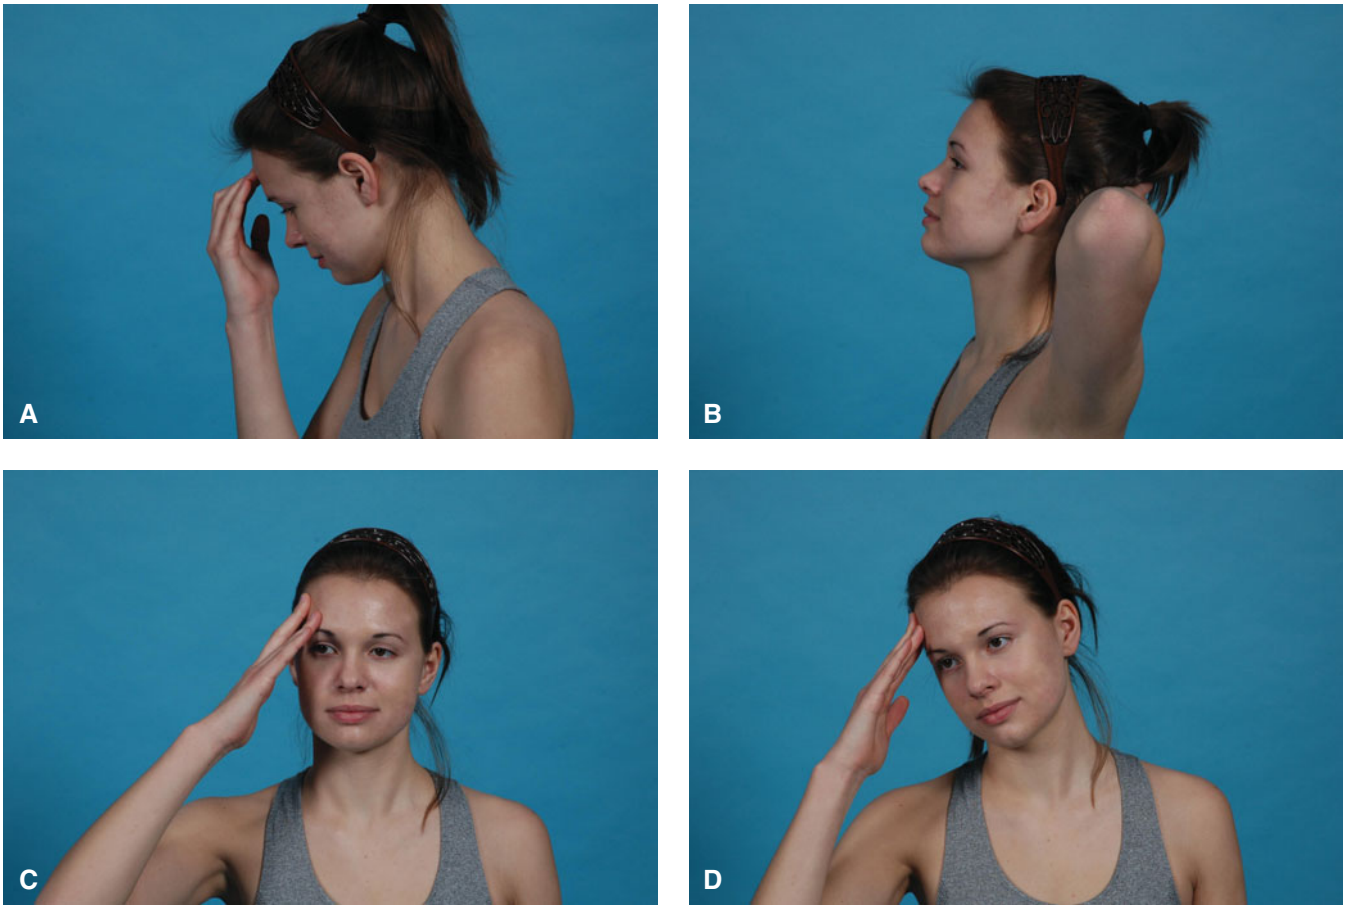

FIGURE 25-78 Cervical submaximal isometrics in four planes. **A** Flexion. **B** Extension. **C** Rotation **D** Side bending.

and lateral rotation of the scapula. Exercises include shoulder shrugging VIDEO, and shoulder square (retraction) exercises VIDEO. The scapula retraction exercises are initially performed supine, with the glenohumeral joint in internal and external rotation. The patient is asked to isometrically retract the shoulders against the bed.

- exercises designed to increase the endurance capacity of the scapular stabilizers, and scapular control with arm movements and loads (see Chap. 16).
- for nerve irritation hip and knee flexion–extension exercises and ankle dorsiflexion in non–weight-bearing position (to help move the dura).

TABLE 25-17 Retraining Progression for the Cervical Flexors and Extensors

Exercise	Patient Position	Description
Cervical bracing	Four-point kneeling	The patient is asked to protract the head and then to perform upper cervical flexion while maintaining the lower cervical spine in a neutral position. This position is held for at least 10 seconds.
Cervical bracing with extremity movements	Four-point kneeling	The patient is asked to combine cervical bracing with arm and leg movements. While maintaining the stability of the body and cervicothoracic region, the patient raises an arm. The patient then raises a leg. These movements are alternated (right arm, left leg; right leg, left arm) until the patient can maintain them and perform the correct movement pattern. To provide more challenge, the patient can be asked to balance a light book on the head.
Cervical bracing with extremity movements on unstable base	Push-up position with lower legs on a Swiss ball	The patient is asked to combine cervical bracing while balancing on a Swiss ball.

Data from Murphy DR: Conservative Management of Cervical Spine Syndromes. New York, NY: McGraw-Hill, 2000; O'Grady WH, Tollan MF: The role of exercise in treating cervical hypermobility or instability. *Orthop Phys Ther Clin North Am* 10:475–501, 2001.

- isometric, shoulder and abdominal exercises (using the Valsalva maneuver, not pelvic tilting or sit-ups).
- postural reeducation.

As with any exercise progression, these exercises are replaced with more challenging exercises, as the patient's healing progresses. Guidelines are provided for safe home exercising by teaching the patient to identify warning signs that could lead to exacerbation or recurrence of symptoms. In the event of an increase of symptoms, the techniques are adjusted by reducing either the amplitude of the movements or the number of movements, or both.

Other movements, such as cervical retraction **VIDEO**, and cervical protrusion can be added to the program, depending on which movements are found to be beneficial during the progression.

The efficacy of electrotherapeutic modalities has not been subjected to randomized clinical trials.[214] Although passive modalities have their uses in the acute phase, the clinician should remember that they must only be used as an adjunct to the more active program, and with a specific goal in mind, such as to help in the reduction of pain and inflammation. Thus, the patient should be weaned off the use of modalities as early as possible. Cervical traction (see Chap. 8) has been advocated for neck sprains, and for the pain of radiculopathy, but no clinical or statistically significant change in pain or overall range of motion has been identified.[215–218]

- ***Ultrasound.*** Pulsed ultrasound should be used precisely.[219] It can be applied to the posterior aspects of the zygapophyseal joints to control pain and reduce swelling or to a torn muscle.
- ***Non-thermal agents.*** Theoretically, ice is the preferred choice during this phase. However, ice can often increase pain that arises from trigger points. At the earliest opportunity the application of heat is introduced because of its ability to relax musculature, and stimulate vasodilation.[220]
- ***Electrical muscle stimulation.***[96] Providing that none of the muscles stimulated are torn, electrical muscle stimulation can be used in the early stages as an effective pain reliever and as a venous pump. The patient is positioned supine. A small electrode is placed on each of the left and right suboccipital muscles, and a large common electrode is placed along the upper thoracic spinous process. The channels are made to stimulate asynchronously with a long "on" ramp, and a contraction length of 2 or 3 seconds (certainly no longer than 5, because this becomes uncomfortable). The session can last anywhere from a few minutes to 30 minutes, once it is established that there are no adverse effects from the intervention.

Numerous manual therapy techniques are available to the clinician, each with its own uses. These techniques, described later under "Therapeutic Techniques" section, can be used with hypomobilities, and soft tissue injuries. The nature and location of the dysfunction, as well as the intention of its effect, guide the selection of a particular technique. Movement gained by a manual technique must be reinforced by both the mechanical and neurophysical benefits of active movement.[68]

No randomized controlled trials (RCTs) have been done on the efficacy of manipulations for patients with predominantly acute neck pain. A number of RCT studies have been done with subacute and chronic neck pain, most of which have shown that manipulation is probably slightly more effective than mobilization or other interventions.[221]

Cervical Collars

The use of cervical collars is controversial. Although several studies have concluded that the wearing of a cervical collar results in delayed recovery, these studies looked at the use of collars and other passive therapies versus other more active forms of intervention, such as early patient activation and exercise. A study by Mealy and colleagues[222] found that early active mobilization techniques following a WAD improved pain reduction and increased mobility, compared with a control group receiving 2 weeks' rest with a soft cervical collar and gradual mobilization thereafter. Another study[25] found physical therapy or exact instructions in a home program of self-mobilization to be better than 2 weeks' rest, with a soft collar at the 1- and 2-month follow-ups. A similar result was found at the 2-year follow-up.[224] Borchgrevink and colleagues[225] found that patients encouraged to continue with daily activities had a better outcome than patients prescribed sick leave and immobilization.

With those patients who have a severe capsular restriction of motion, however, a cervical collar should be issued. Soft cervical collars do not rigidly immobilize the cervical spine and if used judiciously can provide support for the head and neck in the very acute stages.[214,226]

The collar serves a number of functions, among them are

- providing support in maintaining the cervical spine erect;
- reminding the patient that the neck is injured and, thereby, preventing the patient from engaging in unexpected or excessive movements;
- allowing the patient to rest the chin during activities, thereby offsetting the weight of the head;
- allowing the patient to perform cervical rotations while the weight of the head is offset.

Prolonged reliance on the use of a collar may induce stiffness and weakness, but this can be avoided by recommending a time-limited use of the collar, which is based on specific factors such as the patient's condition and function. Certain situations warrant the use of a collar, such as long drives in a vehicle or prolonged postures of standing and sitting. However, patients should be weaned off the collar once there is significant improvement in the range of motion and pain levels.

Functional Phase

Although strengthening exercises have been advocated for the intervention of neck pain,[207,227] only a few controlled intervention studies have been conducted to examine their benefit. However, in one randomized study, investigators found that a multimodal intervention of postural, manual, psychological, relaxation, and visual training techniques was superior to traditional approaches involving ultrasound and electric

stimulation.[228] Patients returned to work earlier, and they had better results in pain intensity, emotional response, and postural disturbances.[228]

The stabilization of this region must include postural stabilization retraining of the entire spine.

Cervicothoracic stabilization is a specific type of therapeutic exercise that can help the patient to (1) gain dynamic control of cervicothoracic spine forces, (2) eliminate repetitive injury to the motion segments, (3) encourage healing of the injured segment, and (4) possibly alter the degenerative process.[229]

Cervicothoracic stabilization exercises include the following:

Shoulder Shrugs and With Resistance

These exercises, initiated in the acute phase without resistance, are progressed so that the patient performs them with resistance added by asking the patient to hold a weight in each hand. The shrug strengthens the upper trapezius, levator scapulae, and rhomboids. The shoulder circles strengthen the upper trapezius, levator scapulae, and rhomboids.

Scapular Retraction

Once this exercise can be performed in supine without pain, the patient performs the exercise in the side-lying position and then prone or standing without resistance **VIDEO**. Resistance is added as tolerated. Scapular retraction in internal rotation of the glenohumeral joint strengthens the infraspinatus, teres minor, middle and posterior deltoids, and the rhomboids. Scapular retraction in external rotation of the glenohumeral joint strengthens the infraspinatus, teres minor, middle and posterior deltoids, and middle trapezius **VIDEO**.

Serratus Punch

This exercise is performed initially with the patient supine, one shoulder flexed to 90 degrees, and the elbow extended. From this position, the patient raises the extended arm toward the ceiling and protracts the shoulder girdle. This exercise can be progressed by adding a weight to the hand and performing it against a wall or a chair, before progressing to a push-up on the floor.

Tree Hug

The patient is asked to wrap a length of elastic tubing around the back and to hold the two ends, with the thumbs pointing forward and the arms in about 60 degrees of abduction (Fig. 25-79). From this position, the patient is asked to imagine hugging a tree and to reproduce that motion.

FIGURE 25-79 Tree hug.

Upright Rows Video

The muscles involved with this exercise (Fig. 25-80) include the deltoids, supraspinatus, clavicular portion of the pectoralis major, long head of the biceps, upper and lower portions of the trapezius, levator scapulae, and serratus anterior.

Elastic tubing is placed under the feet and the ends are held in each hand. Keeping the back straight, and the elbows out to the side, the patient raises their hands from about waist height to just below the chin (Fig. 25-80).

Lateral Arm Raise

This exercise (Fig. 25-81) is initiated without resistance. Once it can be performed without pain, resistance in the form of

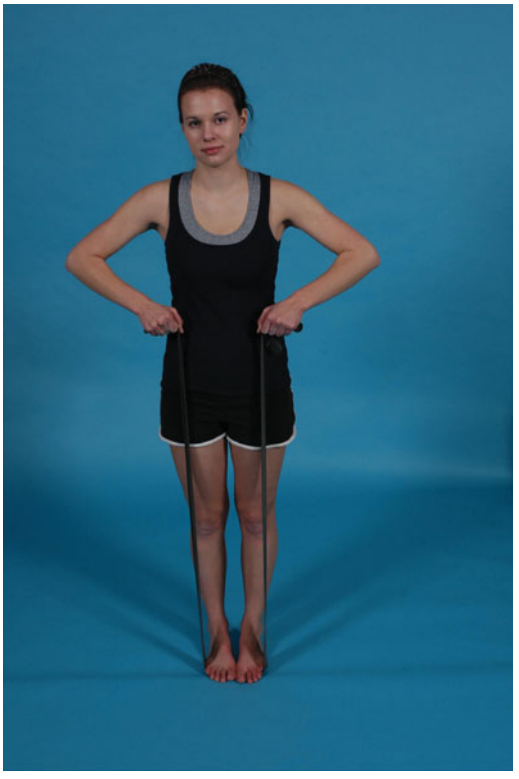

FIGURE 25-80 Upright rows.

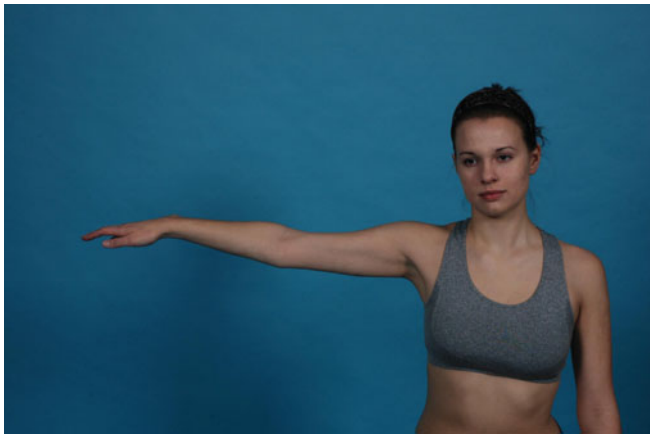

FIGURE 25-81 Lateral arm raise.

tubing or hand weights is added. Lateral arm raises involve the deltoid, supraspinatus, serratus anterior, and upper and lower trapezius.

Front Arm Raise

Again, this exercise (Fig. 25-82) is initiated without resistance. Once it can be performed without pain, resistance in the form of tubing or hand weights is added. Front arm raises involve the anterior deltoid, pectoralis major (upper portion), coracobrachialis, serratus anterior, and upper and lower trapezius.

Cervical Retraction Against Gravity

To strengthen the cervicothoracic stabilizers, the patient is positioned prone, with the head off the end of the bed and supported in a protracted position of the neck. The patient is asked to retract the chin from this position, raising the head toward the ceiling, while maintaining the face parallel to the floor (see Fig. 25-14).

Gravity Cervical Stabilization

These exercises can be performed into extension, rotation **VIDEO**, and side bending **VIDEO**. Cervical side translations also can be performed against gravity.

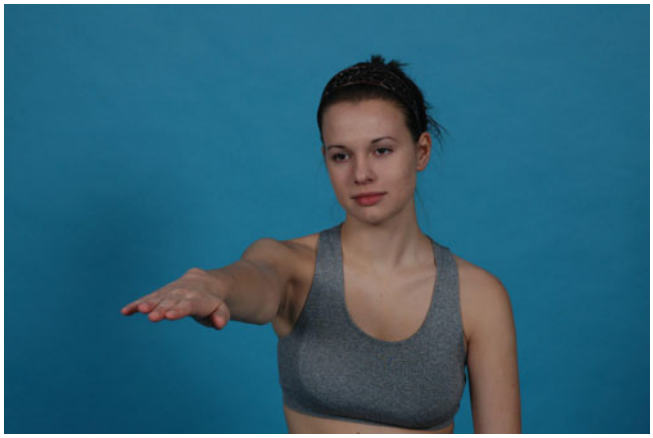

FIGURE 25-82 Front arm raise.

Closed kinetic chain activities can also be very helpful in rehabilitating weak shoulder girdle muscles and the cervical stabilizers (see Chap. 16).

It should be emphasized that all exercises should be performed correctly and without pain, although some degree of postexercise soreness can be expected. Isokinetic exercises of the neck are not functional and are not recommended as a strengthening tool.

Strength training can progress to manually resisted cervical stabilization exercises in various planes. Cervical proprioceptive neuromuscular facilitation patterns are ideal for this purpose (Chap. 10). Muscle cocontraction of agonist and antagonist can be used for joint stabilization, by increasing joint stiffness and supporting the independent torque-producing role of the muscles that surround the joint.[230–232]

Continued efforts must be made to progressively reduce the patient's pain and advance physical function through exercise.[137] However, the use of pain medication to help control pain and inflammation, probably helps patients to progress, while experiencing considerably less pain and enabling their return to work.

Ergonomics

The patient's workstation and lifestyle ergonomics should be addressed (Table 25-18). A chair that provides adequate support and encourages the patient to maintain lumbar lordosis provides a stable platform for the cervical spine.[233] The feet should easily touch the floor, and the thighs should be horizontal to the ground. Computer monitors should be positioned to allow a slight 20-degree downward slope of the eyes.

Postural Retraining

It is important to retrain the patient to assume a correct upright and neutral spine position and to be able to consciously activate and hold the supporting muscles in a variety of functional positions.[68] Few studies have investigated the association between posture and active range of motion. Hanten and colleagues[234] measured resting head posture and total range between full protraction and retraction in the horizontal plane, in subjects with and without neck pain, and found that the neck pain group had less range than the normal group. Lee and colleagues[235] investigated associations between subclinical neck pain/discomfort, and range of motion and physical dimensions of the cervicothoracic spine. Their data suggested that there are early range changes associated with the development of neck pain.

The retraining of the cervicothoracic postural muscles usually begins at the lumbopelvic region, ensuring that the patient does not adopt the chest-out, shoulders-back position, which results in an incorrect thoracolumbar or thoracic lordosis, rather than a correct balance between all of the spinal curves.[68]

Overall Strength and Fitness

Strengthening of the entire kinetic chain should always be a consideration but will depend on the physical requirements of the patient. Strengthening exercises for the kinetic chain can

TABLE 25-18 Workstation Setup and Keyboard Technique Checklist

Fault	Correction
Visual field	
Monitor positioned to side of keyboard	Monitor directly in front of chair and parallel to keyboard
Stationary monitor	Monitor mounted on adjustable support
Screen too high or too low	10–15-degree downward viewing angle to center of screen
Copy on desk surface	Copy secured along side of monitor
Glare from direct and reflected light	Clean antiglare screen (glare filter and angle screen away from window)
Overhead fluorescent lights	Task-appropriate lighting
Incorrect focal distance for visual acuity	Focal distance (eyeglasses) corrected for computer use (i.e., 20–24 in)
Posture	
Head forward	Ears aligned with shoulders; chin retracted
Shoulders elevated	Shoulder girdle muscle balance
Scapular winging	Scapulothoracic proximal stability
Hypertonic upper trapezii	Lower keyboard or desk height
Shoulder protraction/internal rotation	Neutral shoulder alignment
Elbow flexion >90 degrees	Keyboard parallel to or slightly below elbow level (i.e., 80–90 degrees of elbow flexion)
Elbow flexion <80 degrees	Keyboard moved closer to minimize reach
Wrist flexion or extension	Height of keyboard or chair adjusted to achieve wrist in position of function[a]
Elbows locked at sides	Arms stabilized from scapulothoracic region
Wrists against keyboard or desk edge	Hard keyboard or desk edge padded
Wrist extension	Keyboard positive incline eliminated; flat keyboard or negative incline
Wrist ulnar deviation	Reeducate neutral wrist positioning; split keyboard
Finger MCP joint hyperextension	Fingers in position of function
Flat of kyphotic back	Back supports in chair to match individual spinal contours
Stationary chair back and seat pan	Versatile chair allowing forward, upright, and reclined postures; seat pan inclined forward with "waterfall" edge
Hips lower than knees	Seat height raised; seat pan inclined to position hips slightly higher (5–10 degrees) than knees
Feet dangling	Feet flat on floor or foot rest
Keyboard technique	
Wrist extensor/flexor co-contraction	Light key touch; relaxation-biofeedback training
Wrist ulnar deviation	Wrist aligned with forearm
Intrinsic plus keystrike	Hand postures in position of function
Intrinsic minus keystrike (zig-zag)	
Digital extensor habitus	Thumb lightly resting on spacebar; spacebar use with thumb press versus lift and strike
Thumb held in horizontal abduction and extension	
Excessive force of keystrike	Keystrike with finger press versus lift and strike; keystrike with arm bounce
Ulnar deviation at wrist and fingers	Wrist aligned with forearm; use of external rotation–abduction at shoulder for lateral key reach with lateral keystrike
Excessive leaning on wrist rests	Wrist glide versus wrist rest technique
Fifth finger lateral reach and strike	Index finger use for lateral keystrike: slight supination with fifth finger keystrike
Hands play with combination keystrikes	Combination key command efficiency; macroprogram development
Typing too fast	Kinesthetic awareness training
Infrequent breaks and poor work–rest cycles	Periodic rest breaks and task rotation; computer programmed to signal rest breaks

MCP, metacarpophalangeal.

[a]Position of function: forearm, wrist, and hand aligned, 20–30-degree wrist extension, natural curve to digits with MCP joints at about 50 degrees of flexion, and thumb in line with radius.

Data from Rempel DM, Harrison RJ, Barnhart S: Work-related cumulative trauma disorders of the upper extremity. *JAMA* 267:838–842, 1992; Armstrong TJ: Ergonomics and cumulative trauma disorders. *Hand Clin* 2:553–565, 1986.

include lat pull-downs VIDEO, PREs for the middle trapezius and rhomboids VIDEO, and upper extremity PNF patterns VIDEO. It is important throughout the rehabilitation process for patients to maintain their level of cardiovascular fitness as much as possible. Aerobic exercise, which increases endurance and the general sense of well-being, should be a part of all exercise programs.[236,237] Cardiovascular conditioning should be started as soon as possible to prevent deconditioning. These exercises also serve as a great warm-up before a stretching program.

PRACTICE PATTERN 4B: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH IMPAIRED POSTURE

Fiber composition studies have demonstrated that the primary dysfunction in neck muscles is a loss in the tonic supporting capacity, with the dysfunction being greater within the neck flexors.[68,238] Several postural syndromes of the cervical have been identified over the years.

Upper (Proximal) Crossed Syndrome

This syndrome involves adaptive shortening of the levator scapulae, upper trapezius, pectoralis major and minor, SCM, and weakness of the deep neck flexors and lower scapular stabilizers. The syndrome is characterized by[84,85]

- elevation and protraction of the shoulder;
- rotation and abduction of the scapula;
- scapular winging;
- forward head (see discussion that follows);
- decreased stability of the glenohumeral joint;
- increased muscle activity of the levator scapula and trapezius.

The positional changes that occur with the proximal crossed syndrome may alter the structural relationships of the shoulder and the cervical spine. This alteration may result in changes in the length–tension relationships and the kinematics of the scapular and cervical muscles. The consequences of these changes may include posterior nerve root irritation, cervical radiculopathy, segmental hypermobility, and instability at C4–5.[117,239]

The intervention for this syndrome is based on the clinical findings. Any changes in the length–tension relationships should be addressed through stretching and strengthening.

Forward Head

Abnormal posture adaptations have long been considered by many to be the cause of numerous musculoskeletal and neurovascular impairments (see Chap. 6).[51,59,70,240–249] These adaptations are further perpetuated by the natural cycle of aging of the spine, which involves disk degeneration, vertebral wedging, ligamentous calcification, and reduction in the cervical and lumbar lordoses, producing a position of spinal flexion, or stooping.

Habitual movement patterns or positions may contribute to the development of these changes and produce muscular hyperactivity, ligamentous stress, and alteration of the anatomic and biomechanical relationship of the joints. It is theorized that if a muscle lengthens as part of this compensation, muscle spindle activity increases within that muscle, producing reciprocal inhibition of the muscle's functional antagonist, and resulting in an alteration in the normal force–couple and arthrokinematic relationship, thereby affecting the efficient and ideal operation of the movement system.[126,128,250–252]

Because the zygapophyseal joints in the midcervical region incur more weight bearing, as a result of the protruding head, marginal osteophytosis may occur. The common levels for this to occur are C5–6 and C6–7. These changes also alter the scapulothoracic rhythm because of alterations in the muscle tone of the rhomboids and serratus anterior. These altered relations increase the distance between the origin and insertion of the trapezius, of the rhomboid major and minor, and of the levator scapulae, which results in further stress.

The intervention for postural dysfunction focuses on the correction of any strength and flexibility imbalances. Once the mechanical source is identified, the focus is the simultaneous retraining of the muscles, by contracting the lengthened muscle when it is in a shortened position, and stretching the shortened muscle.[128] An exercise program for forward head posture should address underlying soft tissue imbalances by including deep cervical flexor and shoulder retractor strengthening and cervical extensor and pectoral muscle stretching. Therapeutic exercise programs initially should focus on the achievement of good movement patterns. Pearson and Walmsley[253] found that repeated upper cervical retractions changed resting neck posture. Roddey and colleagues[254] demonstrated improvements in resting scapular position following a stretching program of the pectoralis minor muscle. Wright and colleagues[255] in a randomized, controlled study of a postural correction program consisting of scapular strengthening and neck stretching exercises for clients with temporomandibular disorder and pain, reported a significant improvement in symptoms (jaw and neck pain) as compared to the control group.[256]

Recommended exercises include the following:

- The head nod exercise progression.
- The return to normal exercise progression.
- Resisted shoulder retraction exercises in standing using theraband. This is progressed to shoulder retraction in prone using weights.
- Unilateral and bilateral pectoralis minor stretches.
- Exercises to reposition the head into a natural head posture, as appropriate, using a mirror. Once the patient is able to reposition the head with the eyes open, the task is repeated with the eyes closed and the clinician providing feedback.[257]
- Exercises to retrain the oculomotor system. These exercises are initiated by asking the patient to keep the head stationary in the natural head posture and using the eyes to track objects.[257] Once this is mastered, the patient is asked to

combine eye movements and head movements. For example the patient is asked to rotate the head and eyes at the same time in the same direction, then to rotate the head and eyes in the opposite direction at the same time. Obviously, these exercises should not be performed if symptoms such as dizziness and unsteadiness appear. A study by Humphreys and Irgen found that these exercises reduced pain intensity and improved the accuracy of repositioning of the head after 4 weeks of treatment in patients with chronic neck pain, compared with patients who did not receive treatment. However, as the authors acknowledged, a link still has to be made to establish the connection between craniovertebral kinesthesia, head reposition accuracy, and neck pain.

PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND FORMAT RANGE OF MOTION ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Cervical Disk Pathology

The cervical spine is vulnerable to the same impairments as those of the lumbar spine and any weakness in the surrounding structures results in either a disk bulge or a rupture. Cervical radiculopathy is, by definition, a disorder of the cervical spinal nerve root and, most commonly, is caused by a cervical disk herniation or other space-occupying lesion, resulting in nerve root inflammation, impingement, or both. Considering the structure of the cervical AF, the possibilities that emerge for mechanisms of diskogenic pain are strain or tears of the anterior AF, particularly after hyperextension trauma, and strain of the alar portions of the PLL when stretched by a bulging disk.[9]

Analysis of the anatomic proportions of the cervical spine indicates that cervical diskogenic disease can have an impact on neural structures in the bony spinal canal. The anterior–posterior diameter of the cervical spinal canal tends to be narrower in patients with herniation resulting in myelopathy.[75,258,259] That is, patients with wide canals might be nonmyelopathic even with the same degree of herniation. In the lumbar disk, a prolapse is common. In the cervical spine, a straightforward prolapse is uncommon, and a cervical disk herniation should not be considered as a miniature version of lumbar disk herniation. It is, unlike lumbar disk herniation, extremely rare under the age of 30 years, with the age range of peak incidence between 45 and 54 years, and only slightly less common in the 35–44-year-old group.[260] Acute disk herniations may result in compression of nerve roots. Cervical disks may become painful as part of the degenerative cascade, from repetitive microtrauma, or from macrotrauma. The indication that degeneration plays a greater role in cervical disk herniation may explain why cervical disk herniation is extremely rare in those less than 30 years of age and why the mean age is around 50 years.[261,262]

The most common level of cervical nerve root involvement has been reported at the seventh (C7, 60%) and sixth (C6, 25%),[20,263] followed by C4–5 disk (Table 20-4).[3,261,262] In a study of 18 cadavers by Tanaka et al.,[17] the C5 nerve roots were found to exit over the middle aspect of the IVD, whereas the C6 and C7 nerve roots were found to traverse the proximal part of the disk. The C8 nerve roots had little overlap with the C7–T1 disk in the intervertebral foramen. The C6 and C7 rootlets passed two disk levels in the dural sac. Also, a high incidence of the intradural connections between the dorsal rootlets of C5, C6, and C7 segments was found.[17] These intradural connections between dorsal nerve roots and the relation between the course of the nerve root and the IVD may explain the clinical variation of symptoms resulting from nerve root compression in the cervical spine.[17]

Cervical IVDs with herniation usually remain normal in height or change only slightly without abnormality in the uncovertebral joints.[261] Sclerosis and formation of osteophytes in the uncovertebral joints accompany narrowed disks in spondylosis. These facts indicate that the uncovertebral joints bear a part of the axial load to the IVD in the cervical spine. Accordingly, disk degeneration may play a more important role than trauma in the production of herniation in the cervical spine, and it is common for a patient to awake with a cervical disk herniation, misinterpreting it as a "crick" in the neck.

CLINICAL PEARL

Asymptomatic cervical disk herniation is often found in magnetic resonance images for other diseases.[20] Boden et al.[14] reported the incidence of cervical disk protrusions in the asymptomatic population to be 10–15%, depending on age.

Other factors associated with increased risk include heavy manual labor requiring lifting of more than 25 lb, smoking, and driving or operating vibrating equipment.[264]

Cervical disk degeneration occurs in a predictable fashion. The NP and AF form small cysts[265,266] and fissures as the first disruptive changes after the death of chondrocytes and the separation of fibers or fiber bundles. Subsequently, they extend and unite to form horizontal and vertical clefts.[261] Shearing stress to the disk by translational motion may lead to fibrillation of the matrix, as in osteoarthritic joint cartilage. Some of the vertical clefts extend to the cartilaginous end plate, and portions of the cartilaginous end plate may be torn off.

The cervical IVD is innervated by the sinuvertebral nerve, formed by branches from the anterior (ventral) nerve root and the sympathetic plexus.[267] Once formed, the nerve turns back into the intervertebral foramen along the posterior aspect of the disk, supplying portions of the AF, PLL, periosteum of the vertebral body and pedicle, and adjacent epidural veins. As in the lumbar spine, the pain associated with cervical disk lesions probably occurs from an inflammatory process initiated by nerve root compression, resulting in nerve root swelling.

Within the compressed nerve root, intrinsic blood vessels show increased permeability, which secondarily results in edema of the nerve root.[268] Chronic edema and fibrosis within the nerve root can alter the response threshold and increase the sensitivity of the nerve root to pain.[269] Neurogenic

chemical mediators of pain released from the cell bodies of the sensory neurons and nonneurogenic mediators released from disk tissue may play a role in initiating and perpetuating this inflammatory response.[270] The posterior (dorsal) root ganglion has been implicated in the pathogenesis of radicular pain. Prolonged discharges originate from the cell bodies of the posterior (dorsal) root ganglion as a result of brief pressure.[268] In addition to the chemicals produced by the cell bodies of the posterior (dorsal) root ganglion, the membrane surrounding the posterior (dorsal) root ganglion is more permeable than that around the nerve root, allowing a more florid local inflammatory response.[268] The blood supply to the nerve root usually is not compromised by an acute herniation, unless the compression is severe.[21,271] A study involving patients under local anesthesia found that compression of the cervical nerve root produced limb pain, whereas pressure on the disk produced pain in the neck and the medial border of the scapula.[11,272] Intradiskal injection and electrical stimulation of the disk have also suggested that neck pain is referred by a damaged outer AF.[272,273] Muscle spasms of the neck have also been found after electrical stimulation of the disk.

The capacity of the disk to self-repair is restricted by the fact that only the peripheral aspects of the AF receive blood, and a small amount at that.

Numerous clinical examination findings are purported to be diagnostic of cervical radiculopathy including patient history, cervical range of motion limitations, neurologic examination, and specific maneuvers (e.g., Spurling). Most of these items have demonstrated a fair or better level of reliability.[153] However, because the clinical presentation of cervical radiculopathy is so variable, it is advisable to use a combination of test results before making a diagnosis.[153]

It is important to obtain a detailed history to establish a diagnosis of a cervical radiculopathy and to rule out other causes, such as TOS and brachial neuritis. The clinician should first determine the main complaint (i.e., head or neck pain, numbness, weakness, decreased neck function) and location of symptoms.[10,218] Anatomic pain drawings can be helpful by supplying the clinician with a quick review of the pain pattern.

CLINICAL PEARL

Patients with a cervical disk herniation are often younger, whereas patients with radicular symptoms due to cervical disk degeneration are often middle aged.

Henderson and colleagues reviewed the clinical presentations of cervical radiculopathy in 736 patients[274]: 99.4% had arm pain, 85.2% had sensory deficits, 79.7% had neck pain, 71.2% had reflex deficits, 68% had motor deficits, 52.5% had scapular pain, 17.8% had anterior chest pain, 9.7% had headaches, 5.9% had anterior chest and arm pain, and 1.3% had left-sided chest and arm pain (cervical angina). Neurologic deficits corresponded with the offending disk level in approximately 80% of patients.[268]

The patient usually reports a history of neck pain before the onset of arm pain. The onset of neck and arm discomfort with cervical disk herniation is usually insidious and can range from a dull ache to severe burning pain.[10,218] The symptoms may be referred to the medial scapula initially and then along the upper or lower arm and into the hand, depending on the nerve root that is involved.[10,218]

Patients with a cervical disk lesion typically have severe pain that prevents them from getting into a comfortable position.[268] The symptoms are usually aggravated by extension or rotation of the head to the side of the pain (the Spurling maneuver) (Fig. 25-56). Aggravation of the symptoms by neck extension often helps differentiate a radicular etiology from muscular neck pain or a pathologic condition of the shoulder with secondary muscle pain in the neck.[268]

The common radicular syndromes of the cervical spine are outlined in Table 25-19.

C2-3 disk herniations are rare,[275] in either traumatic or spontaneous etiology, and affected only 8 of 2786 patients (0.28%) of the surgical cervical spondylotic cases over 10 years in one study.[276] These herniations are difficult to identify on clinical examination, because these patients usually have no specific motor weakness or reflex abnormality. Radiculopathy of the third cervical nerve root results from pathologic changes

TABLE 25-19 Common Radicular Syndromes of the Cervical Spine

Disk Level	Nerve Root	Motor Deficit	Sensory Deficit	Reflex Compromise
C4–5	C5	Deltoid Biceps	Anterolateral shoulder and arm	Biceps
C5–6	C6	Wrist extensors Biceps	Lateral forearm and hand Thumb	Brachoradialis Pronator teres
C6–7	C7	Wrist flexors Triceps Finger extensors	Middle finger	Triceps
C7–T1	C8	Finger flexors Hand intrinsics	Medial forearm and hand and ring and little fingers	None
T1–2	T1	Hand intrinsics	Medial forearm	None

Data from American Medical Association: *Guides to the Evaluation of Permanent Impairment*, 5th ed. Chicago, IL: American Medical Association, 2001.

in the disk between the second and third cervical levels and is unusual. The posterior ramus of the third cervical nerve innervates the suboccipital region, and involvement of that nerve causes pain in this region, often extending to the back of the ear.

Radiculopathy of the fourth cervical nerve root may be an unexplained cause of neck and shoulder pain.[268] Numbness extending from the caudad aspect of the neck to the superior aspect of the shoulder may be present. Difficulty with breathing during exercise may be reported in diaphragmatic involvement (C3–5).

Radiculopathy of the fifth cervical nerve root can present with numbness in an "epaulet" distribution, beginning at the superior aspect of the shoulder and extending laterally to the midpart of the arm.[268] The absence of pain with a range of motion of the shoulder and the absence of impingement signs at the shoulder help to differentiate radiculopathy of the fifth cervical nerve root from a pathologic shoulder condition.[268]

Radiculopathy of the sixth cervical nerve root presents with pain radiating from the neck to the lateral aspect of the biceps, down the lateral aspect of the forearm, to the posterior (dorsal) aspect of the web space between the thumb and the index finger, and into the tips of those digits.[268] Numbness occurs in the same distribution.

The seventh cervical nerve root is considered to be the most frequently involved by cervical radiculopathy. The patient has pain radiating along the back of the shoulder, often extending into the scapular region, down along the triceps, and then along the posterior aspect of the forearm and into the posterior aspect of the long finger.[268] The patient usually pronates the forearm while trying to describe the location of the symptoms, and this is a useful observation in differentiating the hand symptoms from those of sixth cervical radiculopathy and carpal tunnel syndrome.[268]

Radiculopathy of the eighth cervical nerve root usually presents with symptoms extending down the medial aspect of the arm and forearm and into the medial border of the hand and the ulnar two digits.[268] Numbness usually involves the posterior and anterior aspects of the ulnar two digits and hand and may extend up the medial aspect of the forearm. The patient reports difficulty with using the hands for routine daily activities.[268]

Patients can also present with radicular symptoms that result from other pathologies. These can include schwannomas, meningiomas, and benign or malignant vertebral body tumors.[268] A Pancoast tumor of the apical lung can involve the more inferior cervical nerve roots and, additionally, the sympathetic chain.[268] Idiopathic brachial plexus neuritis is thought to be viral in nature and presents with severe arm pain that resolves and leaves behind polyradicular motor deficits. Polyradicular involvement may also be seen with epidural abscesses.[268]

In middle-aged and older patients, the symptoms are often the result of degenerative changes and compression of the neural structures by osteophytes rather than disk herniation. Prior episodes of similar symptoms or localized neck pain are important for the diagnosis and ultimate intervention. The older patient may have had previous episodes of neck pain or give a history of having arthritis of the cervical spine. Leg symptoms associated with neck dysfunction, especially in the elderly, should arouse the suspicion of cervical spondylotic myelopathy.[259]

The position of the head and neck at the time of injury should also be noted. Acute disk herniations and sudden narrowing of the neural foramen may occur from injuries involving cervical extension, side bending, or rotation and axial loading.[277,278]

The clinician should be aware that upper trunk brachial plexus disorders can be confused with a C5 or C6 radiculopathy. This condition, often referred to as a *burner*, or *stinger*, is thought to result from either traction or compressive forces to the brachial plexus or cervical nerve roots.[279,280] At times, electrodiagnostic studies and MRI are needed to establish the diagnosis.

Peripheral nerve entrapment within the upper limb, including entrapment or compression of the suprascapular, median, and ulnar nerves, may also be confused with a cervical radiculopathy[10,218]:

- A suprascapular neuropathy can be confused with a C5 or C6 radiculopathy but would spare the deltoid and biceps muscles.
- C6 and C7 radiculopathies are most likely to be confused with median neuropathies.
- A C8 radiculopathy must be differentiated from ulnar neuropathies and TOS.

It is important to differentiate an eighth cervical radiculopathy from ulnar nerve weakness. The function of the flexor digitorum profundus in the index and long fingers and of the flexor pollicis longus in the thumb can be affected by an eighth cervical radiculopathy, but they are not affected by ulnar nerve entrapment.[268] With the exception of the adductor pollicis, the short thenar muscles are spared with ulnar nerve involvement but are involved with an eighth cervical or first thoracic radiculopathy.[268] Entrapment of the anterior interosseus nerve may masquerade as an eighth cervical or first thoracic radiculopathy, but it does not cause the sensory changes or have thenar muscle involvement.[268]

The head and neck positions or motions that increase or decrease the symptoms can be used by the clinician both to help in the diagnosis and to plan the intervention. Typically, the patient with cervical radiculopathy has a head list away from the side of injury and holds the neck stiffly. These patients complain of increased posterior neck pain with neck positions that cause foraminal narrowing: extension, side bending, or rotation toward the symptomatic side.

Active range of motion is usually reduced in the direction of pain, which is usually extension, rotation, and side bending, either toward or away from the affected nerve root. Side bending away from the affected side can cause increased displacement of a disk herniation upon a nerve root, whereas same-side bending induces pain by an impingement of a nerve root at the site of the neural foramen.[277,278]

Anterior neck pain along the SCM muscle belly, which is aggravated by rotation to the contralateral side, is most often a result of muscular strain.[268] Pain in the posterior neck muscles, which is worsened by flexion of the head, suggests a myofascial etiology.[268] Patients who present with severe pain

in the suboccipital region often have pathologic changes in the upper cervical spine.[268] The pain in these patients may radiate to the back of the ear or the lower neck. Rotation of the neck is often markedly restricted.

On palpation, a nonspecific finding is tenderness noted along the cervical paraspinals, along the ipsilateral side of the affected nerve root, and over the upper trapezius. There may also be muscle tenderness along muscles where the symptoms are referred (e.g., medical scapula, proximal arm, and lateral epicondyle), as well as associated hypertonicity or spasm in these painful muscles.

Manual muscle testing determines a nerve root level on physical examination and can detect subtle weakness in a myotomal, or key muscle, distribution. Weakness of shoulder abduction suggests C5 pathology, elbow flexion and wrist extension weakness suggests a C6 radiculopathy, weakness of elbow extension and wrist flexion can occur with a C7 radiculopathy, and weakness of thumb extension and ulnar deviation of the wrist is seen in C8 radiculopathies.[272]

On sensory examination, a dermatomal pattern of diminished, or loss of, sensation should be present. In addition, patients with radiculitis may have hyperesthesia to light touch and pinprick examination.[272] The sensory examination can be quite subjective, however, in as much as it requires patient response.

Muscle stretch reflexes are helpful (see Table 25-19). Any grade of reflex can be normal,[281] so the asymmetry of the reflexes is most helpful:

- The biceps brachii reflex occurs at the level of C5–6. The brachioradialis is another C5–6 reflex.
- The triceps reflex tests the C7–8 nerve roots.
- The pronator reflex can be helpful in differentiating C6 and C7 nerve root problems. If it is abnormal in conjunction with an abnormal triceps reflex, then the level of involvement is more likely to be C7. This reflex is performed by tapping the anterior aspect of the forearm, with the forearm in a neutral position and the elbow flexed.[281,282]

Little is known about the natural history of cervical radiculopathy, and there are few controlled randomized studies comparing operative with conservative intervention, although the outcome data support the concept that an extruded disk actually may have a more favorable prognosis than contained disk pathology.[217,283]

Conservative intervention consists of modified rest, a cervical collar, oral corticosteroid "dose-packs," and NSAIDs.[284,285] Oral corticosteroids have been used to reduce the associated inflammation from compression, although there is no controlled study to support their use in the intervention of cervical radiculopathy.[217,277] The beneficial effect of corticosteroids may occur as a result of the anti-inflammatory properties of these drugs. Cervical epidural corticosteroids have also been used in patients who have not responded to medications, traction, and a well-designed physical therapy program.

Exercise programs for patients with disk herniations are individualized.[218] Cervical and cervicothoracic stabilization exercises form the basis of the therapeutic exercise progression. Most patients obtain analgesia using the controlled use of cervical retraction or posterior gliding of the lower cervical spine, in combination with extension of the lower cervical spine and flexion of the upper cervical spine (chin tuck),[286] although repetitive use of this exercise has the potential to cause harm and should be used only as long as the patient is achieving benefit.

The majority of studies investigating the outcomes of patients with cervical radiculopathy have used generic self-report measures or measures of pain. Two condition-specific measures that have been shown to be reliable and valid in patients with cervical radiculopathy are the NDI (Chap. 5) and the Patient Specific Functional Scale.[287]

Surgical Intervention

Surgical intervention is reserved for patients with persistent radicular pain who do not respond to conservative measures (see later discussion).[288] In general, the decision to proceed with surgical intervention is made when a patient has significant extremity or myotomal weakness, progressive neurologic deficits, severe unremitting pain, or pain that persists beyond an arbitrary "conservative" intervention period of 8–12 weeks.[289] Based on this criteria, surgical treatment for cervical disk herniation is needed in only a very small percentage of individuals. Compressive pathologic lesions causing cervical radiculopathy (soft disk fragment herniation or spondylotic bone spurs) are most often located anterior to the nerve root.[290] Typically, lateral cervical disks are removed by the posterior approach, whereas the anterior approach is used with prolapsed midline disks that compromise the spinal cord, or some paramedian disks that compromise either the spinal cord or the nerve root but do not extend beyond the lateral margin of the cervical cord.[291]

The common surgical procedures for cervical disk injuries include (1) anterior cervical discectomy and fusion, (2) laminectomy and laminotomy–facetectomy, (3) laminectomy or laminoplasty (with or without fusion), and (4) anterior corpectomy and fusion.

Anterior Cervical Discectomy and Fusion

A herniated disk in the neck is commonly approached anteriorly. Both lateral and central disks can be removed through this anterior approach. The results from cervical diskectomy have shown an approximately 95% chance of good-to-excellent relief from the radiating arm pain.[285] Numbness in the upper extremity generally improves. Typically, the patient may resume full, unrestricted activities within 3–6 months following surgery. Complications from this surgery are very rare, with the most common being a transient sore throat, hoarseness, difficulty swallowing, failure of bony fusion, and pseudoarthrosis. Although fusions provide inherent stability to the motion segment and immobilize potentially painful degenerative disk and facet joints, the disadvantages, especially in a highly mobile cervical spine segment, include the increased possibility of further progression of degenerative changes at other disk levels, which eventually requires further surgery.[292]

Anterior Corpectomy and Fusion

The anterior approach for this technique is the same as for the anterior cervical discectomy and fusion. The appropriate disks

are incised and removed back from the PLL. The cervical spine is stabilized after corpectomy with strut bone grafts. Internal fixation is often indicated to provide additional rigidity. Postoperatively a rigid cervical orthosis is typically used.

Laminectomy

This procedure, typically indicated for spinal stenosis, is designed to resect the lamina on one or both sides, to increase the axial space available for the spinal cord. The indication in the context of cervical disk disease is when more than three levels of disk degeneration with anterior spinal cord compression are present. Single-level cervical disk herniation is ideally managed from the anterior approach. The complications of the posterior approach include instability leading to kyphosis, recalcitrant myofascial pain, and occipital headaches. Postlaminectomy kyphosis requires revision surgery. If preexistent kyphosis is present, an anterior approach is favorable because in a patient with kyphosis, laminectomy may accelerate kyphosis. As an alternative to laminectomy, a foraminotomy can be used to remove a single-level unilateral lateral disk herniation. This involves removal of 50% of the zygapophyseal joint on one side. This procedure is effective when radicular arm pain is greater than axial neck pain. Foraminotomy can also be performed anteriorly and has a success rate of 91% in relieving radicular pain.[292]

Laminaplasty

Laminaplasty is commonly indicated for multilevel spondylotic myelopathy. Comparative studies with laminectomy have shown that patients with laminaplasty have superior functional recovery in spondylotic myelopathy.[293–296] The incidence of spinal cord injury with laminaplasty is approximately 10 times lower than that of laminectomy.[293–296] Nerve root injury is commonly seen in about 11% of the surgeries.[293–296] This complication is unique to laminaplasty, and the suggested etiology is traction on the nerve root with posterior migration of the spinal cord.[293–296]

In the best-case scenario, the surgeon chooses the technique that directly eliminates the nerve-compressing lesion, while preserving the motion segment of the spine. The anterior microforaminotomy procedure has shown promising results in preserving the remaining disk and the intervertebral space as much as possible, while directly eliminating the compressive pathologic lesion.[297,298] The advantages of this technique are many, including removal of only the offending mass, preservation of most of the disk and motion segment, a shorter operative procedure and hospital stay, avoidance of a fusion procedure and the attendant potential problems, and an earlier return to full activity. The disadvantages are the long-term issues related to disk degeneration and unilateral removal of an uncovertebral joint.[292]

Patients who undergo spinal surgery may receive physical therapy as part of their rehabilitation. Although there is a large amount of information from evidence-based clinical practice guidelines for the management of many musculoskeletal conditions, there is relatively little information available on the physical therapy management of patients who have undergone spinal surgery.

The RCTs comparing various physical activity programs[299–302] have demonstrated the benefits of these programs. These benefits have included less pain and disability, improved range of motion, and greater satisfaction with care.

Before the surgery, the patients may receive advice on spine care, postsurgical precautions, and instructions on basic exercises.

The postsurgical intervention following surgery is as varied as the number of types of surgery. The following are guidelines for postsurgical rehabilitation. The primary goals for the initial period following the surgery are

- reduction of pain and inflammation;
- prevention of postsurgical complications;
- protection of the surgical site;
- prevention of a recurrent herniation;
- maintenance of dural mobility;
- improvement of function;
- minimizing of the detrimental effects of immobilization.[303–308]
- Early return to appropriate functional activities. Patients usually are permitted to shower 1 week after the surgery.
- Safe return to occupational duties. Patients with a sedentary occupation may return to work within 7–10 days after the surgery. Prolonged positions and postures are to be avoided.
- Patient education on correct body mechanics and independent self-care.

The patient is given guidance on the gradual resumption of daily activities. Immobilization or prolonged rest should be avoided. Instead, the patient is encouraged to walk for short periods and distances several times a day.

Outpatient physical therapy, if appropriate, usually begins in the second or third week. The physical therapy examination includes

- a thorough history;
- inspection of the wound site;
- anthropometric data;
- postural examination;
- neural examination, including neurodynamic mobility, and strength testing.

The components of the physical therapy intervention include a graded exercise program, with gentle range of motion, submaximal isometrics, and arm and leg exercises as appropriate.

Additional interventions may include electrotherapeutic modalities, physical agents, and scar massage. Patient education is very important, particularly postural education and information on body mechanics.

Progressive strengthening exercises for the spinal stabilizers usually are initiated by the fourth postoperative week.

Cardiovascular conditioning exercises are introduced at the earliest opportunity based on patient tolerance. These include riding a stationary bicycle, using an upper body ergonometer and a stair-stepper, and swimming in a pool. The sessions for

these exercises are initially brief (5–10 minutes) and are gradually increased up to 30–60 minutes.

Activities such as jogging are usually permitted at 6–8 weeks if there is minimal pain. When the patient does resume these activities, they should be done in the morning hours when the IVD is maximally hydrated.[309] High-impact sports such as basketball and soccer are usually permitted after the 12th week.

Cervical Spondylosis

Cervical spondylosis is a chronic degenerative condition affecting the contents of the spinal canal (nerve roots and/or spinal cord) and the cervical vertebral bodies and IVDs, is the most common cause of progressive spinal cord and nerve root compression. The characteristics of degenerative joint disease (DJD) and degenerative disk disease (DDD) relate to bony changes, and the two often occur concurrently.[8] Abnormalities in the osseous and the fibroelastic boundaries of the bony cervical spinal canal or in the lateral recess, and foramina affect the availability of space for spinal cord and nerve roots, resulting in a myelopathy or stenosis, respectively. Cyriax[163,106] reserved the term *spondylosis* for the end stage of spinal diseases, although the term is now used to describe varying levels of degenerative changes in the cervical spine.[8] Although this condition often remains asymptomatic for a long time, it can become a major influence in the production of radiculomyelopathic compressive disturbances, when other conditions such as spondylosis, diskal hernia, and trauma become superimposed. As the resulting space for neural structures becomes smaller, the risk of developing motor and/or sensory disturbances increases.

Progressive degenerative changes are expected to appear over time on radiographs as part of the natural history of the aging spine. Radiographic evidence of cervical degeneration is observed in some 30-year olds and is present in more than 90% of people older than 60 years of age.[310] The areas most commonly and most severely affected are C5–6 and C6–7.[33] Although aging of the cervical spine is ubiquitous, controversy remains about whether the process of spondylosis may be accelerated in patients with a history of soft tissue injuries to the neck and persistent pain. However, in the absence of pain, the finding of degenerative changes on radiographs should not be misconstrued as pathologic. One study reported evidence of cervical spondylosis in 35% of asymptomatic individuals.[311]

Kirkaldy-Willis[312] categorized spondylosis of the spine into three stages:

- Dysfunctional. During this stage, the patient complains of a gradual onset of neck or arm symptoms (radiculopathy), or both, that have increased frequency and severity.[8]
- Unstable. During this stage, the pain is often worse when the patient is in certain positions, and can interfere with sleep. Morning stiffness of the neck, which gradually improves throughout the day, is a common finding.
- Stabilization. During this stage, lateral nerve root entrapment becomes more common. In some cases the spinal cord or anterior spinal vessels may be compressed resulting in cervical myelopathy and/or vertebrobasilar insufficiency.[313] The blood supply of the spinal cord is an important anatomic factor in the pathophysiology. Radicular arteries in the dural sleeves tolerate compression and repetitive minor trauma poorly. The spinal cord and canal size are also factors.

CLINICAL PEARL

Osteoarthritis in the cervical spine is, in effect, the later stages of spondylosis, and is marked by progressive degeneration of the IVD and, especially, the zygapophyseal joint. Osteoarthritic changes can include osteophyte formation, hypertrophy of the synovial membrane and, in some cases, a chronic inflammatory response.

The physical examination findings depend on the degree of severity but can include reduced motion in the sagittal plane, with a decrease in side bending in the early stages. As the degeneration progresses, a capsular pattern develops.[163] Cervical spondylotic myelopathy is the most serious consequence of cervical IVD degeneration, especially when it is associated with a narrow cervical vertebral canal. Five categories of cervical spondylotic myelopathy are described in Table 25-20, based on the predominant neurologic findings.

TABLE 25-20 Characteristics of the Different Syndromes of Cervical Spondylotic Myelopathy

Syndrome	Pain	Gait Abnormality	Involvement of the Extremities	Laterality
Lateral (radicular)	Yes	Sometimes	Upper	Often unilateral
Medial (myelopathic)	No	Yes	Lower	Usually bilateral
Combined	Sometimes	Yes	Upper and lower	Unilateral in upper extremities and bilateral in lower extremities
Vascular	No	Yes	Upper and lower	Bilateral
Anterior (painless weakness of the upper extremity)	No	No	Upper	Often unilateral

Data from Spivak JM, DiCesare PE, Feldman DS: *Orthopaedics: A Study Guide*. New York: McGraw-Hill, 1999:349.

Myelography, with CT, is usually the imaging test of choice to assess spinal and foraminal stenosis.

The conservative intervention for cervical spondylosis without radiculopathy or myelopathy involves the use of electrotherapeutic modalities to control pain and increase the extensibility of the connective tissue. These modalities usually include moist heat, electrical stimulation, and ultrasound. Immobilization of the cervical spine may be considered for patients with nerve irritation to limit the motion of the neck and further irritation. In such instances, soft cervical collars are recommended initially. More rigid orthoses (e.g., Philadelphia collar and Minerva body jacket) can significantly immobilize the cervical spine. With the use of any of the braces, the patient's tolerance and compliance are under consideration. The use of the brace should be discontinued as soon as feasible. Molded cervical pillows can better align the spine during sleep and provide symptomatic relief for some patients. Manual techniques may be used to stretch the adaptively shortened tissues. Range-of-motion exercises are performed as tolerated. These exercises initially are performed in the pain-free direction and then in the direction of pain. As the patient regains motion, isometric exercises and cervical stabilization exercises are prescribed.

Zygapophyseal Joint Dysfunction

The patient with a zygapophyseal joint dysfunction typically reports an onset of unilateral neck pain, or "neck locking," following sudden backward bending, side bending, or rotation of the neck, or pain that followed a sustained head position. The condition is thought to result from entrapment of a small piece of synovial membrane by the zygapophyseal joint.[99,115,314]

Palpation just lateral to the midline often indicates regional soft tissue changes in response to the underlying zygapophyseal joint injury, and combined motion testing usually shows a closing pattern of restriction corresponding to the injured zygapophyseal joint.[98]

Because traditional images (plain radiographs, computed tomography, and MRI) are typically unremarkable in the presence of zygapophyseal joint pain,[314] clinical suspicions of these joint injuries can be confirmed if necessary by diagnostic intra-articular zygapophyseal joint injections, or a block of the joint's nerve supply.[315,316]

The conservative intervention involves the use of cryotherapy and electrotherapeutic modalities to control pain and inflammation. Joint mobilization techniques, involving combinations of flexion or extension and rotation, with traction superimposed, are applied initially in the pain-free direction and then in the direction of pain.

As the patient regains motion, range-of-motion and isometric exercises are prescribed until full range of motion is restored, at which time the strengthening exercises are progressed.

An interesting study by Cleland and colleagues[317] investigated the predictive validity [clinical prediction rule (CPR)] of variables from the initial examination to identify patients with neck pain who are likely to benefit from thoracic spine thrust manipulation. The study identified a CPR with six variables are as follows:

1. Symptoms of less than 30 days
2. No symptoms distal to the shoulder
3. Looking up does not aggravate symptoms
4. Fear avoidance-beliefs questionnaire (FABQ) (see Chap. 4) physical activity score less than 12.
5. Diminished upper thoracic spine kyphosis
6. Cervical extension range of motion less than 30 degrees

The study found that if three of these (positive likelihood ratio = 5.5) were present, the chance of experiencing a successful outcome from a thoracic spine thrust manipulation improved from 54 to 86%.

Acute Torticollis (Acute Wry Neck)

Torticollis is both a symptom and a disease. An acute form of torticollis, known as acute wryneck, typically develops overnight in young and middle-aged adults. The precise etiology is unclear, but as most patients appear to experience symptoms shortly after awakening, it may be the result of an injury to the muscles, joints, or ligaments through sleeping with the neck in an unusual position. This unusual position may place the involved joints in a position of extreme motion, stretching the structures and increasing the risk of impingement when the joint position is returned to normal.

The most common clinical presentation includes painful neck, which are both visible and palpable. There is a marked limitation in range of motion of the neck and the patient may hold the head in a position of comfort toward the side of the involved muscle. A common feature is the presence of limited to no radiographic correlation between the degree of pain presented by the patient in the neck and the degree of radiographic changes.

The hanging head method is a simple but successful method for treating acute painful wry neck of spontaneous onset.[318] The technique requires a table with the capacity to tilt the head down. The patient is positioned in supine at the end of the table and a head down tilt of about 20 degrees is provided. This position, which is maintained for 5–10 minutes, provides a gentle traction force allowing the SCM to relax. Alternatively, gentle traction can be applied manually. If this treatment is successful, no further intervention is necessary. In the cases where this technique is unsuccessful, the patient is reassured that they have a self limiting condition, and that the symptoms will usually resolve significantly within 7 days, with complete resolution within 2 weeks.[319]

Cervical Spine Instability

Punjabi defined clinical stability as "the ability of the spine, under physiological load, to limit patterns of displacement so as not to damage or irritate the spinal cord or nerve roots, and, in addition, to prevent incapacitating deformity or pain due to structural changes."[320] Cervical instability can occur secondary to trauma, surgery, systemic disease, or degenerative changes to the motion segment. Signs and symptoms associated with minor cervical instability include[107]

- history of major trauma;
- reports of catching/locking/giving way;
- unpredictability of symptoms;
- subjective reports of neck weakness (head feels heavy);
- altered range of motion;
- neck pain with or without muscle spasms;
- reports of headaches.

To date, there is no gold standard for diagnosing minor instability in the mid-cervical spine, only a high degree of suspicion based on signs and symptoms. In these cases, a cervicothoracic stabilization program is recommended to restore lost functional capacities, range of motion, muscular strength, and endurance.

PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH LOCALIZED INFLAMMATION

Whiplash-Associated Disorders

Over recent years, the role of the physical therapist in the intervention of the consequences of whiplash has increased dramatically. It is thus imperative that the clinician have a strong understanding of the mechanisms that produce the myriad of symptoms associated with this disorder.

The term *whiplash injury* was introduced in 1928 by the American orthopedist H. E. Crowe,[321] and it was defined as the effects of sudden acceleration–deceleration forces on the neck and upper trunk as a result of external forces exerting a "lash-like effect." Crowe emphasized that the term *whiplash* "describes only the manner in which a head was moved suddenly to produce a sprain in the neck."

Despite a great deal of attention, WADs remain an enigma as the subjective nature and high prevalence of the symptoms, in the absence of focal physical findings and positive imaging studies, have led to controversy over their cause.[322] In addition, the diagnosis has been associated with issues of financial compensation.[323–325]

Definition

There is little agreement as to the definition of WAD. Some authors of whiplash articles, such as Gay and Abbot,[326] do not define whiplash clearly. Neither Gotten,[327] nor Macnab[328,329] offered definitions, although Macnab noted that "a significant soft tissue injury can result from the application of an extension strain to the neck by sudden acceleration."[261] And Farbman[330] classified the whiplash injury as a musculoligamentous neck sprain, which did not involve nerve root damage, fractures, and other complications. Nordhoff[331] describes the whiplash injury in equally simplistic terms, as an injury that occurs because of occupant motions within a vehicle that is rapidly decelerating or accelerating, without reference to the body parts involved. Even the definition provided by the Quebec Task Force on WADs,[332] that, for whatever reason, did not include front-end collisions, offered the following vague definition:

Whiplash is an acceleration–deceleration mechanism of energy transfer to the neck. It may result from rear-end or side-impact motor vehicle collisions, but can also occur through diving and other mishaps. The impact may result in bony or soft tissue injuries (whiplash injury), which in turn may lead to a variety of clinical manifestations.

Mechanism

A number of mechanisms have been proposed that result in a WAD. These include

- motor vehicle accidents (MVAs);
- sporting injuries involving a blow to the head or neck, or a heavy landing;
- pulls and thrusts on the arms;
- falls, landing on the trunk or shoulder.

Perhaps the most common mechanism of WAD is the MVA. According to reports, more than 1 million whiplash injuries occur each year in the United States.[324] Eighteen percent of MVAs involving passenger cars in the United States in 1994 were rear-end impacts.[333]

The extent of injury from a WAD following an MVA depends, in part, on three factors: (1) the position of the head at the point of impact, (2) the amount of force involved, and (3) the direction of those forces.

Head Position

Pure extension injuries seem to be uncommon in a WAD, because most injuries involve forced combinations of motion. These include a flexion or extension force applied to a rotated head and neck, resulting from a turned position on impact.[334] As many as 57% of persons sustaining whiplash injury, with symptoms persisting 2 years after collisions, reported having their heads rotated out of the anatomic position at the time of impact.[335,336] In fact, head position has been reported as the only accident feature of a collision event that has a statistically significant correlation with symptom duration.[336]

Amount of Force

The amount of force applied to the neck is approximately equal to the weight of the head and the speed with which the head moves. Consequently, the heavier the head or the faster it moves, the greater the stress that is put through the neck. However, it is well recognized by clinicians with any experience with post-MVA patients that some patients who have survived high-velocity accidents do better than many who appear to have been involved in trivial impacts.

Force Direction

Force direction plays a significant role in the degree of damage sustained by the patient. The direction of the applied forces depends on[96]

1. where the car is hit, that is, front end, rear end, or side;
2. symmetry of the impact, that is, directly head on or rear end, or the forward or backward side;

3. whether the car is pushed ahead into another vehicle, the curb, or other stationary object;
4. the position of the victim in relation to the impact.

During the early phase of a rear-end collision, the occupant's trunk is forced upward toward the head, and the cervical spine undergoes a sigmoid deformation, resulting in the head being moved upward and backward.[337] During this motion, at about 100 milliseconds after impact, the lower cervical vertebrae undergo extension, but without translation.[337] This motion causes the vertebral bodies to separate anteriorly and the zygapophyseal joints to impact posteriorly.[337] These forces may lead to posterior dislocations.[328,338,339]

The reason for the greater severity of hyperextension injuries over the other force directions is believed to be related to several factors, including[331]

- whether the seat back breaks;
- whether the occupant hits the front of the occupant space;
- the differential motion between the seat back and occupant;
- hyperextension of the neck over the head restraint;
- rebound neck flexion as the head rebounds off the head rest.

Hyperflexion injuries are typically less severe because the amount of head excursion is limited by the chin striking the chest. The damage incurred by cervical side-bending traumas depends on whether the head hits an object or the shoulder.[96]

A number of other variables also determine the type and extent of the injury[331]

- seat position;
- occupant size, height, and posture;
- vehicle interior design;
- size of vehicle.
- Sex of driver. Women generally position their seats more forward than men, which places their bodies closer to the front car structures and, therefore, at higher risk of impacting the front interior.
- Seat belt. The subject of seat belts is controversial, because the seatbelt appears to be responsible for more injuries than any other contact source in the car, albeit minor ones.[340] This is, in part, because of their design, which restrains only one shoulder, and because the belt acts as a fulcrum for energy concentration on the occupant.[331] As of 1997, federal law has required all passenger vehicles to have air bags. Mortality reductions in frontal collisions associated with airbags have been estimated to be no greater than 25–30%[341] and perhaps substantially less[342] when compared with the approximately 50% reduction associated with proper use of seat belts.[343] Because airbags provide supplemental protection for occupants wearing a seat belt, it is necessary to compare the combined effect of airbags and seat belts either relative to device alone or completely unrestrained in order to adequately evaluate their effectiveness. A study by McGwin and colleagues[344] conducted a retrospective cohort study of front seat occupants involved in police-reported, tow-away, frontal motor vehicle collisions, using data from the 1995 to 2000 National Automotive Sampling System. Compared with completely unrestrained occupants, those using a seat belt alone or in combination with an airbag had a reduced overall risk of injury (relative risks, 0.42 and 0.71, respectively); no association was observed for those restrained with an airbag only (relative risk, 0.98). The study concluded that airbag deployment does not appear to significantly reduce the risk of injury either alone or in combination with seat belts.[344] Population-based studies of airbag effectiveness against less serious injuries, which have been rare, seem to suggest that airbags may merely be altering the distribution of injuries.[331,345]
- Headrest height. Headrest height appears to play a role, with the driver often setting the head rest too low, or sitting too far forward to obtain adequate support from the head rest.[346,347] However, the fatal accidents involving hyperextension appear to occur in the absence of a head restraint, where there is no structural limitation to the head movement except anatomic structures.

Clinical Findings

It should be obvious that a meticulous examination of the traumatized patient is of paramount importance.[348] Signs and symptoms to alert the clinician include

- UMN signs and symptoms;
- periodic loss of consciousness;
- that the patient does not move the neck, even slightly (fractured dens);
- painful weakness of the neck muscles (fracture);
- gentle traction and compression of the neck that are painful (fracture);
- severe muscle spasm (fracture);
- complaints of dizziness.

The symptoms following a WAD usually begin in the neck and interscapular area within a few hours of the injury. Headaches often accompany the neck and shoulder girdle symptoms.[111]

Sources of Symptoms

The causes for symptoms following a whiplash injury are numerous. The resulting damage from a WAD can include an injury to one or more of the following types of structures:

- ***Soft tissue structures.***[101] A cervical strain may be produced by an overload injury to the cervical muscle–tendon unit because of excessive forces. These forces can result in the elongation and tearing of muscles or ligaments, edema, hemorrhage, and inflammation. Many cervical muscles do not terminate in tendons but, instead, attach directly to bone by myofascial tissue that blends into the periosteum.[349] Muscles respond to injury in a variety of ways, including reflex contraction, which further increases the resistance to stretch and serves as a protection to the injured muscle.
- ***Joint capsule and ligaments.*** Both mechanoreceptors and nociceptors have been identified in the human cervical joint capsule[350] and ligaments,[314] indicating a neural input in

pain sensation and proprioception. Postmortem studies have found that after whiplash injuries, ligamentous injuries are extremely common in the cervical spine, but that herniation of the NP is a rare event.[351–354] The motion segment lesions found in the cervical spine included bruising and hemorrhage of the uncinate region, the so-called rim lesions or transections of the anterior annulus fibrosus, rupture of the alar ligaments, and avulsions of the vertebral end plate.[351–355] As in the lumbar spine, the outer layers of the cervical annulus are innervated,[356] and are, therefore, a reasonable source of pain.[357]

- ***Zygapophyseal joint.*** Fractures or contusions of the zygapophyseal joints can occur, although postmortem studies reveal that many of these injuries are undetectable by plain radiographs.[351,355,358,359] Zygapophyseal joint pain is the only basis for chronic neck pain after whiplash that has been subjected to scientific scrutiny.[115,360,361] However, it cannot be diagnosed clinically or by medical imaging. The diagnosis relies on fluoroscopically guided, controlled diagnostic blocks of the painful joint. Although there is uncertainty about the exact pathway that elicits neck pain, the cervical zygapophyseal joint has been identified as a source of pain in between 25 and 65% of people with neck pain.[115,314–316,362–364] Specifically, the prevalence of lower cervical facet joint pain has been reported to be 49%.[363] It is worth remembering that although the so-called neck sprains from MVAs usually involve the cervical spine, one of the upper eight thoracic spinal joints is sometimes found to be affected, so these structures should be assessed in the examination of a whiplash injury.[365]
- ***Central or peripheral neurologic systems.*** These systems may be injured secondary to traction, impingement, hemorrhage, avulsion, or concussion. Although neck pain and headache are the two most common symptoms of a whiplash injury,[4] other symptoms such as visual disturbances, balance disorders, and altered cerebral function are reported. In 1927, Klein and Nieuwenhuyse[366] first demonstrated that simple rotation of the patient's neck, while the head was maintained fixed, caused vertigo and nystagmus. In 1976, Toglia[367] reported objective electronystagmography (ENG) abnormalities in about 57% of 309 patients with whiplash injuries. Wing and Hargrove-Wilson[368] reported that all of their 80 patients showed nystagmus in ENG records with the head flexed, extended, or rotated to the right and left. Abnormal peripheral vestibular function was found using platform posturography in about 90% of the 48 patients examined by Chester.[369] Fractures and dislocations, many causing cord damage, have been demonstrated on human victims of hyperextension injuries, who had no radiographic evidence of the severity of these lesions.[96,370]
- ***Intervertebral disk.*** Experimental and clinical studies have consistently demonstrated how poorly and slowly disk lesions heal after a hyperextension trauma, with very small lesions taking as long as 18 months to heal.[359,371] A follow-up study, averaging a review time of nearly 11 years,[372] found that 40% of patients were still having intrusive or severe symptoms (12% severe and 28% intrusive). The same study also found that in general, the symptoms did not alter after 2 years postaccident.
- ***Posterior (dorsal) root ganglia.***[359]
- ***Vascular structures (vertebrobasilar arteries).*** Postmortem studies have shown that vertebral artery lesions are found in about one-third of fatally injured MVA victims with vertebral atlas injury.[373]
- ***Visceral structures (secondary to ruptures, or contusions).***

The physical examination usually reveals tenderness over the transverse and spinous processes, or over the anterior vertebral body, depending on the structures involved. Depending on the severity of the strain, motion can be markedly restricted as a result of muscle guarding.

Other than perhaps to screen for possible fractures, there is no valid indication for medical imaging after whiplash, unless the patient has neurologic signs.[322] Findings on plain films are typically normal, although there may be a loss of the cervical lordosis. MRI reveals nothing but age-related changes with the same prevalence as in asymptomatic individuals.[374–376] An enticing, but small, recent study suggests that, in patients with persisting acute neck pain, single photon emission computed tomography, at 4 weeks after injury revealed occult, small fractures of the vertebral rims or the synovial joints of the neck.[377]

Intervention

Once the physician has ruled out the possibility of fracture, dislocation, IVD injury, or neurovascular compromise, a conservative approach is recommended. Initially, brief use of a cervical collar may be prescribed to reduce muscle guarding. Bed rest, along with analgesics and muscle relaxants, for no more than 2–3 days is prescribed for patients with a severe injury. However, in less severe cases, bed rest has not been shown to improve recovery and, when compared with mobilization or patient education, rest tends to prolong symptoms.[25,224]

CLINICAL PEARL

A study by Scholten-Peeters[378] and colleagues reported that the physical prognostic factors associated with delayed recovery following a WAD included decreased mobility of the cervical spine immediately after injury, pre-existing neck trauma, older age, and female gender.

Ice and electrical stimulation are applied to the neck during the first 48–72 hours to help control pain and inflammation. Range-of-motion exercises in the pain-free ranges of flexion and rotation are initiated as early as possible to reduce the likelihood of hypomobility. Gentle cervical isometrics also are introduced. Aggressive strengthening of the cervical musculature should not begin until full range of motion is restored. Strengthening of the trapezius muscle and other scapular stabilizers can be performed using upper extremity exercises, taking care to avoid an increase in symptoms.

Many patients improve within 8 weeks, although complete resolution is less common.[286] If pain persists for more than

3 months, more severe ligamentous, disk, associated zygapophyseal joint injuries, or other factors (see later) should be suspected. If significant neck pain persists past 6–8 weeks, flexion and extension radiographs may be useful to exclude, or confirm, instability.

Outcomes

Studies addressing the natural history of WAD have yielded variable results. In one series, symptoms had resolved in 52% of patients at 8 weeks and in 87% of the patients at 5 months.[379] In another series, most patients rapidly recovered following an acute injury, with some 80% being asymptomatic by 12 months.[335] After 12 months, between 15 and 20% of patients remained symptomatic, and only about 5% were severely affected. In addition to the distress resulting from neck and upper extremity pain, costs to society associated with absenteeism from work also are incurred.

The majority of studies reveal that, although most patients with WAD have a spontaneous resolution of symptoms, a small subgroup of patients are symptomatic beyond 1 year.[322] This group of patients constitutes the major burden to insurance companies and to health care resources, because in spite of aggressive imaging and diagnostic testing, clinicians are routinely unable to identify the specific source of these symptoms or apply interventions that are successful. It is in this small subgroup of patients with persisting chronic symptoms that the need for a better understanding of the risk factors, pathophysiology, natural history, and effectiveness of intervention options is apparent.[322]

When symptoms persist beyond 6 months, evidence for preexisting degenerative disease is most often found.[380] Preexisting symptoms, such as headache, and radiologic degenerative changes appear to be important predictors for an unfavorable outcome.[124]

One study[335] examined a group of 117 consecutive patients, who were followed on a regular basis from shortly after the initial injury through 2 years, to determine whether preinjury status, mechanism of injury, physical examination, and somatic, radiographic, or neuropsychologic factors could be used to predict eventual outcome. At 2 years, the patients with persistent symptoms were found to have been older at the time of injury than the asymptomatic group and had a higher incidence of pretraumatic headache. There was a higher incidence of a rotated, or inclined, head position at the time of impact, as well as a higher intensity of initial neck pain and headache, a higher incidence of initial radicular symptoms, a greater number of initial overall symptoms, and a higher average score on a multiple symptom analysis.[335]

Financial compensation, which is determined by the continued presence of pain and suffering, appears to provide a barrier to recovery and may promote persistent illness and disability. The incidence of insurance claims for whiplash is about one per 1000 population per year,[360] yet not all persons involved in motor vehicle crashes develop symptoms, and not all symptomatic patients experience chronic injury. The differences in the rating of prolonged symptoms between systems with and without compensation raises questions about the real incidence of chronic WADs.[381]

INTEGRATION OF PATTERNS 4B, 4F, AND 5F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION SECONDARY TO IMPAIRED POSTURE, SYSTEMIC DYSFUNCTION (REFERRED PAIN SYNDROMES), SPINAL DISORDERS, MYOFASCIAL PAIN DYSFUNCTION, AND PERIPHERAL NERVE ENTRAPMENT

Thoracic Outlet Syndrome[193,382]

The thoracic outlet is the anatomic space bordered by the first thoracic rib, the clavicle, and the superior border of the scapula, through which the great vessels and nerves of the upper extremity pass (Fig. 25-4). TOS is a syndrome characterized by symptoms attributable to compression of the neural or vascular anatomic structures that pass through the thoracic outlet. The bony boundaries of the outlet include the clavicle, first rib, and scapula, and the outlet passage is further defined by the interscalene interval, a triangle with its apex directed superiorly. This triangle is bordered anteriorly by the anterior scalene muscle, posteriorly by the middle scalene muscle, and inferiorly by the first rib (see Fig. 25-4).

The other names used for TOS are based on descriptions of the potential sources for its compression. These names include cervical rib syndrome, scalenus anticus syndrome, hyperabduction syndrome, costoclavicular syndrome, pectoralis minor syndrome, and first thoracic rib syndrome.

TOS was first noted in 1743 when an association was made between the cervical rib and TOS, although it was not until 1818, that the medical management of TOS was discussed.[383] In the early twentieth century, Adson stressed the role of the scalene muscles in neurovascular compromise, and Wright showed that shoulder hyperabduction could produce thoracic outlet obstruction.[383] It was Peet[384] who coined the term "TOS" in 1956. Then, in the early 1960s, Roos[63] emphasized the importance of the first rib and its muscular and ligamentous attachments in causing thoracic outlet obstruction.

The lowest trunk of the brachial plexus, which is made up of rami from the C8 and T1 nerve roots, is the most commonly compressed neural structure in TOS. These nerve roots provide sensation to the fourth and fifth fingers of the hand and motor innervation to the hand intrinsic muscles.

The subclavian artery and the lower trunk of the plexus pass behind the clavicle, and into the costoclavicular space (see Fig. 25-4). From there they pass over the first rib, between the insertions of the anterior and middle scalene muscles and are joined by the subclavian vein.

Thus, the course of the neurovascular bundle can be subdivided into three different sections, based on the areas of potential entrapment:

1. As the brachial plexus and subclavian artery pass through the interscalene triangle (see Fig. 25-4), interscalene triangle compression can result from injury of the scalene or

scapular suspensory muscles. In some cases, fibromuscular bands can develop between the anterior and middle scalenes, or between the long transverse processes of the lower cervical vertebrae, producing entrapment. The subclavian vein is not involved, because it usually passes anterior to the anterior scalene muscle. Entrapment at this site may also result from cervical ribs, which are present in 0.2% of the population and occur bilaterally in 80% of those affected.[63] However, the presence of a cervical rib does not necessarily precipitate signs and symptoms, with fewer than 10% of individuals with cervical ribs ever experiencing TOS.[63]

2. As it passes the first rib, clavicle, and subclavius: the costoclavicular interval. Entrapment in this space between the ribcage and the posterior aspect of the clavicle may occur with clavicle depression, rib elevation caused by scalene hypertonicity, repetitive shoulder abduction, or a first rib-clavicular deformity. A postfracture callus formation of the first rib or clavicle can also increase the potential for entrapment.
3. As it passes the coracoid process, pectoralis minor, and clavipectoral fascia to enter the axillary fossa. At this point, the subclavian artery and vein become the axillary artery and vein. At this third site, the neurovascular bundle can be compromised with arm abduction or elevation, especially if external rotation is superimposed on the motion. Pectoralis minor tendon compression is associated with shoulder hyperabduction. During hyperabduction, the tendon insertion and the coracoid act as a fulcrum, about which the neurovascular structures are forced to change direction. Hypertrophy of the pectoralis minor tendon has also been noted as a cause of outlet compression.[383]

There may be multiple points of compression of the peripheral nerves between the cervical spine and hand, in addition to the thoracic outlet. When there are multiple compression sites, less pressure is required at each site to produce symptoms. Thus, a patient may have concomitant TOS, ulnar nerve compression at the elbow, and carpal tunnel syndrome. This phenomenon has been called the *multiple crush syndrome*.[385]

Symptoms vary from mild-to-limb threatening and often mimic common but difficult to treat conditions such as tension headache or fatigue syndromes. The chief complaint is usually one of diffuse arm and shoulder pain, especially when the arm is elevated beyond 90 degrees. Potential symptoms include pain localized in the neck, face, head, upper extremity, chest, shoulder, or axilla; and upper extremity paresthesias, numbness, weakness, heaviness, fatigability, swelling, discoloration, ulceration, or Raynaud phenomenon.[382] Neural compression symptoms occur more commonly than vascular symptoms.[63]

Karas[386] described five symptom patterns of TOS, characterized by the primary structures compressed.

1. The lower trunk pattern reflects lower plexus compression and manifests with pain in the supraclavicular and infraclavicular fossa, back of the neck, rhomboid area, axilla, and medial arm and may radiate into the hand and fourth and fifth fingers. The history includes reports of feelings of coldness, or electric shock sensations in the C8–T1 or ulnar nerve distributions.
2. The upper trunk pattern results from upper plexus compression and is distinguished by pain in the anterolateral neck, shoulder, mandible, and ear, and paresthesias that radiate into the upper chest and lateral arm in the C5–7 dermatomes.[386,387]
3. With venous involvement, the signs and symptoms can include swelling of the entire limb, nonpitting edema, bluish discoloration, and venous collateralization across the superior chest and shoulder.
4. Arterial involvement produces coolness, ischemic episodes, and exertional fatigue.[386]
5. The mixed pattern consists of a combination of vascular and neurologic symptoms.[386]

Mechanisms

Proposed mechanisms for TOS:

- ***Traumatic.*** Twenty-one percent to 75% of TOS patients have an association with trauma.[387] This may involve macro-trauma, as in the case of an MVA, or microtrauma, as in the case of a muscle strain of the scapular stabilizers, resulting from repetitive overhead activities.[388–390]
- ***Developmental.*** During the normal growth of children and adolescents, the scapulae gradually descend upon the posterior thorax, with the descent being slightly greater in women than in men. A strain injury to the scapular suspensory muscles, which lengthen in conjunction with scapular descent during normal development, is known to be associated with TOS. These facts help to explain the rarity of symptomatic TOS until after puberty, and the increased prevalence in women.[193,391]

Diagnosis

TOS is a clinical diagnosis, made almost entirely on the basis of the history and physical examination (see Special Tests). To help rule out other conditions that can mimic TOS, the physical examination should include the following:

- A careful inspection of the spine, thorax, shoulder girdles, and upper extremities for postural abnormalities, shoulder asymmetry, muscle atrophy, excessively large breasts, obesity, and drooping of the shoulder girdle.
- Palpation of the supraclavicular fossa for fibromuscular bands, percussion for brachial plexus irritability, and auscultation for vascular bruits that appear by placing the upper extremity in the position of vascular compression.
- Assessment of the neck and shoulder girdle for active and passive ranges of motion, areas of tenderness, or other signs of intrinsic disease.
- A thorough neurologic examination of the upper extremity, including a search for sensory and motor deficits and abnormalities of muscle stretch reflexes.
- Assessment of respiration to ensure patient is using correct abdominodiaphragmatic breathing.

- Assessment of the suspensory muscles: the middle and upper trapezius, levator scapulae, and SCM (thoracic outlet "openers"). These muscles typically are found to be weak.
- Assessment of the scapulothoracic muscles: the anterior and middle scalenes, subclavius, pectoralis minor and major (thoracic outlet "closers"). These muscles typically are found to be adaptively shortened.
- First rib position or presence of cervical rib.
- Clavicle position and history of prior fracture, producing abnormal callous formation or malalignment.
- Scapula position, acromioclavicular joint mobility, and sternoclavicular joint mobility.
- Neurophysiologic tests, which are useful to exclude coexistent pathologies such as peripheral nerve entrapment or cervical radiculopathy. An abnormal reflex F wave conduction and decreased sensory action potentials in the medial antebrachial cutaneous nerve may be diagnostic.[392]

Intervention

Conservative intervention should be attempted before surgery and should be directed toward muscle relaxation, relief of inflammation, and attention to posture. This intervention approach may require a change of occupation for the patient, because TOS is more common in those who stoop at work. Aggressive physical therapy, particularly traction, may worsen symptoms.[393]

The focus of the intervention is the correction of postural abnormalities of the neck and shoulder girdle, strengthening of the scapular suspensory muscles, stretching of the scapulothoracic muscles, and mobilization of the whole shoulder complex and the first and second ribs.

Kenny and colleagues[394] prospectively evaluated a group of eight patients, composed mainly of middle-aged women, whose TOS was treated with a supervised physical therapy program of graduated resisted shoulder elevation exercises.[193] All patients showed major symptomatic improvement.

If symptoms progress or fail to respond within 4 months, surgical intervention should be considered.[395] Lower plexus TOS is surgically treated by first rib and (if present) cervical rib excision.[396] Although it has been suggested that the insured patient is more likely to have an operation, results are independent of any associated litigation.[397]

THERAPEUTIC TECHNIQUES

TECHNIQUES TO INCREASE JOINT MOBILITY

Joint Mobilizations

Most joint mobilizations use the same technique as the assessment but, by using grades, convert it into a treatment method. The purpose of joint mobilization techniques is to

- reduce stresses through both the fixation and the leverage components of the spine;
- reduce stresses through hypermobile segments by mobilizing the hypomobile joints;
- reduce the overall force needed by the clinician, thus giving greater control.

The selection of a manual technique is dependent on several factors, including:

- The acuteness of the condition, the cause of the restriction, and the goal of the intervention. If the structure is acutely painful (pain is felt before resistance or pain is felt with resistance), pain relief, rather than a mechanical effect, is the major goal. Joint oscillations (grades I and II) that do not reach the end of range are used. The segment or joint is left in its neutral position, and the mobilization is carried out from that point.
- Whether the restriction is symmetric, involving both sides of the segment, or asymmetric, involving only one side of the segment.

A number of specific manual techniques can be employed. Spinal locking techniques can be used to augment the comfort and safety of a manual technique. Locking is simply a method of taking up any available soft tissue tension or slack, thereby making a manual technique more specific. Two types of locking techniques are commonly advocated: craniovertebral locking and locking through segmental translation. Because of the potential for vertebral artery compromise in the craniovertebral region, the craniovertebral joints are often "locked" first before continuing motion into the middle and/or lower cervical spine joints. In the following example, a left side-bending technique is used. Although this locking technique may be used with the patient positioned in sitting or supine, if it used in supine it is important to apply a small amount of compression to compensate for the loss of the spinal loading due to the weight of the head.

While palpating the C2 spinous process, the clinician slowly side-bends the patient's head to the left. If the side bending is performed around a sagittal craniovertebral axis, the C2 spinous process should be felt to move to the right, indicating left rotation of the C2 on the C3. Maintaining the left side-bent position, the head is now rotated to the right until the C2 spinous process regains a central position. The head is again side bent slightly to the left, and the C2 spinous process de-rotated back to midline. These motions are continued until a firm end-feel is reached. At this point, motion in the craniovertebral joints has now been exhausted, while the rest of the cervical joints remain in neutral. Being careful to maintain the position of the head, especially the right rotation, the side bending is continued left to the middle or lower cervical level required. As the cervical joints are prevented from rotating to the left, the middle cervical side bending motion is exhausted very quickly.

The vast majority of biomechanical dysfunctions of the cervical spine involve the posterior quadrant (a loss of extension and a loss of side bending and rotation to one side or both). The loss of cervical flexion is usually associated with a cervical disk protrusion, a cervicothoracic dysfunction, or a craniovertebral dysfunction. However, for completeness, the techniques described here will address a loss in both the anterior and the posterior quadrants.

The C4–5 level is used in the following examples. Midrange is considered the biomechanical neutral resting position of the joint, and is the ideal start point for techniques that are not intended to stress the barrier and that are intended to avoid causing pain or increasing inflammation. The various methods of grading manual therapy techniques are described in Chapter 10.

Basic Techniques to Restore Motion in the Posterior Quadrant

Seated Mobilization Technique to Restore Extension and Left Side Bending-Rotation **VIDEO**. If the clinician has large hands, mobilizing into extension can be a problem, because the stabilizing hand prevents the full glide into extension from occurring. To overcome this problem, the stabilization of the inferior segment is performed by pushing the thumb up against the side of its spinous process, thereby preventing the rotation induced by the mobilization of the superior segment. For example, if the left side of C4–5 is being mobilized into extension, left side bending, and left rotation by the upper hand, the thumb of the inferior hand is pushed against the right side of the C5 spinous process, preventing rotation of C5 to the left (Fig. 25-83).

Supine Mobilization Technique to Restore Extension and Left Side Bending-Rotation (Left Side Bending-Rotation shown on **VIDEO***).*[167] The patient is positioned supine, with the head being supported. The clinician stands at the patient's head, facing the shoulders. With the radial aspect of the right index finger, the clinician palpates the spinous process and the right inferior articular process of the C4 vertebra. With the other hand, the clinician supports the head and neck superior to the level being treated (Fig. 25-84). A lock of the superior segment is accomplished by left side bending and right rotating the C3–4 joint complex, leaving the craniovertebral joints in a neutral position. The motion barrier for extension, left side bending, and left rotation of C4–5 is then localized by pushing the right inferior articular process of C4 in a posteroinferior and medial direction on C5.

- ***Passive.*** The clinician applies a grade I–V force to the C4 vertebra to produce a posteroinferor and medial glide of the left zygapophyseal joint at C4–5.

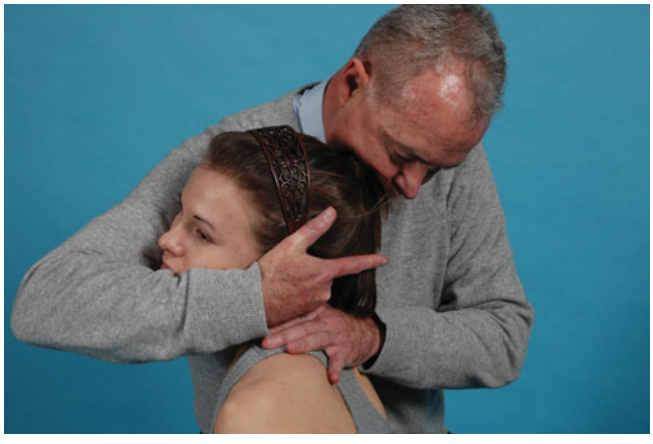

FIGURE 25-83 Seated mobilization to increase extension and left rotation.

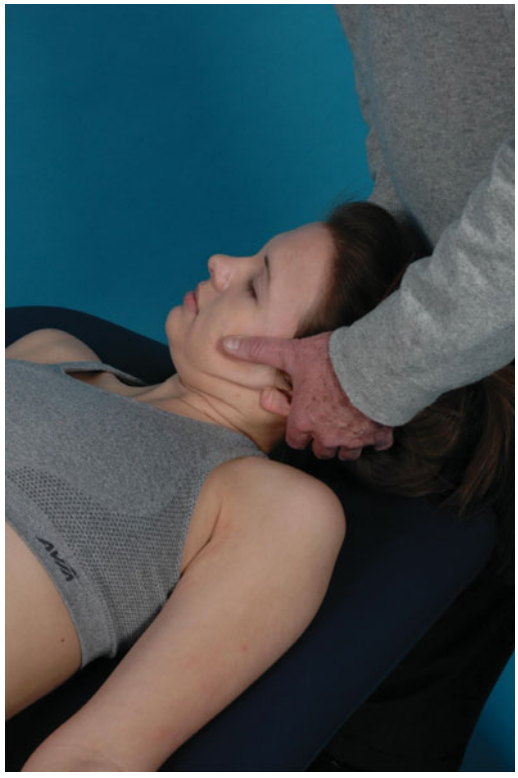

FIGURE 25-84 Supine Mobilization Technique to Restore Extension and Left Side Bending-rotation.

- ***Active.*** From the motion barrier, the patient is asked to turn the eyes in a direction that facilitates further extension, left side bending, and right rotation. The isometric contraction is held for up to 5 seconds and followed by a period of complete relaxation. The joint is then passively taken to the new motion barrier. The technique is repeated three times and followed by a reexamination of joint function.

Basic Techniques to Restore Motion in the Anterior Quadrant

Seated Mobilization Technique to Restore Flexion and Right rotation (Rotation Right Side Bending-Rotation shown on **VIDEO**). The patient is positioned sitting, and the clinician stands on the right side. Using one hand, the clinician stabilizes the C5 segment using a lumbrical grip (Fig. 25-85). The other hand reaches around the head of the patient, securing it to the clinician's chest, and the ulnar border of the fifth finger is applied to the left transverse process and neural arch of C4. The C4–5 segment is then flexed and rotated to the right to the barrier (see Fig. 25-85). The mobilization is carried out by the clinician applying pressure into flexion and right rotation.

- ***Passive.*** A grade I–IV mobilization force is applied to the C4 vertebra to produce a superoanterior glide at the zygapophyseal joints, thus flexing the C4–5 joint complex and feeling the spinous processes separate.
- ***Active.*** At the motion barrier, the patient is instructed to turn the eyes in a direction that facilitates further flexion at C4–5. The isometric contraction is held for up to 5 seconds

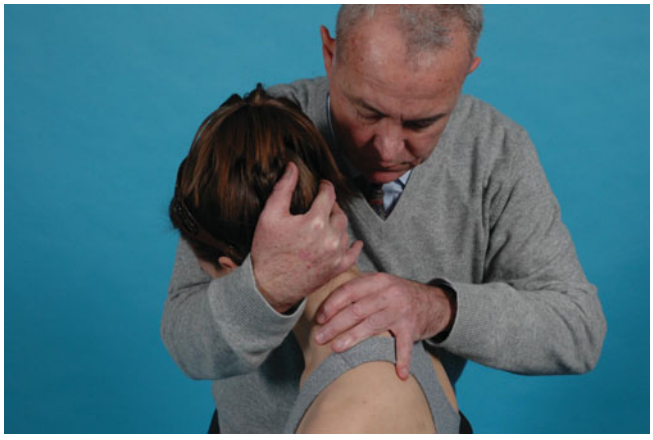

FIGURE 25-85 Seated mobilization into flexion and right rotation.

and followed by a period of complete relaxation. The joint is then passively taken to the new motion barrier. The technique is repeated three times and followed by a reexamination of joint function.

Supine Mobilization Technique to Restore Flexion and Right Side bending-Rotation (Left Side Bending-Rotation shown on **VIDEO***).* The patient is positioned supine, with the head being supported. The clinician stands at the head of the table facing the patient. The C4–5 segment is flexed, right side bent, and left translated to bring the right joint to its flexion barrier. The clinician hooks a fingertip under the right articular process and lays a fingertip pad over the articular process on the right (see Fig. 25-86). The mobilization is achieved by pulling the left process cranially, as steady light pressure is applied to the back of the left process to maintain a normal axis of motion.

- ***Passive.*** A grade I–V mobilization force is applied to the C4 vertebra to produce a superoanterior and medial glide of the right zygapophyseal joint at C4–5.
- ***Active.*** At the motion barrier, the patient is instructed to turn the eyes in a direction that facilitates further flexion, right side bending, and rotation at C4–5. The isometric contraction is held for up to 5 seconds and followed by a period of complete relaxation. The joint is then passively taken to the new motion barrier. This technique is repeated three times and followed by a reexamination of function.

Techniques to Restore Motion in Bilateral Extension Hypomobility

Bilateral hypomobilities can be treated with unilateral techniques performed to each side when only the last part of the range of movement is absent.

Seated Technique for the Cervicothoracic Junction

The patient is seated with the arms behind the head. The clinician stands in front of the patient and threads the arms through the patient's arms, before resting both of the hands on the top, and back, of each of the patient's shoulders (Fig. 25-87). By gently leaning the patient forward, the cervical spine is extended until the stiff segment is located at the cervicothoracic junction. Gradually, the clinician increases

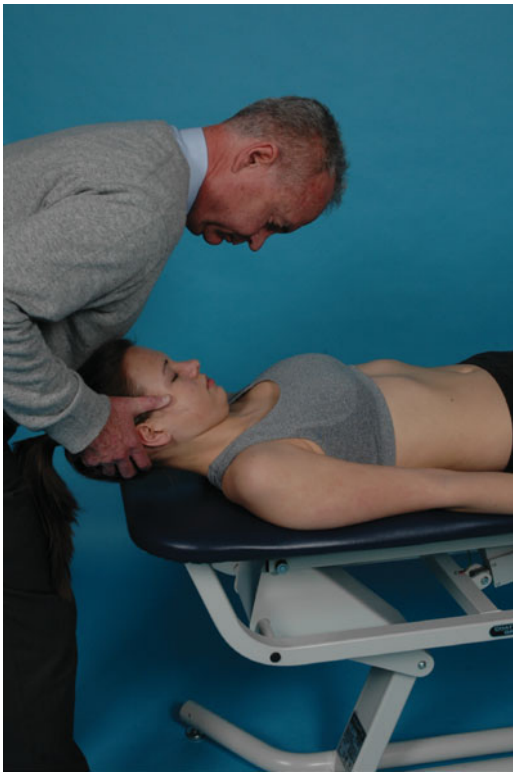

FIGURE 25-86 Supine Mobilization Technique to Restore Flexion and Left Side Bending-Rotation.

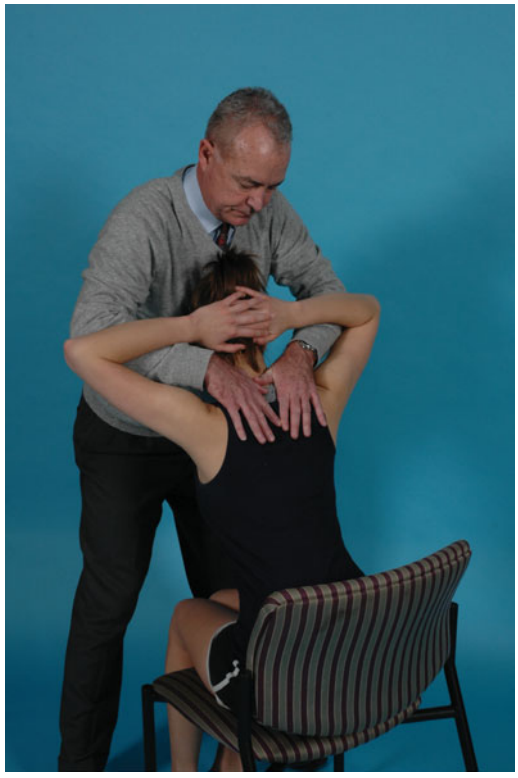

FIGURE 25-87 Seated Technique for the Cervicothoracic Junction.

the amount of cervicothoracic extension by gently kneading the mid-scapular area. Distraction, side flexion, or rotation motions can also be introduced. Care should be taken to avoid overextending the lumbar spine during this technique, by pulling the patient too far forward.

Mobilizations with Movement

To Improve Flexion. The patient is positioned sitting, with the clinician standing to the side, facing the patient.[398] The patient's head is held in neutral against the clinician's lower chest, and the distal phalanx of the little finger is hooked under the spinous process of the superior vertebra of the segment being treated. The rest of the fingers wrap around the patient's neck to provide firm support, and the wrist is extended, with the forearm placed in the plane of the facets. The lateral border of the thenar eminence of the other hand is placed below the little finger (see Fig. 25-88), and the palm of the hand rests on the upper back of the patient.

The patient is asked to flex the neck, and the glide of the superior segment is produced along the correct plane by a pull from the little finger in an anterior and superior direction, while the other hand stabilizes the lower segment.

This technique can be taught as part of the patient's home exercise program using a towel, belt, or strap.

To Improve Extension. The patient is positioned sitting, with the clinician standing to the side, facing the patient. The patient's head is held in neutral against the clinician's lower chest, and the distal phalanx of the little finger is hooked under the spinous process of the superior vertebra of the segment being treated. Using a key grip between the index finger and thumb, the clinician places the grip over the articular pillar on either side of the inferior spinous process of the segment (Fig. 25-89).

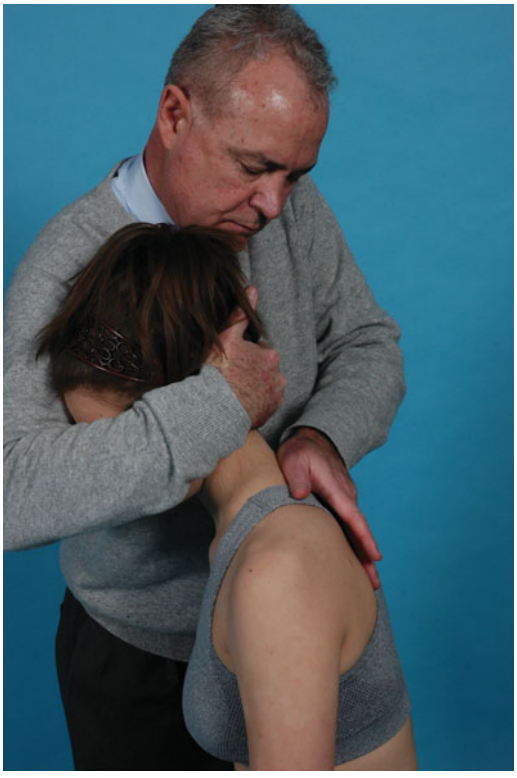

FIGURE 25-88 Mobilization with movement to improve cervical flexion.

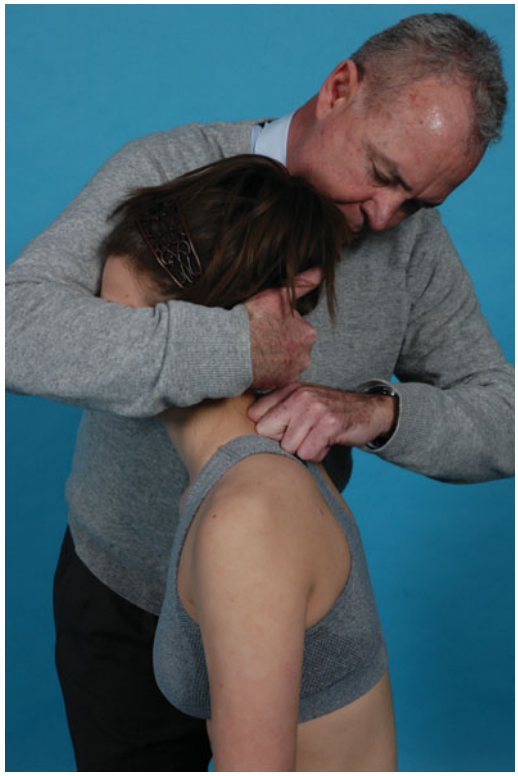

FIGURE 25-89 Mobilization with movement to improve cervical extension.

The patient is asked to extend the neck, while the clinician simultaneously applies a glide of the inferior vertebra by pushing with the key grip hand.

This technique can be taught as part of the patient's home exercise program using a towel, belt, or a strap.

To Improve Rotation to the Right. The patient is positioned sitting, with the clinician sitting behind. The clinician places the thumb of one hand over the articular pillar over the right aspect of the spinous process of the superior vertebra of the segment to be treated. The other thumb is placed over the first thumb to help reinforce. The remaining fingers of the two hands are placed around the neck and upper back.

The patient is asked to rotate the head and neck slowly to the right, while the clinician simultaneously applies the glide along the correct joint plane using pressure from both thumbs (see Fig. 25-90). The same technique can be used to improve cervical rotation to the right by altering the position of the thumbs.

This technique can be taught as part of the patient's home exercise program using a towel, belt, or a strap (Fig. 25-91).

Techniques to Increase Soft Tissue Extensibility

A variety of soft tissue techniques for the cervical region is available to the clinician. The choice of technique depends on the goals of the treatment and the dysfunction being treated.

FIGURE 25-90 Mobilization with movement to improve cervical rotation to the left.

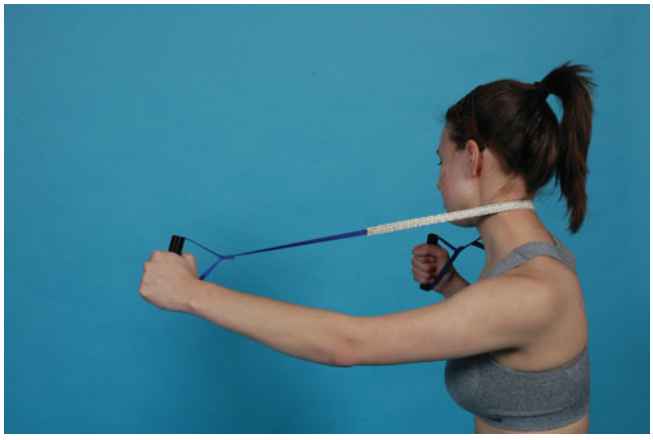

FIGURE 25-91 Home exercise to improve cervical rotation to the left.

Myofascial Trigger Point Therapy

Ischemic compression is advocated for myofascial trigger points and is achieved by sustaining direct pressure over a trigger point, using the thumb to apply pressure.[286] The pressure is held for 5–7 seconds and then quickly withdrawn.[399] The procedure is repeated on each trigger point. After each trigger point has been treated, the clinician returns to the first trigger point. The procedure is repeated three times on each trigger point.[399]

To facilitate self-treatment for inaccessible regions such as the rhomboid muscles, lying on a tennis ball, or using the handle of a cane can be substituted for direct manual compression.[286]

Muscle Stretching

Pectoralis Minor. The pectoralis minor can be stretched effectively using a corner and placing the forearms on the walls. The patient needs to avoid adopting a forward head posture during the stretch. The patient attempts a contraction of horizontal aduction and internal rotation into the wall. The clinician is cautioned against using this exercise with any patient with shoulder pathology, especially an anterior instability.

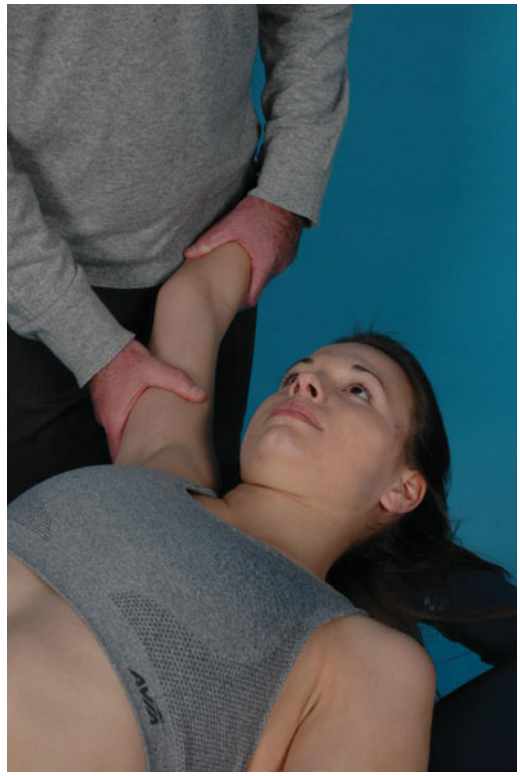

FIGURE 25-92 Pectoralis major stretch.

Pectoralis Major. The pectoralis major can be specifically stretched if the orientation of its fibers is considered (clavicular and costosternal), by having the patient lie supine and extending the arm off the table in either approximately 140 degrees of shoulder abduction (costosternal fibers) or approximately 45–50 degrees of abduction (clavicular fibers) (see Fig. 25-92).

For the following muscles, the same technique that is used to assess the length of this muscle is used for the stretch:

Sternocleidomastoid. The SCM functions to flex and rotate the neck and extend the occipitoatlantal joint. The patient is positioned in sitting or supine (see Fig. 25-37). The patient is positioned supine, with the head supported. From this position, the clinician induces side bending of the neck to the contralateral side, and extension of the neck. The clinician stabilizes the scapula and rotates the patient's head and neck toward the ipsilateral side.

Anterior and Middle Scalenes. The patient is positioned in supine. After stabilizing the first two ribs with the heel of one hand, the clinician performs passive cervical extension, contralateral side bending, and ipsilateral rotation (see Fig. 25-38).

Levator Scapulae. The stretch can be passively applied by the clinician. The patient is positioned supine, with the head at the edge of the table. The elbow and hand of the side to be treated are placed above the head. The clinician stands at the head of the table and presses his or her thigh against the point of the patient's elbow, fixing it caudally. Using both hands, the clinician then flexes the neck and side flexes the patient's head to the opposite side, until resistance is felt. The patient is then asked to look toward the treated side, a motion that is resisted by the clinician. When the patient relaxes, the clinician moves the head into further side flexion and flexion.

Upper Trapezius. This procedure is similar to that of the levator scapulae except that the amount of neck flexion is reduced (see Fig. 25-34). The patient is positioned supine, with the head at the edge of the table. Using both hands, the clinician then flexes the neck and side bends the patient's head to the opposite side. Rotation to the ipsilateral side is then added until resistance is felt. The patient is then asked to look toward the treated side, a motion that is resisted by the clinician. When the patient relaxes, the clinician moves the head into further flexion, side bending, and rotation.

In addition to the muscles described here, the clinician should assess the following muscles for adaptive shortening:

- rectus capitis posterior major;
- rectus capitis posterior minor;
- obliquus capitis inferior;
- obliquus capitis superior.

The stretches for these muscles are described in Chapter 23.

Self-Stretching Techniques

Levator Scapulae

The patient is seated with good posture. The patient flexes the neck fully and then side bends the head, while maintaining the neck flexion (see Fig. 25-93). The side bending continues until a gentle stretch is felt. Gentle overpressure can be applied using one hand. The stretch is maintained for 8–10 seconds and then the patient relaxes. The stretch is repeated 10 times.

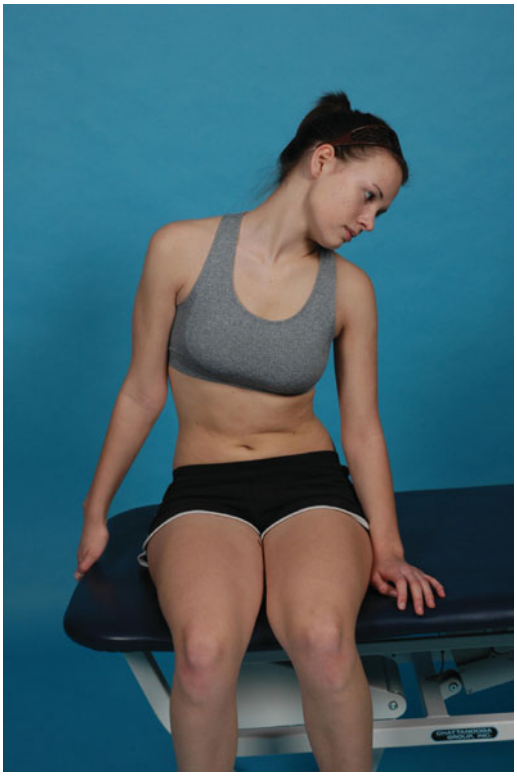

FIGURE 25-93 Self stretch of levator scapulae.

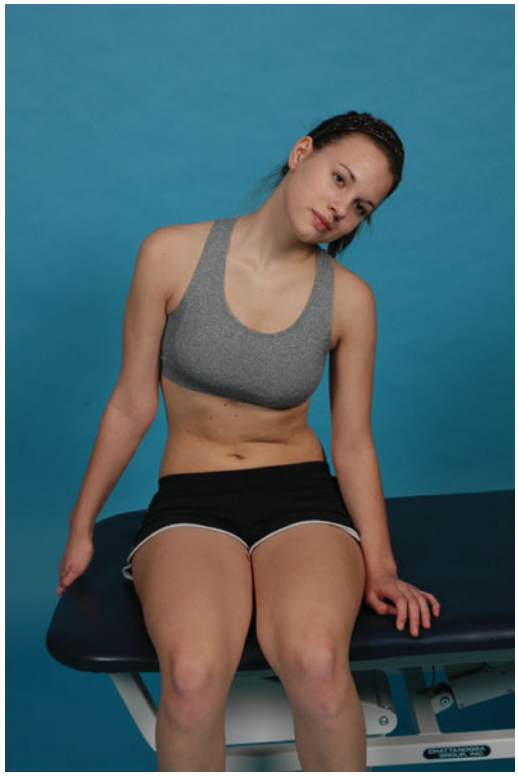

FIGURE 25-94 Self-stretch of upper trapezius.

Upper Trapezius

The self-stretch of the right upper trapezius depicted in Fig. 25-94, is described.[400] The stretch is maintained for 8–10 seconds, and then the patient relaxes. The stretch is repeated 10 times.

Three-Finger Exercise

Active range of motion in the cervical spine can be increased through patient participation, using the three-finger exercise.[401] The patient's mandible rests on digits two, three, and four. The motions of flexion (Fig. 25-95), side bending (Fig. 25-96), and rotation (Fig. 25-97) can all be performed.

FIGURE 25-95 Three finger exercise into cervical flexion.

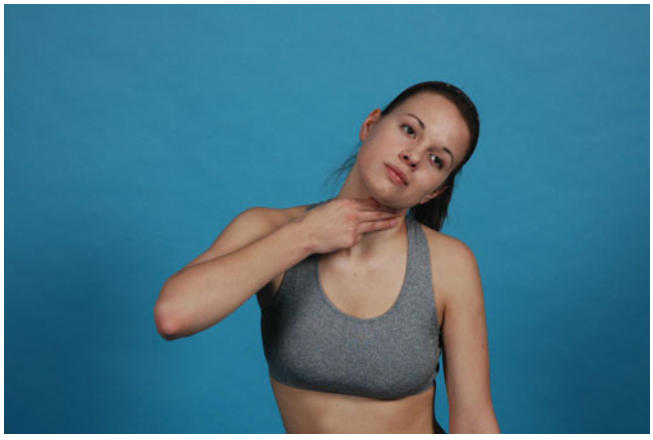

FIGURE 25-96 Three finger exercise into cervical side bending.

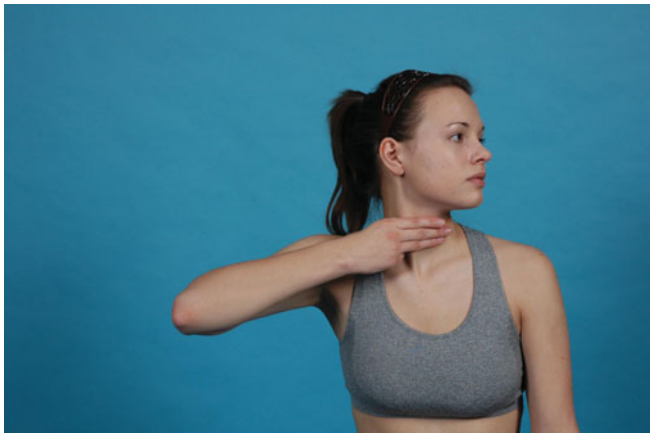

FIGURE 25-97 Three finger exercise into cervical rotation.

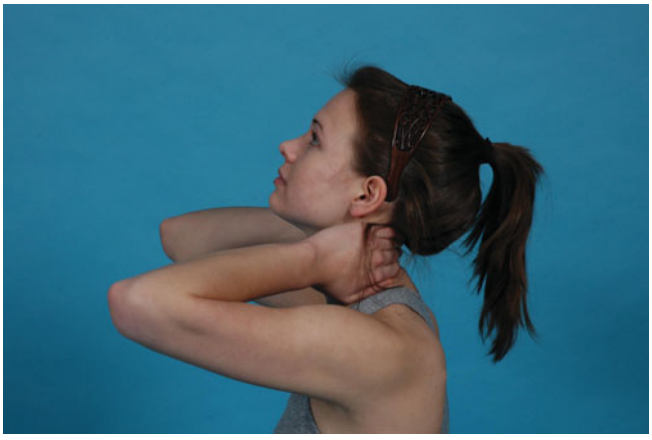

FIGURE 25-98 Active exercise into cervical extension.

The patient is cautioned against reproducing sharp pain, while attempting to feel a stretch at the end of the available motion.

With a different hand position, cervical extension can be performed in a controlled and safe manner. The fingers are interlocked and placed behind the neck, with the little fingers at the lowest segmental level of the joint restriction (at C 5 for a C4-5 restriction). Using the little finger as a fulcrum, the patient extends the cervical spine to the point just shy of pain. This position is held for a few seconds and the neck is returned to the neutral position (Fig. 25-98).

CASE STUDY

NECK PAIN AND ARM PARESTHESIA

HISTORY

A 21-year-old woman presented to the clinic with complaints of right neck and shoulder pain, and paresthesias that often radiated into the medial arm, forearm, and fourth and fifth fingers of the right upper extremity. The patient also reported that her right upper extremity often felt tired and heavy and that her right hand occasionally would appear to have a weak grip. The patient reported that her symptoms began shortly after she was involved in an MVA about 2 months previously and have increased slightly since that time. The patient denied any history since the accident of dizziness, tinnitus, blurred vision, or headaches. No left-sided neck pain or left upper extremity symptoms were reported.

The patient described her overall health as good. Her past medical history was unremarkable, and there was no past history of any surgeries.

Questions

1. What are some of the potential causes for upper extremity paresthesias? Can you rule out any of these causes from the history given? What further questions would you ask to help rule out some of the causes?
2. Which conditions could be associated with a weak grip? Could you rule these in or out with the history?
3. Which conditions could be associated with a report of a tired and heavy upper extremity? How would you rule these in or out?
4. Would the results from any imaging studies be helpful in this case? If so, which ones and why?
5. Is an upper quarter scanning examination warranted in this case? Why or why not?
6. Is this an irritable condition? Why or why not?
7. What type of conditions were the questions about dizziness, tinnitus, blurred vision, and headaches designed to help rule out?

CASE STUDY

LOW NECK PAIN

HISTORY

A 33-year-old woman presented with a diagnosis of low neck and upper back pain that, over the past few weeks, had become constant. Initially, the pain had been minimal, but it had worsened progressively. The pain was localized to the midline at the base of the neck, and there was no report of arm pain or symptoms. The patient worked as a computer operator for a local bank. Sleeping had become difficult, and all motions of the neck were reported to reproduce the symptoms. The patient denied any dizziness or nausea, or history of neck trauma.

The patient described her overall health as excellent. The past medical history was unremarkable.

Questions

1. Make a list of all of the possible causes of midline neck pain.
2. What could the gradual onset of the pain tell the clinician?
3. What is your working hypothesis at this stage? List the tests you would use to rule out the various causes of midline neck pain.
4. Should the reports of night pain concern the clinician?
5. Does this presentation/history warrant a Cyriax upper quarter scanning examination? Why or why not?

CASE STUDY

BILATERAL ARM AND WRIST WEAKNESS

HISTORY

A 36-year-old man who sustained a left tibial plateau fracture presented at the clinic with complaints of bilateral arm and wrist weakness that had worsened progressively over the past month since his discharge from the hospital. The patient was ambulating with crutches and non–weight-bearing on the left side. There was no history of cervical trauma. The patient reported no pain in his upper extremities but had noticed a mild and vague numbness in his hands. There was no report or evidence of a preceding viral infection and no proximal migration of the weakness, nor did he have any other areas of weakness. The patient did complain of pain in his axillae, and commented that his crutches had been rubbing against his axillae.[402]

Questions

1. What structure(s) could be at fault when weakness is the major complaint?
2. Why was the history of no cervical trauma pertinent?
3. Why was the statement about preceding viral infection pertinent?
4. Why was the statement about the proximal migration of the weakness pertinent?
5. What is your working hypothesis at this stage? List the various diagnoses that could present with bilateral arm numbness and the tests you would use to rule out each one.
6. Does this presentation/history warrant a scanning examination? Why or why not?

CASE STUDY

RIGHT-SIDED NECK PAIN

HISTORY

A 45-year-old woman awoke with right-sided neck pain 10 days earlier. The pain was felt over the right neck on an intermittent basis. She related that the pain was worse with head turning to the right, and further aggravated with activities involving cervical extension. She described no neurologic pain or paresthesia. The pain sites and intensity were unchanged since the onset.

Further questioning revealed that the patient was otherwise in good health and had no reports of bowel or bladder impairment, night pain, dizziness, or radicular symptoms.

Questions

1. What structure(s) could be at fault with complaints of right-sided neck pain?
2. What should the motion pattern of restriction/pain tell you?
3. What is your working hypothesis at this stage? List the various diagnoses that could present with right-sided neck pain and the tests you would use to rule out each one.
4. What do the questions about night pain and dizziness pertain to?
5. Does this presentation/history warrant a scanning examination? Why or why not?

REVIEW QUESTIONS*

1. Contraction of one SCM muscle results in
   a. rotation of the face to the same side;
   b. side bending of the head and neck to the opposite side;
   c. flexion of the head and neck;
   d. rotation of the face to the opposite side.
2. Which of the following groups of muscles performs cervical rotation to the opposite side?
   a. longus capitis, RCP, and rectus capitis posterior;
   b. splenius cervicis and splenius capitis;
   c. SCM, scalenus anterior, and obliquus capitis;
   d. SCM and scalenus medius.
3. Which of the following muscles is thin and sheet-like and has fibers that extend from the chest upward over the neck?
   a. levator scapula;
   b. buccinator;
   c. orbicularis oris;
   d. platysma.
4. Which cervical structure is thought to help prevent cervical disk protrusions?
5. Which nerve trunk of the plexus is the most commonly compressed neural structure in TOS?

The Temporomandibular Joint

CHAPTER 26

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the temporomandibular joint (TMJ), including the bones, ligaments, muscles, and blood and nerve supply.
2. Describe the biomechanics of the TMJ, including the movements, normal and abnormal joint barriers, kinesiology, and reactions to various stresses.
3. Summarize the various causes of temporomandibular dysfunction (TMD).
4. Describe the close association between the TMJ, the middle ear, and the cervical spine.
5. Perform a comprehensive examination of the temporomandibular musculoskeletal system, including palpation of the articular and soft tissue structures, specific passive mobility and passive articular mobility tests, and stability tests.
6. Evaluate the total examination data to establish a diagnosis.
7. Recognize the manifestations of abnormal TMJ function and develop strategies to correct these abnormalities.
8. Apply active and passive mobilization techniques to the TMJ, using the correct grade, direction, and duration.
9. Describe and demonstrate intervention strategies and techniques based on clinical findings and established goals.
10. Evaluate the intervention effectiveness in order to progress or modify an intervention.
11. Plan an effective home program and instruct the patient in this program.

OVERVIEW

Housed within the skull are the components of the stomatognathic system, which includes the TMJ, the masticatory systems, and the related organs and tissues such as the inner ear and salivary glands.[1] An interrelationship exists between the stomatognathic system and the head and neck due to their proximity and shared embryological development. An understanding of this relationship is vital to understand the reasons for the myriad of symptoms that this region can exhibit.

The embryologic structures from which the head, the face, and the neck originate are segmentally organized during development with the appearance and modification of six paired branchial or pharyngeal arches.[1] These branchial arches contain the cranial nuclei of the trigeminal nerve (ophthalmic; maxillary and mandibular), the facial, the glossopharyngeal, and the laryngeal branch of the vagus nerve as well as the hypoglossal nerve.

The first of these arches, the mandibular arch, consists of a large anterior (ventral) part (mandibular process of Meckel's cartilage) and a small posterior (dorsal) (maxillary) process. As development progresses, both processes disappear except for two small portions at the posterior (dorsal) ends, which persist. The first brachial arch forms

- the mandible;
- the rudiments of the inner ear bones, the malleus, and incus;
- the anterior malleolar and sphenomandibular ligaments of the TMJ;
- the tensor tympani and the tensor veli palatini of the inner ear;
- the mylohyoid and the anterior belly of the digastric muscle;
- the trigeminal mandibular nerve.

The second pharyngeal arch (the hyoid arch) consists of Reichert's cartilage. This arch is involved in the formation of

- the superior component of the hyoid bone and the lesser cornu bone;
- the stapes muscle;
- the temporal styloid process;
- the stylohyoid ligament;
- the stapedius muscle;
- the stylohyoid muscle;
- the posterior belly of the digastric muscle;
- the muscles of facial expression and mastication;

- the platysma muscle;
- the glossopharyngeal nerve.

The third pharyngeal arch is involved in the formation of the greater cornu of the hyoid and its body, the stylopharyngeal muscle, and the sensory apparatus of the posterior one-third of the tongue.

The fourth pharyngeal arch combines with the sixth arch to form the thyroid, cricoid, and arytenoid cartilages of the larynx. The muscles derived from this arch are the pharyngeal constrictors (the cricothyroid) and the intrinsic muscles of the larynx. The pharyngeal constrictors are innervated by the superior laryngeal branch of the vagus nerve. The intrinsic muscles of the larynx are innervated by the recurrent laryngeal branch of the vagus nerve.

In primitive creatures, and the human fetus, vibrations through the jaw are used as a basis for hearing. At around $8^1/_2$ weeks, the small bones of the inner ear (the malleus, incus, and stapes) can be seen as distinct entities. The development of the malleus bone and the tensor tympani are intimately related to that of the lateral pterygoid muscle. Due to this embryological relationship, it is theorized that a spasm of the lateral pterygoid muscle can increase the tension within the tensor tympani (similar to that of a drum skin)[1] resulting in an increased sensitivity to pitch and vibration. Theoretically, this increased tension could produce sensorineural tinnitus, or ringing in the ears,[1] a common associated symptom of a temporomandibular disorder (TMD), and an injury to the craniovertebral region. TMD is a collective term used to describe a number of related disorders affecting the stomatognathic system and its related structures, all of which may have common symptoms. The term *TMJ dysfunction* as an overall descriptor of stomatognathic system dysfunction has been discontinued because it implies structural problems when none may exist, and does not include the many other factors that may be involved.[2]

The diagnosis of TMD, like that of whiplash syndrome, remains controversial.[3] This is due in part to a paucity of studies regarding the incidence, course, management, and prognosis of claimed TMDs.[4,5] However, reports of TMD appear to be quite common. About 60–70% of the general population has at least one sign of a TMD, yet only around one in four people with signs is actually aware of, or reports, any symptoms,[6,7] and only about 5% of people with one or more signs of a TMD will actually seek an intervention.[7–9] After a technology assessment conference in 1996 about managing TMD, the National Institutes of Health (NIH) concluded that the natural history and etiology of TMD are not well understood and that most TMD symptoms are self-limiting, can recur, and may fluctuate over time.[10] The most common TMD by far, comprising 90–95% of all TMD cases, is a condition with multiple musculoskeletal facial pain complaints and a variety of jaw impairments, without an identified structural cause.[11]

TMD is best approached as a biopsychosocial dysfunction. Although TMD originally was approached as one syndrome, current research supports the view that TMD is a cluster of related disorders in the stomatognathic system that have many common symptoms.[6,12] McNeill and colleagues[13] have described three etiologic factors of TMD: (1) predisposing factors, (2) precipitating or triggering factors, and (3) perpetuating or sustaining factors[14]:

- Predisposing factors include the structural, neurologic, hormonal, and metabolic features of an individual.
- Precipitating factors generally fall into the following four categories: (1) overt, extrinsic trauma to the head, the neck, or the jaw; (2) repeated low-grade extrinsic trauma, such as nail biting and chewing gum; (3) repeated low-grade intrinsic trauma such as teeth clenching or bruxism (grinding teeth); and (4) stress that passes a certain threshold, which is individual for each patient.
- Perpetuating or contributing factors are those that aid in the continuation of symptoms. These can include systemic disease and cervical pathology.

Thus, the clinical course of TMD does not reflect a progressive disease but rather a complex disorder that is molded by many interacting factors, such as stress, anxiety, and depression, which serve to maintain the disease.[12] Headaches, orofacial pain, earache, and neck pain are common complaints. Persistent or recurrent pain is considered the main reason that more than 90% of patients with TMD seek an intervention.[8,15] A diagnosis of TMD must, therefore, include an examination of all of the following:

- Jaw muscles
- Bone and cartilage joint structures
- Facial structures
- Soft tissue joint structures, including the articular disk and synovium
- Jaw and joint function
- Cervical and upper thoracic spine function
- Posture and dysfunction
- Systemic disease
- Psychosocial issues

Given the number of potential causes of jaw and face pain, a diagnosis of TMD can rarely be ascribed solely to the TMJ. Examples of appropriate diagnoses for TMD are more likely to include

- rheumatoid arthritis with synovitis, arthralgia, condylar degenerative disease, and open bite deformity;
- chronic pain with a behavioral disorder;
- myofascial pain and impairment;
- internal disk derangement, with displacement and reduction.

CLINICAL PEARL

Most of those who seek medical intervention for TMDs are female, outnumbering male patients by at least four to one.[8,9,16] The reason for the higher prevalence of TMD in women, and the overrepresentation of females at orofacial pain clinics, remains obscure. One explanation could be that women more readily seek treatment for illness than do men.[17]

Nonsurgical interventions such as counseling, physical therapy, pharmacotherapy, and occlusal splint therapy continue to be the most effective way of managing more than 80% of patients with TMD.[12] Although dentists are the primary professionals involved in the examination and intervention of TMD, physical therapists can play an important role in assisting the dentist in restoring function to the stomatognathic system. However, the procedures in physical therapy intervention are not well described in the literature in this area.

ANATOMY

The TMJ (Fig. 26-1) is a synovial, compound, modified ovoid bicondylar joint, which is formed between the articular eminence of the temporal bone, the intra-articular disk, and the head of the mandible.

The TMJ is unique in that, even though the joint is synovial, the articulating surfaces of the bones are covered not by hyaline cartilage but by fibrocartilage.[18,19] Fibrocartilage has the same general properties found in hyaline cartilage but tends to be less distensible, owing to a greater proportion of dense collagen fibers (see Chap. 1). The development of fibrocartilage over the load-bearing surface of the TMJ indicates that the joint is designed to withstand large and repeated stresses and that this area of the joint surface has a greater capacity to repair itself than would hyaline cartilage.[20]

The area of load bearing is affected by the congruity of the contacting tooth surfaces (occlusion), head position, and the coordination of muscle function. The fibrocartilage is at its thinnest at the roof of the fossa, but load bearing here occurs only in the presence of dysfunction.[21]

The mandible works like a class-three lever (see Chap. 1), with its joint as the fulcrum. Although there is no agreement among the experts concerning force transmission through the joint, there does appear to be agreement that postural impairments of the cervical and upper thoracic spine can produce both pain and impairment of the TMJ.[6]

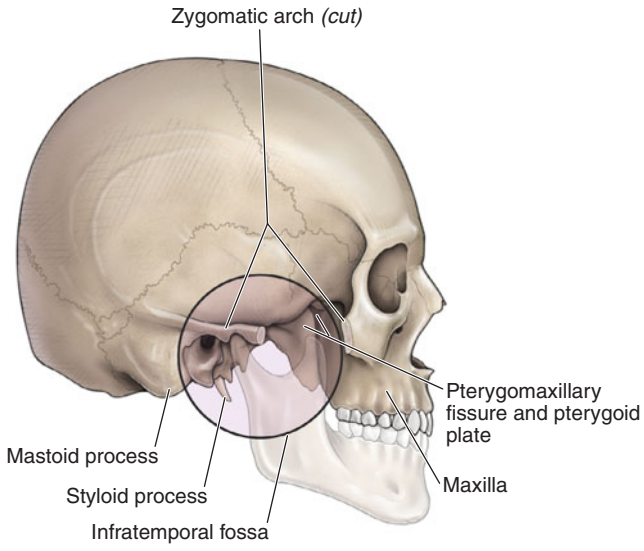

FIGURE 26-1 The temporomandibular joint. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Bony Anatomy

A number of bony components make up the masticatory system: the maxilla and the mandible, which support the teeth, and the temporal bone, which supports the mandible at its articulation with the skull. The sphenoid bone and the hyoid bone also could be included, because they provide important anatomic and functional links to the TMJ.

Maxilla

The borders of the maxillae extend superiorly to form the floor of the nasal cavity as well as the floor of each orbit (Fig. 26-1). Inferiorly, the maxillary bones form the palate and the alveolar ridges, which support the teeth. The maxillae and mandible each contain 16 permanent teeth. The structure of each tooth reflects its function in mastication.

Sphenoid Bone

The greater wings of the sphenoid bone form the boundaries of the anterior part of the middle cranial fossa. From these greater wings, the pterygoid laminae serve as the attachments for the medial and lateral pterygoid muscles.

Hyoid Bone

The U-shaped hyoid bone (Fig. 26-2), also known as the skeleton of the tongue, serves as the attachment for the infrahyoid muscles and for some of the extrinsic tongue muscles. The hyoid bone is involved with the mandible to provide reciprocal stabilization during swallowing and chewing. Theoretically, due to its muscle attachments, the position of the hyoid bone can be affected by cervical and shoulder positions, as occurs during forward head posture, which changes the length–tension relationships.

Mandible

The mandible, or jaw (Fig. 26-1), which supports the lower teeth, is the largest and the strongest bone in the face. It is suspended below the maxillae by muscles and ligaments that provide it with both mobility and stability. The medial surface of the mandible serves as the attachment for the medial pterygoid and the digastric muscles. The platysma, mentalis, and buccinator gain attachment on its lateral aspect.

Two broad, vertical rami extend upward from the mandible: the condyle and the coronoid process. The anterior of the two processes, the coronoid, serves as the attachment for the temporalis and masseter muscles.[22] The condyle process articulates with the temporal bone. The bony surfaces of the condyle and the articular portion of the temporal bone are made of dense cortical bone. The articulating surface of the condyle is flattened from front to back with its medial–lateral length twice as long as its anterior–posterior length. The condyles are generally convex, possessing short bony projections known as medial and lateral poles.[23]

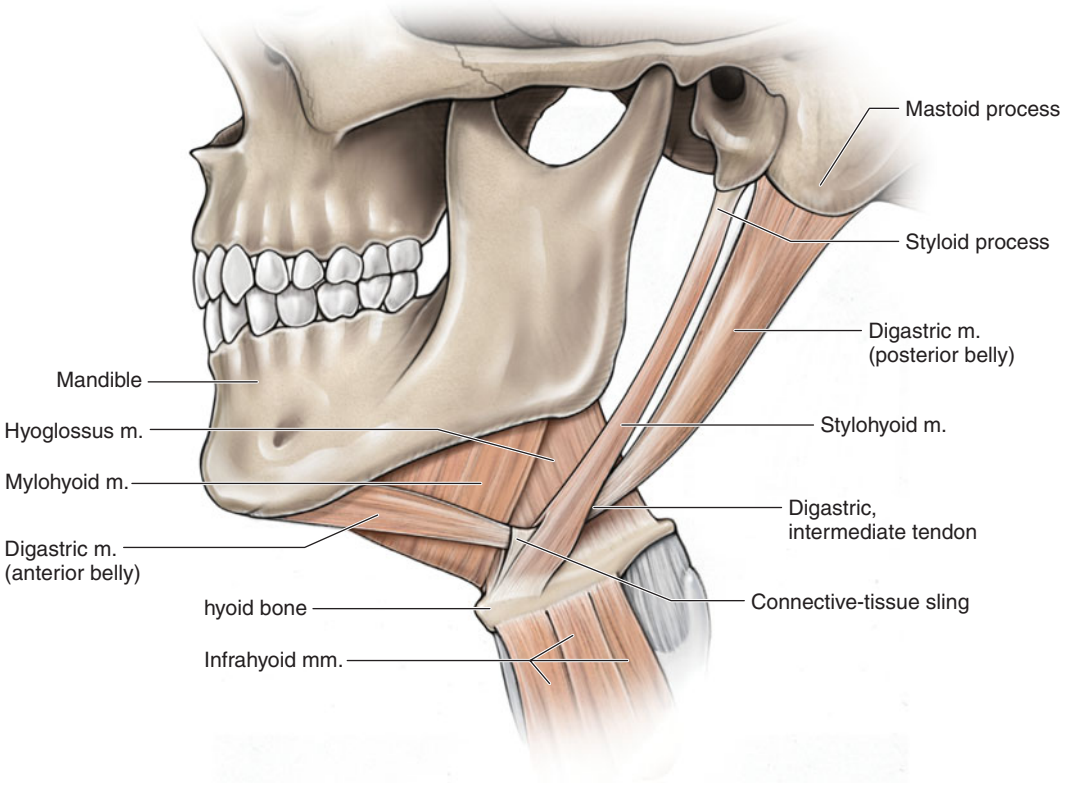

FIGURE 26-2 The hyoid bone and related muscles. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Temporal Bone

The mandibular fossa of the temporal bone is divided into two surfaces: articular and nonarticular.[23] The articulating surface of the temporal bone is made up of a concave mandibular, or glenoid, fossa and a convex bony prominence called the articular eminence.[24] The articular tubercle, situated anterior to the glenoid fossa, serves as an attachment for the temporomandibular (or lateral) ligament.[22] The nonarticular surface of the fossa consists of a very thin layer of bone and fibrocartilage that occupies much of the superior and posterior walls of the fossa.[23]

Fibrocartilaginous Disk

Located between the articulating surface of the temporal bone and the mandibular condyle is a fibrocartilaginous disk (sometimes inappropriately referred to as "meniscus") (Fig. 26-3). The biconcave shape of the disk is determined by the shape of the condyle and the articulating fossa.[25] Rees[19] has described the fibrocartilaginous disk as having three clearly defined transverse, ellipsoidal zones that are divided into three regions—posterior band, intermediate zone, and anterior band—of which the intermediate zone makes contact with the articular surface of the condyle.

Both the disk and the lateral pterygoid muscle develop from the first branchial arch, and there is very little differentiation among the muscle, the disk, and the joint capsule.[26,27] The fibrocartilaginous disk is tethered by a number of structures:

- Medial and lateral collateral diskal ligaments firmly attach the fibrocartilaginous disk to the medial and lateral poles of the condyle, permitting anterior and posterior rotation of the disk on the condyle during mouth opening and closing.[28,29]
- Posteriorly, the disk is attached by fibroelastic tissue to the posterior mandibular fossa and the back of the mandibular condyle.[28,29]
- Anteriorly, the disk is attached to the upper part of the tendon of the lateral pterygoid muscle[28,29] (Fig. 26-3).

The disk usually is located on top of the condyle in the 12 o' clock to 1 o'clock position on the mandibular head when the jaw is closed.[30] Since the only firm attachment of the disk to the condyle occurs medially and laterally, the disk can move somewhat independently of the condyle.[31]

The disk effectively divides the TMJ into a lower and an upper joint cavity (see Fig. 26-3):

- ***Lower compartment.*** This compartment, bordered by the mandibular condyle and the inferior surface of the articular disk, is where, under normal conditions, the osteokinematic spin (rotation) of the condyle occurs.[6]
- ***Upper compartment.*** This compartment, bordered by the mandibular fossa and the superior surface of the articular disk, primarily allows only translation of the disk and condyle along the fossa, and onto the articular eminence.[6]

Blood vessels and nerves are found only in the thickened periphery of this disk, especially its posterior attachment; its middle articular portion is avascular and aneural.[32]

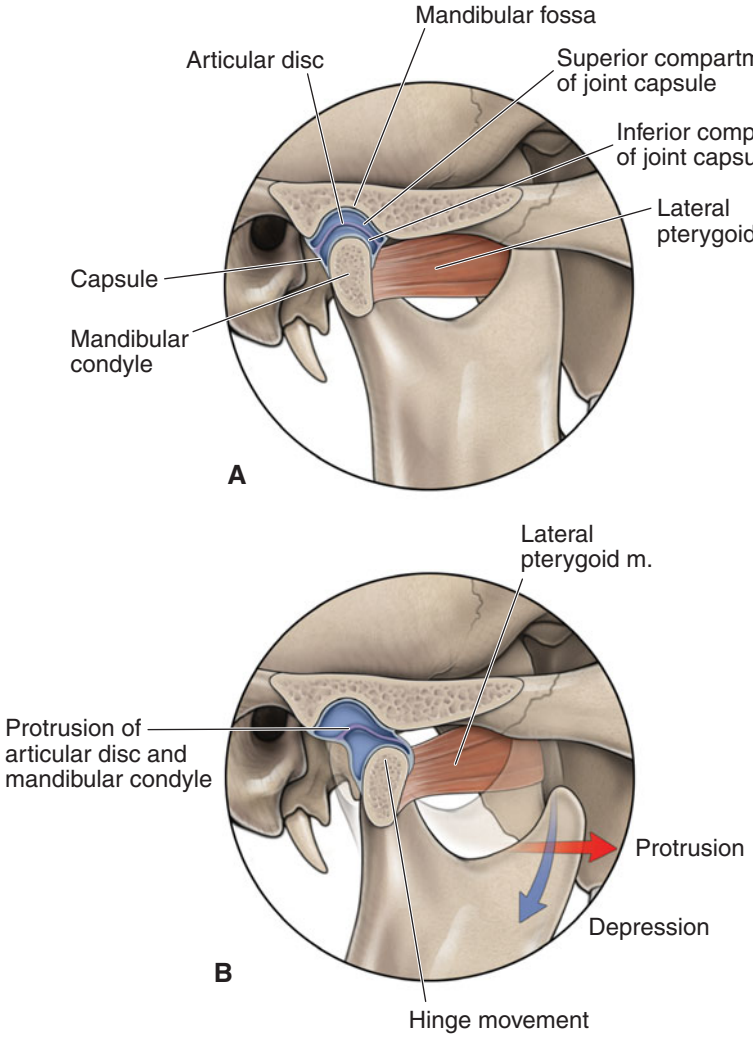

FIGURE 26-3 The TMJ disk and the pterygoid. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Supporting Structures

The supporting structures of the TMJ consist of periarticular connective tissue (ligament, tendon, capsule, and fascia). As its name implies, the periarticular connective tissue serves to keep the joints together and to limit the ranges of motion at the joint. For example, the ligaments of the TMJ protect and support the joint structures and act as passive restraints to joint movement. The synovial cavities are surrounded by loose connective tissue rather than by ligaments.

The intercapsular structures are located posteriorly to the condyle. Anterior to the joint are the muscles of the medial and lateral pterygoid (see next section). There are no well-defined anterior or posterior ligaments between the mandibular condyle and the temporal bone. However, two strong ligaments help to provide joint stability:

1. ***Joint capsule or capsular ligament.*** This structure, which surrounds the entire joint, is thought to provide proprioceptive feedback regarding joint position and movement.[33,34]
2. ***Temporomandibular (or lateral) ligament.*** The capsule of the TMJ is reinforced laterally by an outer oblique portion and an inner horizontal portion of the temporomandibular ligament, which function as a suspensory mechanism for the mandible during moderate opening movements. The ligament also functions to resist rotation and posterior displacement of the mandible.

Two other ligaments assist with joint stability:

- ***Stylomandibular ligament.*** The stylomandibular ligament is a specialized band that splits away from the superficial lamina of the deep cervical fascia to run deep to both pterygoid muscles.[24] This ligament becomes taut and acts as a guiding mechanism for the mandible, keeping the condyle, disk, and temporal bone firmly opposed.
- ***Sphenomandibular ligament.*** The sphenomandibular ligament is a thin band that runs from the spine of the sphenoid bone to a small bony prominence on the medial surface of the ramus of the mandible, called the lingula. This ligament acts to check the angle of the mandible from sliding

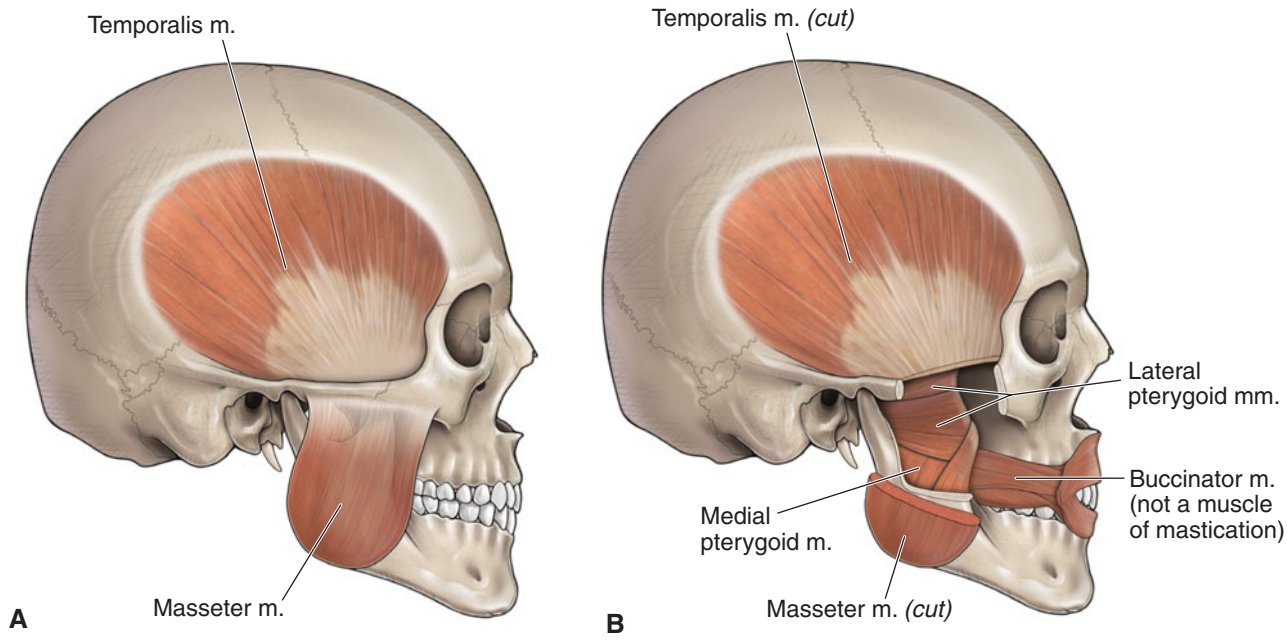

FIGURE 26-4 Lateral view of TMJ. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

as far forward as the condyles during the translatory cycle and serves as a suspensory ligament of the mandible during wide opening.[24] It is this ligament that hurts with any prolonged jaw opening, such as that which occurs at the dentist.

CLINICAL PEARL

Pinto's ligament[35] is a vestige of Meckel's cartilage, an embryological tissue. It arises from the neck of the malleus of the inner ear and runs in a medial superior direction to insert into the posterior aspect of the TMJ capsule and the disk. While the role of this ligament in mandibular mechanics is thought to be negligible, its relationship to the middle ear and the TMJ could be a basis for the middle ear symptoms, which are often present with TMD. Stack[36] postulated that auditory symptoms of fullness and pressure in the middle ear may be present as a result of direct transmission of TMJ capsular tension to the ossicles of the middle ear through this ligament.

Muscles

The muscles of mastication are the key muscles when discussing TMD. Three of these muscles, the masseter, the medial pterygoid, and the temporalis (Fig. 26-4), function to raise the mandible during mouth closing. The lateral pterygoid and digastric muscles work together to depress the mandible during mouth opening.

Although these muscles work most efficiently in groups, an understanding of the specific anatomy and action(s) of the individual muscles is necessary for an appreciation of their coordinated function during masticatory activity (Tables 26-1 and 26-2).

Temporalis

The temporalis muscle (Fig. 26-4) has its origin from the floor of the temporal fossa and the temporal fascia. The muscle travels inferiorly and anteriorly to insert on the anterior border of the coronoid process and the anterior border of the ramus of the mandible. The temporalis muscle is innervated by a branch of the mandibular division of the trigeminal nerve. In addition to assisting with mouth closing and side-to-side grinding of the teeth, the temporalis muscle provides a good deal of stability to the joint.

The Masseter

The masseter (Fig. 26-4) is a two-layered quadrilateral-shaped muscle. The superficial portion arises from the anterior two-thirds of the lower border of the zygomatic arch. The deep portion arises from the medial surface of the zygomatic arch. Both sets of fibers blend anteriorly and form a raphe with the medial pterygoid.[24] The masseter inserts on the lateral surface of the coronoid process of the mandible, upper half of the ramus and angle of the mandible. The masseter muscle is innervated by a branch of the mandibular division of the trigeminal nerve. The major function of the masseter is to elevate the mandible, thereby occluding the teeth during mastication.

The Medial Pterygoid

The medial pterygoid muscle is a thick quadrilateral muscle, with a deep origin situated on the medial aspect of the mandibular ramus (Fig. 26-4). The muscle travels posteriorly to insert on the inferior and posterior aspects of the medial subsurface of the ramus and angle of the mandible. The medial pterygoid muscle is innervated by a branch of the mandibular division of the trigeminal nerve. Working bilaterally, and in

TABLE 26-1 Muscles of the Temporomandibular Joint

Muscle	Proximal	Distal	Innervation
Medial pterygoid	Medial surface of lateral pterygoid plate and tuberosity of maxilla	Medial surface of mandible close to angle	Mandibular division of trigeminal nerve
Lateral pterygoid	Greater wing of sphenoid and lateral pterygoid plate	Neck of mandible and articular cartilage	Mandibular division of trigeminal nerve
Temporalis	Temporal cranial fossa	By way of a tendon into medial surface, apex, and anterior and posterior borders of mandibular ramus	Anterior and posterior deep temporal nerves, which branch from anterior division of mandibular branch of trigeminal nerve
Masseter	Superficial portion: from anterior two-thirds of lower border of zygomatic arch; deep portion from medial surface of zygomatic arch	Lateral surfaces of coronoid process of mandible, upper half of ramus, and angle of mandible	Masseteric nerve from anterior trunk of mandibular division of trigeminal nerve
Mylohyoid	Medial surface of mandible	Body of hyoid bone	Mylohyoid branch of trigeminal nerve and mandibular division
Geniohyoid	Mental spine of mandible	Body of hyoid bone	Anterior (ventral) ramus of C1 via hypoglossal nerve
Stylohyoid	Styloid process of temporal bone	Body of hyoid bone	Facial nerve
Anterior and posterior digastric	Internal surface of mandible and mastoid process of temporal bone	By intermediate tendon to hyoid bone	Anterior: mandibular division of trigeminal nerve; posterior: facial nerve
Sternohyoid	Manubrium and medial end of clavicle	Body of hyoid bone	Ansa cervicalis
Omohyoid	Superior angle of scapula	Inferior body of hyoid bone	Ansa cervicalis
Sternothyroid	Posterior surface of manubrium	Thyroid cartilage	Ansa cervicalis
Thyrohyoid	Thyroid cartilage	Inferior body and greater horn of hyoid bone	C1 via hypoglossal nerve

association with the masseter and temporalis muscles, the medial pterygoids assist in mouth closing. Individually, the medial pterygoid muscle is capable of deviating the mandible toward the opposite side. The medial pterygoid muscle also acts as an assistance to the lateral pterygoid and anterior fibers of the temporalis muscle to produce protrusion of the mandible.

The Lateral Pterygoid

Two divisions of the lateral pterygoid muscles are recognized, each of which is functionally and anatomically separate (Fig. 26-3 and Fig. 26-4). The superior head arises from the infratemporal surface of the greater wing of the sphenoid. The inferior head arises from the lateral surface of the lateral pterygoid plate. Despite several investigations,[37–39] no consensus has been reached regarding the insertion of the lateral pterygoid muscle. However, the most commonly described insertion is at the anterior aspect of the neck of the mandibular condyle and capsule of the TMJ. The lateral pterygoid muscle is innervated by a branch of the mandibular division of the trigeminal nerve.

The superior head of the lateral pterygoid is involved mainly with chewing and functions to anteriorly rotate the disk on the condyle during the closing movement.[40,41] It has also been suggested that in normal function of the craniomandibular complex, the superior lateral pterygoid plays an important role in stabilizing and controlling the movements of the disk.[42]

The inferior head of the lateral pterygoid muscle exerts an anterior, lateral, and inferior pull on the mandible, thereby opening the jaw, protruding the mandible, and deviating the mandible to the opposite side.

Infrahyoid or "Strap" Muscles

The infrahyoid muscles comprise the sternohyoid, omohyoid, sternothyroid, and thyrohyoid muscles (Fig. 26-5).

Sternohyoid

The sternohyoid muscle is a strap-like muscle that functions to depress the hyoid and assist in speech and mastication.

Omohyoid

The omohyoid muscle, situated lateral to the sternohyoid, consists of two bellies and functions to depress the hyoid. In addition, the muscle has been speculated to tense the inferior aspect of the deep cervical fascia in prolonged inspiratory efforts, thereby releasing tension on the apices of the lungs and

TABLE 26-2 Actions of the Temporomandibular Joint Muscles

Action	Muscles Acting
Opening of mouth	Lateral pterygoid Mylohyoid Geniohyoid Digastric
Closing of mouth	Masseter Temporalis Medial pterygoid
Protrusion of mandible	Lateral pterygoid Medial pterygoid Masseter Mylohyoid Geniohyoid Digastric Stylohyoid Temporalis (anterior fibers)

Lateral deviation of mandible	Lateral pterygoid (ipsilateral muscle) Medial pterygoid (contralateral muscle) Temporalis Masseter

on the internal jugular vein, which are attached to this fascial layer.[24]

Sternothyroid and Thyrohyoid

The sternothyroid and thyrohyoid muscles (see Fig. 26-5) are located deep to the sternohyoid muscle. The sternothyroid muscle is involved in drawing the larynx downward, whereas the thyrohyoid depresses the hyoid and elevates the larynx.

These infrahyoid muscles are innervated by fibers from the upper cervical nerves. The nerves to the lower part of these muscles are given off from a loop, the ansa cervicalis (cervical loop) (see Chap. 3).

Suprahyoid Muscles

The suprahyoid muscles (Fig. 26-2), working with the infrahyoid muscles, play a major role in coordinating mandibular function, by providing a firm base on which the tongue and mandible can be moved.

Geniohyoid

The geniohyoid muscle is a narrow muscle situated under the mylohyoid muscle. The muscle functions to elevate the hyoid bone.

Digastric

As its name suggests, the digastric muscle consists of two bellies. The posterior belly arises from the mastoid notch of the temporal bone, while the anterior belly arises from the digastric fossa of the mandible. The posterior belly is innervated by a branch from the facial nerve. The anterior belly is innervated by the inferior alveolar branch of the trigeminal nerve. The two bellies of the digastric muscle are joined by a rounded tendon that attaches to the body and greater cornu of the hyoid bone through a fibrous loop or sling.[24]

Bilaterally, the two bellies of the digastric muscle assist in forced mouth opening by stabilizing the hyoid. The posterior bellies are especially active during coughing and swallowing.[24]

CLINICAL PEARL

Working in combinations, the muscles of the TMJ are involved as follows:

- Mouth opening—bilateral action of the lateral pterygoid and digastric muscles.
- Mouth closing—bilateral action of the temporalis, masseter, and medial pterygoid muscles.
- Lateral deviation—action of the ipsilateral masseter, and contralateral medial and lateral pterygoid muscles.
- Protrusion—bilateral action of the lateral pterygoid, medial pterygoid, and anterior fibers of the temporalis muscles.
- Retrusion—bilateral action of the posterior fibers of the temporalis muscle, the digastric, stylohyoid, geniohyoid, and mylohyoid muscles.

Mylohyoid

This flat, triangular muscle is functionally a muscle of the tongue, stabilizing or elevating the tongue during swallowing and elevating the floor of the mouth in the first stage of deglutition.[24]

Stylohyoid

The stylohyoid muscle elevates the hyoid and base of the tongue and has an undetermined role in speech, mastication, and swallowing.

Nerve Supply

The TMJ is primarily supplied from three nerves that are part of the mandibular division of the fifth cranial (trigeminal) nerve (Fig. 26-6) (Box 26-1). Portions of the middle ear ossicles, middle ear musculature, and muscles of mastication all originate from the first branchial arch and are innervated by this nerve. Therefore, in a patient with altered bite mechanics, spasm of the muscles of mastication caused by a displaced condyle may cause neuromuscular dysfunction of all the muscles innervated by the trigeminal nerve, including the tensor palatini.[43]

There is considerable clinical interest in the interactions between the cervical and craniofacial regions. This interest

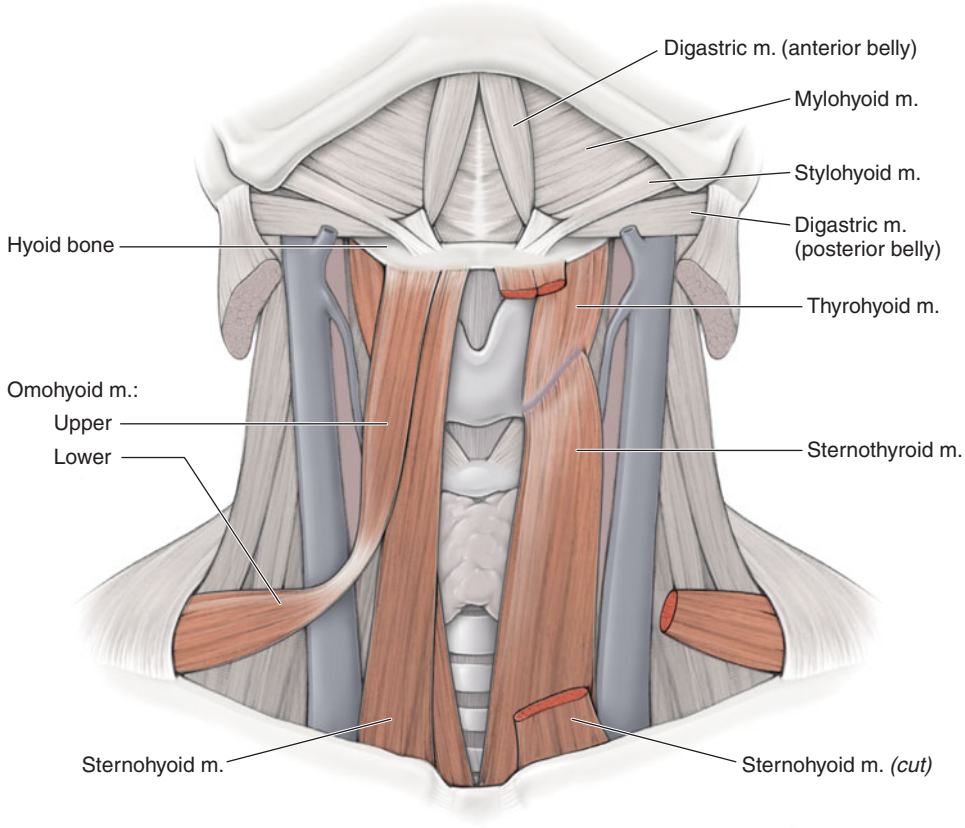

FIGURE 26-5 The infrahyoid muscles. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

stems from a number of reports concerning patients who have pain in the cervical and craniofacial areas simultaneously.[31,44–47]

In the suboccipital region, a series of dense neural connections, called the *trigeminocervical complex,* exists among trigeminal, facial, glossopharyngeal, and vagus nerves, with those of the upper C1–4 cervical spinal nerves (Fig. 26-7).[14] Postural abnormalities resulting from various acute or chronic etiologies that produce suboccipital compression may, therefore, be responsible for craniofacial pain anywhere in the head, in addition to symptoms of dizziness or nystagmus.[5,14,48]

TMJ-related headaches usually include pain near the TMJ and ear, ear fullness, temporal headaches, and facial pain.[49] The dizziness associated with TMD tends to be of the nonvertiginous variety, with the patient complaining of unsteadiness, giddiness, or lightheadedness.[50] Although the exact mechanism is unclear, postural influences, alteration in the position of the jaw by the malocclusion, and the subsequent mismatching between the cervical muscles might be the cause.[50]

BIOMECHANICS

The movements that occur at the TMJ are extremely complex. The TMJ has three degrees of freedom, with each of the degrees of freedom being associated with a separate axis of rotation.[51] Two primary arthrokinematic movements (rotation and anterior translation) occur at this joint around three planes: sagittal, horizontal, and frontal.

Rotation occurs from the beginning to the midrange of movement. In addition to the rotational motions during mouth opening and closing and lateral deviations, movements at the TMJ involve arthrokinematic rolls and slides. Gliding, translation, or sliding movements occur in the upper cavity, whereas rotation or hinged movement occurs in the lower cavity. The motions of protrusion and retrusion are planar glides. Thus,

- mouth opening, contralateral deviation, and protrusion all involve an anterior osteokinematic rotation of the mandible and an anterior, inferior, and lateral glide of the mandibular head and disk;
- mouth closing, ipsilateral deviation, and retrusion all involve a posterior osteokinematic rotation of the mandible and an anterior, inferior, and lateral glide of the mandibular head and disk.

Occlusal Position

Occlusal positions are functional positions of the TMJ. The occlusal position is defined as the point at which contact between some or all of the teeth occurs. Under normal circumstances, the upper molars rest directly on the lower molars and the upper incisors slightly override the lower incisors. The ideal position provides mutual protection of the

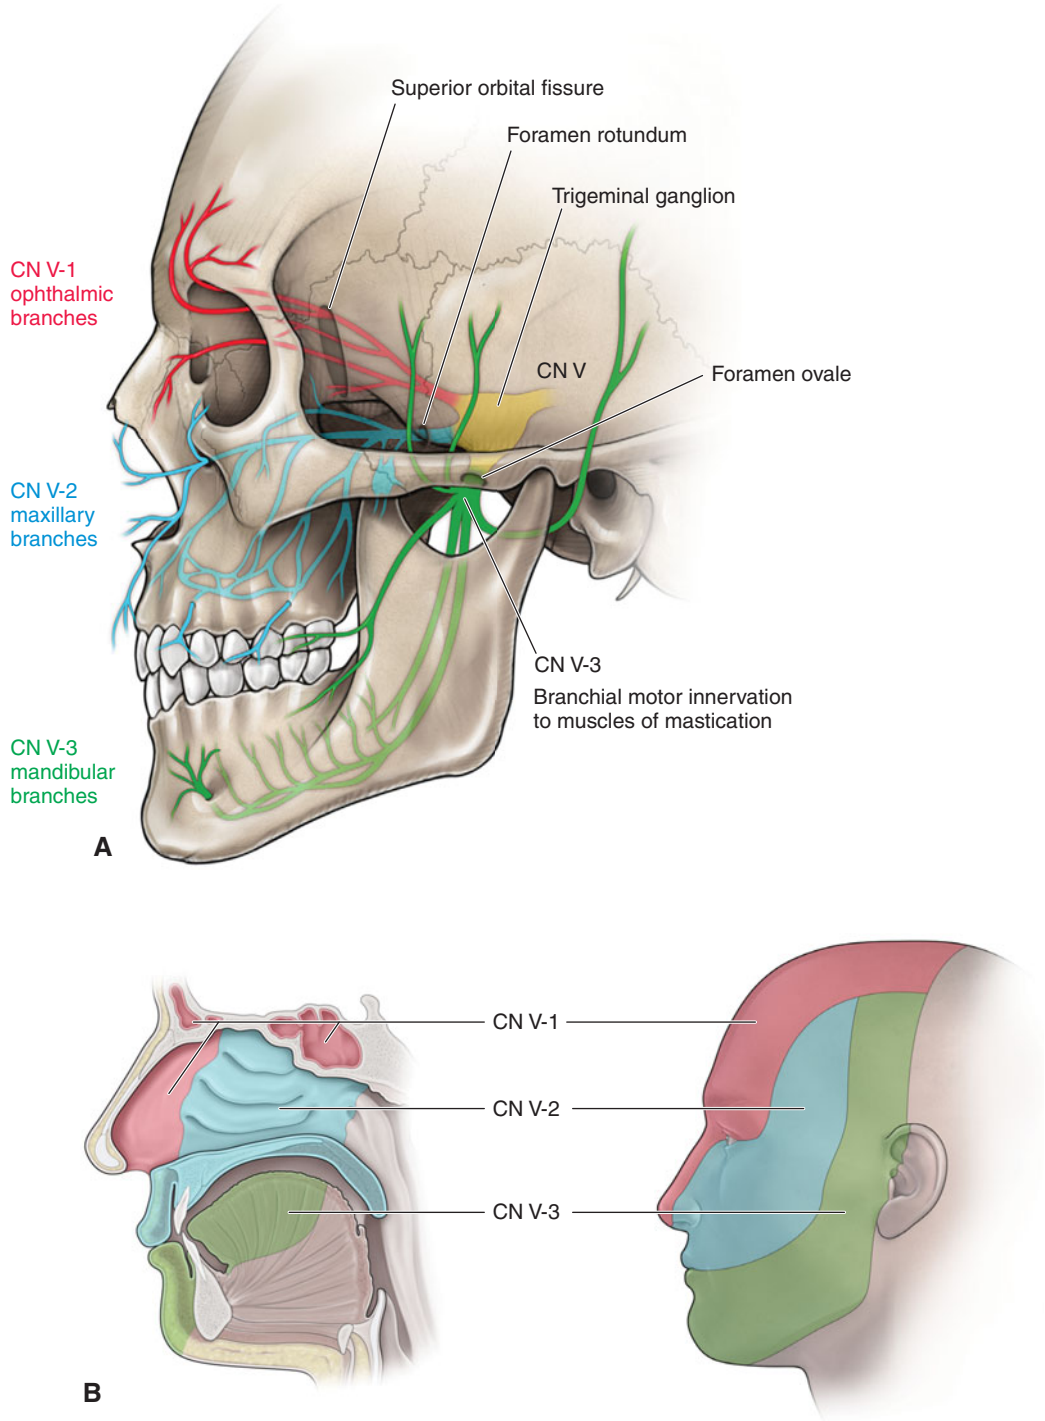

FIGURE 26-6 The trigeminal nerve. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

anterior and posterior teeth, comfortable and painless mandibular function, and stability.[14]

- The median occlusal position corresponds to the position in which all of the teeth are fully interdigitated[18] and is considered the start position for all mandibular motions. The median occlusal position is dependent on the presence, shape, and position of the teeth. Protrusion of the upper or lower incisors, failure of the upper incisors to overlap with the lower incisors, absent or abnormally shaped teeth, and back teeth that do not meet are all causes of malocclusion.
- The centric position is considered to be the position that implies the most retruded, unstrained position of the mandible from which lateral movements are possible and the components of the oral apparatus are the most balanced.[52] Ideally, the centric position should coincide with the median occlusal position.[52] It is worth remembering that malocclusion is probably very common in the general nonsymptomatic patient and may or may not be relevant to the presenting symptoms.[53] Rather than being a primary etiologic factor in TMD, malocclusion is likely to have a secondary or contributory role.[14,54]

Box 26-1 Characteristics of the Trigeminal Nerve

Motor Nucleus

The anterolateral upper pons.

Sensory Nucleus

There are two nuclei: (1) the chief sensory nucleus in the posterior (dorsal)–lateral pons and (2) the mesencephalic nucleus, which extends from the chief sensory nucleus upward through the pons to the midbrain.

Spinal Nucleus

The spinal tract consists of small- and medium-sized myelinated nerve fibers and runs caudally to reach the upper cervical segments of the spinal cord. The lowest nerve fibers in the tract mix with the spinal fibers in the tract orf Lissauer.

Nerves

- Mandibular
- Ophthalmic
- Maxillary

Termination

- Muscles of mastication, both pterygoids, tensor veli palatini, tensor tympani, mylohyoid, and anterior belly of digastric.
- Skin of vertex, temporal area, forehead, and face; mucosa of sinuses, nose, pharynx, anterior two-thirds of tongue, and oral cavity.
- Lacrimal, parotid, and lingual glands; dura of anterior and middle cranial fossae.
- External aspect of tympanic membrane and external auditory meatus, TMJ, and teeth.
- Dilator pupillae and probably proprioceptors of extraocular muscles.
- Sensation from upper three or four cervical levels.

Mouth Opening

Mouth opening occurs in a series of steps (Table 26-3). In the erect position, the condyles begin to rotate anteriorly and translate inferiorly and laterally during the first 25 degrees of opening as the jaw opens. The upper head of the lateral pterygoid muscle and the anterior head of the digastric muscle draw the disk anteriorly and prepare for condylar rotation during movement.[31] This initial condylar rotation occurs as the mandibular elevators (masseter, temporalis, and medial pterygoid muscles) gradually relax and lengthen, allowing gravity to depress the mandible (see Fig. 26-8).[31] The directions of the fibers of the lateral and medial temporomandibular ligaments also keep the condyle from moving posteriorly. The fibrous capsule and parts of the temporomandibular ligament limit excessive lateral movement of the condyle. The rotation occurs through the two condylar heads between the articular disk and the condyle. As the mandible moves forward on opening, the disks move medially and posteriorly until the collateral ligaments and the lateral pterygoid stop their movement. During the last 15 degrees of opening, the rotation ceases due to tightening of the collateral ligaments, and is replaced by an anterior translation of the condyles (see Fig. 26-8).[55] During this translation, the condyle and disk move together. The anterior translation, which is produced mainly by muscle contraction, serves to prevent mandibular encroachment of the anterior neck structures. Opening is also assisted by the other suprahyoid muscles.[31] In extremely wide opening, such as that occurs with yawning, the functional joint contact is on the distal aspect of the condyle, and the anterior lateral aspect of the condyle contacts the posterior part of the masseter muscle. In this position, the soft tissue structures are in a position of stretch, making them more prone to dysfunction.[56]

Mouth Closing

Closing of the mouth involves a reversal of the movements described for mouth opening. The condyles translate posteriorly as a result of an interaction between the retracting portions of the masseter and temporalis muscle and the retracting portions of the mandibular depressors (see Fig. 26-8).[51] As the condyles translate posteriorly and glide medially, they hinge on the disks. The disks then glide posteriorly and superiorly on the temporal bone along with the condyles (as a result of the actions of the masseter, medial pterygoid, and temporalis muscles).[41] When the jaws are closed to maximal occlusal contact, the condyles contact the disks and the disks contact the posterior slopes of the articular tubercles and the glenoid fossae.

Protrusion

Protrusion is a forward movement of the mandible that occurs at the superior joint compartments, which consists of the disk and condyle moving downward, forward, and laterally. The muscles responsible for protrusion are the anterior fiber of the temporalis and the medial and lateral pterygoid muscles.

Retrusion

Retrusion is a backward movement of the mandible, produced by the posterior fiber of the temporalis and assisted by the suprahyoid muscles. The retrusive range is limited by the extensibility of the temporomandibular ligaments.[57]

Lateral Excursion

If a protrusion movement occurs unilaterally, it is called a *lateral excursion, or deviation.* For example, if only the left TMJ protrudes, the jaw deviates to the right.

Lateral movements of the mandible are the result of asymmetric muscle contractions (Fig. 26-9). During lateral excursion to the right, the condyle and the disk on the left side glide inferiorly, anteriorly, and laterally in the sagittal plane and medially in the horizontal plane along the articular eminence. The condyle and the disk on the right side rotate laterally on a sagittal plane and translate medially in the horizontal plane, while remaining in the fossa.

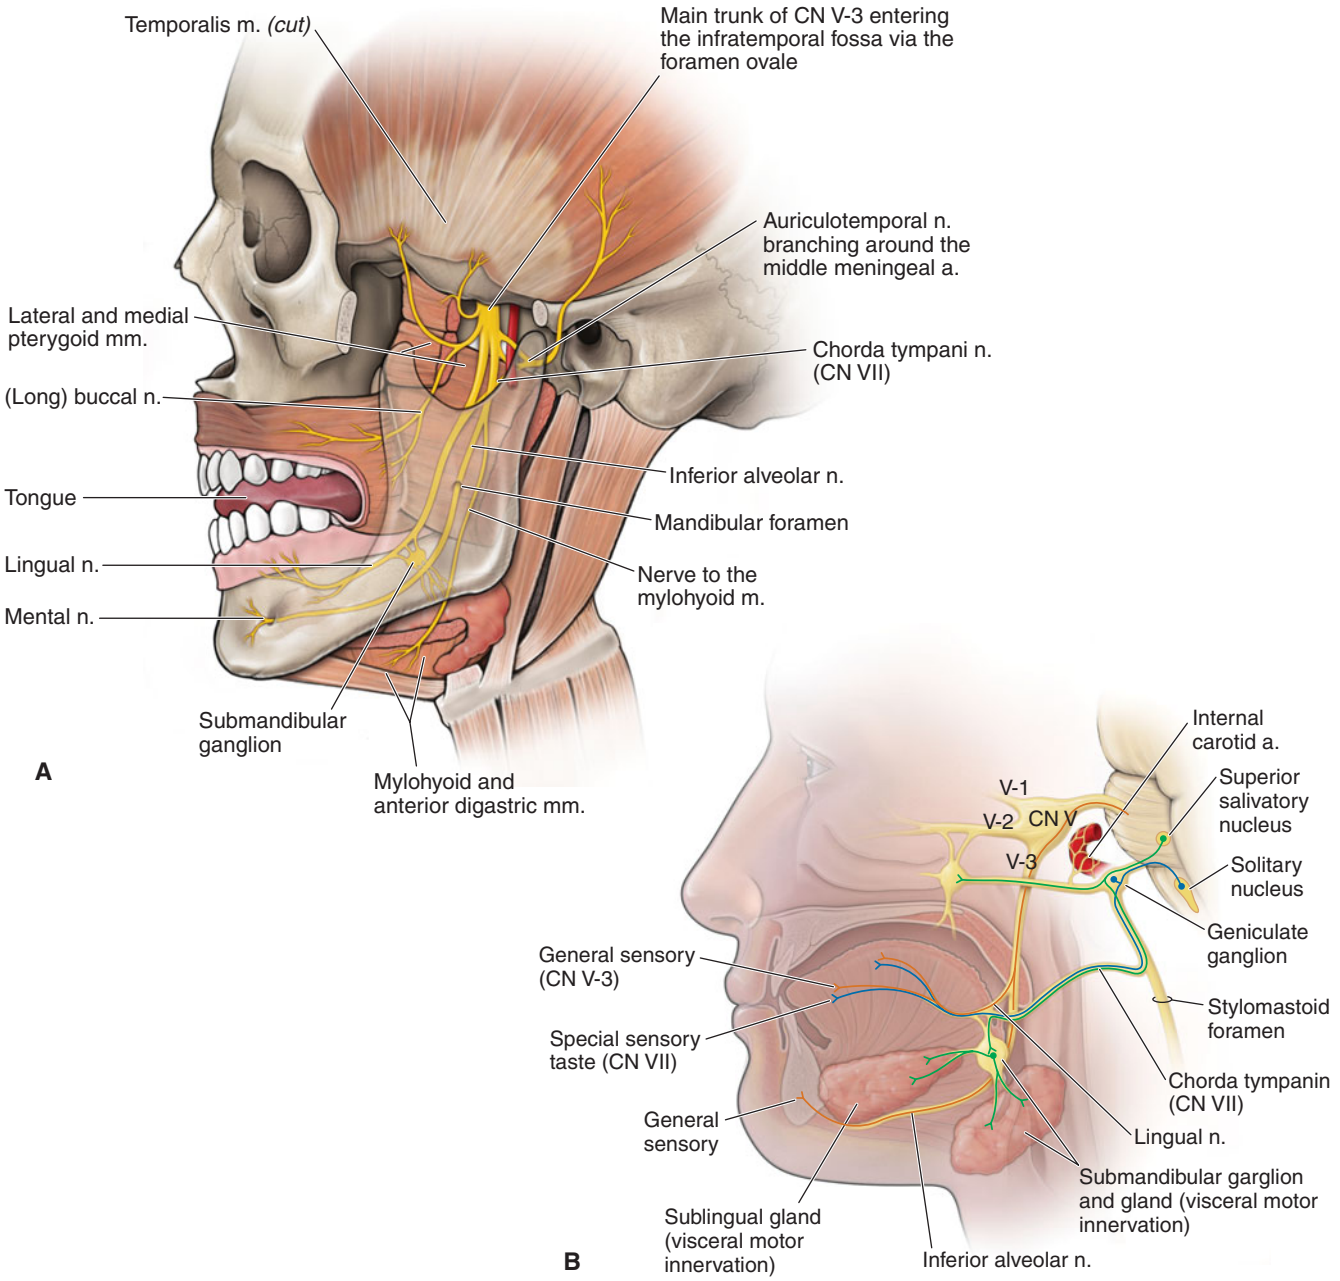

FIGURE 26-7 Neurology of the TMJ. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

CLINICAL PEARL

The translation of the human condyle during jaw opening and lateral jaw movements is referred to as the *Bennett shift.*

The Close- and Open-Packed (Resting) Positions

The close-packed position of the TMJ is difficult to determine because the position of maximal muscle tightness is also the position of least joint surface congruity and vice versa. Rocabado[50] considers there to be two close-packed positions, named according to the end position of the mandibular head in the fossa:[55]

- ***Anterior close-packed position.*** This position is the position of maximum opening of the joint.
- ***Posterior close-packed position.*** This position is the maximum retruded position of the joint.

Under this premise, the open-packed, or "rest" position is any position away from the anterior or posterior close-packed positions of the joint.[55] The rest position, or "freeway space" corresponds to the position of the TMJ where the residual tension of the muscles is at rest and no contact occurs between maxillary and mandibular teeth. In this position, the tongue is against the palate of the mouth with its most anterior–superior tip in the area against the palate, just posterior to the rear of the upper central incisors.[58]

TABLE 26-3 Arthrokinematic Steps of the Temporomandibular Joint

Step	Movement
Rest position	Joint is in an open-packed position.
Rotation	There is a mid-opening. Condylar joint surfaces glide forward, inferior joint surface of disk has a relative posterior glide, upper lateral pterygoid relaxes, inferior pterygoid contracts, and posterior connective tissue is in a functional state of rest.
Functional opening	Disk and condyle experience a short anterior translatory glide; superior and inferior heads of lateral pterygoid contract to guide disk and condyle forward. Posterior connective tissue is in a functional tightening.
Translation	There is full opening. Disk and condyle glide anteriorly and caudally. Superior and inferior heads of lateral pterygoid contract to guide disk and condyle fully forward. Posterior connective tissues tighten.
Closure	Surface of condyle joint glides posteriorly, and disk glides relative to anterior surface. Superior head of lateral pterygoid contracts and inferior head relaxes. Posterior connective tissue returns to its functional length.

Data from Rocabado M: Arthrokinematics of the temporomandibular joint. In: Gelb H, ed. *Clinical Management of Head, Neck and TMJ Pain and Dysfunction.* Philadelphia, PA: WB Saunders, 1985.

Capsular Pattern

The capsular pattern of the TMJ is limitation of mouth opening. If one joint is more involved than the other, the jaw will laterally deviate to the same side during opening.

CLINICAL PEARL

The significance of the rest position is that it permits the tissues of the stomatognathic system to rest and undergo repair.[59]

EXAMINATION

Currently, clinical examination is the gold standard for diagnosing TMDs. Given the multifactorial causes of TMD, a comprehensive examination of the entire upper quadrant, including the cervical spine and shoulders, usually is warranted. In general, the TMJ and the upper three cervical joints all refer symptoms to the head, whereas the mid-to-low cervical spine typically refers symptoms to the shoulder and the arm.[60–62] An accurate diagnosis of TMD involves a careful evaluation of the information gleaned from the history, systems review, and tests and measures. In most chronic cases, a behavioral or psychological examination is required.[2,30,62–67] Since postural dysfunctions are closely related to TMJ symptoms, the clinician should always perform a postural examination as part of a comprehensive examination of this joint. An examination form for the TMJ examination is shown in Table 26-4.

History

During the history, the clinician should observe the patient's mouth to see whether the mouth moves comfortably while speaking, or whether mouth movements appear guarded.

The clinician should determine from the patient the main reason for the visit. There are three cardinal features of TMDs, which can be local or remote:

1. ***Restricted jaw function.*** Limited mouth opening, which may be reported as intermittent or progressive, is a key feature of TMD. Patients may describe a generalized tight feeling, which may indicate a muscular disorder, or capsulitis, or the sensation that the jaw suddenly "catches" or "locks," which usually is related to a mechanical interference within the joint (an internal derangement).[12] Associated signs of an internal derangement include pain and deviation of mandibular movements during opening and closing (refer to Practice Pattern 4D, under "Intervention Strategies" section later), and biting firm objects. Pain in the fully open position is probably caused by an extra-articular problem. Locking may imply that the mouth does not fully open or does not fully close and is often related to problems of the disk or joint degeneration.
2. ***Joint noises.*** Joint noises (crepitus) of the TMJ may or may not be significant, because joint sounds occur in approximately 50% of healthy populations.[68] Some joint sounds are not audible to the clinician, so a stethoscope may be required. "Hard" crepitus is a diffuse sustained noise that occurs during a significant portion of the opening or closing cycle, or both, and is an evidence of a change in osseous contour.[56] Clicking describes a brief noise that occurs at some point during opening, closing, or both (see the discussion of range of motion testing, later). Jaw clicking during mouth opening or closing may be suggestive of an internal derangement consisting of an anterior disk displacement with reduction.[69,70]

CLINICAL PEARL

TMJ sounds should be related to symptoms, as joint noise in of itself, is of little clinical importance in the absence of pain.[64,71]

3. ***Orofacial pain.*** Approximately 50% of all cases of TMD are masticatory myalgias.[72] TMJ pain should be evaluated carefully in terms of its onset, nature, intensity, site,

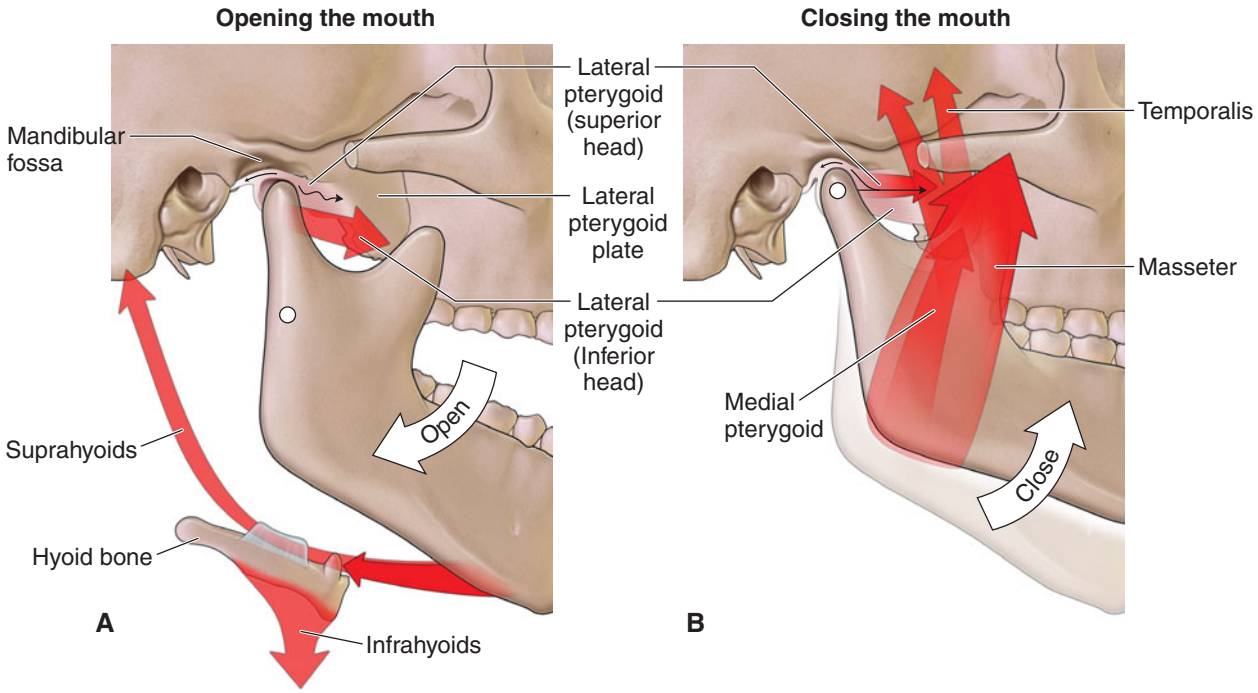

FIGURE 26-8 Mouth opening and closing.

duration, aggravating and relieving factors, and how it relates to joint noise and restricted mandibular movements.[12] Orofacial pain associated with mouth opening or closing, and jaw crepitus is suggestive of osteoarthrosis, capsulitis, or internal derangement consisting of an anterior disk displacement with reduction.[69,70,73–76] In a study by Magnusson and colleagues,[77] five different scales of self-assessment of pain were tested in patients with TMJ disorders. The precision and sensitivity and the capacity to register memory of pain and discomfort were compared for each of the five scales (Table 26-5). From these results, the behavior rating scale can be recommended when measuring pain and discomfort in patients with TMJ disorders.

CLINICAL PEARL

Pain that is centered immediately in front of the tragus of the ear and that projects to the ear, temple, cheek, and along the mandible is highly diagnostic for TMD.[78]

A gradual onset of symptoms after minor or prolonged physical activity may be indicative of a mechanical derangement.[79] Symptoms of a mechanical nature generally are eased with rest. The irritability of a disorder is determined by the degree of activity necessary to provoke a symptom response.

TABLE 26-5 Patient Reports of Pain in TMJ Disorders

Data from Magnusson T, List T, Helkimo M: Self-assessment of pain and discomfort in patients with temporomandibular disorders: A comparison of five different scales with respect to their precision and sensitivity as well as their capacity to register memory of pain and discomfort. *J Oral Rehabil* 22:549–556, 1995; Cleland J: *Temporomandibular Joint, Orthopaedic Clinical Examination: An Evidence-Based Approach for Physical Therapists.* Carlstadt, NJ: Icon Learning Systems, LLC, 2005:39–89. With permission from Icon Learning Systems.

The severity of the symptoms and the time before the symptoms subside provide the clinician with valuable information regarding possible pathology.[80] Specific questions about activities and postures of a sustained nature, such as sitting, sleeping, and driving, should be asked.[81] It is important to determine:

- If the presenting symptoms were caused by trauma or surgery, or if the onset of pain occurred gradually. Questions should focus on any history of trauma during birth or childhood, as well as more recently.
- If there are any emotional factors in the patient's background that may provoke habitual protrusion or muscular tension.
- If the patient is aware of any parafunctional habits (cheek biting, nail biting, pencil chewing, teeth clenching, or bruxism). For example, does the patient chew on one side more than the other? Chewing more on one side versus the other is typically the result of malocclusion (see later). In addition, favoring one side can lead to a loss of vertical dimension (the distance between any two arbitrary points on the face). A simple way to measure the aforementioned is to measure from the lateral edge of the eye to the corner of the mouth and from the base of the nose to the chin.
- The behavior of symptoms over a 24-hour period. This information assists the clinician in formulating causal relationships.
- Whether the symptoms are improving or worsening.
- The relationship of eating to the symptoms. Alcohol, chocolate, and other foods such as ice cream can cause head pain in some individuals, suggesting a vasomotor-related pain.
- The patient's past dental and orthodontic history.
- Whether the patient has experienced any locking, clicking, or catching of the jaw.[48]

Chronic head, neck, and back pain often are associated with psychogenic causes. Psychiatric disorders, usually, are manifested in patients whose afflictions seem to be excessive or persist beyond what would be normal for that condition. The checklist outlined in Table 26-6 can be used by the clinician to identify factors that may warrant an examination by a mental health professional.

Systems Review

Clinicians often see patients with a TMD who present with nonspecific symptoms such as neck pain, headaches, earaches, and tinnitus. However, because these symptoms are not considered specific for TMDs, other possible causes should be sought and ruled out during the systems review.[82–84] Pain or dysfunction in the orofacial region often results from nonmusculoskeletal causes such as otolaryngologic, neurologic, vascular, neoplastic, psychogenic, and infectious diseases.

Unexplained weight loss, ataxia, weakness, fever with pain, nystagmus, and neurologic deficits are characteristic of intracranial disorders.[85] Neurovascular disorders are associated with migraine headache and its variants, carotidynia, and cluster headaches (see Chap. 5). Neuropathic disorders include trigeminal neuralgia, glossopharyngeal neuralgia, and occipital neuralgia.

TABLE 26-6 Checklist of Psychological and Behavioral Factors

Inconsistent, inappropriate, or vague reports of pain
Overdramatization of symptoms
Symptoms that vary with life events
Significant pain of >6 months' duration
Repeated failures with conventional therapies
Inconsistent response to medications
History of other stress-related disorders
Major life events (e.g., new job, marriage, divorce, and death)
Evidence of drug abuse
Clinically significant anxiety or depression
Evidence of secondary gain

Note: The significance of these factors depends on the particular patient. Data from McNeill C, Mohl ND, Rugh JD, et al.: Temporomandibular disorders: Diagnosis, management, education, and research. *J Am Dent Assoc* 120:253–260, 1990.

The seriousness of head, face, mouth, and neck disorders that are detectable by a careful history and physical examination runs the gamut from a trivial (though discomforting) viral upper respiratory tract infection to a malignant tumor.[86]

Once the possibility of cervical, systemic, psychogenic, or ear or sinus problems has been ruled out, the next step is to consider the possibility of TMJ pain and impairment, particularly if the pain is accompanied by jaw clicking and limited mouth opening.[87]

Tests and Measures

In a study by Lobbezoo-Scholte and colleagues,[88] the interexaminer reliability of six orthopaedic tests for the TMJ (palpation, active motions, joint compression and distraction, joint mobility testing, detection of joint sounds, and resistive tests) was determined in a group of 79 patients with signs and/or symptoms of craniomandibular disorders (CMD), subdivided into three subgroups of patients with a mainly arthrogenous, and a combination of myogenous and arthrogenous disorders. Multi-test scores were composed for each test and combinations of tests for the three main symptoms of CMD: pain, joint noises, and restriction of movement. Although the orthopaedic tests showed different reliability scores, overall reliability of the determination of these three main symptoms of CMD was satisfactory. In the subgroups, arthrogenous signs and symptoms could be determined reliably with the set of six tests, whereas the reliability of the tests in determining pain and joint noises in the myogenous group was rather low. It may be concluded that these tests are well suited to evaluate arthrogenous signs and symptoms, but that the clinician should be aware of erroneous results of the tests in evaluating pain of a myogenous origin.

In another study by Dworkin and colleagues,[89] the interexaminer reliability was found to be excellent for vertical range of motion measures and for summary indices measuring the overall presence of a clinical sign that could arise from several sources (for example, summary indices of muscle palpation and pain). However, many clinical signs important in the differential diagnosis of subtypes of TMD were not measured with high reliability. In particular, assessment of pain in response to muscle palpation and identification of specific TMJ sounds seemed to be possible only with modest, sometimes marginal, reliability.

Observation

The posture of the head and neck are assessed for asymmetry. The forward head posture (FHP–see Chaps. 6 and 25) frequently is associated with TMD.[33,90,91] This is likely because of the direct impact a FHP can have on oral symmetry during occlusion. Occlusion occurs when the teeth are in contact and the mouth is closed—when tapping the teeth together in the neutral position, all of the teeth appear to strike simultaneously. However, if the same task is attempted while placing the head forward, it is the anterior teeth that occlude first. A deviation from normal occlusion is defined as malocclusion—improper positioning of the teeth and jaws. Malocclusion is a variation of normal growth and development which can affect the bite, the ability to clean teeth properly, gum tissue health, jaw growth, speech development and appearance. The consequences of this repetitive functional malocclusion during food or gum chewing should be apparent. A chronic FHP may result in an adaptive shortening of the deep cervical fascia and muscles, which can exaggerate the functional malocclusion. Most people have some degree of malocclusion, although it is not usually serious enough to require treatment. Malocclusions can be divided mainly into three types, depending on the sagittal relations of teeth and jaws, by Angle's classification method, which is based on the relative position of the first maxillary molar:[92]

- Class I (Neutrocclusion): The molar relationship of the occlusion, but the other teeth have problems such as spacing, crowding, and over or under eruption.
- Class II (Distocclusion): The upper molars are placed anteriorly. There are two subtypes:
  - Class II Division 1 (large overjet): The molar relationships are like that of Class II and the anterior teeth are protruded.
  - Class II Division 2 (deep overbite): The molar relationships are like that of class II but there is lateral flaring of the lateral maxillary incisors.
- Class III (Mesiocclusions): The lower front teeth are more prominent than the upper front teeth. In this case the patient very often has a large mandible or a short maxillary bone.

The clinician should also note whether the teeth are normally aligned or whether there is any crossbite, underbite, or overbite.

- Crossbite: This occurs when the teeth of the mandible are lateral to the upper maxillary teeth on one side and medial on the opposite side. An anterior crossbite occurs when the lower incisors are anterior to the upper incisors, whereas a posterior crossbite occurs when there is a transverse abnormal relationship of the teeth.
- Underbite: This occurs when the mandibular teeth are anterior to the maxillary teeth either unilaterally, bilaterally, or in pairs.
- Overbite: This occurs when the anterior maxillary incisors extend below the anterior mandibular incisors when the jaw is in central occlusion.

CLINICAL PEARL

Overjet, not to be confused with overbite, is a measure of how far the top incisor teeth are ahead of the bottom incisors. Normally, the top and bottom front teeth should be touching upon closure leaving no or zero overjet. If the top teeth are ahead by some distance, this is referred to as positive overjet. If the top teeth are behind the bottom teeth, this is referred to as negative overjet, or underjet.

The face is also assessed for asymmetry, such as swelling or flattening of the cheek. Asymmetry is an important finding, because developmentally the facial structures evolve in a proportional relationship, some determined by genetics, others in response to the physical environment.[93]

Orthognathy relates to the amount of projection of the lower face in relation to an imaginary perpendicular line from the eyes when viewed from the side. Three types of facial profile are recognized:

- Orthognathic: A straight facial profile in which the upper and lower lips are in line with the tip of the chin.
- Retrognathic: Describes a facial profile in which the tip of the chin is posterior to the upper and lower lips.
- Prognathic: Describes a facial profile in which the tip of the chin is anterior to the upper and lower lips.

In addition, the clinician should note the presence of any abnormal jaw deviation, unusual dryness of the lips, changes in eye position, and signs of tissue stress such as overdeveloped masseter and mentalis muscles, or a hypertrophied lower lip.[31] A lateral deviation of the jaw, evidenced by a malalignment or malocclusion of the upper and lower teeth, or hypertonus of one of the masseter muscles, may cause an adaptive shortening of the mastication muscles on the ipsilateral side of the deviation, and a lengthening of the muscles on the contralateral side. Since the role that malocclusion plays in TMD remains unclear, the relevance of the malalignment to the patient's symptoms must be determined by passively attempting to correct the deformity.[53,57] An increase in pain with the correction suggests the presence of a protective deformity.

The teeth should be examined for symmetry. Cavities, wear patterns, and restored and missing teeth should be noted. Defects in dimensions can be measured radiographically.[94] The vertical dimension of dental occlusion (i.e., depth of bite) has been implicated as a possible craniomandibular component associated with TMD.[36] It has been proposed that a deep dental overbite may have pathologic effects on cranial nerve V, the tensor veli palatini, and the soft tissue surrounding the TMJ.[36,95] Seldin[96] and Sicher[97] proposed that a deep bite results in a displaced condyle, which causes inflammation and muscle spasm in the retrodiscal tissue and muscles surrounding the TMJ. Tooth wear and fracture are often destructive signs of parafunctional habits (abrasive diet, bruxism, and teeth clenching). Loss of teeth can cause disruption in the working and nonworking interfaces of the teeth, which may cause unilateral function and subsequent overloading of the remaining teeth and the TMJ.[14] The clinician should also ask the patient if there are any painful or sensitive teeth, which can lead to incorrect biting, and subsequent abnormal loading of the TMJs.

The tongue should be examined. The tongue should appear dull red, moist, and glistening. Its anterior portion should have a smooth yet roughened appearance.[86] The posterior portion should have a smooth, slightly uneven appearance.

- A hairy tongue with yellow–brown to black elongated papillae on the posterior surface sometimes follows antibiotic therapy.[86]
- A dry or white tongue may indicate a salivary gland dysfunction or an oral yeast or bacterial infection respectively.[86]

The tongue should be observed while the patient swallows to check for any deviations. The tongue is tested for frenulum length. A short frenulum may interfere with tongue function. The tongue should have no difficulty in touching the hard palate behind the upper incisors.[52] A large tongue can exert excessive pressure against the teeth and may interfere with occlusion, resulting in bite marks.

The rest position of the TMJ should be noted. The clinician can locate the rest position of the TMJ by gently placing the little finger with the palmar portion facing anteriorly into the external auditory meatus. From an open-mouth position, the patient is asked to slowly close the mouth. At the point of resting position, the patient's mandibular heads are felt to gently touch the finger. The space between the upper and lower incisors should be 2–4 mm. A greater distance may indicate hypermobility of both TMJs.

Range of Motion

The range of motion of the TMJ, the cervical spine, the craniovertebral joints, and the shoulders should be assessed with active range of motion (AROM), and then with passive overpressure, to assess the end-feel. During cervical flexion, the mandible moves superiorly and anteriorly, whereas during cervical extension, the mandible moves inferiorly and posteriorly. The patient should be able to open and close the mouth while keeping a fist in place under the chin. During side bending or rotation of the cervical spine, maximum occlusion occurs on the ipsilateral side. Although it is unclear how the individual components of the examination contribute to the final diagnosis, most clinicians would agree that substantially reduced mandibular motion is a strong indicator of the presence of a serious TMD and helps to distinguish TMD patients from non-TMD controls.[98,99] However, there is little evidence to suggest that mandibular motion measurements add critical information to the process of differential diagnosis among the common TMD subgroups.[98]

The clinician observes the opening and closing of the mouth, noting both the range and the quality of movement. All movements of the TMJ should be smooth and without noise or pain. Normally, the mandible should open and close in a straight line. To help detect crepitus, the clinician can palpate over the mandible heads during opening and closing (Fig. 26-10). If crepitus or clicking occurs on opening and/or closing, the clinician notes where they occur in the range. If pain occurs, a determination should be made as to where in the range the pain occurs, and the location of the pain. A Boley gauge, T-bar, or ruler, can be used to measure the range of the TMJ in millimeters.[93] Walker et al.[100] used a prospective descriptive study to determine the discriminant validity and intra- and interrater reliability of measurements of TMJ range of motion using a ruler. Two groups of subjects were tested: 15 subjects (two men, 13 women; mean age = 35.2 years) with a TMD and 15 subjects (three men, 12 women; mean age = 42.9 years) without a TMD. Six motions were measured (opening, left lateral deviation, right lateral deviation, protrusion, overbite, and overjet) by two physical therapists. The study concluded that mouth opening was the only TMJ ROM measurement to discriminate between subjects with and without a TMD (mean 36.2 ± 6.4 versus 43.5 ± 6.1 mm). The technical error of measurement of the measures varied from 0.2–2.5 mm. Intrarater reliability coefficients (ICC 3, 1) varied from 0.70 to 0.99. Interrater reliability coefficients (ICC 2, k) varied from 0.90 to 1.0.

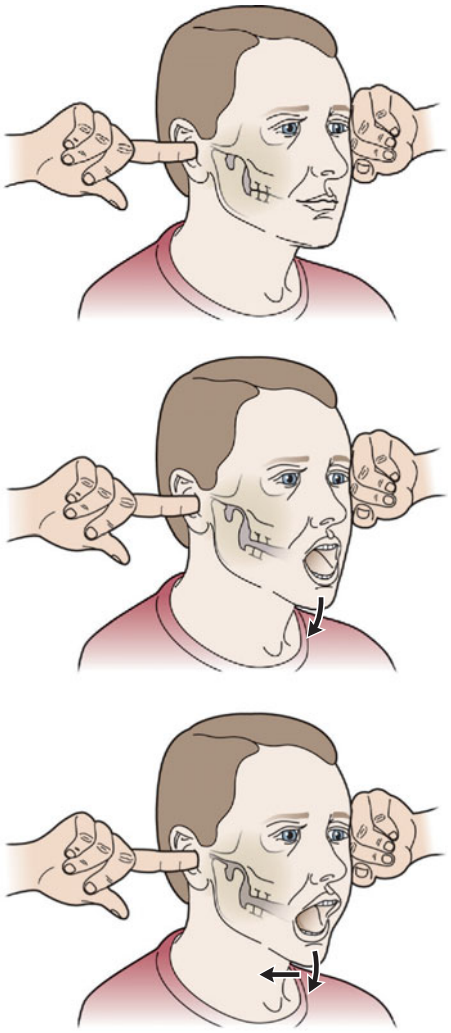

FIGURE 26-10 Palpation of TMJ during mouth opening and deviation.

CLINICAL PEARL

Joint clicking can be a normal occurrence or it may be caused by one of the types of internal derangement (refer to Practice Pattern 4D, later) including disk displacements, adhesive disk hypomobility, and deviation in form (articular surface damage). Clicking may also be a result of hypermobility or muscle incoordination.[101]

The type and temporal sequence of joint clicking can provide the clinician with the following information:

1. Reciprocal clicking is defined as clicking that occurs during opening and again during closing. The opening click occurs when the condyle moves under the posterior band of the disk until it snaps into its normal relationship on the concave surface of the disk, whereas the closing click reflects the reversal of this process.[102] Reciprocal clicks may be early, intermediate, or late, depending on the degree of opening at which they occur.[55]
   a. Early clicking usually indicates a small anterior displacement.
   b. Late clicking usually indicates that the disk has been further displaced.

Reciprocal clicking is a common finding in patients with a posterosuperior condylar positioning.[31]

2. Clicking that occurs at the end of opening often results from articular hypermobility and is accompanied by a deviation of the jaw toward the contralateral side.
3. The "soft" and "popping" opening and closing clicks associated with muscular incoordination are usually intermittent and inconsistent. They are thought to be caused by ligament movement or articular surface separation. Muscle tenderness to palpation is a frequently associated symptom.

Elevation of the Mandible (Mouth Closing)

The primary muscles involved with mouth closing are the masseter, the temporalis, and the medial pterygoid.[52] Since the maxillary teeth are fixed, the upper midline of the incisors can be used as a landmark to assess lower jaw deviation during mouth closing. Under normal conditions, the midline relationship between the upper and lower incisors should remain constant in the closed and open positions. Overpressure can be applied to the mouth closing by placing the fingers under the chin and pushing superiorly in a controlled fashion (Fig. 26-11). The normal end-feel for mouth closing should be bone on bone (teeth contact).

Depression of the Mandible (Mouth Opening)

The opening of the mouth is considered the most revealing and diagnostic movement for TMD.

While approximately only 25–35 mm of mouth opening measured between the maxillary and mandibular incisors is required for everyday activities, the maximum range of motion is approximately 50 mm.[78] At this extreme, the periarticular structures are stretched to 100% of their total length. The functional range of motion is considered to be closer to 40 mm, or approximately a two-to-three-knuckle width of the nondominant hand[12,55,103] (see Fig. 26-12). At this point in the range, the periarticular structures are stretched to 70–80% of their total length. Excessive opening is indicated when the patient is able to insert three or more knuckles between the incisors. Excessive opening is associated with large anterior translatory movements at the beginning of

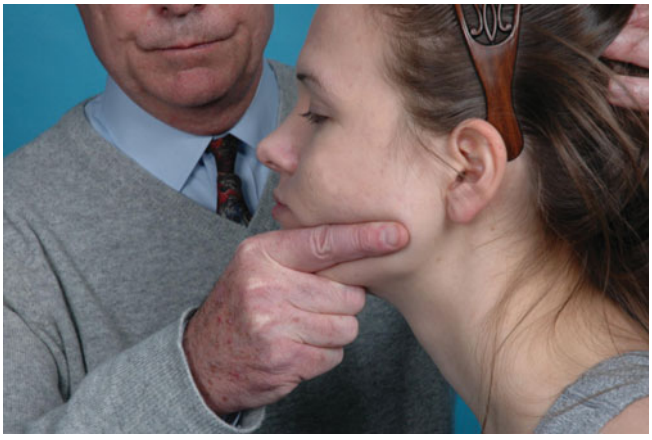

FIGURE 26-11 Mouth closing with overpressure.

FIGURE 26-12 Three-knuckle width of mouth opening.

FIGURE 26-13 Mouth opening with overpressure.

mouth opening, accompanied by excessive protrusive movements of the mandible.[55]

If deviation occurs to the left on opening (a C-type curve) or to the right (a reverse C-type curve), hypomobility is evident toward the side of the deviation. If during mouth opening, an S-type or reverse S-type curve is noted, the problem is probably a muscular imbalance or medial displacement of the disk. Reduced mouth opening can result from a number of disorders including chronic muscle contraction, ankylosis, acute disk displacement without reduction, and severe trismus of the jaw muscles (the limitation of jaw opening caused by spasm of the masticatory muscles) and gross osteoarthritis.[82] Muscle contractures and ankylosis tend to develop after a substantial trauma or are developmental disorders occurring early in life and are not often misdiagnosed.[82] If contracture of the masticatory muscles is present, the mandibular opening can be as limited as 10–20 mm between the incisors.[104] Acute disk displacement without reduction and trismus are difficult to distinguish because both conditions present with recent onset, and painful limitation of jaw opening.[98] To be certain of the anatomic basis of acute disk displacement without reduction, most clinicians feel that joint imaging with magnetic resonance of the disk is required.[70,98,105] A limited opening of the jaw may also indicate joint hypomobility, muscle tightness, or the presence of trigger points within the elevator muscles: the temporalis, the masseter, and the medial pterygoid.

Translation of the lateral pole of the condyle should occur after 11 mm of mouth opening. If an opening deviation occurs, it is important to note where in the opening cycle it occurs. Opening and closing deviations are observed simply by taking a small ruler or tongue depressor and laying the edge down the midline of the face.[56] While the clinician "eyes" the straight edge, the patient opens and closes the mouth slowly[101]:

- Limited opening with deviation to one side should alert the clinician to an internal derangement without reduction, which limits the translation on the involved side and causes the jaw to deviate toward the less-mobile side, even if that is the normally mobile side and the other side is hypermobile. Early deviation suggests hypomobility, and late deviation indicates hypermobility.
- If hypomobility resulting from internal derangement with reduction of one TMJ is present, the mandible will deviate in a C pattern of motion to that side of the open mouth in the midrange of opening before returning to normal.
- The patient who demonstrates an S movement of the jaw while opening the mouth may have a muscle imbalance (often caused by trigeminal facilitation and masticatory hypertonicity), or it may be a momentary locking of a deranged disk. Lateral excursion of the mandible with mouth opening implicates contralateral structures such as the contralateral disk, the masseter, the medial and lateral pterygoid, or the lateral ligaments.

Overpressure can be applied to the opening movement using a lumbrical grip placed on the patient's chin, under the bottom lip (Fig. 26-13). The overpressure is applied to ensure that the jaw is maximally depressed. The normal end-feel should be tissue stretch. Locking of the jaw can be associated with three types of abnormal end-feel[56]:

- ***Hard.*** This type of end-feel is associated with osseous abnormalities.
- ***Springy.*** This type of end-feel is associated with a displacement of the disk.
- ***Capsular.*** This type of end-feel is associated with adaptive shortening of the periarticular tissues.

Excursion of the Mandible

The superior and inferior incisors are assessed for any deviation of the jaw laterally (cross-bite) or anteroposteriorly (overbite or underbite).

Protrusion of the Mandible. The patient opens the mouth slightly and protrudes the lower jaw. The normal movement of the lower teeth is greater than 7 mm, measured from the resting position to the protruded position.[93] The amount and direction of the protrusion are noted:

- An abnormal protrusive position may be associated with a residual pediatric tongue thrust (deviant swallowing) or an acquired adult tongue thrust secondary to a forward head posture or habitual protrusion.
- Any lateral excursion of the mandible during protrusion may indicate involvement of the contralateral structures, such as the contralateral disk, the masseter, the medial and lateral pterygoid, or the lateral ligaments.

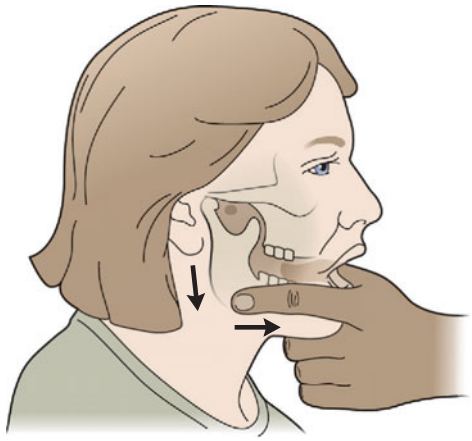

FIGURE 26-14 Manual jaw protrusion.

The clinician can apply overpressure by grasping the patient's mandible with the index and the middle fingers behind the mandibular angles and the thumbs on the patient's cheeks, and then gently pulling the jaw anteriorly (Fig. 26-14).

Retrusion of the Mandible. The patient is asked to retrude the jaw as far back as possible. The normal movement is 3–4 mm.[57] Pain at the end range of retrusion may indicate an intracapsular injury.[6] Overpressure can be applied using a lumbrical grip positioned under the patient's bottom lip and pushing the mandible posteriorly (Fig. 26-15).

Lateral Deviation of the Mandible. The patient opens the mouth slightly and moves the lower jaw to the left and to the right. The right and left motions are compared. Normal range of motion for lateral deviation is approximately one-fourth of the opening range (10–15 mm).[34] Lateral deviation can be measured as the amount of lateral excursion between the center of the mandibular incisors and the center of the maxillary incisors. An appreciable difference between the two sides is more significant than a limited range occurring bilaterally.[31] Passive overpressure can be applied in a lateral direction. Pain reported on the side away from the direction of overpressure may indicate ligamentous or joint capsule damage.[31]

Tongue Movements. Tongue movements give valuable information about the function of the hypoglossal nerve (CN XII). Any deviation or atrophy of the tongue during tongue protrusion may indicate a lesion of this nerve. Unilateral weakness of the tongue is manifested by a deviation of the protruded tongue toward the weaker side. A test for weakness of the tongue is to ask the patient to stick the tongue into the cheek, while the clinician presses against the bulging cheek. A comparison is made between both sides.

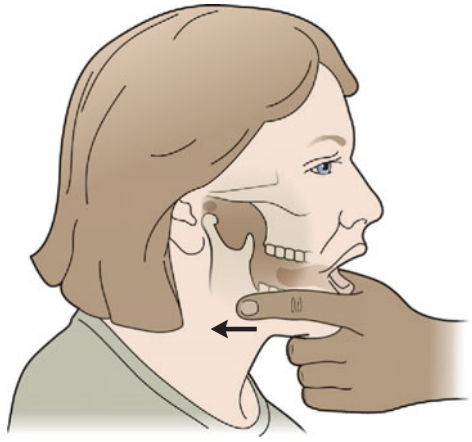

FIGURE 26-15 Manual jaw retrusion.

Palpation

Palpation of the TMJ can be used to assess tenderness, patterns of pain referral, skin temperature, muscle tone, swelling, skin moisture, and the location of trigger points. A study by de Wijer and colleagues[106] found the inter-examiner reliability of the multitest scores for muscle palpation and joint palpation in 79 patients referred to a TMD and orofacial pain department to be moderate (kappa = 0.51) and fair (kappa = 0.33), respectively. In a study by Manfredini and colleagues,[107] 61 patients with TMJ pain were assessed by means of a standardized clinical examination and magnetic resonance imaging (MRI). The aim of this work was to evaluate the predictive value of clinical symptoms for MRI findings of TMJ effusion. The study reported that a clinical examination based on the assessment of pain in the TMJ with lateral palpation, with posterior palpation, during motion, and during maximum-assisted opening, and the presence of click and crepitus sounds demonstrated an accuracy of 78.7% to predict TMJ effusion. Among the single clinical symptoms, the most reliable predictor of TMJ effusion was found to be the presence of pain with lateral palpation (accuracy 76.2%; *kappa* = 0.53).[107]

For comparison and expediency, palpation of the lateral and posterior aspects of the TMJs is performed bilaterally and simultaneously. The palpation begins with gentle touch and light pressure, because the muscles of mastication can be highly sensitive if they are in spasm.

Anterior Aspect

Zygomatic Arch. The zygomatic arch is located anterior to the condylar process of the mandible. The temporal muscle lies above and the masseter muscle lies below the zygomatic arch.

Hyoid Bone. The hyoid bone, located anterior to the C2 and C3 vertebrae, is palpated for normal, painless movement as the patient swallows.

Digastric Muscle (Anterior Belly). The anterior belly of the digastric muscle can be palpated from its origin on the lingual side of the mandible to its tendinous insertion on the hyoid bone.

Thyroid. The thyroid cartilage, located anterior to the C4 and C5 vertebrae, is palpated and moved. Crepitation of this structure may be felt during neck extension as the cartilage becomes taut.

Lateral Aspect

Temporomandibular Joint. The clinician palpates the lateral aspect of the TMJ by placing the tip of the forefinger just anterior to the tragus of the ear (see Fig. 26-10). As the individual opens the mouth wide, the clinician's finger will identify a depression posterior to the condylar head and

overlying the joint that is created by the translating condyle. Tenderness in this depression may indicate inflammation.[31] Alternatively, the lateral aspect of the joint capsule can be palpated on the lateral pole of the condyle just anterior to the tragus. To facilitate identification of the lateral pole, the patient is asked to open and lightly hold a cotton roll in the premolar region.[98]

Mandible. The mandible should be palpated along its entire length. Any asymmetry from side to side should be noted. The mandibular angle serves as an important landmark for orientation. The mandibular ramus is covered by the masseter muscle. The condylar process of the mandible is located just in front of the ear. The parotid gland is located anterior to and below the auricle, and normally extends from the sternomastoid muscle anteriorly to the masseter muscle. Enlargement of the parotid gland causes the earlobe to move outward on the involved side. Enlargement of the parotid gland can have a number of causes, including infection, trauma, diabetes mellitus, lymphoma, or chronic alcoholism.[86] The submandibular gland is palpable in front of the mandibular angle and underneath the mandibular body, about halfway between the chin and the mandibular angle. Normally, the gland has a firm, irregular consistency.

Sternocleidomastoid Muscle. The sternocleidomastoid is palpated from its dual origin on the sternum and the clavicle along its course upward and posteriorly to its insertion on the mastoid process.

Trapezius Muscle. The trapezius muscle is palpated from its origin on the acromion process to its insertion along the midline of the spine to the base of the skull. The trapezius is perhaps the most common site for muscular trigger points and often refers pain to the base of the skull and the temporal region.[108]

Masseter Muscle. Both the superficial and deep portions of the masseter run from the zygomatic arch to the mandibular ramus. The clinician should place the palpating finger against the ramus and then ask the patient to gently clench the teeth.

Temporalis Muscle. The temporalis muscle can be palpated in front of, and above, the ear. The clinician places a finger against the temporal region and then asks the patient to gently clench the teeth.

Posterior Aspect. Posterior TMJ palpation is performed by placing the tip of the little finger in the patient's external auditory canal and exerting anterior pressure as the patient repeatedly opens and closes the mouth.[31] Alternatively, the palpation can be performed with the teeth in the intercuspal position.[98] If inflammation is present, pain is felt on jaw closing as the tissue is compressed between the clinician's finger and the condyle.[30] The examination also may reveal a posterosuperiorly positioned condyle and disk dysfunction. This posterosuperior position of the condyle can be a result of occlusal factors or trauma. The position results in an anteriorly displaced disk and an impingement by the condyle on the space normally occupied by the disk. This displacement may cause reciprocal clicking or locking.

The masseter, temporalis, and perihyoid muscles are palpated extraorally for hypertonicity and tenderness. In addition, the lateral aspect of the joint capsule and the lateral TMJ ligament are palpated for tenderness.

Medial Pterygoid. The patient is asked to move the tongue to the opposite side. The clinician slides a thumb onto the medial aspect of the lower gum and toward the back of the mouth and angle of the mandible. The thumb is maintained at the bottom of the mouth to prevent the gag reflex. The insertion site for the medial pterygoid is located on the medial aspect of the mandibular angle.

Lateral Pterygoid. It is questionable whether the lateral pterygoid can be palpated.[109] Nonetheless, descriptions detailing palpation of this muscle exist. The muscle is said to be palpated by sliding a thumb back to the medial aspect of the base of the upper molars. The patient is asked to open the mouth wider, and the clinician slides the thumb back and up at an angle of 45 degrees and inspects the muscle and area for tenderness.

Muscle Tests

It is important to be able to selectively stress the muscles of mastication and facial expression to determine whether they are implicated in the symptoms. All these tests cannot replace a thorough palpation of the muscles. All test positions, resisted motions, and attempted facial expressions may be used as exercises to rehabilitate any identified deficits. For each of the following, the patient is seated.

Temporalis

The clinician palpates the side of the head in the temporal fossa region. The patient is asked to elevate and retract the mandible. Resistance can be applied using a tongue depressor placed between the teeth. Both sides are tested.

Masseter

The clinician palpates the cheek, just above the angle of the mandible. The patient is asked to elevate the mandible, as in closing the jaw. Resistance can be applied using a tongue depressor placed between the teeth.

Lateral Pterygoid

The clinician palpates the pterygoid at the neck of the mandible and joint capsule. The patient is asked to protrude and depress the mandible against manual resistance.

Medial Pterygoid

The patient is asked to elevate and protrude the mandible. Resistance can be applied using a tongue depressor placed between the teeth.

Suprahyoid Muscles

The clinician palpates the floor of the mouth. The patient is asked to press the tip of the tongue against the front teeth. Resistance can be applied to the surface of the hyoid bone in an attempt to protrude the tongue.

Infrahyoid Muscles

The clinician palpates below the hyoid bone, immediately lateral to the midline. The patient is asked to swallow, while the clinician palpates for the movement of the hyoid and the larynx.

TABLE 26-7 Muscles of Facial Expression

Muscle	Action	Innervation
Occipitofrontalis	Wrinkles forehead by raising eyebrows	Facial nerve
Corrugator	Draws eyebrows together, as in frowning	Facial nerve
Procerus	Draws skin on lateral nose upward, forming transverse wrinkles over bridge of the nose	Facial nerve
Nasalis	Dilates and compresses aperture of the nostrils	Facial nerve
Orbicularis oculi	Closes eyes tightly	Facial nerve
Superior levator palpebrae	Lifts upper eyelid	Oculomotor nerve
Orbicularis oris	Closes and protrudes lips	Facial nerve
Major and minor zygomatic	Raises corners of mouth upward and laterally, as in smiling	Facial nerve
Levator anguli oris	Raises upper border of lip straight up, as in sneering	Facial nerve
Risorius	Draws corners of mouth laterally	Facial nerve
Buccinator	Presses cheeks firmly against teeth	Facial nerve
Levator labii superioris	Protrudes and elevates upper lip	Facial nerve
Depressor anguli oris and platysma	Draws corner of mouth downward and tenses skin over neck	Facial nerve
Depressor labii inferioris	Protrudes lower lip, as in pouting	Facial nerve
Mentalis	Raises skin on chin	Facial nerve

Muscles of Facial Expression

This group of muscles, most of which are innervated by the facial nerve, can be assessed by having the patient attempt to make the specific facial expression attributed to each muscle (Table 26-7). Facial strength can be evaluated with the House–Brackmann facial nerve grading system[110–113] (Table 26-8), which separates facial nerve paralysis into six grades, based on the severity of findings. In 1985, the American Academy of Otolaryngology, Head and Neck Surgery adopted the House–Brackmann six-point subjective grading scale as a universal standard. Parameters evaluated during the examination include:

- overall macroscopic and gross appearance;
- appearance at rest;
- forehead movement;
- eyelid closure;
- mouth appearance;
- synkinesis contracture or hemifacial spasm, or both.

Ligament Stress Tests

The ligament stress tests assess the integrity of the capsule and ligaments. Positive findings include excessive motion compared with the other side, or pain. The patient is seated.

Temporomandibular (Lateral) Ligament

This test is only performed if there is a painful loss of AROM of the TMJ. The purpose of the test is to determine if the painful restriction is caused by damage to one of the ligaments or the joint capsule.

The clinician cradles and stabilizes the patient's head with one hand. The index and middle fingers of this hand can be used to palpate the joint line. The patient is asked to open their mouth to the point of restriction; mandible is positioned slightly open. The clinician places the thumb of the mobilizing hand on the ipsilateral molars of the side to be tested. The clinician then applies a downward force on the molars creating a caudal shear (Fig. 26-14). There should be slight movement with this technique, and the end-feel should be capsular.

Joint Capsule

The clinician stands at the head of the patient. The patient's mandible is closed. The clinician places one hand on top of the patient's head, and the other hand on the ramus and angle of one side. The clinician then applies a contralateral protrusion and ipsilateral deviation force (Fig. 26-16).

Joint Loading Tests

Selective loading of the TMJ may be used to help determine the presence of an intracapsular pathology. A positive finding is pain with the test. These tests include dynamic loading and joint compression.[52]

Dynamic Loading

The patient is asked to bite forcefully on a cotton roll or tongue depressor on one side. This maneuver loads the contralateral TMJ.

Joint Compression

The patient is positioned supine, with the clinician standing at the head of the bed. The clinician places the fingers of each hand under each side of the mandible, with the thumbs resting on the ramus. The mandible is then tipped posteriorly and inferiorly to compress the joint surfaces.

TABLE 26-8 House–Brackmann Facial Nerve Grading System

Parameter	Grade I	Grade II	Grade III	Grade IV	Grade V	Grade VI
Overall appearance	Normal	Slight weakness on close inspection	Obvious but not disfiguring difference between both sides	Obvious weakness and/or disfiguring asymmetry	Only barely perceptible motion	No movement
At rest	Normal symmetry	Normal symmetry	Normal symmetry	Normal symmetry	Asymmetry	Asymmetry
Forehead movement	Normal with excellent function	Moderate-to-good function	Slight-to-Moderate Function	None	None	None
Eyelid closure	Normal closure	Complete with minimum effort	Complete with maximal effort	Incomplete closure with maximal effort	Incomplete closure with maximal effort	No movement
Mouth	Normal and symmetric	Slight asymmetry	Slight asymmetry with maximum effort	Asymmetry with maximum effort	Slight movement	No movement
Synkinesis contracture and/or hemifacial spasm	None	May have very slight synkinesis; no contracture or hemifacial spasm	Obvious but not disfiguring synkinesis contracture and/or hemifacial spasm	Synkinesis contracture and/or hemifacial spasm disfiguring or severe enough to interfere with function	Synkinesis contracture and/or hemifacial spasm usually absent	No movement

Data from House JW, Brackman DE: Facial nerve grading system. *Otolaryngol Head Neck Surg* 93:146–147, 1985.

Passive Articular Mobility Testing

The passive articular mobility tests assess the joint glides and the end-feels. The patient and clinician setup are identical to that described above for the temporomandibular (lateral) ligament stress test.

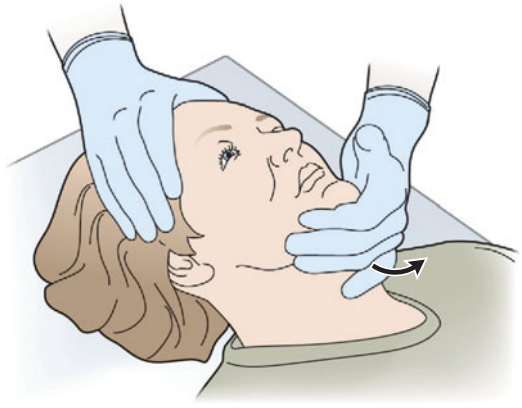

FIGURE 26-16 Contralateral protrusion and ipsilateral deviation force to TMJ.

From the end-range position (or as close as possible, given that the thumb is in the patient's mouth), the following maneuvers are performed assessing for range and end-feel. Findings are compared with each side. Pain, or a restricted glide, are positive findings and may indicate articular involvement or a capsular restriction. It is important to check the specific glides that are related to the loss of active motion. For example, if a patient demonstrated diminished mouth opening, the combined anterior, inferior, and lateral glide is assessed at each joint.

Limited opening can be caused by anterior disk displacement without reduction, elevator muscle spasm, or capsular restraint. By inducing a passive stretch to the joint after the patient has actively opened the mouth to the full extent, the "end-feel" can be used to differentiate between these causes. For example, if a displaced disk is responsible for limited opening, there will be a hard end-feel with little or no play. In contrast, a gummy end-feel is present when muscle spasm or capsular connective tissue is preventing full opening.[55] To help differentiate between elevator muscle spasm and a capsular restriction, passive motions can be used. With elevator muscle spasm, only vertical movement is restricted and protrusive and lateral excursions are normal. Anterior disk displacement without reduction, however, exhibits restrictions in both protrusive movements and contralateral excursions. Movement to the side of the involved

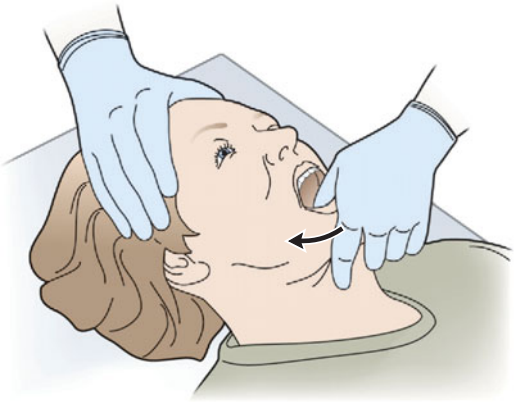

FIGURE 26-17 Medial glide.

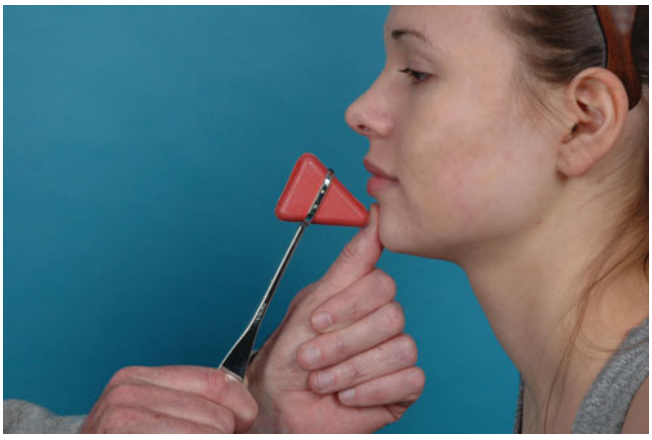

FIGURE 26-18 Jaw jerk test.

joint is usually not mechanically restricted because the main movement occurring in the joint is rotation. While hypomobility may be apparent with passive articular mobility testing, hypermobility is difficult to determine with these tests.

Most of the mobility tests can also be used for mobilizations by changing the grade and the intent. The clinician should remove the thumb from the patient's mouth every 10–15 seconds to allow the patient to swallow.

- Distraction (Fig. 26-14). The mandible is moved inferiorly in a direction perpendicular to the joint surface.
- Anterior glide (see Fig. 26-14). The mandible is moved anteriorly.
- Medial glide (see Fig. 26-17). The clinician stands to the side of the patient and stabilizes the patient's head. A medial force is applied by the other hand. This glide assesses the ability of the TMJ to side glide to the contralateral side from the side of the joint being tested.
- Posterior glide with lateral excursion for the posterior ligaments.

Neurologic Tests

Trigeminal Nerve (CN V)

Sensation. The skin near the midline (there is overlap from the anterior (ventral) rami of C2 and C3 if tested too laterally) of the forehead and face can be stroked with cotton wool or tissue paper or can be tested for pinprick sensation. It is best if the testing is carried out bilaterally and simultaneously.

Reflex. The jaw jerk can be used to test trigeminal function. A lesion superior to the pons would produce hyperreflexia, and a lesion below the pons would result in hyporeflexia or areflexia. The patient's mouth is relaxed and open in the resting position. The clinician places a thumb on the mandible and then lightly taps the thumb with the pointed end of a reflex hammer (Fig. 26-18). A normal response is one in which the mouth closes.

Facial Nerve (CN VII)

The facial nerve can be tested using the Chvostek (Weiss sign) test. The patient is positioned sitting. The clinician taps the parotid gland overlying the mass of the muscle. If the facial muscles twitch (typically a twitch of the nose or lips), the test is considered positive for hypocalcemia (i.e., from hypoparathyroidism, pseudohypoparathyroidism, hypovitaminosis D) with resultant hyperexcitability of the nerves.

Special Tests

At the time of writing, no routine special tests for the TMJ exist. Most, if not all, of the structures of the TMJ are isolated and tested during the standard examination previously described. Although cranial nerve testing (see Chap. 3) is not, strictly speaking, a special test, this testing should be performed if an injury to a cranial nerve is suspected. In addition, the special tests for thoracic outlet syndrome, brachial plexus stretching, and dural mobility should be performed to help rule out any referral of symptoms.

Imaging Studies

With the rapid progress made in TMJ imaging techniques, many studies have focused on the importance of internal derangement and osteoarthrosis as the underlying mechanisms in the etiology of TMJ-related pain and dysfunction. Despite the limitations, plain radiographs of the TMJ, such as high-level orthopantomograms and transcranial projections, are useful ways of visualizing any gross pathologic, degenerative, or traumatic changes in the bony component of the TMJ complex.[12,114] MRI is currently the most accurate imaging modality for identification of disk positions of the TMJ and may be regarded as the gold standard for disk position identification purposes.[115] However, many reports question the utility of TMJ imaging studies because of the number of asymptomatic individuals who demonstrate positive signs of disk displacements and joint arthrosis (degenerative processes affecting the TMJ).[1,116] Postmortem examinations of a total of 140 persons (dental histories unknown) showed that 40–80% had joint pathology or disk displacements.[116] The relevance of bony joint arthrosis was also disputed by evidence that patients with TMJ rheumatoid arthritic pathology actually had fewer symptoms than normal individuals.[117]

INTERVENTION STRATEGIES

The lack of a consistent method for identifying and diagnosing TMD in a research setting, varying durations of treatment, lack of control groups, lack of objective-dependent measures, and lack of specification of symptom duration have prevented significant research on the effectiveness of various treatment modalities for TMD.[118,119,120] Complicating matters is the fact that the majority of the symptoms associated with TMD are self-limiting and resolve without active intervention.[48] The chronic pain associated with TMD most likely occurs because of secondary factors. These factors include a fixed FHP, abnormal stress levels, depression, or oral parafunctional habits (such as bruxism). This prolonged pain is frequently due to adaptive shortening of the tissues, or from a secondary hypermobility. It is likely that the longer the duration of the symptoms, the smaller the likelihood that the patient will benefit from a conservative intervention.[78] A number of authors[121,122] have recommended that the intervention for TMD should be directed at the following factors[123]:

- Treatment of symptoms to reduce or eliminate pain or joint noises, or both.
- Treatment of the underlying cause or the predisposing factor (poor posture, stress, depression, and oral parafunctional habits).[68,124]
- The restoration of normal mandibular and cervical function.[101]

Recently, there has been an interest in the relative effectiveness of specific conservative interventions for TMD and, as a result, a number of systematic reviews have been performed in the area.[53,98,120,125–129] For example, Kulekcioglu and colleagues[127] reported that low-level laser therapy can be considered as an alternative physical modality in the management of TMD, and Tegelberg[130] and Au[131] have reported significant symptom reduction after exercise management of TMD. However, most of the studies have demonstrated the importance of a multifactorial approach in the conservative management of TMD. For example, the results of a systematic review by McNeely and colleagues[129] found manual therapy, and the use of active and passive oral exercises, and exercises to improve posture, as effective interventions to reduce symptoms associated with TMD. However, this review also found no evidence to support the use of electric physical modalities to reduce TMD pain.[129] A single case study by Cleland and Palmer[132] found manual physical therapy (anterior joint glides, distraction and contract–relax stretching to upper trapezius, levator scapulae, and posterior occipitals), therapeutic exercise (scapulothoracic muscles) and patient education with regards to posture, parafunctional habits, soft diet, tongue resting position, and activity modification to be an effective management strategy for a patient with bilateral disk displacement without reduction within 8 visits.[132] Gatchel and colleagues[120] conducted a randomized clinical trial with a 1 year follow-up to evaluate the efficacy of a biopsychosocial intervention for patients who were at high risk of progressing from acute to chronic TMD-related pain. The study reported that the group who received behavioral skills training and biofeedback demonstrated reduced pain levels, improved coping abilities, and reduced emotional distress at the 1 year point.[120]

It should be clear from the studies that TMD is complex and that there is a clear need for further well-designed RCTs examining physical therapy interventions for TMD, which include valid and reliable outcome measures.

Acute Phase

Acute injuries to the TMJ most frequently have a traumatic origin, such as a direct blow,[133–135] or from a sudden locking of the jaw caused by an internal derangement.[136,137]

The typical patient presentation for an acute injury demonstrates a capsular pattern of restriction (decreased ipsilateral opening and lateral deviation to the involved side), with pain and tenderness on the same side.

Physical Therapy

PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medications) are recommended during the acute phase, with the exception of elevation, which is neither appropriate or feasible. Cold is applied to reduce edema, inflammation, and muscle spasm. Chapman[138] concluded that local application of cold provides short-term relief of pain, possibly because of its analgesic effects and ability to reduce inflammation. No single drug has been proved to be effective for all cases of TMD. Thus, a wide variety of drug classes have been described for chronic orofacial pain, ranging from short-term treatment with nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, and muscle relaxants for pain of muscular origin to chronic administration of antidepressants for less well-characterized pain. The analgesic effect of NSAIDs is specific only in cases of TMD, in which pain is the result of an inflammatory process such as synovitis or myositis. At the doses usually prescribed clinically, opiates are more effective in dampening the patient's emotional response to pain than eliminating the pain itself.[118]

The patient should receive instruction on how to obtain the rest position of the TMJ.[139]

Motion of the TMJ should be restricted to pain-free movements to allow the rest or immobilization of any painful muscular and articular structures. However, very gentle and pain-free active exercises should be performed frequently (every hour or so) to help stimulate the mechanoreceptors and modulate pain, as well as improve vascularization. Kropmans and colleagues[140] report at least 6 mm of change has to be seen to be a detectable difference when doing more than one measurement or to determine the effect of treatment.

Appropriate exercises during the acute stage include the so-called 6 × 6 exercise protocol of Rocabado,[141] which are thought to aid in strengthening, coordination, and the reduction of muscle spasm. The patient should be instructed to perform the following exercises six times each at a frequency of six times per day.

1. ***Tongue rest position and nasal breathing.*** The patient places the tip of the tongue on the roof of the mouth, just behind the front teeth. With the tongue in this position, the patient is asked to breathe through the nose and

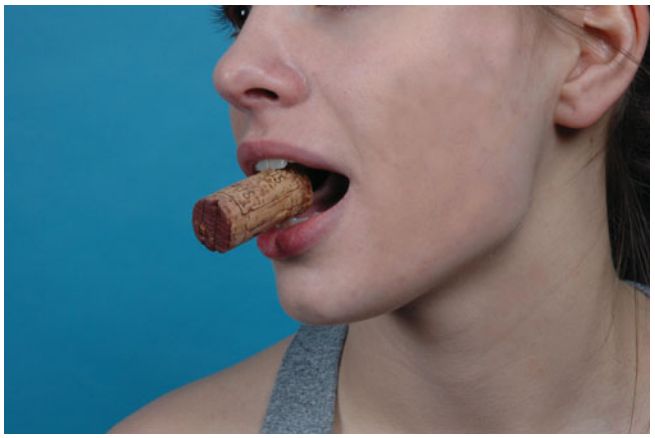

FIGURE 26-19 Cork exercise

to only use the diaphragm muscle for expiration (no accessory breathing muscles).

2. ***Controlled opening.*** The patient positions the tongue in the rest position and practices chewing and opening the mouth to the point where the tongue begins to leave the roof of the mouth. Another gentle exercise to help increase joint mobility and articulation is the 'cork' exercise. The size (height) of the cork depends on the available motion. The patient holds the cork between his or her teeth while talking for approximately 2 minutes (Fig. 26-19). The talking exercise is then repeated with the cork removed.
3. ***Rhythmic stabilization.*** The patient positions the tongue in the rest position and grasps the chin with one or both hands. The patient then applies a resistance sideways to right deviation and then left deviation. The patient then applies a resistance against mouth opening and closing. Throughout all of these exercises, the patient must maintain the resting jaw position.
4. ***Release of cervical flexion.*** The patient places both hands behind the neck and interlaces the fingers to stabilize the entire cervical region. The neck is kept upright while the patient performs craniovertebral flexion (see Chap. 23), which produces a distraction of the occiput from the atlas and helps to counteract the craniovertebral extension produced by the FHP.
5. ***Longitudinal neck extension.*** The patient is asked to glide the neck backward and stretch the head upward in one movement to improve the functional and mechanical relationship of the head to the cervical spine. This exercise needs to be monitored closely to prevent hypermobility of the cervical segments.
6. ***Shoulder retraction.*** The patient is asked to pull the shoulders back and downward in one motion while squeezing the shoulder blades together to help restore the shoulder girdle to an ideal postural position and to establish stability of the entire head–neck–shoulder complex.

Neuromuscular education techniques can be used to control premature or excessive translation. If premature translation has been found to be occurring, the patient is taught to maintain the tongue on the posterior portion of the palate and to monitor the lateral pole of the condyles during opening to ensure that only rotation occurs during the early phase of opening.[101]

One of the most commonly overlooked problems during TMJ intervention is altered swallowing sequence and tongue position.[101] Few other forces can match the ability of the tongue to cause occlusal and skeletal deformation.[142] The presence of a residual pediatric tongue thrust or an acquired adult tongue thrust secondary to a forward head posture can affect the response to all other interventions. Presence of a tongue thrust is manifested by the hyoid moving slowly up and down during swallowing, contraction of the suboccipitals during swallowing, or head rocking and excessive lip activity during swallowing.[101] Patients with these findings should be shown the normal resting position for the tongue, and swallowing should be practiced without movement of the head and with the correct sequencing of tongue movements.[142]

Patient Education

The clinician should explain the cause and nature of the disorder to the patient, and to reassure him or her of the benign nature of the condition.[124] A successful self-care program allows healing and prevents further injury and is often enough to control the problem.[143]

A typical self-care home program includes the following:[124]

- Limitation of mandibular function (rest). The patient is advised to eat soft foods and avoid those that need a lot of chewing and is discouraged from wide yawning, singing, chewing gum, and any other activities that would cause excessive jaw movement.
- An exercise program, including the 6×6 protocol.
- Habit awareness and modification.
- Stress avoidance. Patients should be advised to identify anysource(s) of stress and to try to change their lifestyle accordingly.
- The patient's sleeping position. If the intrinsic ligaments are injured, the patient should be advised to sleep on the back, with the neck supported by a cervical pillow.[68] The prone position should be avoided as it compresses the TMJ, and stresses the cervical spine by extending and rotating it.

Occlusal Appliance Therapy

The most common form of intervention provided by dentists for TMD is occlusal appliance therapy, alone or in combination with other interventions.[144] Occlusal appliances include bite-raising appliances, occlusal splints, or bite guards. These removable custom-made appliances are usually made of hard acrylic, which are custom made to fit over the occlusal surfaces of the teeth in one arch.[124] The function of the occlusal device is to provide a stable jaw posture by creating single contacts for all of the posterior teeth in centric relation and centric occlusion.[144]

Although occlusal appliance therapy has been shown clinically to alleviate symptoms of TMD, the experimental evidence has been lacking and thus the physiologic basis of the response to treatment has never been well understood.[145,146]

Malocclusion, in itself, is not established as an important factor in TMD,[54,147] because very few patients with malocclusion actually go on to develop TMD.[148] In an evidence-based assessment of occlusal adjustment as a treatment for TMDs, Tsukiyama and colleagues[53] concluded that the experimental evidence reviewed was neither convincing nor powerful enough to support the performance of occlusal therapy as a general method for treating a nonacute TMD, bruxism, or headache.[53]

Functional Phase

The interventions described for this phase are best used in combination and are dependent on the patient's needs.[1,78,149,150]

Postural Education

In a study of postural problems in 164 patients with head and neck pain, Fricton and colleagues[151] found poor sitting and standing posture in 96%, FHP in 84.7%, rounded shoulders in 82.3%, abnormal lordosis in 46.3%, and scoliosis in 15.9%. These findings indicate that there may be a correlation with TMJ dysfunction and poor posture, although comparisons would need to be made with a controlled group of normal individuals before final conclusions are drawn.

The focus of the postural intervention should be to educate the patient on correct posture of the head, neck, shoulder, and tongue, in order to help minimize symptoms. Oftentimes, the focus of the education is to teach the patient mental reminders to reduce the times spent in habitual positions during work and recreation. These positions, which cause an alteration in the tensile properties of the muscles and adaptive shortening of the joint capsule and ligaments, result in a variety of problems, including joint strain and improper weight-bearing through the joint.[152–154] The pathologic posture then becomes associated with, or the precursor of, other deformities. A balanced and relaxed position, on the other hand, affords the best mechanical advantage for the body.[144] Since these postural deviations do not always cause symptoms,[155] and the corrected positions require effort to maintain, patients need reassurance that the benefits in changing their posture may take time.[104,156]

Psychotherapy

Recent studies suggest that, on occasion, TMD may be the somatic expression of an underlying psychological or psychiatric disorder such as depression.[124,157–162] These studies have demonstrated increased psychometric scores denoting pain, chronic disability, and depression in TMD patients that far exceed the general population. A study by Gardea and colleagues[163] evaluated the relative long-term efficacy of electromyographic biofeedback, CBST, combined biofeedback and CBST, and no treatment in 108 patients suffering from chronic TMD. After an initial evaluation, patients were assigned to one of the four treatment groups. The three biobehavioral interventions consisted of 12 standardized sessions. Patients were reevaluated 1 year after completing treatment. Results demonstrated that patients who received the biobehavioral interventions reported significant improvement in subjective pain, pain-related disability, and mandibular functioning 1 year after receiving the treatment. The no-treatment comparison group did not demonstrate such improvements, whereas the combined biofeedback and CBST treatment produced the most comprehensive improvements across all outcome measures.

Where persistent habits exacerbate or maintain the TMD, a more structured program of behavioral therapy may be required. Such behavioral therapy may include counseling on lifestyle, relaxation therapy, sleep interruption devices, or hypnosis.[164] Medical hypnosis has been demonstrated to be an effective treatment modality for TMD, in terms of reducing both symptoms and medical use.[165,166]

Manual Therapy

The specific manual techniques for the TMJ are described under "Therapeutic Techniques" section later.

Trigger Point Therapy

The most common intervention for masticatory muscle disorders is trigger point therapy.[167] Chapter 11 reviews the basis for the various intervention procedures for trigger points, which include deep massage, soft tissue mobilizations, postural exercises, ultrasound, acupuncture, and trigger point injections. Spray and stretch techniques may also be used. These techniques involve the application of a vapocoolant spray during the stretching of soft tissues to reduce trigger points and eliminate referred pain.[108] Vapocoolants may also be applied to rapidly cool the skin and overlying musculature during stretching. When using vapocoolants in this region, care must be taken to cover the patient's eyes and to prevent any inhalation of the vapors.

Exercise

Some evidence suggests that exercise of the specific painful area during the functional phase is effective in strengthening the muscles, improving function, and reducing pain. Tegelberg and Kopp[168] ran parallel studies of jaw exercise versus a no-treatment control in subjects with rheumatoid arthritis and ankylosing spondylitis. Significant differences were detected for both conditions in mean maximal opening, but no between-group differences were detected for change in the subjective symptoms (pain and stiffness).

Because of the association of TMD and poor posture, the prescribed exercises for TMD include strengthening exercises for the cervicothoracic stabilizers (see Chap. 25) and the scapular stabilizers (see Chap. 16). Stretching exercises are prescribed for the scalenes, trapezius, pectoralis minor, and levator scapulae (see Chap. 25) and the suboccipital extensors (see Chap. 23).

A restriction of mouth opening is treated with range-of-motion exercises to elongate the soft tissues and with joint mobilizations. The patient should be encouraged to begin full active range-of-motion exercises as early as tolerated (see the discussion of automobilizations under "Therapeutic Techniques" section later). However, if jaw deviation is occurring, the exercises should be performed in a range in which the patient can control the deviation.

Excessive mandibular motion is treated by muscle reeducation, with isometrics performed at the desired opening range.

Thermal and Electrotherapeutic Modalities

A multitude of electrotherapeutic modalities, especially ultrasound and electrical stimulation, have been applied to patients with TMDs,[12,73,123] but there appears to be little evidence that passive modalities alone can cause long-lasting reductions, and very few studies have systematically evaluated the effect of these treatments.[123,149,150,169,170] The American Academy of Craniomandibular Disorders recommends the use of thermal and electrotherapeutic modalities and intraoral splints in conjunction with other interventions, including mobilization of the TMJ.[171]

Moist Heat Packs. Conventional hot packs or face packs may be used in the functional stage and are applied for approximately 15 minutes. Thermotherapy is used to help the soft tissues relax and to increase circulation.

High-Voltage Electric Stimulation. High-voltage stimulators deliver a monophasic, twin-peak waveform. Because of the short duration of this twin-peak wave, high voltages with high-peak current but low average current can be achieved. These electrical characteristics provide patient comfort and safety in application. In addition, in contrast to low-voltage direct-current devices, thermal and galvanic effects are minimized.[172]

High-voltage stimulators have been applied clinically to reduce or eliminate muscle spasm and soft tissue edema, as well as for muscle reeducation (non—CNS-produced muscle contraction), trigger point therapy, and increasing blood flow to tissues with decreased circulation.[62,63,172]

Ultrasound. The effects of ultrasound are partly thermal, because of the increase in blood flow and tissue temperature produced. Thus, ultrasound may be used to help the soft tissues relax and to increase circulation. Ultrasound is an ideal modality both before and during joint and soft tissue mobilization. There is also a mechanical effect associated with ultrasound, because the sound waves produce pressure changes in the tissues, which may result in a micromassage of the tissues.[123] A 3-MHz frequency is recommended, with an intensity of between 0.75 and 1.0 W/cm^2. Tongue depressors can be inserted in the patient's mouth to apply a gentle stretch during the ultrasound treatment.[101]

Iontophoresis. Iontophoresis may be used to introduce medications such as cortisol, dexamethasone, salicylates, and analgesics.[173,174] Kahn[175] found that following TMJ surgery, the use of iontophoresis in conjunction with ultrasound produced a decrease in pain, paresthesia, and trismus.

Surgical Intervention

Published reports show that about 5% of patients undergoing an intervention for TMD may eventually require surgery.[8,9] A range of surgical procedures is currently used to treat TMD, ranging from TMJ arthrocentesis and arthroscopy to the more complex open joint surgical procedures, referred to as *arthrotomy*.[9]

The proximity of the medial aspect of the TMJ to the structures of the infratemporal fossa raises the possibility of complications associated with TMJ surgery on the medial aspect of the joint.[176] These complications include involvement of the inferior alveolar, lingual, and auriculotemporal nerves.[177] A further study found that the location of such vital structures as the middle meningeal artery, the carotid artery, the internal jugular vein, and the trigeminal nerve varied, increasing the likelihood of significant intraoperative or postoperative complications.[178]

In terms of intervention, the postsurgical patient is treated as though in the acute phase of healing and is progressed gradually, as outlined under "Intervention Strategies" section earlier.

PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Internal Derangement: Intra-articular Disk Displacement

TMJ internal derangement is one of the most common forms of TMD and is associated with characteristic clinical findings such as pain, joint sounds, and irregular or deviating jaw function.[66,179] The term *internal derangement* when related to TMD denotes an abnormal positional relationship of the articular disk to the mandibular condyle and the articular eminence.[64] This abnormal positional relationship may result in mechanical interference and restriction of the normal range of mandibular activity. Theoretically, internal derangement of the TMJ involves the anterior (and medial) displacement of the disk, resulting from the action of the upper head of the lateral pterygoid muscle, a tear or thinning of the disk, osteoarthrosis, or malocclusion.[27,42,180]

The diagnosis of internal derangement of the TMJ requires the use of a classification system, such as the one devised by Pertes and Attanasio[181]:

1. Deviation in form
   a. frictional disk incoordination (FDI)
   b. articular surface defects
   c. disk thinning and perforation
2. Disk displacements
   a. partial anteromedial disk displacement
   b. anteromedial disk displacement with reduction
      –partial
      –complete
   c. anteromedial disk displacement with intermittent locking

d. anteromedial disk displacement without reduction
   –acute
   –chronic

3. Adhesive disk hypomobility
4. Displacement of disk–condyle complex

   a. subluxation
   b. dislocation

Deviation in Form

Frictional Disk Incoordination

FDI may occur when the intra-articular disk adheres to the eminence.[181] FDI usually occurs after a prolonged period of TMJ inactivity, such as that occurs with post surgical immobilization. Other causes of this condition include occlusion, bruxism, excessive biting force, and trauma. The adhesion can result in a loss of the translatory glide of the condyle, which in turn can result in excessive pressure between the disk and the eminence and a strain on the discal ligaments, predisposing the patient to a true disk displacement of the joint.

Clinical findings with this condition may include a discrete opening click with momentary discomfort, while the remainder of the translatory cycle is accomplished without difficulty.[182] The click associated with deviation in form usually occurs at the same point in the range of opening and closing.

The conservative intervention for this condition should focus on the elimination of any occlusal disharmony, the reduction of parafunctional habits, and methods to prevent the disk–condyle complex from returning to the closed position.[6] The latter goal can be accomplished by applying a permanent stabilization splint for a few months. When symptoms have been reduced, the patient should be weaned off the splint during the day and, eventually, night.

Articular Surface Defects

An articular surface defect located on the articulating surface of the eminence, the superior surface of the disk, or both, may cause an obstruction to the normal translatory movement of the disk.[183] The defect may be caused by trauma to the mandible when the teeth are apart, habitual abuse, or developmental and growth anomalies.[6]

Clinical findings for articular surface defects include a reciprocal click at the same point during both opening and closing movements. In addition, a lateral deviation frequently occurs on opening, as the patient attempts to circumvent the interference. Although the condition itself is painless, it can be worsened by any activities that increase intra-articular pressure.[6,184]

Conservative intervention for this condition includes habit training to develop a path of mandibular movement that avoids the interference. In addition, the patient is asked to make a conscious effort to reduce the force of chewing and eliminate parafunctional habits. Chewing on the affected side, by decreasing the intra-articular pressure, may also be helpful. A stabilization splint may serve to reduce pressure on the joint structures.[6,182]

Disk Thinning and Perforation

Disk thinning can result from the application of excessive pressure on the TMJ and can lead to a deformation of the joint structures. Continuous pressure eventually may cause perforation of the disk.

The symptoms of disk thinning and perforation depend on the extent of disk damage. Theoretically, thinning of the central part of the disk should be painless, because that part of the disk is not innervated. However, variable joint tenderness and muscle pain often is associated with any activity that deepens the central bearing area of the disk.

If the disk should perforate, grating sounds or crepitus during the translatory cycle are likely because of damage of the articular surfaces.[185,186] The diagnosis of disk perforation usually is made by imaging, arthrography, or arthroscopy. MRI, which is ideal for visualizing disk displacement, may not be so accurate for a perforation.[187]

Conservative intervention for disk thinning usually involves the application of a stabilization splint to prevent a perforation. If perforation has occurred and the patient can no longer tolerate the symptoms, surgical intervention is indicated.

Disk Displacements[181]

A pathologic click in a disk displacement may be caused by the condyle subluxing anteriorly or medially later than normal in the opening cycle. The click may also occur as the condyle relaxes onto the disk, or it may represent the sudden snapping back of the disk by the less than adequately elastic posterior ligament of the disk.

Partial Anteromedial Disk Displacement. In a healthy joint, the center of the posterior band of the disk is in the 12 o'clock position on the condyle when the teeth are occluded. With partial anterior disk displacement, the disk is permitted to slide anteriorly on the condyle and the terminal position of the posterior band of the disk occurs anteriorly to the normal position on the condyle in the closed-joint position. The anterior displacement is thought to occur because of two factors: some thinning of the posterior band and minimal elongation of the discal ligaments.[182]

The conservative intervention for partial displacements should focus on preventing any worsening of the disk displacement. This can be achieved using intraoral appliances in combination with psychological stress reduction.

Anteromedial Intra-articular Disk Displacement with Reduction. Disk displacement with reduction is both an anatomic and a functional disorder that is cyclic in nature.[187] Anteromedial disk displacement with reduction is described as an unexpected alteration or interference of the disk–condyle structural relation during mandibular translation with mouth opening and closing.[68] The misalignment of the disk is thought to be the result of articular surface irregularity, disk–articular surface adherence, synovial fluid degradation, or myofascial imbalances around the joint.[188]

The temporarily misaligned disk reduces or improves its structural relationship with the condyle when mandibular translation occurs with mouth opening. This change often is associated with an "opening click," and a reciprocal "closing click," which occurs just before the teeth occlude during

mouth closing. Pain, if present, usually occurs at the time of the disk reduction.

Disk displacement with reduction may be characterized by five progressive stages.[93,189,190]

- ***Stage I.*** In stage I, the disk may be positioned slightly anteromedially on the mandibular head. Pain is usually mild or absent. As the disk becomes deformed from the repetitive microtrauma, it begins to interfere with the normal translation of the condyle.[68]
- ***Stage II.*** In this stage, the disk slips further anteromedially on the mandibular head. The reciprocal click may occur in the early phase of opening and late in the phase of closing.[68] Stage II is characterized by a loss of integrity of the ligamentous and intracapsular structures. This loss of integrity may result in increased mobility and a decrease in control of the disk, which increases the potential for impingement and deformation of the disk, resulting in severe pain, and increases the potential for intermittent *open locking* or subluxation of the joint.[102] An *open lock* is characterized by two opening clicks, and two clicks on closing. During opening, the first click occurs when the condyle moves over the posterior rim of the disk and the second click as the condyle moves over the anterior rim.[68] If, after the second click occurs on opening, the disk lies posterior to the condyle, the condyle may be prevented from sliding back.[191]
- ***Stage III.*** Stage III, often the most painful stage, is characterized by a reciprocal click that occurs later in the opening cycle and earlier in the closing cycle.[68] Occasionally, the intra-articular disk becomes adherent to the mandibular condyles in both the open and closed positions. This is known as a *closed-lock* position.[68] The sustained closed-lock condition produces a sudden limitation of opening, as the disk becomes permanently lodged anteriorly, thereby interfering with the normal condylar rotation and translation.[102] This closed-lock condition results in a hard end-feel in the joint when the clinician attempts to induce a passive stretch to the joint.[55] The impingement on the posterior attachment of the disk by the condylar head may result in a prolonged stretching of the tissue. The limitation of opening usually is restricted to 25–30 mm. Since condylar translatory mobility commonly is hindered only on the affected side, the mandible may deviate away from the midline toward the affected side with maximal jaw opening.[68] However, if this condition is chronic, there may be no deviation or limitation of jaw opening because of progressive tearing in the retrodiscal lamina. Tenderness of the masticatory muscles may also occur as a result of the protective splinting of the joint.
- ***Stage IV.*** In this stage, clicking is rare because the disk position is usually so incompatible. If clicking does occur, it is usually a single opening click because of the irregularities in translations.[68] Chronic locking with soft tissue remodeling can occur as a result of routine daily jaw function on the posteriorly or anteriorly positioned disk.[102] Known as *rotational displacement,* this condition is associated with pain and, commonly, with anterior displacement of the disk.[192]
- ***Stage V.*** This stage is characterized by radiographic degenerative changes on the condylar head and, occasionally, on the articular eminences, with evidence of remodeling and osteophytosis.[187] Marked deformity and thickening of the disk may occur, and the shape of the disk may change in configuration from biconcave to biconvex. The joint space typically is narrowed to the point where bone-on-bone contact is evident, resulting in coarse crepitus with jaw motions.

Stages I and II usually are amenable to physical therapy intervention. The focus for these stages is on reducing muscle dysfunction and improving the biomechanics of the joint.[102] The intervention usually involves using mandibular-repositioning appliances that stabilize a protrusive position to keep the disk in a more optimal relationship with the condyle.[193] The primary purpose of protrusive splint therapy may be to allow repair and regeneration to occur in the retrodiscal tissue and, possibly, in the discal ligaments.[194]

The intervention for stages III–V, and for those patients who are postsurgical, is directed at promoting and progressing the healing, restoring joint range of motion, and reducing the inflammation associated with capsulitis.[102]

Anteromedial Disk Displacement with Intermittent Locking. As mentioned in the previous section, if the disk remains displaced for longer periods of time, its shape becomes deformed and may slowly change from biconcave to biconvex. This change in shape makes the passage of the condyle under the disk more difficult. To return the disk, the patient must learn to move the mandible to the opposite side in order to activate the superior retrodiscal lamina.[102] Unfortunately, at this point, the retrodiscal tissue has thinned considerably and lost much of its elasticity, making disk reduction difficult to achieve.

The intermittent locking may occur at any time, but it most often occurs in the morning upon awakening, after a prolonged period of clenching, or after chewing on the involved side.[90] Conservative intervention usually involves a mandibular-repositioning appliance to keep the disk in correct alignment with the condyle.

Intra-articular Disk Displacement Without Reduction.[68] Although some patients may show progression through the various stages of disk displacement, it is unclear why some patients remain in the category of anterior disk displacement with reduction for years, whereas others proceed to intermittent locking and anterior disk displacement without reduction within a matter of months.

Disk displacement without reduction is described as an alteration or interference of the disk–condyle structural relation that is maintained during mandibular translation. As a result of continued disk deformation along with elongation of discal ligaments and a loss of tension in the posterior attachment, the disk may remain anteromedially displaced creating a "closed lock." Contact is lost among the condyle, disk, and articular eminence, and the articular disk space collapses, trapping the disk in front of the condyle and thereby preventing translation. Usually, the displacement of the disk becomes worse with jaw motions. Initially, there may be an associated locking with a sudden and marked limited jaw motion. In addition, there may be a deviation of the mandible

toward the involved side during mouth opening, and a marked limitation of lateral deviation to the contralateral side.[68,102]

The limited opening resulting from anterior disk displacement without reduction may have a variety of causes. In addition to the more common causes, including muscle spasm and capsular tightness, limited mouth opening may occur when either the disk is lodged anteriorly to the condyle or the TMJ is dislocated or subluxed. Limited mouth opening as a result of elevator muscle spasm or capsular restraint can be differentiated by determining the end-feel. Elevator muscle spasm tends to limit only vertical movement; the protrusive and lateral excursions are usually normal. Anterior disk displacement without reduction, however, exhibits restrictions in both protrusive movements and contralateral excursions. Movement to the side of the involved joint is usually not mechanically restricted, because the main movement occurring in the joint is rotation. Pain restriction may be the result of impingement on inflamed retrodiscal tissues. Secondary muscle spasm of the elevator muscles may add to the restricted opening as well as capsular involvement.

In the acute phase, joint noise is usually absent. However, crepitus may be detected as the displacement becomes chronic and changes occur in the articular surfaces. As the condition becomes chronic, the pain often is markedly reduced and the range of motion may approach normal dimensions.

The intervention for the acute phase of this type of disk displacement should focus on a reduction of the displaced disk through mobilization of the joint. Since secondary elevator muscle spasm is usually present, as well as some inflammation of joint structures, it may be of benefit for the patient to take a skeletal muscle relaxant and an NSAID prior to physical therapy session. The reduction procedure involves the patient opening the mouth as wide as he/she is comfortable and then moving the mandible toward the opposite joint. If unsuccessful, the clinician may then attempt to reduce the disk manually through downward pressure on the last molar on the involved side.[184] Success in reducing the disk usually can be clinically determined by comparing the amount of vertical opening and contralateral movement after mobilization with the amount of movement before mobilization. This difference should be verified through imaging, because clinical criteria alone may not be accurate. Generally speaking, reductive mobilization is more successful in the more acute conditions. In cases in which changes in the connective tissue capsule may be contributing factors, manual stretching of the vertical fibers of the capsule may be indicated.

Adhesive Disk Hypomobility[181]

Although many cases of intracapsular restriction of mandibular movement or closed lock are caused by an anterior disk displacement without reduction, another frequent abnormality of the TMJ is the formation of intra-articular adhesions. The restriction may also be caused by an adhesion occurring in the superior joint cavity between the disk and the eminence, resulting in a loss of condylar translation. In addition, an adhesion may result in condylar displacement of the disk, with distortion of the disk itself on mandibular opening.[187]

Trauma frequently is implicated as a causative factor. If the trauma is slight, only mild surface damage to the disk may occur, resulting in FDI or an articulating surface defect. A more severe episode could cause intracapsular bleeding and effusion. Fibrosis may result, producing a reduction in the range of motion as well as degeneration. Condylar translation may be lost as a result of disk adhesion.

Clinically, adhesive disk hypomobility is indistinguishable from acute anterior disk displacement without reduction. Since translation does not occur, opening is limited. Pain is variable and may be caused by stretching of the diskal ligaments, as forced opening is attempted.

The conservative intervention for adhesive disk hypomobility is specific joint mobilizations (see "Therapeutic Techniques" section later).

Displacement of the Disk–Condyle Complex

Subluxation[181]

Subluxation between the disk and the articular eminence may occur as a result of excessive opening, which can force the condyle and the disk anteriorly beyond the normal limits of the translatory cycle. If the disk cannot rotate any farther posteriorly and the condyle continues to translate, a partial dislocation or subluxation can occur.

Usually, the patient has a history of jaw clicking with wide mouth opening. Diagnostically, for treatment purposes, this wide opening click must be differentiated from a click that signifies reduction of a displaced disk. A subluxation type of click occurs only on wide opening and not on protrusive movement or lateral excursion. The click associated with reduction of a displaced disk, however, can occur during both protrusive and contralateral excursion. Usually, pain does not accompany subluxation unless it becomes habitual.

Intervention for this condition includes habit training to voluntarily limit mouth opening within normal limits. This training should be accompanied by exercises that strengthen the elevator muscles. Occasionally, injection of a sclerosing solution to reduce the laxity of the capsule may be required.

Dislocation[181]

Dislocation of the TMJ is caused by additional rotation of the mandibular condyle beyond its biomechanical limit, resulting in an anterior displacement of the disk beyond the articular eminence and in direct contact between the condyle and the eminence. As opposed to subluxation, which is a partial loss of contact between the disk and the eminence, dislocation involves a collapse of the articular disk space. Because of the collapsed disk space, the superior retrodiscal lamina cannot retract the prolapsed disk. Adding to the problem is the elevator muscle spasm that frequently accompanies dislocation and preserves the decrease in articular disk space.

Some factors associated with the onset of habitual dislocation include, but are not limited to, yawning, singing, sleeping with the head resting on the forearm, manipulation of the mandible while the patient is under general anesthesia, excessive tooth abrasion, severe malocclusion, loss of dentition (leading to overclosure), and trauma.[195]

Clinical findings include an inability of the patient to close the mandible after wide mouth opening, so that the mouth becomes locked open in a prognathic position and cannot be moved vertically. An acute malocclusion is present with an

anterior open bite and contact between only the most posterior teeth. Depressions may be noted in the preauricular area formerly occupied by the condyles. Pain may be variable, which increases as the patient attempts to close, thus straining the inferior retrodiscal lamina and the collateral discal ligaments.

The main focus of the intervention is to widen the articular disk space. This allows the superior retrodiscal lamina to retract the disk. Forceful closing of the mandible should be avoided. Reduction of the displaced mandible is best accomplished by having the patient yawn as widely as possible, while the clinician exerts slight posterior pressure on the chin. If reduction is not achieved, placement of thumbs behind the molars and pressing down while the patient yawns may produce the reduction by increasing the additional articular space. If these attempts at manual correction fail, the clinician may try stimulation of the gag reflex by touching a mouth mirror to the soft palate. This maneuver can result in an inhibition of elevator muscle activity, thus increasing the articular disk space.

For recurrent dislocations, the conservative approach is addressed according to the stability factors into (1) alteration of the ligaments, (2) alteration of the associated musculature, and (3) alteration of the bony anatomy[195]:

- Alteration to the ligaments can be achieved by the introduction of a sclerosing agent into the capsular space of the TMJ.
- Alteration of the associated musculature can be achieved by exercise. Strengthening the suprahyoid muscles to counterbalance the action of the lateral pterygoid muscles could, theoretically, reduce the likelihood of dislocation. The equipment to perform this type of exercise, however, is elaborate and involves considerable compliance by the patient. A more recently reported treatment modality for alteration of the musculature is the use of type A botulinum toxin. If dislocation is chronic, the patient should be taught how to self-reduce the mandible. Habit training similar to that employed for subluxation should be instituted.
- An alteration of bony anatomy requires a surgical eminectomy.

Arthritis

The TMJ, like other joints in the body, can become a site of osteoarthritis. Degenerative osteoarthritis may be secondary to trauma, surgery, congenital malformation, or, most commonly, long-standing disk derangement. Marginal osteophyte formation, bony erosion sclerosis, and subchondral or subcortical formation may be observed.[187] The temporomandibular disk may become distorted in shape secondary to adhesions seen in osteoarthritis.[196]

Other arthritides are known to affect the TMJ, including rheumatoid arthritis, systemic lupus erythematosus, synovial chondromatosis, ankylosing spondylitis, psoriasis, and crystalline arthritides such as calcium pyrophosphate deposition disease and gout.

To date, no intervention exists that can reverse the anatomic and biochemical alterations of osteoarthrosis. Thus, the intervention approach has to be aimed at restoring function and managing pain through the acute phase of the disease.

Pigmented Villonodular Synovitis

Pigmented villonodular synovitis (PVNS) is a proliferative but nonneoplastic disorder of unknown pathogenesis that affects the synovial membranes of joints.[197,198] Eighty percent of cases involve the knee, followed in order of frequency by the hip, ankle, and shoulder, with involvement of the TMJ being very rare.[199–201] The disorder is generally thought to be a benign, inflammatory process, although it may develop as an aggressive local process.

PVNS is described as expressing multiple manifestations of a histologic lesion occurring in the synovial membrane of joints. PVNS is subdivided into diffuse and localized forms, depending on the extent of synovial involvement. PVNS may extend into bone, and, in most instances, the diffuse form probably represents aggressive extra-articular extension and occasional recurrence after surgical intervention.[197]

The symptoms of PVNS of the TMJ vary but typically include swelling in the preauricular area, progressive TMJ pain during mastication, and a history of progressive difficulty in opening of the mouth.[202]

The recommended intervention for PVNS lesions involves wide synovectomy at all sites involved.[197,198]

PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH LOCALIZED INFLAMMATION

Muscle Spasms

Muscle spasms of the mastication muscles may occur with dysfunction of the TMJ. Such dysfunctions include trauma, occlusal imbalance, changes in the vertical dimensions between the teeth, immobilization, prolonged dental procedures, chronic teeth clenching, and disease. Schwartz[203,204] hypothesized that TMD symptoms originated in mandibular muscles, which went through three pathologic phases:

1. Early incoordination of muscles, producing joint clicking and recurrent subluxation.
2. A middle phase of limitation of mandibular movements by muscle spasm.
3. A final phase of muscle shortening and fibrosis, often irreversible. Psychogenic causes were the most common.

The role of cervical whiplash injuries secondary to motor vehicle accidents (MVAs) in TMD is somewhat controversial. Brooke and Stenn[205] reported that patients with posttraumatic TMD have a poor prognosis for recovery compared with nontraumatic TMD, stating as reasons the consequence of litigation and the personality of the patient. It seems plausible that an injury to the suprahyoid and infrahyoid muscles would affect the function of the mandible, thereby predisposing the joint to dysfunction. Mechanisms have been proposed to explain how an MVA trauma could cause TMDs.[206,207]

During the initial backward movement, the jaw is forced open, stretching and possibly tearing the anterior joint capsule and the intra-articular disk. On the flexion phase, the jaw is snapped shut by the stretch reflex of the masticatory muscles and, in the presence of malocclusion, damages the posterior and temporal attachments of the articular cartilage and disk.

The following descriptions outline the common referral patterns of the TMJ muscles.

Temporalis

Referred pain from the temporalis muscle may extend over the temporal region, to the eyebrow and the upper teeth, and to the maxilla and TMJ.[108] Headache caused by temporalis muscle spasm is common. The patient also may feel pressure behind the eye or have increased eye fatigue.

Lateral Pterygoid

Spasm of the lateral pterygoid may cause a deep ache in the cheek area, maxilla, TMJ, or ear. Pain also is felt with chewing.

Medial Pterygoid

The medial pterygoid may refer pain behind the TMJ, deep in the ear, to the tongue, and to the back of the mouth.[108]

Masseter

Referred pain from a masseter muscle spasm may be projected to the eyebrow, maxilla, anterior mandible, and upper and lower molars.[108]

The intervention for these muscle spasms includes:

- application of moist heat to promote muscle relaxation;
- massage of the affected muscles;
- passive and active self-stretch exercises;
- spray and stretch techniques.

Forced mouth opening should be avoided. In the absence of joint hypomobility, yawning exercises are recommended as a home exercise, because this activity produces a strong reflex inhibition of the mandibular elevators.[108]

The lateral pterygoid can be passively stretched with maximal retrusion, followed by rhythmic sideways oscillations. The medial pterygoid can be passively stretched with jaw opening exercises.

Travell and Simons[108] recommend the use of the mandibular self-stretch exercise for the temporalis and masseter muscles.

The exercise, which consists of three steps, is performed in the sitting position facing a sink:

1. Hot packs are applied to both sides of the face.
2. The index and middle fingers are inserted below the lower incisor teeth, pads facing downward. The thumb of the same hand grasps the chin and pulls the lower jaw forward.
3. The full stretch is achieved by pulling the jaw downward, while continuing to pull it forward.

Synovitis

Synovitis of the TMJ occurs when the internal lining of the joint capsule becomes inflamed, resulting in palpable tenderness of the posterior and lateral aspects of the joint. The cause of the synovitis can be[30]

- condylar impingement of the loose areolar connective tissue located immediately posterior to the condyle, which can result in significant effusion;
- systemic disease, such as osteoarthritis, or rheumatoid arthritis or its variants;
- infection, particularly viral.

INTEGRATION OF PRACTICE PATTERNS 4B, 4C, AND 4F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE AND RANGE OF MOTION SECONDARY TO IMPAIRED POSTURE, SYSTEMIC DYSFUNCTION (REFERRED PAIN SYNDROMES), SPINAL DISORDERS, AND MYOFASCIAL PAIN DYSFUNCTION

Cervical Spine Disorders

Patients with TMD frequently report symptoms related to cervical spine disorders, and vice versa.[82,208–210] Several authors have indicated the existence of neuroanatomic and biomechanical relationships and have suggested that a dysfunction of the cervical spine may be the cause of signs and symptoms in the head.[211–222]

The masticatory and cervical muscles can affect the mandibular rest position, the mechanism of mandibular closure, and the occlusion.[223–225] Thus, a change in the mandibular rest position or habitual cervical posture can affect the occlusion and the masticatory muscles.[62,223,226–228] The most common postural abnormality in the cervical spine with direct impact on the craniofacial area and temporomandibular arthralgia is the forward head posture.[62,223,226–228]

Any increase in the sternocleidomastoid angulation, or distance from the thoracic apex to midcervical region, constitutes a FHP. This posture is considered to be minimal at 60 degrees, moderate at 60–75 degrees, and maximal at 75–90 degrees.[14] Associated signs include a decrease or reversal in the cervical lordosis and an increase in cranial rotation at the occipito atlantal joint, resulting in a shortening and excessive activity of the posterior cervical muscles. The FHP can place undue stress on both the posterior cervical muscles and the anterior submandibular muscles, by increasing their normal resting lengths. This stress may also stretch the TMJ capsule and alter the bite biomechanics of the TMJ, resulting in a posterior migration of the mandible and an altered occlusal contact pattern.

Atypical Facial Pain

Atypical facial pain is characterized by typically unilateral, dull, and relatively constant facial pain, and the presence of tender points. This condition, recently reclassified as facial pain by the

International Headache Society, is not well understood and often defies all modes of intervention.[229] Many authorities believe that atypical facial pain is psychogenic.[230,231] However, it has been reported that intraoral edema and trigeminal V2 nerve distribution area tenderness were consistently found in individuals with atypical facial pain.[232] Furthermore, these individuals experienced relief of their symptoms in response to low-level helium–neon laser therapy.[232]

Bell's palsy, a common form of facial paralysis, and Ramsey Hunt syndrome, a herpetic inflammation of the geniculate or facial nerve ganglia, are described in Chapter 5.

Trigeminal Neuralgia

Trigeminal neuralgia is an intensely painful disorder of the face of brief duration (30 seconds).[233] The pain is spontaneous and can be triggered by touch, cold, shaving, brushing teeth, or make-up application.[234] The cause of trigeminal neuralgia is at present unknown, although most authors place the site of disturbance in the region of the posterior root[235,236] or in the spinal tract of the nerve.[237] Injuries to nerves and soft and hard tissues as a result of repeated traumas have been reported to produce persistent pain because of sensitization of both peripheral and central neurons.[48,238] The sensitization process has been shown to influence subsequent pain experience. Increased postoperative pain resulting from insufficient preemptive analgesia, such as incomplete use of local anesthetics or pain medication before surgery, has been well documented.[238–240] Poorly managed postoperative or posttraumatic pain also is considered to play a role in pain persistence.[238,241]

Myofascial Pain and Dysfunction

Many clinicians over the years have described numerous conditions that share features such as fatigue, pain, and other symptoms in the absence of objective findings. These include illnesses such as chronic fatigue syndrome, fibromyalgia, and TMD.

Myofascial pain and dysfunction associated with TMD generally present with diffuse pain that is cyclic and found in several sites in the head and neck, particularly the muscles of mastication.[12] Pain is frequently at its worst in the morning, the patient often reports sore teeth from clenching, and there is often a history of stress and difficulty sleeping.[12] Masticatory muscle pain associated with TMD does not appear to progress in severity with age.[242]

The intervention for myofascial pain syndromes requires a comprehensive, and often a multidisciplinary, approach. The role of physical therapy in these syndromes is one of patient education, manual therapy techniques and electrotherapeutic modalities to reduce pain, and exercises to improve posture, reduce the adaptive shortening of tissues, and improve the strength of the postural stabilizers.

THERAPEUTIC TECHNIQUES

Manual Therapy

The aim of manual therapy in TMD is to restore normal mandibular function using a number of techniques that serve to relieve musculoskeletal pain and promote healing of tissues.[167]

In the acute phase, manual techniques, if used at all, should be very low grade and very carefully performed, because this joint tends to be very reactive and can flare up easily. Mobilization and massage can be applied to the TMJ to reduce hypomobility and acute locking, as well as to the muscles of mastication to stretch and relax them.[102]

Muscle relaxation and soft tissue techniques often are required before mobilizations of the TMJ can be performed.

Myofascial Release

Myofascial release is a combination of direct, indirect, and reflex neural release procedures.[101] The basis of this technique is sensing palpable changes at various tissue levels and manually directing a gentle force to assist in releasing restricted tissues.

Muscle Stretching

Muscle stretching techniques can be used if the examination shows that the restriction of movement is a result of shortened muscles (or other structures). Techniques to increase the extensibility of the cervical structures are described in Chapters 23 and 25.

Joint Mobilizations

Specific joint mobilizations of the craniovertebral and cervical regions are described in Chapters 23 and 25, respectively. Specific mobilization techniques of the TMJ are indicated for decreased range of motion and pain caused by muscle contracture, disk displacement without reduction, and fibrous adhesions in the joint.[68]

During these procedures, the patient's mandible should be completely relaxed, and the patient should not attempt to open his or her mouth until instructed to do so.

Techniques to Increase Mouth Opening[55,243]

Distraction

This technique is performed to separate the joint surfaces of the TMJ to allow the disk to start repositioning on the condyle and to start realigning the fibers of the tissue caudally. The patient is positioned sitting, and the clinician stands to the patient's side. The clinician grips the patient's head, using his or her forearm and hand, fingers against the patient's forehead. The clinician stabilizes the patient's head between his or her hand, arm, and chest. With a medical-gloved hand, the clinician places his or her thumb on the patient's lower molars on the involved side, as far back in the mouth as possible. The clinician's index and middle fingers grip the angle of the patient's mandible of the involved side, with the ring or little fingers held under the patient's mandible (depending on the size of the clinician's hand and patient's mandible). Using this grip, the clinician applies light distraction inferiorly to the patient's involved TMJ by pressing his or her thumb inferiorly against the lower molars (see Fig. 26-14).

Distraction, Anterior Glide, and Lateral Stretch

This technique is performed to increase the anterior and inferior movement of the mandible for the patient who can only achieve slight opening of the mouth. The patient and clinician positions are the same as those described for the distraction technique. Using the same grip as described earlier, the clinician applies light distraction inferiorly to the patient's involved TMJ by pressing his or her thumb inferiorly against the lower molars. In addition to the distraction, the clinician gradually superimposes an anterior glide of the head of the mandible at the TMJ and a lateral stretch to the joint on the opposite side. Following the technique, the patient is asked to open his or her mouth as much as possible, and the newly acquired range is assessed. The procedure is repeated gradually, until the patient is able to fully open his or her mouth or considerable improvement is attained.

Note: If the restriction of movement is bilateral, the technique may be performed on the opposite side.

Technique to Increase Full Mouth Closing[55,243]

This technique is used to increase the posterior movement of the mandible (retraction) for the patient, with an inability to fully close the mouth. The patient and clinician position is the same as described for the techniques to increase mouth opening. Using the same grip described for those techniques, the clinician gradually and maximally pushes posteriorly against the patient's involved mandible to produce a posterior glide of the head of the mandible at the TMJ (see Fig. 26-15).

Note: If the restriction of movement is bilateral, the same intervention may be performed on the patient's opposite side. The procedure is used when the patient cannot close his or her mouth.

Extraoral Lateral Glide

This technique is used in the presence of severe pain, spasm, and marked limitation of movement caused by recent trauma.[101] The patient is positioned in supine, with the head being supported on a pillow. The patient is asked to rotate the head in the opposite direction of the involved TMJ. The clinician places the thumbs of both hands over the lateral pole of the condyle. Gentle oscillations are performed over the lateral pole, or more distally depending on patient tolerance.

Extraoral Depression

This technique also is used in the presence of severe pain, spasm, and marked limitation of movement caused by recent trauma.[101] The patient is positioned in supine, with the head being supported on a pillow. The clinician gently grasps the angle of the mandible with the index and the thumb bilaterally. Gentle oscillations are then performed in the direction of mandibular depression.

AUTOMOBILIZATIONS

Toothpick Exercise

This exercise can be used for patients who demonstrate lateral deviation with mouth opening or closing. The patient stands or sits facing a mirror. A thick line is drawn down the mirror using a wax crayon. The patient wedges a toothpick between the lower incisors and lines up the toothpick with the line on the mirror. As the patient opens and closes the jaw, if the line becomes visible, the patient corrects the deviation before continuing the movement. If correction is not possible, the exercise is stopped to prevent incorrect learning by the controlling muscles.

Distraction Mobilization

This technique can be taught to patients who demonstrate or report recurrent dislocations. To self-reduce a dislocation, the patient is instructed to place a gauze roll on the back inferior molars of both sides and to place his or her index fingers on the gauze. The patient opens the mouth as wide as possible and then applies a downward force on the gauze and the molars, thereby creating a joint distraction. Following a successful reduction, ice or heat (whichever produces the optimal therapeutic effect) should be applied around the TMJ.

REVIEW QUESTIONS*

1. Name the components of the stomatognathic system?
2. Which muscle develops with the fibrocartilaginous disk of the TMJ?
3. Which three muscles function to raise the mandible during mouth closing?
4. Which of the following alterations occurs (and may need correction via exercise) as a result of posterior capital rotation associated with the forward head posture?
   a. Adaptive shortening of the craniovertebral muscles
   b. Forward migration of the mandible
   c. Elongation of the submandibular muscles
   d. Increased tension in the TMJ joint capsule
   e. All of the above.
5. Define the rest position of the TMJ.

CHAPTER 27 The Thoracic Spine

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the vertebrae, ligaments, muscles, and blood and nerve supply that comprise the thoracic intervertebral segment.
2. Outline the coupled movements of the thoracic spine, the normal and abnormal joint barriers, and the responses of the various structures to loading.
3. Perform a detailed objective examination of the thoracic musculoskeletal system, including palpation of the articular and soft tissue structures, combined motion testing, position testing, passive articular mobility tests, and stability tests.
4. Evaluate the total examination data to establish the diagnosis and estimate the prognosis.
5. Describe the common pathologies and lesions of this region.
6. Apply manual techniques to the thoracic spine using the correct grade, direction, and duration.
7. Describe intervention strategies based on clinical findings and established goals.
8. Design an intervention plan based on patient education, manual therapy, and therapeutic exercise.
9. Evaluate intervention effectiveness in order to progress or modify an intervention.
10. Plan an effective home program, including spinal care and therapeutic exercise, and instruct the patient in this program.

OVERVIEW

The thoracic spine serves as a transitional zone between the lumbosacral region and the cervical spine. Despite the fact that the thoracic spine has not enjoyed the same attention as other regions of the spine in terms of research, it can be a significant source of local and referred pain. The thoracic spine is the most rigid region of the spine and, in this area, protection of the thoracic viscera takes precedence over segmental spinal mobility. In addition, the thorax is an important region of load transfer between the upper body (the head, cervical spine, and upper extremities) and the lower body (the lumbopelvic region and lower extremities).[1,2]

Because each thoracic vertebra is involved in at least six articulations, and as many as thirteen, establishing the specific cause of thoracic dysfunction involved may not always be possible. This task is made more difficult because of the inaccessibility of most of these joints.[3]

ANATOMY

The thoracic spine (Fig. 27-1) forms a kyphotic curve between the lordotic curves of the cervical and lumbar spines. The curve begins at T1–2 and extends down to T12, with the T6–7 disk space as the apex.[4] The thoracic kyphosis is a structural curve that is present from birth.[5] Unlike the lumbar and cervical regions, which derive their curves from the corresponding differences in intervertebral disk (IVD) heights, the thoracic curve is maintained by the wedge-shaped vertebral bodies, which are about 2 mm higher posteriorly than anteriorly.

At the thoracolumbar junction, typically located between T11 and L1, the changes in curvature from one of kyphosis to one of lordosis vary quite widely according to posture, age, and previous compression fractures (see Chap. 5) and resulting deformity.[6,7]

The cervicothoracic junction anatomically comprises the C7–T1 segment and functionally includes the seventh cervical vertebra, the first two thoracic vertebrae, the first and second ribs, and the manubrium.

Thoracic Vertebra

The thoracic vertebrae consist of the usual elements: the vertebral body (centrum), transverse processes, and spinous process (Fig. 27-1).

Vertebral Body

The thoracic vertebral body (Fig. 27-1) is roughly as wide as it is long, so that its anteroposterior and mediolateral

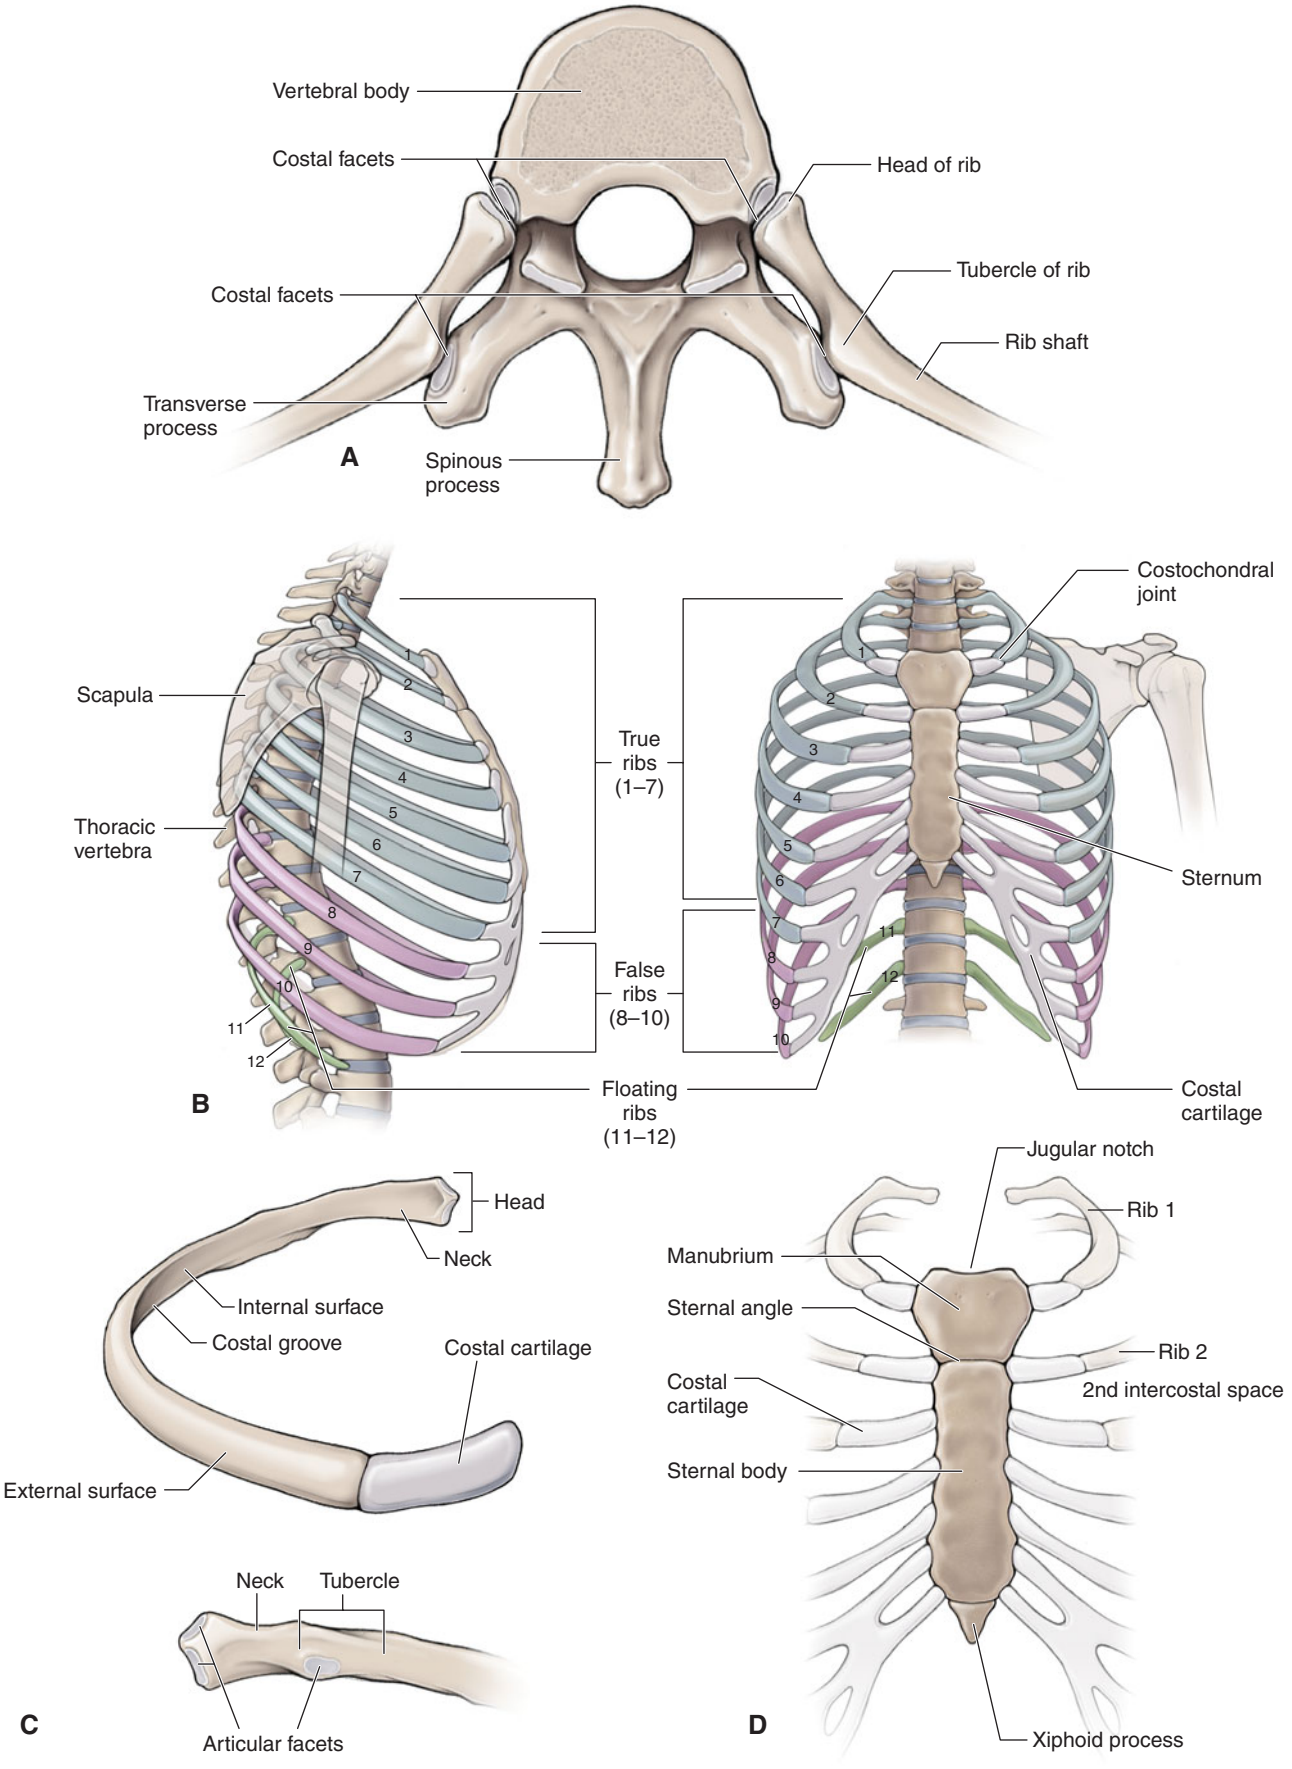

FIGURE 27-1 The thoracic spine and rib cage. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

dimensions are of equal length.[8] The anterior surface of the body is convex from side to side, whereas the posterior surface is deeply concave.[8] The height, end-plate cross-sectional area, and bone mass of the vertebral bodies increase cranially to caudally, particularly in the lower levels.[9,10] Progressive wedging of the thoracic vertebral bodies occurs with increasing age in the majority of individuals, with disk space narrowing at multiple levels occurring from the third decade of life.[11] The vertebral bodies of most of the thoracic spine differ from those of the cervical and lumbar vertebrae because of the presence of a demifacet on each of their lateral aspects for articulation with the ribs (the costovertebral joint; see later discussion).

Intervertebral Disk

The IVDs of the thoracic spine have been poorly researched, although preliminary studies seem to indicate that the typical thoracic disk appears to have been adapted from a cervical design rather than from a lumbar design.[12] The vertebral bodies of thoracic vertebrae 2–10 increase in size and change shape down the vertebral column, and, importantly, each has two demifacets for the attachment of ribs.[12] The IVDs of this region are narrower and flatter than those in the cervical and lumbar spine and contribute approximately one-sixth of the length of the thoracic column.[13] Disk size in the thoracic region gradually increases from superior to inferior. The disk height to body height ratio is 1:5, compared to 2:5 in the cervical spine, and 1:3 in the lumbar spine,[14,15] making it the smallest ratio in the spine and affording the least amount of motion.[16] Motion is further restricted by the orientation of the lamella of the annulus fibrosis (AF),[17] and the relatively small nucleus pulposus (NP), which is more centrally located within the AF, and has a lower capacity to swell.[18] The roughly circular cross-section of the thoracic disk allows the force of torsion to be evenly distributed around its circumference, making it better able to withstand these kinds of forces.[19]

In the thoracic spine, the segmental nerve roots are situated mainly behind the inferior–posterior aspect of the upper vertebral body rather than behind the disk, which reduces the possibility of root compression in impairments of the thoracic disk.[20] In a review of 280 patients, Arce and Dohrmann[21] found that thoracic disk herniation constitutes 0.25–0.75% of all disk herniations. Because the intervertebral foramina are quite large at these levels, osseous contact with the nerve roots is seldom encountered in the thoracic spine,[20] and, as the dermatomes in this region have a fair amount of overlap, they cannot be relied upon to determine the specific nerve root involved.

In contrast to the cervical and lumbar regions, where the spinal canal is triangular/oval in cross-section and offers a large lateral excursion to the nerve roots, the mid-thoracic spinal canal is small and circular (Fig. 27-1), becoming triangular at the upper and lower levels. At the levels of T4–9, the canal is at its narrowest.[20] The spinal canal is also restricted in its size by the pedicles, remaining within the confines of the vertebra and not diverging as they do in the cervical spine. This would tend to predispose the spinal cord to compression more than in the cervical spine, were it not for the smaller cord size and more oval shape of the thoracic canal. Despite this, central disk protrusions are more common in the thoracic region than in other regions of the spine, and, because the NP is small in the thorax, protrusions are invariably of the annular type, and nuclear protrusions are rare.[20] Complicating matters is the fact that this is an area of poor vascular supply, receiving its blood from only one radicular artery. This renders the thoracic spinal cord extremely vulnerable to damage by extra dural masses or by an overzealous manipulation.

Transverse Processes

The transverse processes of the thoracic spine are oriented posteriorly (i.e., they point backward) and are located directly between the inferior articulating process and the superior articulating process of the zygapophyseal joints of each level (Fig. 27-1). This anatomical feature makes the transverse processes useful as palpation points, when performing mobility testing in the mid-thorax.

The transverse processes of the first 10 thoracic vertebrae differ from those of the cervical and lumbar spines because of the presence of a costal facet on the transverse process, which articulates with the corresponding rib to form the costotransverse joint (see later discussion). At the T11 and T12 levels, the costotransverse joint is absent because ribs 11 and 12 do not articulate with the transverse processes but rather with the vertebral body.

Spinous Processes

Two short and thick laminae come together to form the spinous process (Fig. 27-1). The spinous processes of the thoracic region are long, slender, and triangular shaped in cross-section. Although all of the thoracic spinous processes point obliquely downward, the degree of obliquity varies. The first three spinous processes, and the last three, are almost horizontal, whereas those of the mid-thorax are long and steeply inclined. T7 has the greatest spinous process angulation.

As elsewhere in the spine, the thoracic vertebrae are designed to endure and distribute the compressive forces produced by weight bearing, most of which is borne by the vertebral bodies. The compressive load at T1 is approximately 9% of body weight, increasing to 33% at T8 and 47 percent at T12.[22,23]

The thoracic vertebrae are classified as typical or atypical, with reference to their morphology. The typical thoracic vertebrae are found at T2–9, although T9 may be atypical in that its inferior costal facet is frequently absent. The atypical thoracic vertebrae are T1, T10, T11, and T12.

The first vertebra (T1) resembles C7. The centrum of T1 demonstrates a larger transverse than anteroposterior dimension of the vertebral body, being almost twice as wide as its length, and the spinous process is usually at least as long as that of C7. There are two ovoid facets on either side of the T1 vertebral body for articulation with the head of the first rib. The inferior aspect of the vertebral body of T1 is flat and contains a small facet at each posterolateral corner for articulation with the head of the second rib.

Approximately 32 structures attach to the first rib and body of T1.[22,23] Because of the ring-like structure of the ribs, and their attachments both anteriorly and posteriorly, the thoracic spine and ribs can be viewed as a cage-like structure forming a series of concentric rings. Any movement occurring at the

various joints of each ring (costovertebral, costotransverse, sternocostal, and zygapophyseal joints) has the potential to influence motions at the other joints within the ring, or at the neighboring segments.

The third vertebra is the smallest of the thoracic vertebra. The T9 vertebra may have no demifacets below, or it may have two demifacets on either side (in which case, the T10 vertebra will have demifacets only at the superior aspect). The T10 vertebra has one full rib facet located partly on the body of the vertebra and partly on the tubercle. It does not articulate with the 11th rib and so does not possess inferior demifacets, and occasionally there is no facet for the rib at the costotransverse joint.

The T11 and T12 segments form the thoracolumbar junction. The T11 vertebra has complete costal facets, but no facets on the transverse processes for the rib tubercle. The T12 vertebra only articulates with its own ribs and does not possess inferior demifacets.

Ligaments

The common spinal ligaments are present at the thoracic vertebrae (Fig. 27-2), and they perform much the same function as they do elsewhere in the spine. However, the anterior longitudinal ligament in this region is narrower but thicker compared with elsewhere in the spine,[8] whereas the posterior longitudinal ligament is wider here at the level of the IVD, but narrower at the vertebral body than in the lumbar region.[24]

Zygapophyseal Joints

The zygapophyseal joints of the upper thoracic spine show some morphological features of the cervical region, and similarly the joints of the lower thoracic spine progressively approximate those of the upper lumbar region.[25] The middle segments of the thoracic spine are designed for less mobility, as the thoracic cage articulations limit sagittal plane motion while accommodating axial displacements.[25,26]

CLINICAL PEARL

The articulating facets of the thoracic zygapophyseal joints are quite different from those of the cervical and lumbar spines because they are oriented in a more coronal direction, with the angle of inclination changing, depending on the segmental level:

- The upper segments are inclined at 45–60 degrees to horizontal in a similar fashion as to those of the cervical spine.
- The middle segments are inclined at 90 degrees to horizontal in the typical thoracic form.
- The lower segments are inclined as in the lumbar spine. Zygapophyseal tropism (the moving toward or away from a stimulus) occurs most frequently at T11–12.[27] The inferior articular facets of T12 are invariably lumbar in orientation and concavity, with the orientation changing by 90 degrees at either T11 or T12, allowing pure axial rotation to occur.[28,29]

The superior and inferior facets of the zygapophyseal joints arise from the upper and lower parts of the pedicle of the thoracic vertebra. The superior facet lies superiorly with the articular surface on the posterior aspect, whereas the inferior facet lies inferiorly with the articular surface on the anterior (ventral) aspect. The degree of superoinferior and mediolateral orientation is slight. The superior facet arises from near the lamina–pedicle junction and faces posteriorly, superiorly, and laterally.

The inferior articulating facet arises from the laminae to face anteriorly, inferiorly, and medially, lying posterior to the superior facet of the vertebra below. The facet surfaces are concave anteriorly and convex posteriorly, bringing the axis of rotation through the centrum rather than through the spinous process, as in the lumbar vertebrae. This results in the biomechanical center of rotation coinciding with the actual center of rotation formed by body weight.[30]

The zygapophyseal joints function to restrain the amount of flexion and anterior translation of the vertebral segment and to facilitate rotation.[22] They appear to have little influence on the range of side bending.[22]

Ribs

The bony thoracic cage is formed by 12 pairs of ribs, the sternum, the clavicle, and the vertebrae of the thoracic spine (Fig. 27-1). The primary function of the rib cage is to protect the heart and lungs. All of the ribs of the cage are different from each other in size, width, and curvature, although they share some common characteristics. The first rib is the shortest. The rib length increases further inferiorly until the seventh rib, after which they become progressively shorter.

The ribs are divided into two classifications: true/false and typical/atypical.

1. ***True/false.*** Ribs 1–7 are named true ribs because their cartilage attaches directly to the sternum. The remaining ribs are false ribs, so named because their distal attachment is to the costochondral cartilage of their superior neighbor.
2. ***Typical/atypical.*** Ribs 3–9 are typical ribs. The first, ninth, 10th, 11th, and 12th ribs are considered atypical. The typical rib is characterized by a posterior end, which is composed of a head, neck, and tubercle. The head of the typical rib is characterized as two articular facets, a superior costal facet, and an inferior costal facet.
   a. The superior facet attaches to the costal semilunar demifacet of the vertebra above its level.
   b. The inferior facet attaches to the costal semicircular demifacet of the vertebra of the same level.[12]

The first, ninth, 10th, 11th, and 12th ribs are deemed atypical because they only articulate with their own vertebra via one full facet, and the lower two do not articulate with the costochondrium anteriorly.[31]

Typical Ribs

The head of the typical rib projects upward in a very similar manner to that of the uncinate process in the cervical

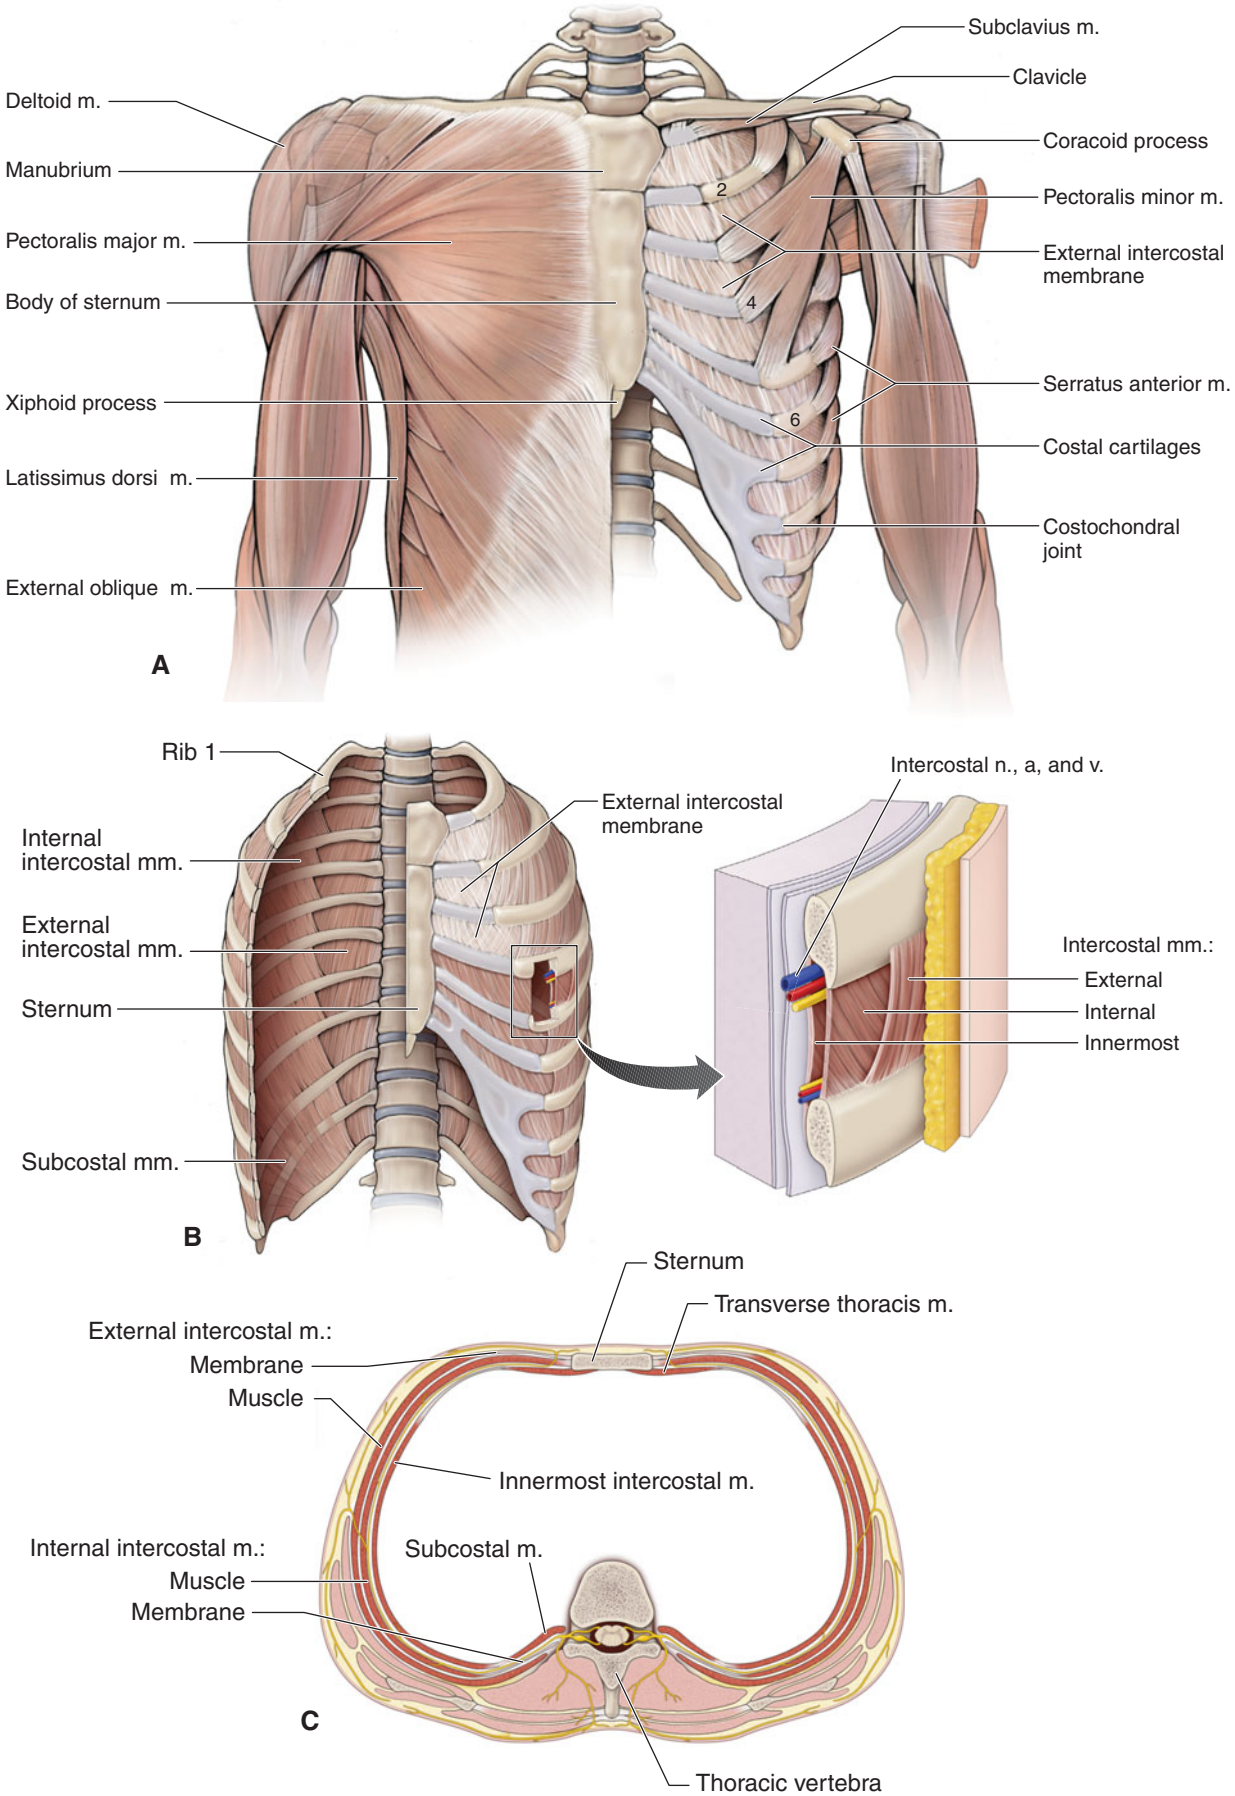

FIGURE 27-2 Muscles of the thoracic spine. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

spine and, in fact, develops in much the same way during childhood, appearing to play a similar mechanical role.[8] The head consists of a slightly enlarged posterior end, which is divided by a horizontal ridge. The ridge serves as an attachment for the intra-articular ligament. The intra-articular ligament, which travels between the head of the rib and the IVD, bisects the joint into superior and inferior portions. Each of these portions normally contains a demifacet for articulation with the synovial costovertebral joints.

The tubercle of the typical rib lies on the outer surface, where the neck joins the shaft, and is more prominent in the upper parts than in the lower. The articular portion of the tubercle presents an oval facet for articulation at the costotransverse joint (Fig. 27-1).

The convex shaft of the rib is connected to the neck at the rib angle. The upper border of the shaft is round and blunt, whereas the inferior aspect is thin and sharp.[8] The anterior end of the shaft has a small depression at the tip for articulation at the costochondral joint.

Atypical Ribs

The atypical first rib is small but massively built. Being the most curved and the most inferiorly orientated rib, it slopes sharply downward from its vertebral articulation to the manubrium. The head is small and rounded and articulates only with the T1 vertebra. The first costal cartilage is the shortest and this, together with the fibrous sternochondral joint (Fig. 27-1), contributes to the overall stability of the first ring of the rib cage. The first rib attaches to the manubrium just under the sternoclavicular joint, and the second rib articulates with the sternum at the manubriosternal junction. The atypical second rib is longer and is not as flat as the first rib. It attaches to the junction of the manubrium and the body of the sternum.

The atypical 10th rib has only a single facet on its head, because of its lack of articulation with the vertebra above. The 11th and 12th ribs do not present tubercles and have only a single articular facet on their heads. The 11th and 12th ribs remain unattached anteriorly, but end with a small piece of cartilage.

Attachment and Orientation of the Ribs

The attachment of the ribs to the sternum is variable (Fig. 27-1). The upper five, six, or seven ribs have their own cartilaginous connection (see "Sternocostal Joint" section).[8] The cartilage of the eighth rib ends by blending with the seventh. The same situation pertains for the ninth and the 10th ribs, thus giving rise to a common band of cartilage and connective tissue.

The strong ligamentous attendance, and the presence of the two joints (costovertebral and costotransverse) at each level, severely limits the amount of movement permitted here to slight gliding and spinning motions, with morphology determining the function of each rib.

The orientation of the ribs increases from being horizontal at the upper levels to being more downwardly oblique in the inferior levels of the thoracic spine (a point worth remembering when performing palpation).

CLINICAL PEARL

The cervical rib is a rare anatomic variant estimated to occur in approximately 0.5–1% of the population and bilaterally in 66–80% of these cases.[18] Diagnosis is most often incidental, as a result of routine chest radiographs or in patients developing thoracic outlet syndrome (see Chap. 25).[32]

Costovertebral Joint

The thoracic vertebrae are connected to their adjacent vertebrae by the bilateral hyalinated, and synovial, costovertebral joints and their surrounding ligaments (see Fig. 27-1). The costovertebral articulation also forms an intimate relationship between the head of the rib and the lateral side of the vertebral body (see Fig. 27-1). The first, 11th, and 12th ribs articulate fully with their own vertebrae via a single costal facet, without any contact with the IVD, while the remaining ribs articulate with both their own vertebra and the vertebra above, as well as to the IVD. This could potentially predispose the first, 11th, and 12th costovertebral joints to early arthritic changes, as a result of more mechanical stress compared to the second to the 10th ribs.[33]

The radiate ligament connects the anterior aspect of the rib head to the bodies of two adjacent vertebrae and their intervening disk in a fanlike arrangement. Each of the three bands of the radiate ligament has different attachments:

1. The superior part runs from the head of the rib to the body of the superior vertebra.
2. The inferior part runs to the body of the inferior vertebra.
3. The intermediate part runs to the intervening disk.

Oda and colleagues[34] reported that the costovertebral joint and rib cage confer stability on the thoracic spine. They performed symmetrically applied resections of the posterior elements first, followed by resection of the bilateral costovertebral joints and then complete obliteration of the rib cage. Their conclusion was that the thoracic spine may become unstable when the posterior elements and the bilateral costovertebral joints are obliterated. In addition, there is an increase in the neutral zone and range of motion in both side bending and rotation, indicating that these joints provide a stabilizing influence during coupled motions.[34]

Feiertag and colleagues[35] reported that rib head joint resection showed significant increases in thoracic spinal motion in the sagittal and coronal planes. As the ossification of the head of the rib is not developed at the superior costovertebral joint until about age 13, younger individuals, such as gymnasts, can demonstrate a vast amount of thoracic rotation and side bending.

Costotransverse Joint

This is a synovial joint located between an articular facet on the posterior aspect of the rib tubercle and an articular facet on the anterior aspect of the transverse process, which is supported by a thin fibrous capsule (see Fig. 27-1). In the lower two thoracic vertebral segments, this articulation does not exist.

The neck of the rib lies along the entire length of the posterior aspect of the transverse process. The short and deep costotransverse ligament runs posteriorly from the posterior aspect of the rib neck to the anterior aspect of its transverse process, filling the costotransverse foramen that is formed between the rib neck and its adjacent transverse process. The ligament has two divisions:

1. The superior costotransverse ligament, also known as the interosseous ligament, or ligament of the neck of the rib, is formed in two layers. The anterior layer, which is continuous with the internal intercostal membrane laterally, runs from the neck of the rib up and laterally to the inferior aspect of the transverse process above. The posterior layer runs up and medially from the posterior aspect of the rib neck to the transverse process above.
2. The lateral costotransverse ligament runs from the tip of the transverse process laterally to the tubercle of its own rib. It is short, thick, and strong but is often damaged with direct blows to the chest (e.g., punch, kick, etc.).

Very little posteroanterior or anteromedial–posterolateral translation is available at this joint. Jiang and colleagues[36] reported that the superior costotransverse ligaments are very important in maintaining the lateral stability of the spine.

CLINICAL PEARL

Working together, the costotransverse and the costovertebral joints help provide stability to the thoracic spine.

Sternum

The sternum consists of three parts: the manubrium, the body, and the xiphoid process.

The manubrium (Fig. 27-1) is broad and thick superiorly and narrower and thinner inferiorly, where it articulates with the body. On either side of the suprasternal notch are articulating facets for the clavicles, and below these are the facets for the first rib. On the immediate inferolateral aspects of the manubrium are two more small facets for the cartilage of the second rib.

The articulation between the manubrium and the sternum is usually a symphysis, with the ends of the bones being lined with hyaline cartilage.

The body of the sternum is made up of the fused elements of four sternal bodies, and the vestiges of these are marked by three horizontal ridges. The upper end of the body articulates with the manubrium at the sternal angle. A facet at the superior end of the body laterally provides a joint surface common with the manubrium for the second costal cartilage. On each lateral border are four other notches that articulate with the third through sixth costal cartilages. The third rib has the deepest fossa on the sternum, indicating that it may serve as the axis for rotation and side bending during arm elevation. T7 articulates with both the sternum and the xiphoid.

The xiphisternum, or xiphoid process (see Fig. 27-1), is the smallest part of the sternum. It begins life in a cartilaginous state, but, in adulthood, the upper part ossifies.

A study[37] examining the effect of removal of the entire sternum from the intact thorax found that its removal produced an almost complete loss of the stiffening effect of the thorax.

Sternocostal Joint

The first, sixth, and seventh costal cartilages are each linked to the sternum by a synchondrosis. The second to fifth ribs are each connected to the sternum through a synovial joint, whereby the cartilage of the corresponding rib articulates with a socket-like cavity in the sternum.[38]

In all of these joints, the periosteum of the sternum and the perichondrium of the costal cartilage are continuous. A thin fibrous capsule, present in the upper seven joints, attaches to the circumference of the articular surfaces, blending with the sternocostal ligaments. The surfaces of the joints are covered with fibrocartilage and are supported by capsular, radiate sternocostal, or xiphicostal and intra-articular ligaments. The joint is capable of about 2 degrees of motion from full inspiration to full expiration and allows the full excursion of the sternum in these activities.

Muscles

A large number of muscles arise from and insert on the thoracic spine and ribs (Fig. 27-2). The muscles of this region can be divided into those that are involved in spinal or extremity motion, and those that are involved in respiration (Tables 27-1 and 27-2).

Spinal and Extremity Muscles

Spinal Muscles

Iliocostalis Thoracis. The iliocostalis thoracis consists of several muscle straps that link the thoracic vertebrae and sacrum with the lower six or seven ribs. The muscle straps have a number of tendons, varying in different individuals, which insert in all angles in the lower six ribs. The function of the muscle is to extend the spine when working bilaterally and to side bend the spine ipsilaterally when working alone. The iliocostalis consists of three subdivisions—iliocostalis lumborum, iliocostalis thoracis, and iliocostalis cervicis—which are a part of the external portion of the long erector spinae muscle group. The muscle receives its nerve supply by the posterior (dorsal) rami of the thoracic nerves.

Longissimus Thoracis. The longissimus thoracis muscles originate with the intercostalis muscles from the transverse processes of the lower thoracic vertebrae. They insert into all of the ribs and into the ends of the transverse processes of the upper lumbar vertebrae. The function of the muscle is to extend the spine when working bilaterally and to side bend the spine ipsilaterally when working alone. The muscle is innervated by the posterior (dorsal) rami of the thoracic nerves.

Spinalis Thoracis. The spinalis thoracis muscle (spinalis dorsi) originates from the spinous processes of the upper lumbar and two lower thoracic vertebrae. It inserts in the spinous processes of the middle and upper thoracic vertebrae. The function of the muscle is to extend the spine. The muscle is innervated by the posterior (dorsal) rami of the thoracic nerves.

Semispinalis Thoracis. The semispinalis thoracis consists of long straps of muscle that stretch along and surround the vertebrae of the spine. The muscle can have between four and eight upper ends, which originate from the transverse processes of the T6–10. These straps of muscle insert in the spinous processes of the first four thoracic and fifth and seventh processes of C6–T4. The function of the muscle is to extend the spine when working bilaterally and to rotate the spine contralaterally when working alone. The semispinalis thoracis is innervated by the posterior (dorsal) rami of the thoracic nerves.

Multifidus. The multifidus is a deep back muscle that runs along the entire spine and lies deep to the erector spinae muscles. It originates from the sacrum, sacroiliac ligament, mammillary processes of the lumbar vertebrae, transverse processes of the thoracic vertebrae, and the articular processes of the last four cervical vertebrae. The multifidus consists of numerous bundles of fibers that cross over two to five vertebrae at a time and insert into the entire length of the spinous process above. The function of the muscle is to extend the spine when working bilaterally and to minimally rotate the spine contralaterally when working alone. The thoracic multifidus is innervated by the posterior (dorsal) rami of the thoracic spinal nerves.

Rotatores Thoracis (Longus and Brevis). The rotatores muscles are deep spinal muscles that lie beneath the multifidus muscles. The rotatores brevis muscle lies just deep to the rotatores longus muscle. The rotatores muscles are the best developed in the thoracic region. There are a total of 11 small, quadrilateral rotatores muscles on each side of the spine. Each muscle arises from the transverse process of the vertebra and extends inward to the vertebra above. The rotatores muscles help rotate the appropriate thoracic segment. They are innervated by posterior (dorsal) rami of the thoracic spinal nerves.

Intertransversarii. The intratransversals are small muscles located between the transverse process of the vertebrae. In the thoracic region, they are single-bellied muscles and exist only from T10–11 to T12–L1. The function of the muscle is to ipsilaterally side bend the spine. The muscle is innervated by the posterior (dorsal) rami of the thoracic spinal nerves.

The other spinal muscles of the thoracic region act primarily on the cervical spine. These include the trapezius, levator scapulae, and anterior, posterior, and middle scalenes (see Chap. 25).

Extremity Muscles. The muscles of the thoracic region that act primarily on the extremities include the pectoralis major, latissimus dorsi, and serratus anterior (see Chap. 16).

Respiratory Muscles

The respiratory system is essentially a robust, multimuscle pump (Fig. 27-3). Connections to the respiratory mechanism have been found to exert a strong influence on such areas as the shoulder and pelvic girdles, as well as the head and neck. The primary task of the respiratory muscles is to displace the chest wall and, therefore, move gas in and out of the lungs to maintain arterial blood gas and pH homeostasis. The importance of normal respiratory muscle function can be appreciated by considering that respiratory muscle failure caused by fatigue, injury, or disease could result in an inability to maintain blood gas and pH levels within an acceptable range, which could have lethal consequences. Restoration of the respiratory mechanism is, thus, an essential element of thoracic intervention.

The actions of various respiratory muscles, which are broadly classified as *inspiratory* or *expiratory*, based on their mechanical actions, are highly redundant and provide several means by which air can be effectively displaced under a host of physiologic and pathophysiologic conditions.[39,40]

At rest, movement of air into and out of the lungs is the result of the recruitment of several muscles,[41–43] and the expiratory phase of breathing at rest is also associated with active muscle participation.[44] In a resting man, the tidal volume is the result of the coordinated recruitment of the diaphragm, the parasternal intercostal, and the scalene muscles (Tables 27-1 and 27-2).[45,46]

Although some have argued that the performance of the respiratory muscles does not limit exercise tolerance in normal healthy adults,[47,48] heavy or prolonged exercise has been shown to impair respiratory muscle performance in humans.[49,50] Thus, an interest in the adaptability of respiratory muscles to endurance-type exercise has grown significantly during the last decade.

The primary muscles of respiration include the diaphragm, the sternocostal, and the intercostals. The secondary muscles of respiration are the anterior/medial scalenes, serratus posterior, pectoralis major and minor, and, with the head fixed, the sternocleidomastoid.[8]

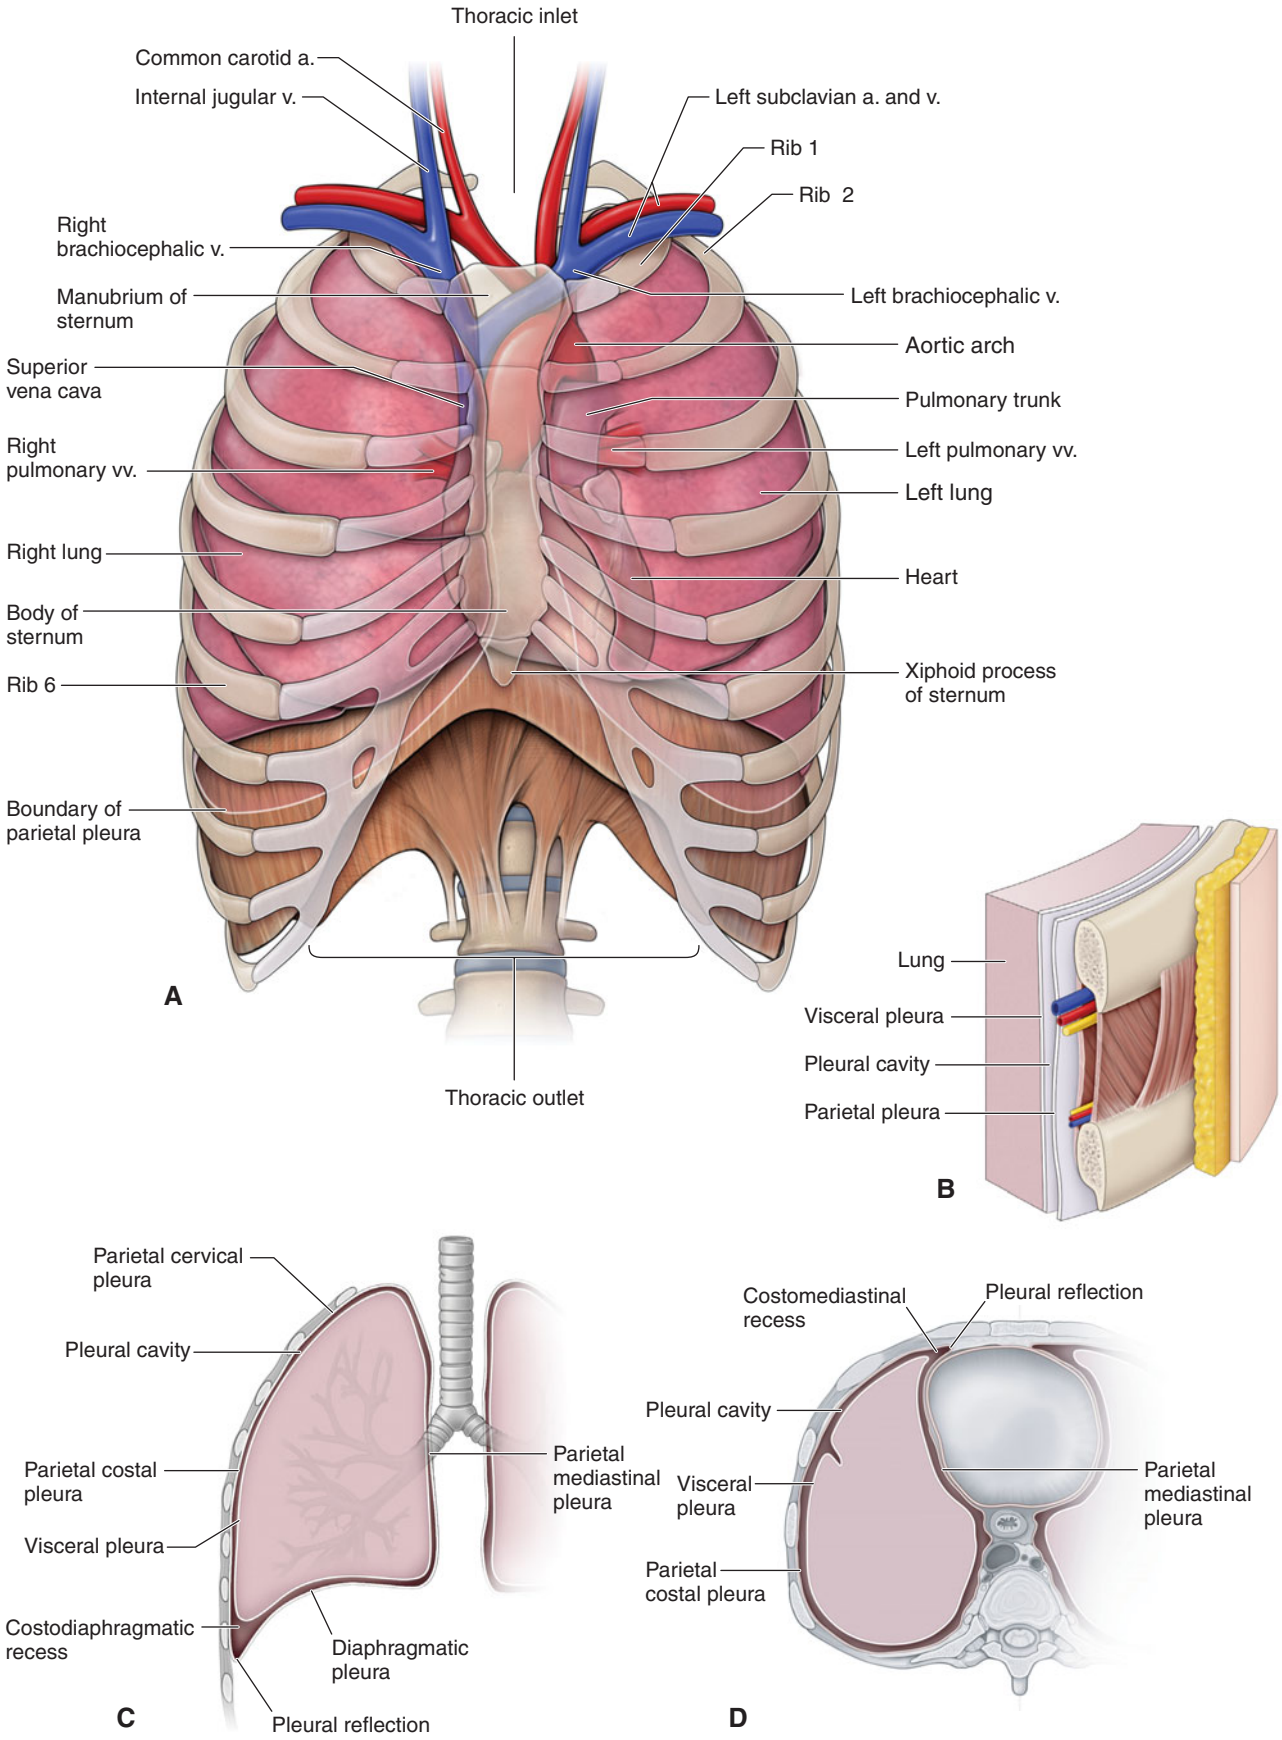

FIGURE 27-3 Components of the respiratory system. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Diaphragm

Anatomically, the diaphragm muscle may be divided into sternal, costal, and lumbar parts:

- The sternal fibers originate from two slips at the back of the xiphoid process.
- The costal fibers originate from the lower six ribs and their costal cartilages.
- The lumbar fibers originate from the crura of the lumbar vertebra, and the medial and lateral arcuate ligaments.

CLINICAL PEARL

Patients with bilateral diaphragm paralysis or severe weakness present a striking clinical picture, with orthopnea as the major symptom. Lesser degrees of diaphragm weakness, however, are hard to detect and need specific testing.

Functionally and metabolically, the diaphragm can be classified as two muscles[51,52]:

1. The crural (posterior) portion that inserts into the lumbar vertebrae.
2. The costal portion that inserts into the xiphoid process of the sternum and into the margins of the lower ribs.

Thus, the muscle is attached around the thoracoabdominal junction circumferentially. From these attachments, the fibers arch toward each other centrally to form a large tendon. Contraction of the diaphragm pulls the large, central tendon inferiorly, producing diaphragmatic inspiration (see later discussion). The diaphragm has a phrenic C3–4 motor innervation and a sensory supply by the lower six intercostal nerves.

Intercostals

Between the ribs are the intercostal spaces, which are deeper both in front and between the upper ribs. Between the ribs lie the internal and external intercostal muscles, with the neurovascular bundle lying beneath each rib.

The intercostal muscles, together with the sternalis (or sternocostalis or transversalis thoracis), phylogenically form from the hypomeric muscles. These muscles correspond to their abdominal counterparts, with the sternalis being homologous to the rectus abdominis, and the intercostals homologous to the external oblique.[8]

External Intercostals. The external intercostal muscles (Fig. 27-2), of which there are 11, are laid in a direction that is superoposterior to inferoanterior (run inferiorly and medially in the front of the thorax and inferiorly and laterally in the back). Because of the oblique course of the fibers, and the fact that leverage is greatest on the lower of the two ribs, the muscle pulls the lower rib toward the upper rib, which results in inspiration. The external intercostals attach to the lower border of one rib and the upper border of the rib below, extending from the tubercle to the costal cartilage. Posteriorly, the muscle is continuous with the posterior fibers of the superior costotransverse ligament. The action of the external intercostals is believed to be entirely inspiratory,[45] although the muscles also counteract the force of the diaphragm, preventing the collapse of the ribs.[42] Innervation of this muscle is supplied by the adjacent intercostal nerve.

Internal Intercostals. The internal intercostals (see Fig. 27-2), which also number 11, have their fibers in an inferoposterior to a superoanterior direction. The internal intercostals are found deep to the external intercostals and run obliquely, and perpendicular, to the externals. The posterior fibers pull the upper rib down, but only during enforced expiration.[42,45] The internal intercostals extend from the posterior rib angles to the sternum, where they end posteriorly. They are continuous with the internal membrane, which then becomes continuous with the anterior part of the superior costotransverse ligament. Innervation of this muscle group is supplied by the adjacent intercostal nerve.

Transverse Intercostals (Intima). The deepest of the intercostals, the transverse intercostals are attached to the internal aspects of two contiguous ribs. They become progressively more significant, and developed, further down the thorax. This muscle is used during forced expiration.[42,45]

Transversus Thoracis. The transversus thoracis is a triangular-shaped sheet muscle, which originates from the posterior (dorsal) surface of the sternum and covers the inner surfaces of both the sternum and the second to eighth sternal costal cartilages. The apex of the muscle points cranially, with muscle slips running inferolaterally and eventually inserting on the sternal ribs quite close to the costochondral junctions. Morphologically, the transversus thoracis is similar to the anterior (ventral) part of the transversus abdominis. Its function is to draw the costal cartilages down. The muscle is innervated by the adjacent intercostal nerves.

Levator Costae

These consist of 12 strong short muscles that turn obliquely (inferolaterally), parallel with the external intercostals, from the tip of the transverse process to the angle of the rib, extending from C7 to T11 transverse processes. These muscles, which are innervated by the lateral branch of the posterior (dorsal) ramus of the thoracic nerve, function to raise the rib, but their importance in respiration is argued. The levator costae may also be segmentally involved in rotation and side bending of the thoracic vertebra.

Serratus Posterior Superior

The serratus posterior superior runs from the lower part of the ligamentum nuchae, the spinous processes of C7 and T1–3, and their supraspinous ligaments, to the inferior border of the second through fifth ribs, lateral to the rib angle.

The muscle receives its nerve supply from the second through fifth intercostal nerves. Its function is unclear, but it is thought to elevate the ribs.[8]

Serratus Posterior Inferior

This muscle arises from the spines and supraspinous ligaments of the two lower thoracic and the two or three upper lumbar vertebrae. It attaches to the inferior border of the lower four ribs, lateral to the rib angle.

The muscle receives its nerve supply from the anterior (ventral) rami of the ninth through 12th thoracic nerves. Its

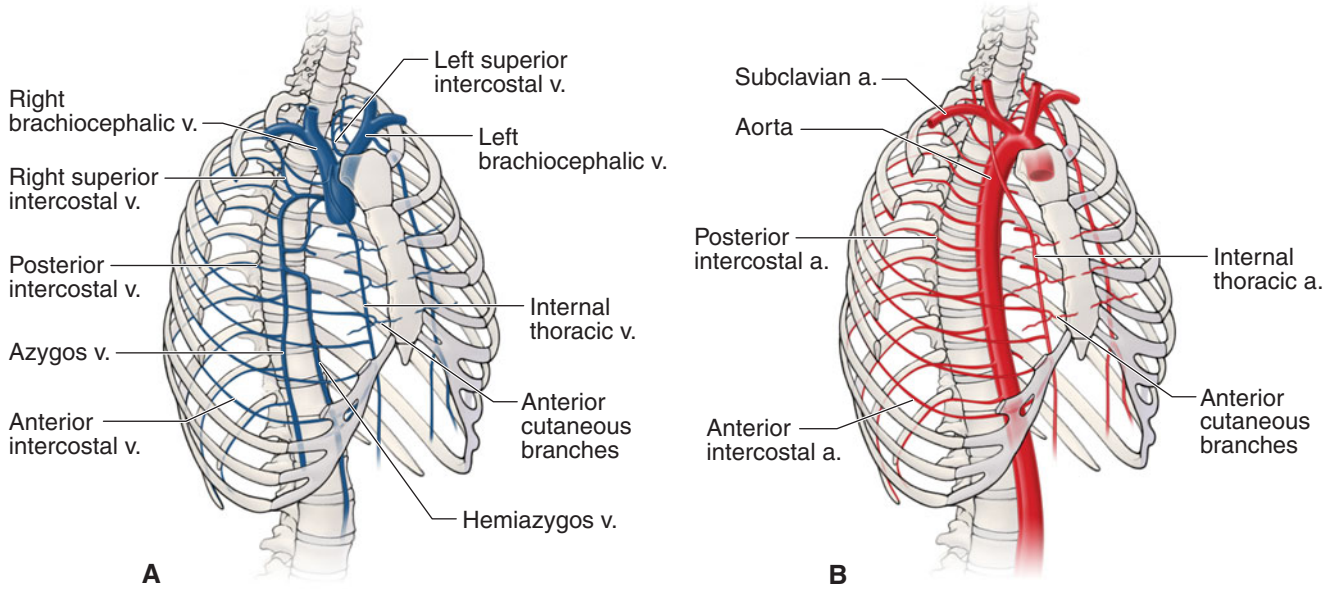

FIGURE 27-4 Vasculature of the thoracic region. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

function is unclear, but it is thought to pull the ribs downward and backward.

Vascular Supply

The blood supply to this region is provided mainly by the posterior (dorsal) branches of the posterior intercostal arteries (Fig. 27-4), while the venous drainage occurs through the anterior and posterior venous plexuses. The spinal cord region between T4 and T9 is poorly vascularized.[53]

Neurology

The spinal canal in this region is narrow, with only a small epidural space between the cord and its osseous environment.[53] Innervation of the thoracic spinal canal is by the sinuvertebral nerve, which arises from the nerve root and reenters the epidural space.

The thoracic spinal cord is unusually susceptible to injury because it occupies a greater percentage of the total cross-sectional area of its surrounding spinal canal than do the cervical or lumbar sections of the spinal cord, and the thoracic cord is tightly packed in the canal and easily injured by displaced fragments of bone or disk material.[54] Furthermore, the blood supply of the mid-thoracic spinal cord is tenuous, and seemingly trivial injuries can disrupt the blood supply to a substantial portion of the thoracic cord and result in devastating neurologic deficits.[55]

In the thoracic region, there is great variability in the topography of the nerves and the structures that they serve.[56] Typically, the spinal root arises from the lateral end of the spinal nerve but, in 25% of cases, the spinal root is made up of two parts that arise from the superior border of the spinal nerve.[57] The thoracic spinal nerves are segmented into posterior (dorsal) primary and anterior (ventral) primary divisions (see Chap. 3). As elsewhere, the dermatomes of this region are considered to represent the cutaneous region innervated by one spinal nerve through both of its rami.[58]

The peripheral nerves, which travel through the thoracic spine and chest wall, include the posterior (dorsal) scapular, thoracodorsal, and long thoracic nerves (see Chap. 3).

BIOMECHANICS

Knowledge of the regional biomechanics of the thoracic spine and rib cage assists the clinician in the interpretation of active movement and motion palpation examination in relation to the patient's symptoms.[59] The thoracic spinal segments possess the potential for a distinctive array of movements. Most of the understanding with regard to the biomechanics of the thoracic spine is based largely on the ex vivo studies of White,[22] and Panjabi et al.,[1,60] and a variety of 'clinical models.'[28,61] In addition, although normative ranges of spinal motion have been reported for the lumbar spine, no such reliable data exists for the thoracic region.[62]

It is widely recognized that the mechanical behavior of the spine is influenced by load.[63] Axial load has been shown to increase motion segment stiffness and decrease mobility. In addition, due to the modifying influence of the cage-like structure of the ribs, which provide a significant degree of stability,[36] and the kyphotic shape of the curve, the biomechanics of the thoracic spine is considerably different from those of the lumbar and cervical regions. The increased stability/reduced mobility of the thoracic segments has been reported to produce three primary affects[23,64]:

1. It influences the motions available in other spinal regions as well as the shoulder girdle.
2. It increases the potential for postural impairments.[65]
3. It provides an important weight-bearing mechanism for the vertebral column.[66] The load-bearing capacity of the spine has been found to be up to three times greater with an intact rib cage.[37,67]

Other biomechanical studies have investigated the stabilizing effects of the individual components of the thoracic spine[34,68]:

- The IVD can be regarded as the most important stabilizer in the thoracic functional unit mechanics.
- The rib head joints serve as stabilizing structures to the human thoracic spine under flexion–extension, side bending, and axial rotation loading, and resection after diskectomy increases range of motion by approximately 80% under all loading modes.
- The lateral portion of the facet joints plays an important role in providing spinal stability.
- In the thoracic spine, total resection of the posterior ligamentous complex leads to an approximately 40% increase in range of motion under flexion–extension, side bending, and axial rotation loading.

Flexion

Flexion of the thoracic spine in weight bearing is initiated by the abdominal muscles and, in the absence of resistance, is continued by gravity, with the spinal erector muscles eccentrically controlling the descent. Flexion may also occur during bilateral scapular protraction.

There are about 4–5 degrees of flexion available at the upper thoracic levels, 6–8 degrees in the middle layers, and 9–15 degrees in the lower levels,[22] giving an overall total range for thoracic flexion of 20–45 degrees.[69] End-range flexion is resisted by the posterior half of annulus and by the impaction of the zygapophyseal joints.

According to Lee,[29] flexion of the cervicothoracic region consists of an anterior rotation of the head of the rib and a superoanterior glide of the zygapophyseal joints, whereas extension and arm elevation in this region consists of a posterior sagittal rotation and posterior translation of the superior vertebra. This latter action pushes the superior aspect of the head of the rib posteriorly at the costovertebral joint, producing a posterior rotation of the rib (the anterior aspect travels superiorly, while the posterior aspect travels inferiorly).[29]

In the remainder of the thorax, flexion results from the superior facets (i.e., the inferior articular processes of the superior vertebra of the segment) gliding superiorly and anteriorly[28] (Table 27-3). This motion at the zygapophyseal joint is accompanied by an anterior translation of the superior vertebra, and a slight distraction of the centrum. It seems likely that the anterior vertebral translation produces a similar motion in the ribs, with a superior glide occurring at the costotransverse joint. During this motion, the anterior aspects of the ribs approximate each other, while the posterior aspects separate.

Studies have shown that the thoracic zygapophyseal facets play an important role in stabilization of the thoracic spine during flexion loading.[60,70]

Extension

Extension of the thoracic spine is produced principally by the lumbar extensors and results in an inferior glide of the superior facet of the zygapophyseal joint (see Table 27-3). One to two degrees of extension is available at each thoracic segment, giving an overall average of 15–20 degrees of thoracic extension for the entire thoracic spine.

Extension of the thoracic spine is restrained by the relative stiffness of the anterior IVD; the anterior longitudinal ligament; bony contact of the posterior elements, including the inferior facet onto the lamina below; and the spinous processes.[23,60] Given the location of the axis of rotation for extension, which is close to the moving segment, more translation than rotation occurs during extension.[71]

The joint motions occurring with extension are essentially the opposite of those of flexion. The translation of the vertebra occurs in a posterior direction, with an accompanying slight compression of the centra. The posterior translation that occurs with extension is controlled by the posteriorly directed lamellae of the annulus, and by the capsule of the zygapophyseal joint.

The transitional region between the thoracic and lumbar spines can produce an inflexion point that may serve to reduce the bending forces in the sagittal plane.[6] However, stiffness in this area also may result in the thoracic spine pivoting over the thoracolumbar region, thereby increasing the risk of compression fracture (see Chap. 5).[72]

In addition to those motions occurring at the zygapophyseal joints and the vertebral body during thoracic extension, motion also occurs at the rib articulations. The ribs rotate posteriorly, with the posterior aspects approximating and the anterior aspects separating, and an inferior glide occurs at the costotransverse joint.[29]

Side Bending

Side bending of the thoracic spine is initiated by the ipsilateral abdominals and erector muscles, and then continued by gravity. A total of 25–45 degrees of side bending is available in the thoracic spine, at an average of about 3–4 degrees to each side per segment, with the lower segments averaging slightly more, at 7–9 degrees, each.[22,73]

At the zygapophyseal joints, the primary motion involves the ipsilateral superior facet gliding inferiorly, and the contralateral gliding superiorly (see Table 27-3). In effect, the ipsilateral zygapophyseal joint extends while the contralateral flexes. Side bending is restrained by the compression of the IVD and approximation of the ribs.

Side bending in the upper thoracic spine is associated with ipsilateral rotation and ipsilateral translation.[74] According to Lee,[29] the coupling that occurs in the rest of the thoracic spine depends on which of the two coupling motions initiates the movement. If side bending initiates the movement, it is called *latexion*, and the biomechanics consist of side bending, contralateral rotation, and ipsilateral translation. The mechanism of this coupling, or actually tripling, is not certain, and one must guard against strong conclusions. The postulated mechanism is as follows: with side bending, a contralateral convex curve is produced. This causes the ribs on the convex side of the curve to separate and those on the concave side to approximate.[29] Trunk side bending is essentially halted, by soft tissue tension or rib approximation, or both, and the ribs become fixed. Further side

TABLE 27-3 Biomechanics of the Thorax

Motions	Z Joint	Rib Motion	Costotransverse Joint
Vertebromanubrial (T1–2)			
Flexion	Superoanterior glide	Anterior rotation	NA

Expiration	NA	NA	SMP glide

NA, not applicable; SMP, superior medial posterior; ILA, inferior lateral anterior.

bending is modified by the fixed ribs.[29] The ipsilateral articular facet of the transverse process glides inferiorly on its rib, resulting in a relative anterior rotation of the neck of the rib, while the contralateral transverse process glides superiorly, producing a posterior rotation of the rib neck.[29] The effect of these bilateral rib rotations is to force the superior vertebra into rotation away from the direction of side bending.

Rotation

The axis of rotation for the thoracic spine varies according to the vertebral level.[75] The axis of rotation lies within the vertebral body in the mid-thoracic joints, but anterior to the vertebral body in the upper and lower joints.[75] Almost pure rotation can occur in the mid-thoracic region, whereas, in the upper and lower segments, rotation can be associated with side bending to either side (see Table 27-3). Axial rotation (rotexion) is produced either by the abdominal muscles and other trunk rotators or by the unilateral elevation of the arm. Pure axial rotation (twisting) can only occur at two points in the spine: at the thoracolumbar and cervicothoracic junctions.

A total of 35–50 degrees of rotation is available in the thoracic spine.[22,73] Segmental axial rotation in the thoracic spine averages 7 degrees in the upper thoracic area, approximately 5 degrees in the middle thoracic spine, and 2–3 degrees in the last two or three segments.[22,69,76] Torsional stiffness is enhanced in the thoracolumbar region by the mortise-type morphology of the zygapophyseal joints and the near sagittal alignment of the upper lumbar articulations.[23,27,66,72,77]

According to MacConaill and Basmajian,[30] thoracic segmental rotation is coupled with contralateral side bending and contralateral translation. However, this finding deviates from what is generally observed clinically, where the coupling of rotation and side bending that occurs seems to depend on the segmental level and the integrity of the joint.

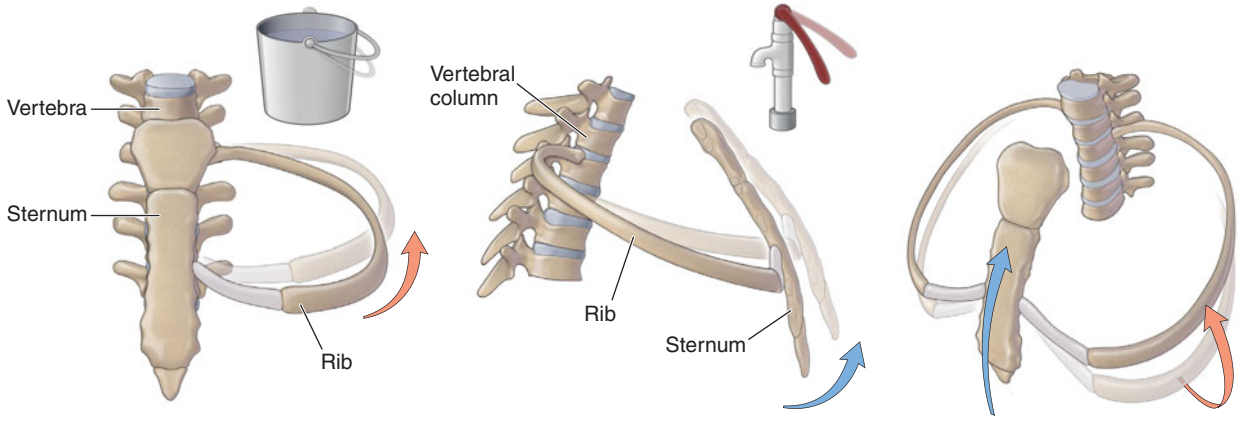

FIGURE 27-5 Bucket and pump handle rib motions. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Respiration

The ribs function as levers, with the fulcrum represented by the rib angle, the effort arm represented by the neck, and the load arm represented by the shaft. Because of the relatively small size of the rib neck, a small movement at the rib neck will produce a large degree of movement in the shaft.

The shapes of the articular facets of the upper six ribs would suggest that the upward and downward gliding movements that occur would produce spinning of the neck of the rib. In fact, the main movement in the upper six ribs during respiration and other movements is one of the rotations of the neck of the rib, with only small amounts of superior and inferior motion. In the seventh through 10th ribs, the principal movement is upward, backward, and medially during inspiration, with the reverse occurring during expiration.[28]

Because the anterior end of the ribs is lower than the posterior, when the ribs elevate, they rise upward, while the rib neck drops down. In the upper ribs, this results in an anterior elevation (pump handle) and in the middle and lower ribs (excluding the free ribs), a lateral elevation (bucket handle), with the former movement increasing the anteroposterior diameter of the thoracic cavity and the latter increasing the transverse diameter (Fig. 27-5).

Both kinds of rib motion are produced by the action of the diaphragm. The seventh through 10th ribs act to increase the abdominal cavity free space to afford space for the descending diaphragm. As the ends of these ribs are elevated, they push up on each other, lifting each successive rib upward and finally lifting the sternum. The two lower ribs are depressed by the quadratus lumborum to provide a stable base of action for the diaphragm.

Quiet respiration involves very little zygapophyseal joint motion.

Inspiration

During inspiration, the diaphragm descends and pulls the central tendon inferiorly through the fixed 12th ribs and L1–3 (Fig. 27-6). When the maximum extensibility (distention) of the abdominal wall is reached, the central tendon becomes stationary. Further contraction of the diaphragm produces an elevation and posterior rotation of the lower six ribs, with torsion of the anterior costal cartilage, and an anterosuperior thrust of the sternum (and eventually the inferior aspect of the manubrium).

During inspiration in the normal population, because the second rib is longer than the first, the superior aspect of the manubrium is forced to tilt posteriorly as its inferior edge is moved anteriorly. As the top of the manubrium tilts back, the clavicle rolls anteriorly. Because the lower ribs are longer, the inferior sternum moves further anteriorly than the superior section during inspiration. The manubriosternal junction acts as the hinge for this motion. If this joint stiffens or ossifies, respiratory function will suffer. In addition, if the central tendon stiffens, inspiration will have to be accomplished, with the ribs moving laterally.

Forced inspiration produces an increase in the activity level of the diaphragm, intercostals, scaleni, and quadratus lumborum. In addition, new activity occurs in the sternocleidomastoid, trapezius, both pectorals and serratus anterior.

During inspiration, the ribs move with the sternum in an upward and forward direction, increasing the anteroposterior diameter of the chest while posteriorly rotating. The tubercles and costotransverse joints of[29]

- T1–7 glide inferiorly;
- T8–10 glide in an anterolateral and inferior direction;
- T11 and T12 remain stationary, except for slight caliper motion increasing the lateral dimension.

Expiration

Quiet expiration occurs passively (Fig. 27-6). During forced expiration, there is activity in a number of muscles (Table 27-1). During expiration, the ribs rotate anteriorly and the tubercles and costotransverse joints of[29]

- T1–7 glide superiorly;
- T8–10 glide in a posteromedial and superior direction;
- T11 and T12 remain stationary, except for slight caliper motion decreasing the lateral dimension.

It may be possible to detect a subluxation of the costotransverse joints by palpating the ipsilateral transverse process

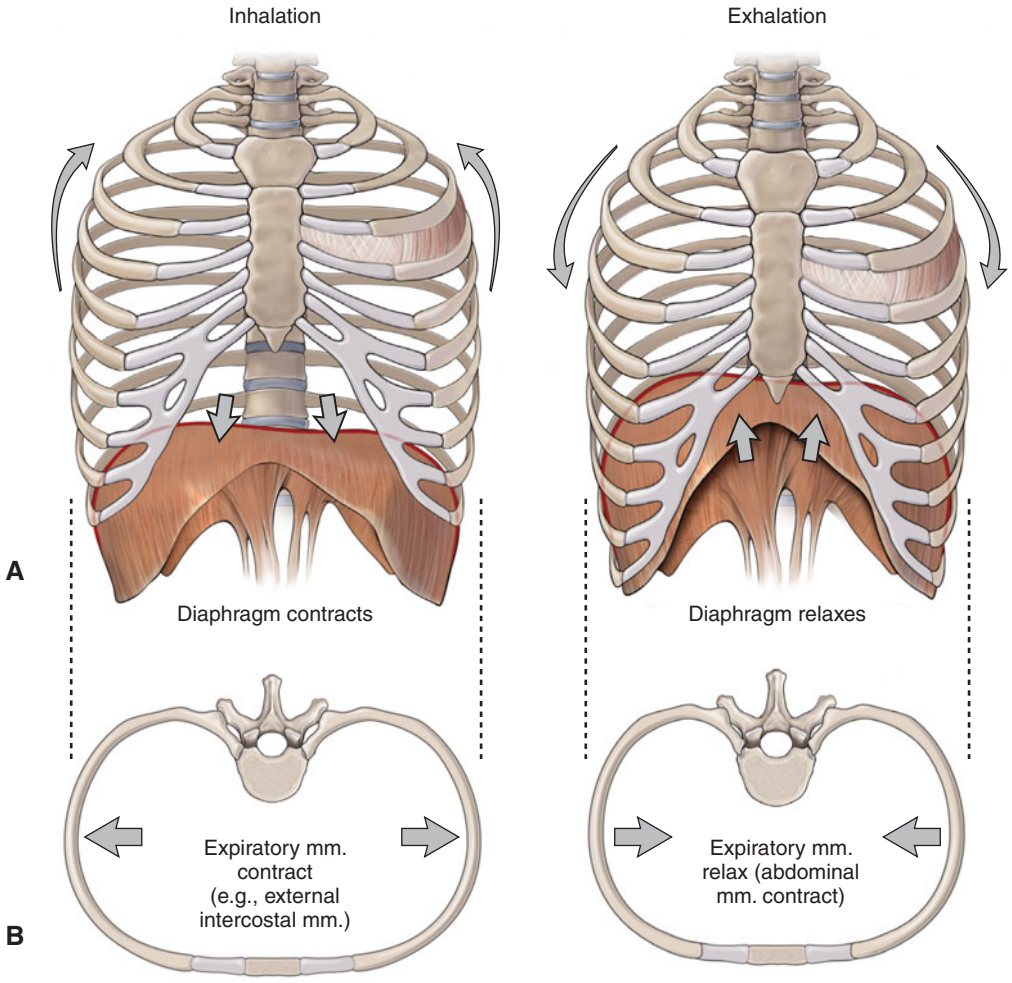

FIGURE 27-6 Biomechanics of respiration. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

and rib during inspiration and thoracic side bending.[29] For example, a superior subluxation of the right rib may produce the following:

- A decreased inferior glide of the rib
- A decreased thoracic motion in the directions of left side bending and right rotation

The findings for other rib dysfunctions are outlined in Table 27-4.

EXAMINATION

Differential diagnosis of thoracic pain can be difficult. This is due to the complicated biomechanics and function of the region, the proximity to vital organs, and the many articulations. Bogduk[78] has cited the following anatomical structures as possible causes of thoracic spine pain: posterior thoracic muscles, spinous processes, anterior and posterior longitudinal ligaments, vertebral bodies, zygapophyseal and

TABLE 27-4 Rib Dysfunctions

Dysfunction	Rib Angle	Intercostal Space	Anterior Rib	Thoracic Findings
Anterior subluxation	Less prominent	Tender	NA	More prominent
Posterior subluxation	More prominent	Tender	NA	Less prominent
External rib torsion	Prominent and tender superior border	Wide above and narrow below	ERS, ipsilateral at the level above	NA
Internal rib torsion	Prominent and tender inferior border	Narrow above and wide below	FRS, contralateral at the level above	NA

ERS, extended, rotated, and side flexed; FRS, flexed, rotated, and side flexed; NA, not applicable.

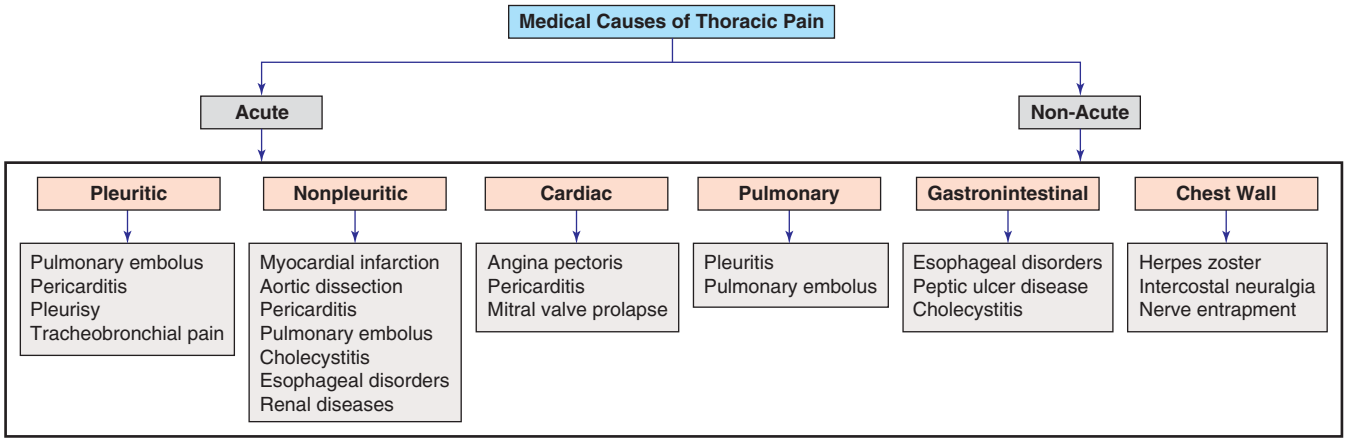

FIGURE 27-7 Medical causes of thoracic symptoms.

costotransverse joints, inferior articular process, pars interarticularis, IVD, nerve root, joint meniscus, and dura mater. Pain arising from inflammation of the axial spine can mimic a variety of serious conditions, including cardiac/pulmonary pathology, renal colic, fracture, a tumor, or numerous visceral and retroperitoneal abnormalities, including abdominal aortic aneurysm.[79]

The thoracic spine is less commonly implicated in musculoskeletal pain syndromes than the lumbar and cervical spines, and when it does occur, there is some disagreement as to whether the ribs or the intervertebral joints are the major source of the biomechanical dysfunction. Complicating matters is the fact that pain arising from the thoracic spinal joints has considerable overlap and can refer symptoms to distal regions (groin, pubis, and lower abdominal wall) (refer to Chap. 5). Apart from musculoskeletal lesions, the thoracic spine is also a common source of systemic pain, and the phenomenon of referred pain poses more diagnostic difficulties in the thoracic spine than in any other region of the vertebral column (Fig. 27-7).[78] The algorithm outlined in Fig. 27-8 can serve as a guide to the examination of the thoracic spine and ribs.

History

The history should include the chief complaints and a pain drawing. Referred chest pain patterns are outlined in Table 27-5. In addition to those questions listed under History in Chapter 4, the following questions should be asked by the clinician:

- Was there a mechanism of injury? Any information regarding the onset is important. For example, most rib injuries are commonly caused by direct trauma. If there was no mechanism of injury a disease process such as scoliosis could be indicated. Costovertebral and costotransverse joint hypomobility and active trigger points are possible sources of upper thoracic pain.[80]
- Do the symptoms occur with breathing? Symptoms reproduced with respiration could indicate a rib dysfunction or pleuritic pain. If the symptoms are aggravated on exertion, the clinician should focus on the relationship of specific movements or activities. Any information regarding the onset, as well as aggravating factors, is important, especially if the pain appears only during certain positions or movements, which would suggest a musculoskeletal lesion. Deep breathing or arm elevation tends to aggravate a rib dysfunction.
- Are the symptoms provoked or alleviated with movement or posture? This type of history indicates a musculoskeletal dysfunction. Chronic problems in this area tend to result from postural dysfunctions. Pain of a mechanical origin tends to worsen throughout the day but is relieved with rest.
- What activities tend to aggravate the symptoms? Pulling and pushing activities typically worsen thoracic symptoms. Aggravation of localized pain by coughing, sneezing, or deep inspiration tends to implicate the costovertebral joint.[81]
- Is the pain deep, superficial, aching, burning, or stabbing? The patient is asked to describe the quality of the pain. Thoracic nerve root pain is often sharp, stabbing, and severe, although it can also have a burning quality. Nerve pain usually is referred in a sloping band along an intercostal space.[20] Vascular pain and visceral pain often are described as being poorly localized and achy. A sudden onset of pain related to trauma could indicate a fracture, muscle strain, or ligament sprain.

CLINICAL PEARL

Pain from a musculoskeletal lesion in this area can vary from a dull ache to a feeling of local fatigue and cramping. Musculoskeletal pain is usually sharp and well localized, whereas muscle or tendon pain is typically dull and aching. Bone pain usually feels very deep and boring.

- Where is the pain located? The patient should be asked to point to the area of pain. If the patient has difficulty localizing the pain, the clinician should suspect referred pain as the source. If the symptoms appear to be referred to the upper or lower extremities, or the head and neck, further investigation is required.
- Are the symptoms related to digestion? Some visceral conditions such as ulcers, can be referred to T4-T6 posteriorly.

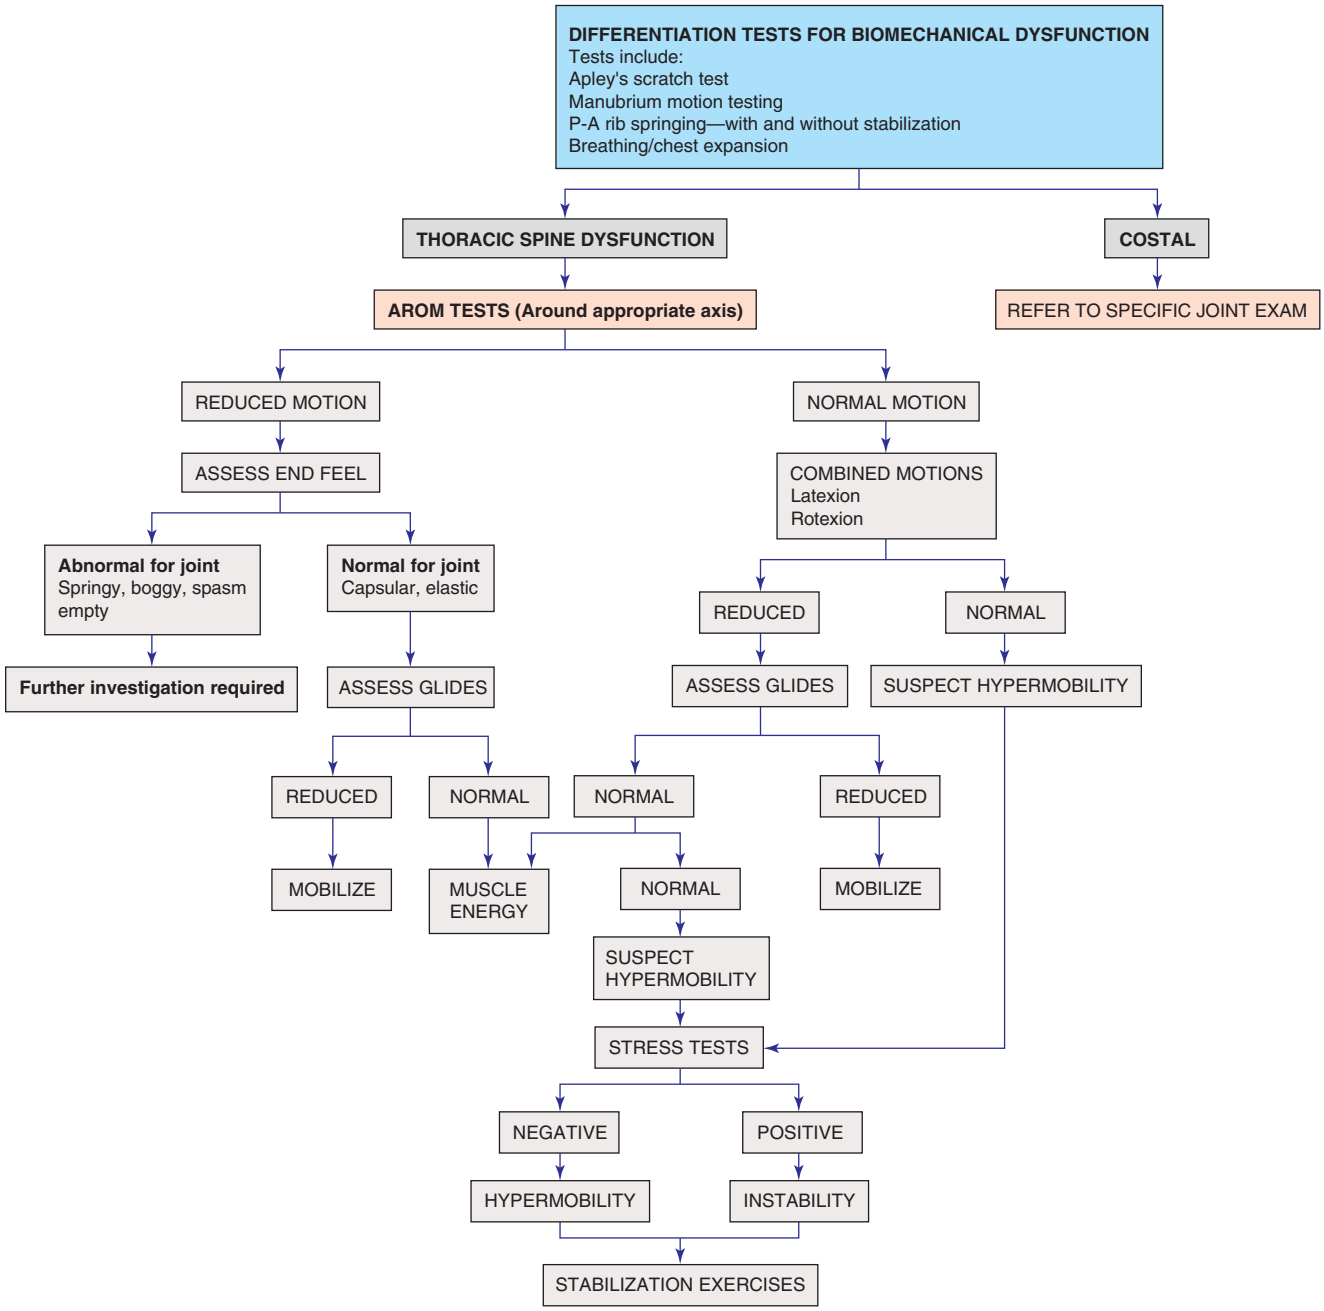

FIGURE 27-8 Thoracic spine examination algorithm.

The administration of the Oswestry Low Back Disability Questionnaire (Table 5-2), Neck Disability Index (Table 5-3), and McGill Pain Questionnaire (Chap. 4) may be helpful in determining the quality of pain and its effect on function.[82–84]

Systems Review

Thoracic pain may originate from just about all of the viscera (Table 27-6; see also Chap. 5). Both visceral and somatic afferent nerves transmit pain messages from a peripheral stimulus and converge on the same projection neurons in the posterior (dorsal) horn. Visceral pain tends to be vague and dull and may be accompanied by nausea and sweating (see Chap. 5). To help differentiate between visceral pain and musculoskeletal pain, the clinician should focus on the relationship of specific movements or activities. A medical screening questionnaire for the thoracic spine and rib cage region is provided in Table 27-7.

The thoracolumbar outflow of the autonomic nervous system (see Chap. 3) has its location here. Stimulation of this outflow can lead to the presence of facilitated segments, and trophic changes in the skin of the periphery.[85]

Systemic illnesses, such as rheumatoid arthritis and malignancy, and conditions causing referred pain must be included in the differential diagnosis. Nonmusculoskeletal causes of thoracic pain (Table 27-8)[86] include the following:

- Dissecting aortic aneurysm.
- Myocardial infarction.
- Intercostal neuralgia.

TABLE 27-5 Chest Pain Patterns

Origin of Pain	Site of Referred Pain	Type of Disorder
Substernal or retrosternal	Neck, jaw, back, left shoulder and arm, and abdomen	Angina
Substernal, anterior chest	Neck, jaw, back, and bilateral arms	Myocardial infarction
Substernal or above the sternum	Next, upper back, upper trapezius, supraclavicular area, left arm, and costal margin	Pericarditis
Anterior chest (thoracic aneurysm); abdomen (abdominal aneurysm)	Posterior thoracic, chest, neck, shoulders, interscapular, or lumbar region	Dissecting aortic aneurysm
Variable	Variable, depending on structures involved.	Musculoskeletal
Costochondritis (inflammation of the costal cartilage): sternum and rib margins.	Abdominal oblique trigger points: pain referred up into the chest area.	
Upper rectus abdominis trigger points (left side), pectoralis, serratus anterior, and sternalis muscles: precordial pain	Pectoralis trigger points: pain referred down medial bilateral arms along ulnar nerve distribution (fourth and fifth fingers)	
Precordium region (upper central abdomen and diaphragm)	Sternum, axillary lines, and either side of vertebrae; lateral and anterior chest wall; occasionally to one or both arms	Neurological
Substernal, epigastric, and upper abdominal quadrants	Around chest area, shoulders, and upper back region	Gastrointestinal
Within breast tissue; may be localized in pectoral and supraclavicular regions	Chest area, axilla, mid-back, and neck and posterior shoulder girdle	Breast pain
Commonly substernal and anterior chest region	No referred pain	Anxiety

TABLE 27-6 Symptoms and Possible Causes of Thoracic Pain

Indication	Possible Condition
Severe bilateral root pain in elderly	Neoplasm (most common areas for metastasis are lung, breast, prostate, and kidney)
Wedging/compression fracture	Osteoporotic (estrogen deficiency) or neoplastic fracture
Onset–offset of pain unrelated to trunk movements	Ankylosing spondylitis, visceral
Decreased active motion: contralateral side flexion painful, with both rotations full	Neoplasm
Severe chest wall pain without articular pain	Visceral
Spinal cord signs and symptoms	Spinal cord pressure or ischemia
Pain onset related to eating or diet	Visceral

TABLE 27-7 Medical Screening Questionnaire for the Thoracic Spine and Rib Cage Region

	Yes	No
Do you have a history of heart problems?		
Have you recently taken a nitroglycerin tablet?		
Do you take medication for hypertension?		
Have you been or are you now a smoker?		
Have you had a recent surgery?		
Have you recently been bedridden?		
Have you recently noticed that it is difficult for you to breathe, laugh, sneeze, or cough?		
Have you recently had a fever, infection, or other illness?		
Have you recently received a blow to the chest, such as during a fall or motor vehicle accident?		
Are your symptoms relieved after eating?		
Does eating fatty food increase your symptoms?		
Do you currently have a kidney stone, or have you had one in the past?		
Do you experience severe back or flank pain that comes on suddenly?		

Data from: DuVall RE, Godges J: Introduction to physical therapy differential diagnosis: The clinical utility of subjective examination. In: Wilmarth MA, ed. *Medical Screening for the Physical Therapist. Orthopaedic Section Independent Study Course 14.1.1*. La Crosse, WI: Orthopaedic Section, APTA, Inc, 2003:1–44.

TABLE 27-8 Red Flags for the Thoracic Spine and Rib Cage

Condition	Red Flags
Myocardial infarction	Chest pain Pallor, sweating, dyspnea, nausea, or palpitations Presence of risk factors: previous history of coronary heart disease, hypertension, smoking, diabetes, and elevated blood serum cholesterol (>240 mg/dL) Men aged over 40 years and women aged over 50 years Symptoms lasting greater than 30 min and not relieved with sublingual nitroglycerin
Stable angina pectoris	Chest pain or pressure that occurs with predictable levels of exertion (if not, suspect unstable angina pectoris) Symptoms are also predictably alleviated with the rest or sublingual nitroglycerin (if not, suspect unstable angina pectoris)
Pericarditis	Sharp or stabbing chest pain that may be referred to the lateral neck or either shoulder Increased pain with left side lying Relieved with forward lean while sitting (supporting arms on knees or a table)
Pulmonary embolus	Chest, shoulder, or upper abdominal pain Dyspnea
Pleurisy	Severe, sharp knife-like pain with inspiration History of a recent or coexisting respiratory disorder (e.g., infection, pneumonia, tumor, or tuberculosis)
Pneumothorax	Chest pain that is intensified with inspiration, ventilation, or expanding rib cage Recent bout of coughing or strenuous exercise or trauma Hyperresonance upon percussion Decreased breath sounds
Pneumonia	Pleuritic pain that may be referred to shoulder Fever, chills, headache, malaise, or nausea Productive cough
Cholecystitis	Colicky pain in the right upper abdominal quadrant with accompanying right scapula pain Symptoms may worsen with ingestion of fatty foods Symptoms unaffected by activity or rest
Peptic ulcer	Dull, gnawing pain, or burning sensation in the epigastrium, mid-back, or supraclavicular regions Symptoms relieved with food Localized tenderness at the right epigastrium Constipation, bleeding, vomiting, tarry colored stools, and coffee ground emeses
Pyelonephritis	Recent or coexisting urinary tract infection Enlarged prostate Kidney stone or past kidney stone
Nephrolithiasis (kidney stones)	Sudden, severe back, or flank pain Chills and fever Nausea or vomiting Renal colic Symptoms of urinary tract infection Reside in hot and humid environment Past episode(s) of kidney stone(s)

- Pleural irritation. When the tissues of an irritated pleura are stretched, chest pain can result. This pain can be increased by breathing, as well as by trunk movements, a situation that could lead the clinician to believe that the problem is musculoskeletal.
- Tumor.
- Acute thoracic disk herniation.
- Unstable or stable angina pectoris.
- Pericarditis.
- Pneumothorax.
- Pneumonia.
- Cholecystitis.
- Peptic ulcer.
- Pyelonephritis.
- Nephrolithiasis (kidney stones).

Questions should be asked with regard to bowel and bladder function; upper and lower extremity numbness, tingling, or weakness; and visual or balance disorders. These symptoms may indicate compromise to the spinal cord, cauda equina, or central nervous system.

Questions must also be asked about unexplained weight loss, fever, chills, and night pain. These symptoms often are associated with cancer or systemic disease, although night pain may just be because the patient has an increased, and fixed, kyphosis and needs a softer bed to accommodate the deformity.[87]

Tests and Measures

Observation

The patient should be suitably disrobed to expose as much of this region as is necessary. As a quick orientation to the relationship of the bony structures (Fig. 27-1), the clinician should confirm the following findings:

- The spine of the scapula is level with the spinous process of T3.
- The inferior angle of the scapula is in line with the spinous processes of T7–9.
- The medial border of the scapula is parallel with the spinal column and about 5 cm lateral to the spinous processes.
- The iliac crests are level and symmetric. One crest higher than the other could suggest a leg-length discrepancy, an iliac rotation, or both.
- The shoulder heights are level. A normal variant is that individuals carry their dominant shoulder slightly lower than the nondominant side.

The clinician also should evaluate the following:

- ***Smoothness of the thoracic curve.*** By running the palm of the hand down the midline of the patient's thoracic spine, the clinician can determine the smoothness of the curvature. Any areas of flatness could suggest a vertebral dysfunction such as an opening restriction (extended, rotated, and side flexed [ERS] lesion), whereas areas of relative increased curvature suggest a closing restriction (flexed, rotated, and side flexed [FRS] lesion); refer to Chapter 25.
- ***Degree of thoracic kyphosis.*** As elsewhere in the spine, posture has an important influence on the available range of motion of the neighboring joints. Conversely, changes in the lumbar posture, such as excessive lordosis, and changes in the cervical spine, such as those rendered by a forward head position, can affect the thoracic spine. An increased lumbar lordosis increases the stresses applied to the thoracolumbar junction, whereas a forward head increases the stresses at the cervicothoracic junction.

The thoracic spine adopts a natural kyphotic curve, which is an increased convexity of the thoracic vertebrae. Varying degrees of kyphosis can occur in the thoracic spine. It is known that the thoracic kyphosis increases with age,[88] and in women more than men.[89] The appearance of increased kyphosis in the young is typically postural, but could be the result of Scheuermann's disease, or ankylosing spondylitis.[23,90] The degree of curvature of the spine also has been found to be diurnal, with a slight flattening of the thoracic kyphosis occurring overnight.[91] Attempts to define the "normal" thoracic kyphosis have demonstrated considerable variation in the asymptomatic population,[65,92] suggesting that any individual differences reflect normal variations rather than deviations.

It has been theorized by a number of authors[93–98] that postural dysfunctions in this region create an imbalance between agonists and antagonists, producing adaptive shortening and weakness. It is likely that these changes are degenerative in nature, resulting from a change in IVD height. Disk height changes commonly are seen in the upper mid-thoracic segments[99] and may result in an alteration of the kyphotic curve, with subsequent compensatory changes in load bearing and movement. These altered load-bearing patterns may result in a compression of the anterior aspect of the thoracic IVDs, and a stretching of the thoracic extensors and the middle and lower trapezius. The posterior ligaments also are lengthened. In addition, the kyphotic posture is associated with adaptive shortening of the anterior longitudinal ligament, the upper abdominals, and the anterior chest muscles. The common kyphotic deformities include[100]:

- ***Dowager's hump.*** This deformity is characterized by a severely kyphotic upper posterior (dorsal) region, which results from multiple anterior wedge compression fractures in several vertebrae of the middle to upper thoracic spine (see Chap. 5), usually caused by post menopausal osteoporosis or long-term corticosteroid therapy (specificity, 0.99).[101]
- ***Hump back.*** This deformity is a localized, sharp, posterior angulation, called *gibbus*, produced by an anterior wedging of one of the two thoracic vertebrae as a result of infection (tuberculosis), fracture, or congenital bony anomaly of the spine.[90]
- ***Round back.*** This deformity is characterized by decreased pelvic inclination and excessive kyphosis.
- ***Flat back.*** This deformity is characterized by decreased pelvic inclination, increased kyphosis, and a mobile thoracic spine.
- ***Pelvic heights.*** A significant leg-length discrepancy (greater than 1/2 inch) can alter the lateral curvature of the spine, resulting in compensation.
- ***Amount of lateral curvature of the thoracic spine.*** When observing the thoracic spine, it is important to note the

morphologic latitude of the spinal curvature.[102] Two terms, *scoliosis* and *rotoscoliosis*, are used to describe the lateral curvature of the spine. Scoliosis is the older term and refers to an abnormal side bending of the spine but gives no reference to the coupled rotation that also occurs. Rotoscoliosis is a more detailed definition, used to describe the curve of the spine by detailing how each vertebra is rotated and side flexed in relation to the vertebra below. For example, with a left lumbar convexity, the L5 vertebra would be found to be side flexed to the right and rotated to the left in relation to the sacrum. The same would be true with regard to the relation between L4 and L5. This rotation, toward the convexity, continues in small increments until the apex at L3. L2, which is above the apex, is right rotated and right side flexed in relation to L3. The small increments of right rotation continue up until the thoracic spine, where the side bending and rotation return to the neutral position. The currently accepted definition of scoliosis is a 10-degree lateral curvature measured radiographically (see Chap. 7), with vertebral rotation of the spine taken with the patient standing upright.[103] This definition is based on the fact that a graph of lateral spinal curvature of the general population is a smooth exponential function in which the sharpest change in slope occurs at 10 degrees.[104] Despite this reasonable approach to the definition of the disease state, it results in an extremely high prevalence of the disorder in the general population of 2–3%.[105] Scoliosis can be found in four forms: static, sciatic, idiopathic, and psychogenic. The cause of the latter is self-explanatory.

- ***Static.*** Static, or structural, scoliosis in adults may be caused by a leg-length difference, a hemivertebra, osteoporosis, osteomalacia, or compression fractures. If a platform under the heel of the shorter limb eases or even abolishes the symptoms while standing or on lumbar flexion or extension, a shoe lift is advised.[106,107]
- ***Sciatic.*** The sight of a patient with a pelvic shift or list is relatively common in patients presenting with LBP. The sciatic, or nonstructural, lumbar scoliosis results from sciatic pain caused by a lumbar disk herniation and unilateral spasm of the back muscles. Sciatic scoliosis usually occurs with convexity to the symptomatic side of the herniated disk.[108] The shift is thought to result from the body finding a position of comfort and protection, as a consequence of an irritation of a spinal nerve or its dural sleeve,[108] although the neuronal mechanisms of sciatic scoliosis have not been well clarified. These postural changes cannot be relieved by voluntary efforts but usually disappear after alleviation of the sciatic pain.[108] The extent of a scoliosis should be noted if it is thought to be contributing to the patient's symptoms and is occurring because of pain or dysfunction. An attempt should be made to manually correct the shift to ascertain whether this can be done painlessly. A compensatory shift or scoliosis is often easy and painless to correct.[109,110]
- ***Idiopathic.*** The curve of an idiopathic scoliosis, present since childhood, differs from the tilt of the spine associated with recent IVD problems in that it is accompanied by a lower thoracic or lumbar rotation deformity.[106] If this deformity is not obvious in the standing posture, it should become obvious during flexion, as it is manifested by the so-called *razor back eminence* of the thoracic cage.

Scoliosis is never normal, although most cases are idiopathic, manifesting in the preadolescent years.[4,111] An abnormal lateral thoracic curve is described as being structural or functional, and can produce a fixed deformity or a changeable adaptation, respectively, with the rib hump occurring on the convex side of the curve. Persistent scoliosis during forward bending (Adam's sign) is indicative of a structural curve. Structural curves may be genetic, congenital, or idiopathic, producing a structural change to the bone and a loss of spinal flexibility. With a structural scoliosis, the vertebral bodies rotate toward the convexity of the curve, producing a distortion.[112] The distortion in the thoracic spine is called a *rib hump*. The rotation of the vertebral bodies causes the spinous processes to deviate toward the concave side. The curvature results in an adaptive shortening of the intrinsic trunk muscles on the concave side and lengthening of the intrinsic muscles on the convex side.

The curve patterns are named according to the level of the apex of the curve. For example, a right thoracic curve has a convexity toward the right, and the apex of the curve is in the thoracic spine. There may be a number of curves spanning the thoracic and lumbar region, and the clinician should determine if the curvature is:

- *Contributing to the patient's pain*. Frequently, these curves can be asymptomatic. A slight lateral curve in the coronal plane is thought to result from right-hand dominance, or the presence of the aorta.[113]
- Nonstructural, in which case the patient is able to correct the curves relatively easily.
- Adaptive, resulting from poor posture, nerve root irritation, leg-length discrepancy, atrophy, or hip contracture.
- ***Chest wall shape.*** On the anterior aspect of the thoracic region, the clinician should look for evidence of deformity.
  - ***Barrel chest.*** In this deformity, a forward and upward projecting sternum increases the anteroposterior diameter. The barrel chest results in respiratory difficulty, stretching of the intercostal and anterior chest muscles, and adaptive shortening of the scapular adductor muscles.
  - ***Pigeon chest.*** In this deformity, a forward and downward projecting sternum increases the anteroposterior diameter. The pigeon chest results in a lengthening of the upper abdominal muscles and an adaptive shortening of the upper intercostal muscles.
  - ***Funnel chest.*** In this deformity, a posterior-projecting sternum occurs secondary to an outgrowth of the ribs.[114] The funnel chest results in adaptive shortening of the upper abdominals, shoulder adductors, pectoralis minor, and intercostal muscles, and in lengthening of the thoracic extensors and middle and upper trapezius.
- ***Motion of the ribs during quiet breathing.***
- ***Asymmetry in muscle bulk, prominence, or length.*** According to Sahrmann,[115] shortness of the rectus abdominis results in anterior rib cage depression, shortness of the internal oblique results in an increase in the

TABLE 27-9 Anterior and Posterior Palpation Points of the Thoracic Region

Anterior Aspect	Posterior Aspect
Suprasternal notch	Spinous and associated transverse processes
Manubriosternal angle	T2—level with base of spine of scapula
Xiphoid process	Spinal gutter (rotatores)
Infrasternal angle	Erector spinae
Sternochondral junctions	Rib angles
Costal cartilage	Rib shafts Rib shafts and rib joint line of costotransverse joint C6—locate largest spinous process at base of neck and have patient extend neck; first spinous process to move anteriorly under your finger is C6

infrasternal angle, and shortness of the external oblique results in a decreased angle. Rotatores atrophy could suggest nerve palsy, whereas rotatores hypertonicity could suggest a segmental facilitation.[97,116]

- ***Any lesions, swellings, or scars on the back and chest.*** This is a common area for the characteristic lesion pattern of herpes zoster (shingles), which follows the course of the affected nerve (see Chap. 5).

Gait

The analysis of the patient's gait pattern can provide valuable information as to whether the condition originates in the spine or lower extremities, resulting in gross weakness of the muscles that affect gait[90] (see Chap. 6). For example, a decreased arm swing during gait can indicate stiffness of the thoracic segments.

Palpation

The spinous processes of the thoracic vertebrae are readily palpated (see Fig. 27-1), because they are not covered by muscle or thick connective tissue.[90] Palpation of the thoracic transverse processes is more difficult, however, due to their depth relative to the more superficial structures of the spine. The landmarks outlined in Table 27-9 may be helpful to determine the segmental level involved.

The spinous processes are long and slender and have varying degrees of caudal obliquity, which changes slightly throughout the kyphotic curvature of the thorax, increasing in caudal angulation to the level of T7 and then decreasing in caudal angulation below T9. Traditionally, palpation of this area has utilized the "rule of threes."

CLINICAL PEARL

The areas of spinous process may obliquity be divided into four regions by the so-called rule of three devised by Mitchell[117] (an alternate version is illustrated in Fig. 27-9):

- The upper three spinous processes (T1–3). The tips of these spinous processes are level with vertebral body of the same level.
- Second group of three spinous processes (T4–6). The tips of these spinous processes are in a plane that is half way between its own transverse process and those of the inferior vertebra (level with the IVD of the inferior level). This can be estimated at about three fingerbreadths.
- Third group of three spinous processes (T7–9). The tips of these spinous processes are level with the transverse processes of the vertebral body of the level below.
- The last three vertebrae (T10–12) reverse the obliquity of the spinous processes:
  - T10 is level with the vertebral body of the vertebra below (same as T7–9).
  - T11 is level with the disk of the inferior vertebra (same as T6).
  - T12 is level with its own vertebral body (same as T3).

The rule of threes has been widely accepted in orthopaedic and manual therapy texts, but until recently, never validated with research. Based on a pilot study to investigate the validity of the rule of threes of the thoracic spine, Geelhoed and colleagues,[118] using five cadaver specimens, determined that the rule of threes was not an accurate predictor of the location of the transverse processes of the thoracic spine. The limitations of the study were the small sample size, the fact that measurements were only performed in the horizontal plane (prone position), and the fact that cadavers were used instead of live subjects, which could affect IVD height, and spinal alignment. In a separate study, Geelhoed et al.[119] have proposed a new model for predicting the location of the transverse processes of the thoracic spine. This proposed method states that the location of the transverse processes of a thoracic vertebra can be found lateral to

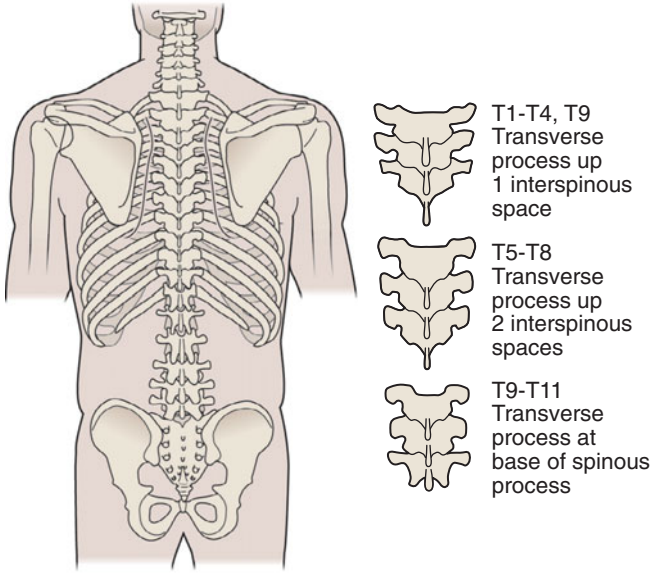

FIGURE 27-9 The rule of threes.

the most prominent aspect of the spinous process of the vertebra one level above.[119]

Surface landmarks can be used to locate the ribs. The first rib is located 45 degrees medially to the junction of the posterior scalene and trapezius. Palpation of the first rib during respiration can detect the presence of asymmetry. Palpation of the first rib can also be performed during testing of the active motions of cervical rotation and side bending in patients with suspected brachialgia (see Chap. 25).

The fifth rib passes directly under, or slightly inferior to, the male mammary nipples (see Fig. 27-11). To palpate the rib angles of the interscapular ribs, the shoulders are positioned in horizontal adduction. The rib angles of 3–10 can then be felt about 2–5 cm lateral to the spinous processes (Fig. 27-11).

When palpating anteriorly, on the sternum, a rib dysfunction will be highlighted by the presence of asymmetry and should be compared with the posterior findings. A prominent rib angle on the back and a depression of that rib at the sternum indicate a posterior subluxation, the reverse occurring in an anterior subluxation, whereas a rib that is prominent both anteriorly and posteriorly indicates a single rib torsion.

The transverse processes are roughly level with their own body. The costal cartilages of the second rib articulate with the junction between the sternum and manubrium (Fig. 27-1).

Palpation of the soft tissues of the region is important. The clinician should note the presence of any tenderness, temperature changes, and muscle spasm. A comparison should be made between the firmness and tenderness of the paravertebral muscles and their relationship from side to side.

Active Motion Testing

Active range-of-motion tests are used to determine the osteokinematic function of two adjacent thoracic vertebrae during active motions, to identify which joints are dysfunctional, as well as the specific direction of motion loss.[120] Active range of motion initially is performed globally, looking for abnormalities, such as asymmetric limitations of motion. A specific examination is then performed on any region that appears to have either excessive or reduced motion. If the history indicated that the patient's symptoms were altered with repetitive motions or sustained positions, these movements and postures should be included. Various techniques are used to correctly assess each area of the thoracic spine.

Movement restriction of the upper thoracic spine may be secondary to pain or a result of adaptive shortening of connective tissue or muscle.[3] Because of the relationship that the first two ribs share with the zygapophyseal joints as part of the manubrial ring, associated movement dysfunction of these ribs is common. Physiologic movement in the thoracic spine decreases with age. Mid-thoracic hypomobilities are the most common thoracic presentation,[110] with the movement restrictions being more common in the sagittal and frontal planes, particularly extension and side bending.[3] Most of the trunk rotation below the level of C2 occurs in the thoracic spine.

The clinician should look for capsular or noncapsular patterns of restriction, pain, or painful weakness (possible fracture or neoplasm). The capsular pattern of the thoracic spine appears to be symmetric limitation of rotation and side bending, extension loss, and least loss of flexion. Joint capsular lesions demonstrate a capsular pattern as equal and grossly severe limitation of movement in every direction.[90] With an asymmetric impairment, such as trauma, the capsular pattern appears to be an asymmetric limitation of rotation and side bending, extension loss, and a lesser loss of flexion.

Overpressure applied at the end of the available range of motion is used to take the joint from its physiologic barrier to its anatomic barrier. During overpressure, an increase in resistance to motion should be felt. The end-feels should be noted.

- If the normal elastic end-feel of thoracic rotation is replaced by a stiffer one, it may indicate the presence of osteoporosis or ankylosing spondylitis.
- During forward flexion, the nonstructural scoliosis disappears, whereas the structural scoliosis does not.
- If side bending is more seriously affected than rotation, neoplastic disease of the viscera or chest wall may be present.[87]
- If, during side bending, the ipsilateral paraspinal muscles demonstrate a contracture (Forestier's bowstring sign), ankylosing spondylitis may be present.[121]
- Side bending away from the painful side, which is the only painful and limited movement, almost always indicates a severe extra-articular impairment, such as a pulmonary or abdominal tumor or a spinal neurofibroma. The functional examination normally confirms the patient history.
- A marked restriction of motion in a noncapsular pattern with one or more spasmodic end-feels could indicate a thoracic disk herniation.
- Anterior or lateral pain with resisted thoracic rotation could indicate a muscle tear. Localized pain with resisted testing could indicate a rib fracture.

Because of the length of the spine in this region, it is important to ensure that all parts of the thoracic spine are involved in the range-of-motion testing. Motion in the thoracic spine requires a synchronous movement between the intervertebral and zygapophyseal joints and the rib articulations. Thus, the presence of joint dysfunction or degeneration, or structural changes in the spinal curvature, will influence the amount of available range of motion, and the pattern of these coupled motions.[23]

CLINICAL PEARL

It is important to remember that maximum arm elevation requires motion in the upper thoracic segments.

The inclinometer techniques recommended by the American Medical Association are used to objectively measure thoracic motion.[122]

Flexion. To measure thoracic flexion, two inclinometers are used and are aligned in the sagittal plane. The center of the first inclinometer is placed over the T1 spinous process. The center of the second one is placed over the T12 spinous process. The patient is asked to slump forward as though trying to place the forehead on the knees, and both inclinometer angles are recorded. The thoracic flexion angle is

calculated by subtracting the T12 from the T1 inclinometer angle. The patient should be able to flex approximately 20–45 degrees.[69,120] The clinician observes for any paravertebral fullness during flexion, which might indicate hypertonus from a facilitated segment. The thoracic spine during flexion should curve forward in a smooth and even manner (Fig. 27-10). There should be no evidence of segmental rotation or side bending. To decrease pelvic and hip movements, McKenzie advocates examining thoracic flexion with the patient seated.[123]

Extension. The clinician places one hand and arm across the upper chest region of the patient and the other hand over the spinous processes of the lower thoracic spine. The patient is guided into a backward slump (Fig. 27-11). Overpressure is applied by the arm across the front of the patient, while avoiding any anterior translation occurring at the lumbar spine.

Clinical guidelines for measurements of thoracic extension recommend that range of motion be defined with reference to the magnitude of the kyphosis measured in standing. However, to date, the relationship between the magnitude of the thoracic kyphosis and the amount of thoracic extension movement has not been reported.[62] Thoracic extension may be measured using the same technique and inclinometer positions as described for flexion. The thoracic extension angle is calculated by subtracting the T12 from the T1 inclinometer angle. The patient should be able to extend approximately 15–20 degrees.[120] Alternatively, thoracic extension can be measured using a tape measure. The distance between two points (the C7 and T12 spinous processes) is measured. A 2.5-cm difference between neutral and extension measurements is considered normal.[121,124] During thoracic extension, the thoracic curve should curve backward or straighten. As with flexion, there should be no evidence of segmental rotation or side bending.

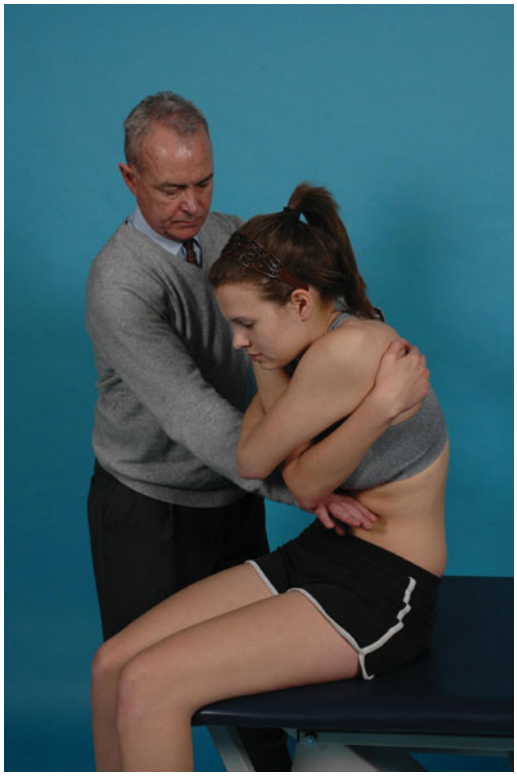

FIGURE 27-10 Thoracic spine flexion.

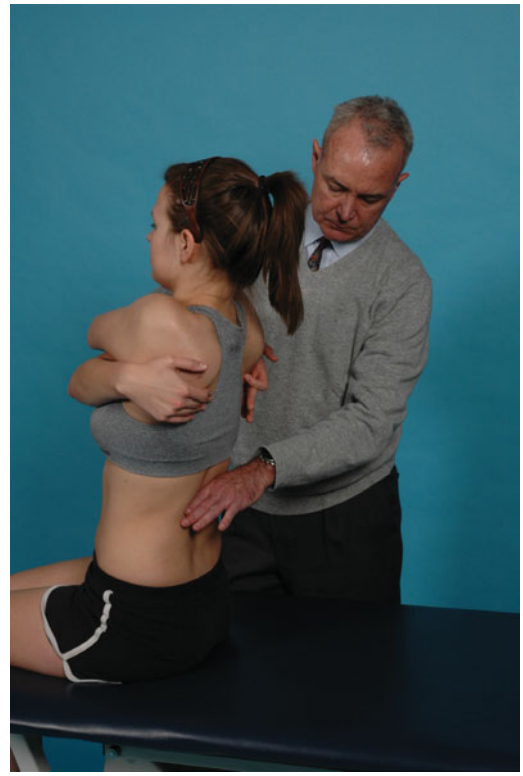

FIGURE 27-11 Thoracic spine extension.

Rotation. The patient is seated and is asked to turn to each side at the waist. Overpressure is applied through both shoulders (Fig. 27-12). This motion tests the ability of the ribs and the superior vertebrae to translate in the direction opposite to the rotation—a motion that is essential if complete rotation and side bending is to occur. A total of 35–50 degrees of rotation is available in the thoracic spine.[22,73] Rotation is a primary movement of the thoracic spine and a key component of functional activities. Active thoracic rotation of 20 degrees or less results in an impairment of function during activities of daily living involving the thoracic spine.[121] Pavelka[125] devised a simple objective clinical method to measure thoracolumbar rotation using a tape measure that can be used to detect

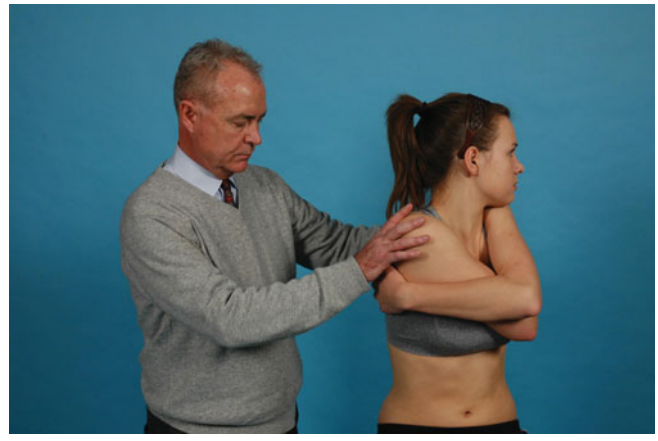

FIGURE 27-12 Thoracic spine rotation.

FIGURE 27-13 Thoracic spine side bending.

asymmetries in rotation. The tape is placed over the L5 spinous process, wrapped around the trunk, and placed over the jugular notch on the superior aspect of the manubrium. A measurement is taken before and after full trunk rotation. The measurements from each side are then compared.

Side Bending. A total of 25–45 degrees of side bending is available in the thoracic spine.[22,73] Using a hand placed against the patient's side, the patient is asked to side bend over the clinician's hand. Overpressure is applied through the contralateral shoulder to avoid compression (Fig. 27-13). Side bending can be measured objectively using a tape measure.[126] Two ink marks are placed on the skin of the lateral trunk. The upper mark is made at a point where a horizontal line through the xiphisternum crosses the coronal line. The lower mark is made at the highest point on the iliac crest. The distance between the two marks is measured in centimeters, with the patient standing erect, and again after full ipsilateral side bending. The second measurement is subtracted from the first and the remainder is taken as an index of lateral spinal mobility.

CLINICAL PEARL

A finding of painful and limited side bending away from the painful side, with both rotations free from pain, should always create a suspicion of a serious lesion.[90]

Inspiration and Expiration. Using a tape measure, the clinician measures the amount of rib expansion that occurs with a deep breath. Respiratory excursion is measured at three levels, using a tape measure placed circumferentially around the chest at the level of the axilla, the xiphoid level, and the 10th rib level. Comparisons are made between the measurements taken at the position of maximum expiration and the measurement taken at full inspiration. The normal difference between inspiration and expiration is 3–7.5 cm (1–3 inches).[126] Ankylosing spondylitis is a disease that can include ossification of the anterior longitudinal ligament, the thoracic disk, and the thoracic zygapophyseal joints. Findings of ankylosing spondylitis are common in the thoracic region, making chest expansion measurements a requirement in this region. Decreased expansion can highlight the presence of ankylosing spondylitis but may also be the result of diaphragm palsy (C4), intercostal weakness, pulmonary (pleura) problems, old age, a rib fracture, or a chronic lung condition.

The motions of the ribs are palpated during breathing. If a rib stops moving in relation to the other ribs on the same side during inspiration, it is classified as a *depressed rib*.[117,127] If a rib stops moving in relation to the other ribs during expiration, it is classified as an *elevated rib*.[117,127] Because of the interrelationship of all of the ribs, if a depressed rib is implicated, it is usually the most superior depressed rib that causes the most significant dysfunction. In contrast, if an elevated rib is implicated, it is usually the most inferior restricted rib that causes the most significant dysfunction.[117,127]

Resisted Testing

Resistance applied at the point of overpressure can give the clinician an indication of the integrity of the musculotendinous units of this area. Resistance is applied at the end range of flexion, extension, rotation, and side bending, while the clinician looks for pain, weakness, or painful weakness. Pain that is exacerbated with motion, but not with resisted isometric contraction, suggests a ligamentous lesion.[120]

Static Postural Testing

Thoracic pain of a postural origin is difficult to provoke with active motion and resistive testing. McKenzie[123] recommends placing the patient in a position for approximately 3 minutes to load the structures sufficiently to provoke postural pain.

Differing Philosophies

The next stage in the examination process depends on the clinician's background. For clinicians who are heavily influenced by the muscle energy techniques of the osteopaths, position testing is used to determine the segment on which to focus. Other clinicians omit the position tests and proceed to the combined motion and passive physiologic tests.

Position Testing: Spinal. The vertebrae may be tested for positional symmetry. If an ERS or FRS is present, passive mobility testing will definitively diagnose the movement impairment. The upper thoracic joints (C7–T4) can be assessed using the cervical techniques described in Chapter 25. The following techniques can be used for the T4–12 levels.

Example: T6–7. The patient is positioned in sitting, with the clinician standing behind. Using one thumb, the clinician palpates the transverse process of the T6 vertebrae. Using the other thumb, the clinician palpates the transverse process of the T7 vertebrae (Fig. 27-14). The joint is tested in the following manner:

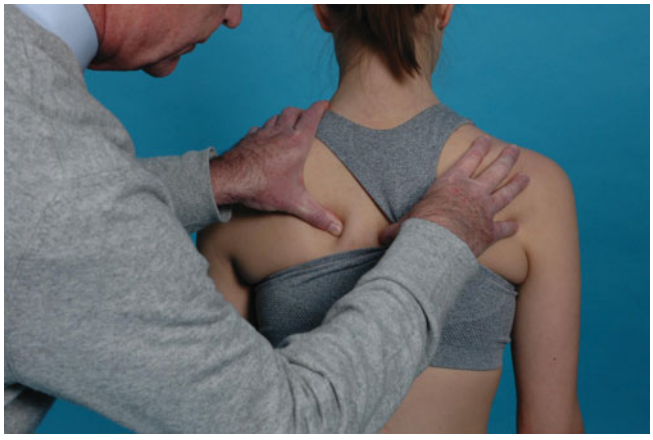

FIGURE 27-14 Position testing for T6–7.

- The patient bends forward so that the joint complex is flexed, and an evaluation is made as to the position of the T6 vertebra relative to T7 by noting which transverse process is the most posterior. A posterior left transverse process of T6 relative to T7 is indicative of a left-rotated position of the T6–7 complex in flexion.
- The patient bends backward so that the joint complex is extended, and an evaluation is made as to the position of the T6 vertebra in relation to T7 by noting which transverse process is the most posterior. A posterior left transverse process of T6 relative to T7 is indicative of a left-rotated position of the T6–7 joint complex in extension.

Once a segment has been localized by one of the preceding techniques, the arthrokinematics of the segment can be tested using the following passive mobility tests, which incorporate specific symmetric or asymmetric motions. Care in the interpretation of the passive mobility tests is important, because local tenderness in the thoracic region is common, especially over the spinous processes as a result of the proximity of the posterior (dorsal) rami over the apex of these bony prominences.[23,128]

Combined Motion Testing. As normal function involves complex and combined motions of the thoracic spine, combined motion testing can also be used. The motions tested include forward flexion with side bending, extension with side bending, side bending with flexion, and side bending with extension. The results from these motions are combined with the findings from the history and the single plane motions to categorize the symptomatic responses. This information can guide the clinician when determining which motions to use in the intervention.

Passive Physiologic Mobility Testing. The upper thoracic zygapophyseal joints (C7–T4) can be assessed using the cervical techniques described in Chapter 25. The following techniques can be used for the T4–12 levels.

Flexion of the Zygapophyseal Joints. The patient is seated at the end of the table, with arms together and hands resting on the back of the head. The clinician stands by the side of the patient and reaches around the front of the patient with one arm and hand. The clinician then applies a slight pressure with the sternum against the patient's shoulder so that the patient is gently squeezed. Using the other hand to monitor intersegmental motion between the spinous processes (Fig. 27-15), the clinician flexes the thoracic spine (Fig. 27-15). The quantity and quality of motion are noted and compared with the levels above and below.

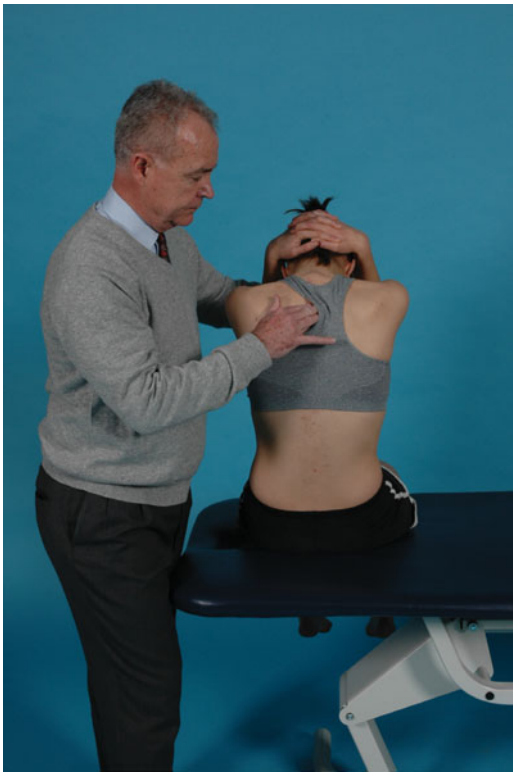

FIGURE 27-15 Passive mobility testing for flexion.

Extension of the Zygapophyseal Joints. The patient is seated with the arms together and both hands behind the head. The clinician stands to the side of the patient. While palpating the interspinous spaces or the transverse processes of the level to be tested with one hand, the clinician wraps the other arm around the front of the patient and rests that hand on the patient's contralateral elbow (Fig. 27-16). Crouching slightly, the clinician then places his or her anterior shoulder region close to the lateral aspect of the patient's shoulder. Using the other hand to monitor inter-segmental motion between the spinous processes, the clinician extends the thoracic spine (Fig. 27-16). The quantity and quality of motion is noted and compared with the levels above and below.

Combined Motions of the Zygapophyseal Joints. The patient is seated with one hand on top of one of the shoulders and the other hand under the opposite axilla. The clinician stands to the side of the patient. While palpating the interspinous spaces or the transverse processes of each level with one hand, the clinician wraps the other arm around the front of the patient, under the patient's crossed arms, resting his or her hand on the patient's contralateral hand. Crouching slightly, the clinician then places the anterior shoulder region against the lateral aspect of the patient's shoulder. Side bending and rotation of the patient's thoracic spine is then performed away from the clinician (Fig. 27-17), as the clinician lifts with his or her body. The palpating hand palpates the concave side of the curve.

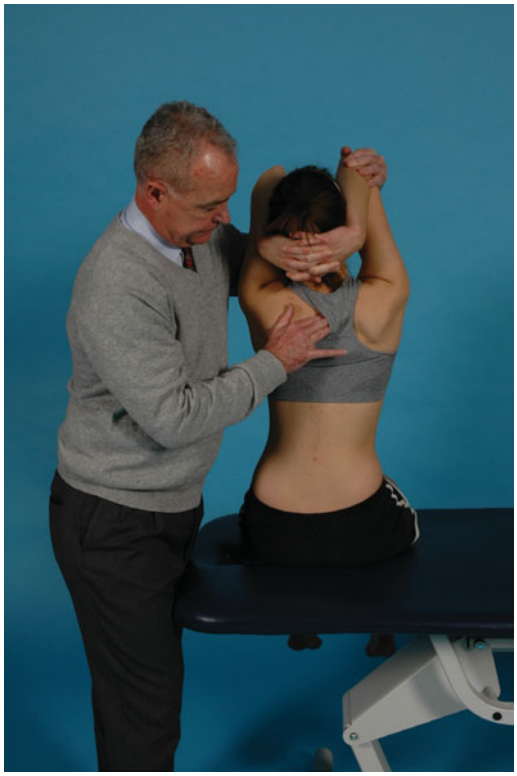

FIGURE 27-16 Passive mobility testing for extension.

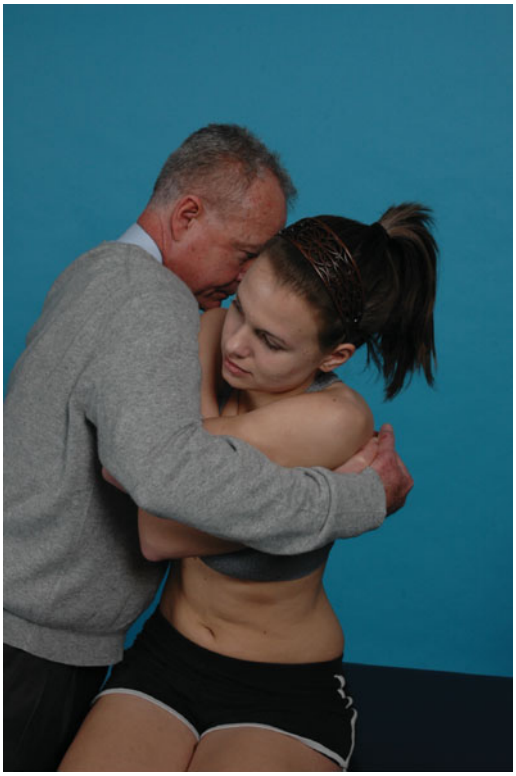

FIGURE 27-17 Passive mobility testing for side bending and rotation away from clinician.

Passive Articular Mobility Testing of the Mid-Thoracic Spine

Under normal circumstances, if the active motions and passive mobility motions of a joint are found to be restricted, the arthrokinematics of the restricted motion(s) are assessed to determine if the hypomobility is articular or extra-articular (myofascial). However, given the number of joints at each segmental level and the proximity of many of them, it is unlikely that passive articular mobility testing in this region will yield any useful information.

Neurologic Tests

A neurologic deficit is very difficult to detect in the thoracic spine. In this region, one dermatome may be absent with no loss of sensation.[129] Several tests have been devised to help assess the integrity of the neurologic system in this area.

The Slump Test. A neurodynamic mobility test can be used as a general assessment (see Chap. 11).

Sensory Testing. Sensation should be tested over the abdomen. The area just below the xiphoid process is innervated by T8, the umbilicus by T10, and the lower abdominal region, level with the anterior superior iliac spines, by T12.[87] Too much overlap exists above T8 to make sensation testing reliable.

Pathological Reflexes. Because of the proximity and vulnerability of the spinal cord in this region, long tract signs (Babinski, Oppenheim, clonus, and muscle stretch [deep tendon] reflexes) should be routinely assessed.

Lhermitte's Symptom. This impairment usually is considered to be a lesion to the cervical spinal cord (see Chap. 3), and it is associated with demyelination, prolapsed cervical disk, neck trauma, or subacute combined degeneration of the cord. Because the thoracic cord is immobilized by the denticulate ligaments, flexion will produce only limited stretching of the cord and thus less excursion. Lhermitte's symptom, characterized by an electric shock-like sensation into the spinal cord and limbs during neck flexion, may be present in the thoracic spine with compression of the thoracic cord by metastatic malignant deposits,[130] impairments of the thoracic vertebrae,[131] and thoracic spinal tumors.[132]

Brown–Séquard Syndrome. This syndrome is characterized by ipsilateral flaccid segmental palsy, ipsilateral spastic palsy below the impairment, and ipsilateral anesthesia, loss of proprioception, and loss of appreciation of the vibration of a tuning fork (dysesthesia). Contralateral discrimination of pain sensation and thermoanesthesia may be present and are both noted below the impairment. If a neurologic impairment is suspected, the clinician must first exclude a neoplastic process, infectious process, or fracture, and then consider a disk protrusion. A nondiscal disorder of the thoracic spine could include a neurofibroma; some of the signs to help confirm its presence are that

- the patient reports preferring to sleep sitting up;
- the pain, which slowly increases over a period of months, is felt mainly at night and is uninfluenced by activities;
- the patient reports a band-shaped area of numbness that is related to one dermatome;
- the patient reports the presence of pins and needles sensations in one or both feet or reports any other sign of cord compression.

Brown–Séquard syndrome symptoms may also occur with an idiopathic spinal cord herniation. This syndrome is caused by damage to the lateral funiculus of the spinal cord. The

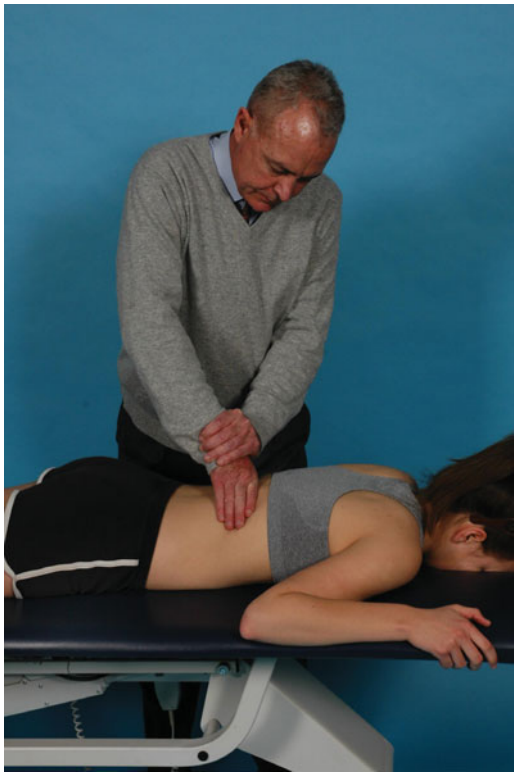

FIGURE 27-18 Rib spring test.

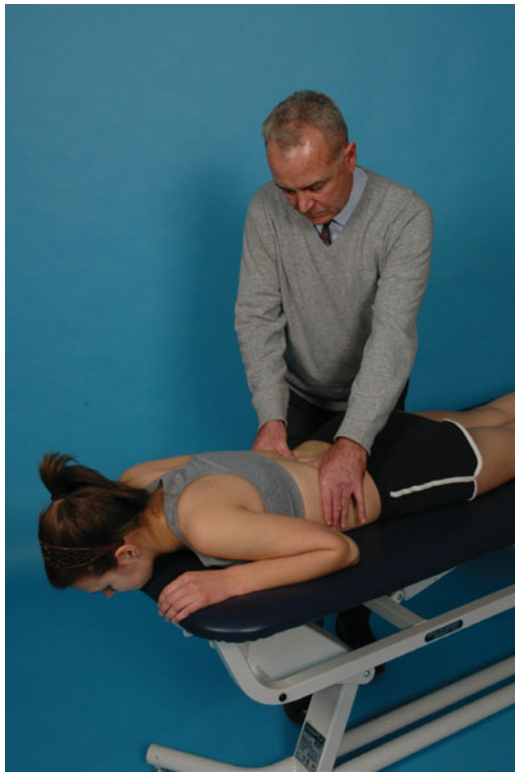

FIGURE 27-19 Thoracic spring test.

spinal cord frequently is shifted ventrolaterally and sometimes rotated toward the side of tethering, which might cause unilateral damage of the lateral funiculus. For the diagnosis of spinal cord herniation, magnetic resonance imaging (MRI) and computed tomography (CT) myelography are essential. An MRI myelogram can show acute, angular, anterior (ventral) deviation of the spinal cord in the sagittal plane. CT myelograms can detect anterior (ventral) or ventrolateral shifts of the spinal cord and, sometimes, an extradural cyst in the anterior (ventral) epidural space.

Special Tests

Very few special tests exist for this region, and even fewer have undergone diagnostic accuracy studies to determine reliability, sensitivity, and specificity.

Rib Spring Test. The patient is positioned prone, and the clinician stands on one side of the patient. Reaching over the patient, the clinician spreads the length of the thumb and index finger over the right rib in question and applies a posteroanterior force (Fig. 27-18). This is the equivalent of a left rotation of the thoracic spine. The clinician then repeats the posteroanterior force on the rib, except this time, the rotation of the thoracic spine is blocked by the clinician placing the ulnar border of the other hand over a group of left transverse processes. Pain produced with this maneuver implicates the rib, because the thoracic spine is stabilized.

Thoracic Spring Test. The patient is positioned as previously. Spring testing in a posteroanterior direction is applied using the thumbs, with the elbows locked over the spinous processes of the thoracic spine (Fig. 27-19). These spring tests are provocative for pain but may also be used for a gross assessment of mobility.

Reflex Hammer Test. The patient is sitting, and the clinician uses a reflex hammer to tap over each spinous process (Fig. 27-20). If tenderness is encountered, especially in a patient with a history of trauma to the area, a fracture must be ruled out.

Deep Breathing and Flexion. This test can be used for patients who complain of pain with thoracic flexion. The patient is seated with the thoracic spine positioned in neutral. The patient is asked to inhale fully and then to flex the thoracic spine until the pain is felt. At this point, the patient maintains the position of flexion and slowly exhales. If further flexion can be achieved after exhalation, the source of the pain is likely to be the ribs rather than the thoracic spine.[133]

The Sitting Arm Lift Test.[134] The **sitting arm lift** (SAL) test is based on the principles of the active straight leg raise (see Chap. 29), a validated test of failed load transfer in the pelvic

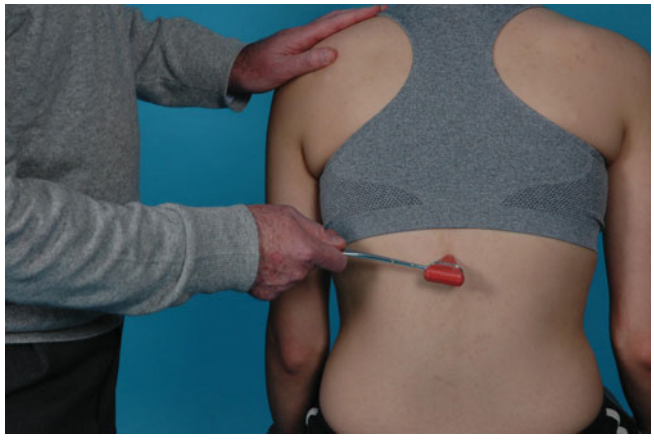

FIGURE 27-20 Reflex Hammer Test.

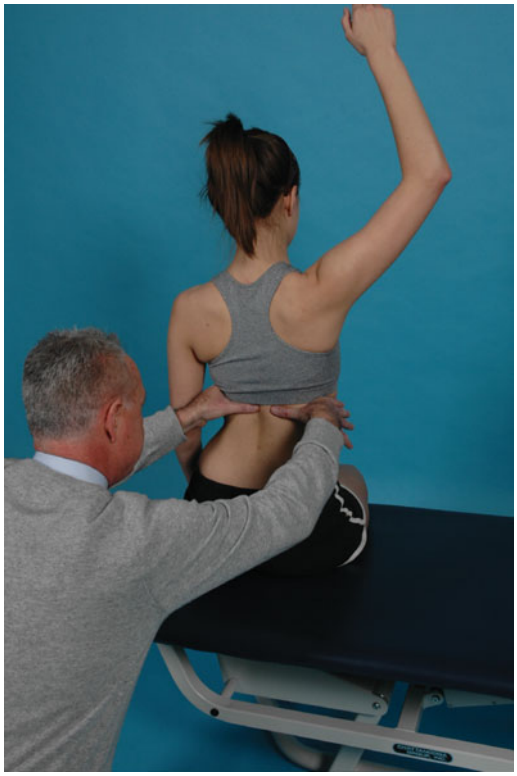

FIGURE 27-21 The sitting arm lift (SAL) test.

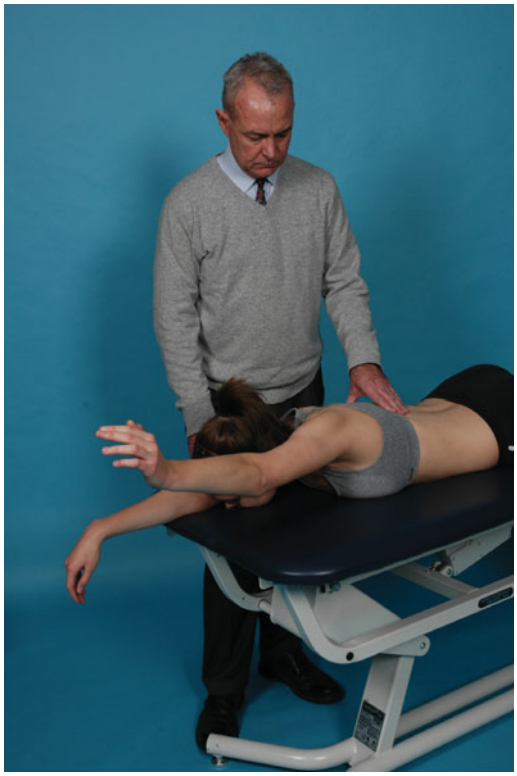

FIGURE 27-22 The prone arm lift (PAL) test.

girdle associated with pregnancy-related pelvic girdle pain. The patient is positioned in relaxed sitting with the hand resting on the thighs. The clinician asks the patient to lift one arm (usually the pain-free side is tested first if ipsilaterally symptoms are present), with the arm straight, into elevation and then to lower the arm (Fig. 27-21). Next, the patient is asked to lift the other arm and lower it and the clinician notes whether symptoms are produced, and also observes which arm looks as if it requires more effort to lift, especially from the initiation of movement to the first 70° to 90° of elevation. Then, the patient is asked "does one arm feel heavier to lift on the other, or different to lift than the other?" If one arm is reported to be heavier or required more effort to lift, the test result is positive for loss of neuromuscular control and indicates a load transfer problem. To determine the affected level or levels, the clinician then palpates the osteokinematic motion of each thoracic ring as the patient performs active elevation through flexion with the heavier arm. A positive test result is indicated when a thoracic ring or rings is/are felt to translate along any axis or rotate in any plane, or any component of the ring (vertebra or rib) translates or rotates along any axis or plane.

The Prone Arm Lift Test.[134] The **prone arm lift** (PAL) test is a modification of the SAL test as it is performed in a higher load position (prone). The patient is positioned in prone with both arms overhead in approximately 120 degrees of flexion and fully supported on the bed (the head of the bed needs to be dropped down). The clinician instructs the patient to lift one arm and then lower it (Fig. 27-22). The movement is then repeated on the other side. The arm that tests positive for loss of neuromuscular control is the arm that is heavier to lift. As with the sitting arm lift test, the same techniques can be used to assess the osteokinematic motions. It is particularly important to assess this ability in patients who require this position functionally (e.g., overhead workers).

INTERVENTION STRATEGIES

Interventions for thoracic and rib dysfunctions require a multifaceted and eclectic approach because of the complexity of this area. Once the causes for referral of symptoms have been ruled out, dysfunctions of the thoracic spine and rib cage may be categorized as somatic or biomechanical.

The intervention approaches are for the upper thoracic spine is similar to that of the cervical spine (see Chap. 25), whereas the approach for the lower thoracic spine is similar to that of the lumbar spine (see Chap. 28). The approach to the mid-thoracic region is variable and depends on the cause. This region is prone to both postural and biomechanical dysfunctions. The evidence supporting the use of mobilization and high-velocity thrust techniques in the thoracic spine continues to increase.[135–139]

The overall goal of treatment should be to optimize load transfer and the sharing of forces throughout the thorax, the spine, and the entire body, which requires restoration of mobility to restrict areas, restoration of muscle control and the capacity to stabilize poorly controlled areas.[2]

The techniques to increase joint mobility and soft tissue extensibility are described later, under "Therapeutic Techniques" section.

Acute Phase

In the acute phase of rehabilitation for the thoracic spine, the intervention goals are to

- decrease pain, inflammation, and muscle spasm;
- promote healing of tissues;
- increase pain-free range of vertebral and costal motion;
- regain soft tissue extensibility;
- regain neuromuscular control;
- initiate postural education;
- promote correct breathing;
- educate the patient about activities to avoid and positions of comfort;
- allow progression to the functional phase.

Pain relief may be accomplished initially by the use of modalities such as cryotherapy and electrical stimulation, gentle exercises, and occasionally the temporary use of a spinal brace. Thermal modalities—especially ultrasound, with its ability to penetrate deeply—may be used after 48–72 hours. Ultrasound is the most common clinically used deep-heating modality to promote tissue healing.[140–142]

Electrical stimulation can be used in the thoracic region to

- create a muscle contraction through nerve or muscle stimulation. The purpose of this muscle contraction and stimulation is to create a muscle pump to aid in the healing process. Electrical stimulation of muscles for the correction of scoliosis has not been found to be effective in preventing scoliosis progression[143];
- decrease pain through the stimulation of sensory nerves (TENS);
- provide muscle reeducation and facilitation through both motor and sensory stimulation.

Once the pain and inflammation are controlled, the intervention can progress toward the restoration of full strength, range of motion, and normal posture. Range-of-motion exercises are initiated at the earliest opportunity. These are performed during the early stages in the pain-free ranges. Submaximal isometric exercises are then performed throughout the pain-free ranges. These exercises are progressed as the range of motion and strength increase.

Manual techniques during this phase may include myofascial release, grade I and II joint mobilizations, massage, gentle stretching, and muscle energy techniques.

Functional Phase

The duration of this phase can vary tremendously and depends on several factors:

- Severity of the injury
- Healing capacity of the patient
- How the condition was managed during the acute phase
- Level of patient involvement in the rehabilitation program

The goals of this phase are the following:

- To achieve a significant reduction or to complete resolution of the patient's pain.
- To restore full and pain-free vertebral and costal range of motion. During this phase, the patient learns to initiate and execute functional activities without pain and while dynamically stabilizing the spine in an automatic manner.
- Full integration of the entire upper and lower kinetic chains. The exercises prescribed must challenge and enhance muscle performance, while minimizing loading of the thoracic spine and ribs to reduce the risk of injury exacerbation. Interindividual differences in injury status or training goals may allow for a continuum of required muscle stress and acceptable loading of the spine.[144]
- Complete restoration of respiratory function;
- Restoration of thoracic and upper quadrant strength and neuromuscular control. The stabilization of this region must include postural stabilization retraining of the entire spine, including the stabilization progressions outlined in Chapters 25 and 28, to (1) gain dynamic control of spine forces, (2) eliminate repetitive injury to the motion segments, (3) encourage healing of the injured segment, and (4) possibly alter the degenerative process.[145]

Practice Pattern 4B: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Impaired Posture

Postural Dysfunction

Postural dysfunctions of the thoracic spine are relatively common. Postural pain is not typically reproducible with the typical physical examination, and the diagnosis is based solely on the history of pain following sustained positions or postures. Occasionally, patients with this type of pain may report that their pain is aggravated by stress, or fatigue.[146]

Maigne's Thoracic Pain of Lower Cervical Origin. Although the pain from this condition may originate in the thoracic spine, Maigne[110] believes that the vast majority of these cases originate from the lower three cervical segments. The typical patient is female, with complaints of stiffness and tenderness of the shoulder girdle and thoracic muscle groups, particularly the interscapular muscles. The chief complaint is often described as a unilateral and intense pain, which is increased with sustained positions of sitting, and with the lifting and carrying of heavy weights. The pain generally is decreased with rest, although it can sometimes be worse in the morning upon awakening. There may also be accompanying cervical and low-back pain associated with postural habits or standing or sitting positions.

The physical examination usually reveals tenderness at the level of T5–6 (interscapular point), 1–2 cm lateral of the midline. Mild pressure at this point is sufficient to reproduce the patient's pain.

The intervention for this condition involves a therapeutic trial of cervical mobilization.

Abnormal Pelvic Tilting. Good mobility of the pelvis in all directions is important for the thoracic spine. Two postural deviations are associated with pelvic tilting:

1. Posterior pelvic tilting in the sitting position produces an increase in lumbar and thoracic spine flexion and a forward head posture (FHP). This posture is thought to result in a

posterior shifting of the thoracic disk, which in turn places a stress on the posterior longitudinal ligament and the dura mater. This stress can produce both local and nonsegmental referrals of pain. This condition can be treated by having the patient sit on a wedge that tilts the pelvis anteriorly.

2. Anterior pelvic tilting in the standing position causes the trunk to lean backward and results in overstretching of the rectus abdominis and a pulling forward of the shoulders, shortening of the posterior neck muscles, and increased extension of the atlanto-occipital joint.[147] This condition can be treated by having the patient perform posterior pelvic tilts while standing, or by standing with one foot in front of the other.

Precordial Catch Syndrome. This is a benign self-limiting condition occurring mainly in adolescents and young adults.[148,149] It is characterized by sharp, stabbing pain in the precordial and left parasternal region that does not radiate. This pain usually lasts a few seconds and may occur at rest or with mild-to-moderate exercise.[148] When occurring at rest, it is often associated with being seated in a slouched position and may be relieved by stretching into a more upright position.[150] It affects males and females equally but is uncommon after the age of 35 years.[149] The etiology of this condition is unknown, but it may originate from the pleura.[149] After excluding other causes, management consists of explanation, reassurance, postural education, and exercises to correct any muscle imbalances.

CLINICAL PEARL

Patients with any form of postural dysfunction often benefit from the movement therapies of the Alexander technique, Feldenkrais method, Trager psychophysical integration, Pilates, and Tai chi chuan[151–157] (see Chap. 10).

Practice Pattern 4D: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Ligament or Other Connective Tissue Disorders

Thoracic Disk Pathology

Herniated disks have been found at every level of the thoracic spine, although they are more common in the lower thoracic spine.[11,158]

At the cervical and lumbar levels, the thoracic spinal nerves emerge from the cord as a large anterior (ventral), and a smaller posterior (dorsal) ramus, which unite to form a short spinal nerve root. There are no plexuses in this area, and the spinal nerves form the intercostal nerves.[8] The intraspinal course of the upper thoracic nerve root is almost horizontal (as in the cervical spine). Therefore, the nerve can only be compressed by its corresponding disk. More inferiorly in the spine though, the course of the nerve root becomes more oblique, and the lowest thoracic nerve roots can be compressed by disk impairments of two consecutive levels (T12 root by 11th or 12th disk).[8]

The major etiological factor in most cases of thoracic disk herniation appears to be degenerative changes in the disk.[159] McKenzie[123] argues that the derangement syndrome can be divided into posterior and anterior disk derangements because of the distinct clinical presentations. The McKenzie classification system is outlined in Chapter 22. Anterior derangement is rare in the thoracic spine. The following derangement patterns are seen in the thoracic spine[123]:

- ***Derangement 1.*** This type of derangement typically produces central or symmetric pain between T1 and T12. These derangements are rapidly reversible.
- ***Derangement 2.*** This type of derangement, which is rare and the result of acute trauma or serious pathology, produces an acute kyphosis.
- ***Derangement 3.*** This type of derangement typically produces unilateral or asymmetric pain across the thoracic region, with or without radiation around the chest wall. These derangements are rapidly reversible.

CLINICAL PEARL

The clinical manifestations of thoracic disk herniation are extremely variable and vague. This often results in long delays between presentation and diagnosis.

Midline back pain and compressive myelopathy symptoms progressing over months or years are the predominant clinical features of a thoracic disk herniation.[160] One study[161] found that 70% of patients had signs of spinal cord compression, but that isolated root pain occurred in only 9% of patients. Unusual features of thoracic disk herniation include Lhermitte's symptom precipitated by rotation of the thoracic spine,[162] neurogenic claudication with positional dependent weakness,[163] and flaccid paraplegia.[164]

Some thoracic disk herniations are asymptomatic. The incidence of asymptomatic thoracic disk protrusions is approximately 37%, reinforcing the view that clinicians should interpret thoracic MRI findings with caution.[11,158]

T1 and T2 Levels. Disk herniations at these levels are extremely rare.[165] This rarity may be due to the protection afforded by the presence of the first and second ribs. Compression of the nerve at the T1 and at T2 segmental levels may result in numbness, tingling and weakness of the hand, and pain in arm and medial forearm.[165] T1 radiculopathy may also be associated with a Horner's syndrome.[165] The patient may also have reduced biceps and triceps reflexes.[165]

T2 and T3 Levels. A disk herniation at these levels is the rarest type.[166] Symptoms produced with this herniation include pain referred toward the clavicle, to the scapular spine, and down the inner side of the upper arm.[166]

T3–8 Levels. Compression of the nerves at these lower levels may result in symptoms that are experienced at the side, or front of the trunk.[90] Compression of the dura in the thoracic spine results in unilaterally referred pain, which is extrasegmental. A T6-level compression of the dura can cause pain up to the base of the neck and down to the waist, whereas a dural compression at T12 can refer pain up to T6 and down to the sacrum.[90]

T9–11 Levels. Lower thoracic disk herniations have been associated with pain radiating to the buttock in some cases,

confusing the diagnosis with that of a lumbosacral root compression.[167] How a herniated disk at a low thoracic level could appear to be a lumbosacral radiculopathy may be best explained by the anatomic arrangement of the spinal cord and vertebral bodies. In adults, the conus medullaris ends between the 12th thoracic and third lumbar vertebrae, and the lumbar enlargement of the spinal cord is usually located at the lower thoracic level. Therefore, a lower thoracic disk herniation could compress the lumbosacral spinal nerves after their exit from the lumbar enlargement of the spinal cord and thus produce symptoms of compressive lumbosacral radiculopathy; thus, a herniation into an already tight canal may produce bilateral symptoms and sphincter disturbance, as in patients with a conus medullaris impairment.[168]

A retrospective study by Brown and colleagues[169] found that 77% of the 40 patients with symptomatic thoracic disk herniations, who were treated nonsurgically, were able to return to their previous level of activity.

Thoracic disk herniations requiring surgical management are uncommon and account for less than 2% of all operations performed on herniated IVDs.[170]

Electrodiagnosis of Thoracic Disk Lesions. Electrodiagnostic studies are important in identifying physiologic abnormalities of the nerve root in the cervical, thoracic, and lumbar spine, and they have been shown to be a useful diagnostic test in the diagnosis of radiculopathy,[171] correlating well with findings on myelography and surgery.[172,173]

There are two parts to the electromyogram: nerve conduction studies and needle electrode examination. The nerve conduction studies are performed by placing surface electrodes over a muscle belly or sensory area and stimulating the nerve, supplying either the muscle or the sensory area from fixed points along the nerve. From this, the amplitude, distal latency, and conduction velocity can be measured. The amplitude reflects the number of intact axons, whereas the distal latency and conduction velocity are more of a reflection of the degree of myelination.[174–176]

The timing of the examination is important, as positive sharp waves and fibrillation potentials will first occur 18–21 days after the onset of a radiculopathy.[175,177] It is, therefore, best to delay this study until 3 weeks after the injury, so that it can be as precise a study as possible. The primary use of electromyography is to diagnose nerve root impairment when the diagnosis is uncertain or to distinguish a radiculopathy from other impairments that are unclear on physical examination.[175] Electrodiagnostic abnormalities can persist after clinical recovery for months to years and in some may persist indefinitely.[178,179]

Traction: Mechanical or Manual for Thoracic Disk Lesions. Manual or mechanical traction has long been a preferred intervention throughout the spine with the intent of improving range of motion, and to treat both zygapophyseal joint impairments as well as disk herniation.[180–185] The efficacy of traction has not been scientifically proved in a randomized controlled trial, but it is commonly used and thought to be of benefit in reducing radicular pain.[186]

For traction to be effective, the imparted force must be sufficient to overcome soft tissue resistance prior to the relaxation of the involved musculature.

Traction can be applied continuously, or intermittently, and with the patient positioned in sitting or lying.[187] Intermittent traction produces twice as much separation as sustained.[188] The duration of traction recommended varies from 2 minutes to 24 hours.[189]

Performed manually, traction can be very time consuming and, in the lumbar and thoracic spines, requires a good deal of strength—approximately 12 times a patient's body weight is needed to develop significant distraction of the vertebral bodies. However, a greater degree of specificity can be obtained using manual traction, especially if it is performed using spinal locking techniques to localize the distraction to a specific level. Pain relief, or a centralization of symptoms, with manual traction may also be an indication for the use of mechanical traction.

Vertebral axial decompression, a newer method to cause distraction, probably represents a higher-tech version of traction, although there is no evidence in the current peer-reviewed literature to support this type of intervention.

Outcome studies of traction have demonstrated varying results.[180,185] From clinical experience, it would appear that traction yields better results if at least one of the spinal motions is full and pain free. However, a one-session trial of short duration is worthwhile, even if all of the motions are restricted.

Spinal traction is contraindicated in the following conditions:

- acute lumbago;
- instability;
- respiratory or cardiac insufficiency;
- respiratory irritation;
- painful reactions;
- a large extrusion;
- medial disk herniation;
- altered mental state; this includes the inability of the patient to relax.

Electrotherapeutic and Physical Modalities of Thoracic Disk Lesions. Modalities such as electrical stimulation also have been found helpful in uncontrolled studies.[190] They appear to be helpful in reducing the associated muscle pain and spasm but should be limited to the initial pain-control phase of the intervention.

Once there is control of pain and inflammation, the patient's intervention should be progressed to restore full range of motion and flexibility of the spine, trunk, and extremity muscles.

Zygapophyseal Joint Dysfunction

Apart from the upper and lower segments of this region, little is known about the extent or patterns of thoracic zygapophyseal joint degeneration. However, these joints have been found to be potential sources of local and referred pain.[191]

The pathomechanics describing mechanical dysfunction in this region are largely based on expert opinion and the principles of anatomy and biomechanics. Given the controversy surrounding the nature of coupled motions in the thoracic spine, and the number of structures involved in executing motion at these levels, the clinician is advised to

diagnose dysfunction in this region based on restrictions of motion, rather than on specific structures.

Restriction of motion can have many causes in this region, including zygapophyseal joint hypomobility, soft tissue contracture, and costovertebral–costotransverse joint hypomobility. Differentiation among these structures, to find the specific cause of dysfunction, requires a great deal of expertise.

For the sake of simplicity, and because the spinous and transverse processes are more easily palpated in this region, the osteopathic approach of diagnosing a positional dysfunction using position testing is recommended.

As elsewhere in the spine, dysfunctions can be either symmetric or asymmetric. Symmetric impairments are more common in the thoracic region than in the lumbar, particularly in the upper and cervicothoracic spine as a result of fixed postural impairments. These, of course, will not be apparent on position testing and must be sought after when the position tests are negative. If no asymmetry is found on position testing, then the segment of interest should be separately passively flexed, extended, and rotated in all directions.

To determine which lesion is present, layer palpation is used. The position of the superior vertebra and the posteroanterior relationship of the transverse processes to the coronal body plane is noted and compared with the level above and below, in thoracic flexion and then extension (see "Position Testing: Spinal" section earlier).

Rib Dysfunction

The costovertebral joint may be involved in inflammatory or degenerative joint disease. Complaints of symptoms in these joints are common in conditions such as ankylosing spondylitis as a result of synovitis. The clinical features of severe arthropathy of the costovertebral joint include pain with deep breathing, trunk rotation, sneezing, or coughing. CT scans are helpful in confirming the diagnosis. Inflammation of the costovertebral joint commonly causes localized pain about 3–4 cm from the midline, where the rib articulates with the transverse process and the vertebral body.[81]

According to the osteopaths, rib dysfunctions are described as structural, torsional, or respiratory.[117,192,193]

- ***Structural.*** Structural rib dysfunctions are true joint subluxations that occur secondary to trauma. These dysfunctions are extremely painful and significantly reduce motion of the ribs during inspiration and expiration. The most important landmarks for structural rib dysfunctions are the rib angle and the anterior rib. Ribs can sublux anteriorly or posteriorly (see Table 27-4). The first rib can sublux superiorly.
- ***Torsional.*** As their name suggests, these rib dysfunctions are twisting injuries, in which the rib is held in a position of internal or external rotation. These dysfunctions affect the thoracic spine motions as well as the motions of respiration (see Table 27-4).
- ***Respiratory.*** Respiratory rib dysfunctions usually are related to poor posture and result in a restriction of either inspiration or expiration.

The first rib can sublux anteriorly, posteriorly, or, more commonly, superiorly. If the motion is perceived as abnormal, passive movement testing should be performed. The arthrokinematic is tested with the patient seated and the clinician standing behind. Using the medial aspect of the MCP joint of the index finger, the clinician applies an anterior–inferior–medial glide of the rib to assess the inspiration glide, while a posterior–superior–lateral glide is applied to assess the expiration glide. The end-feel is assessed. If it is abrupt and hard (pathomechanical) in both glide directions as compared with the same rib on the other side, then the problem is a subluxation. If it is stiff (hard capsular) in both directions as compared with the same rib on the other side, then a pericapsular restriction is present. If both glides are normal, then the problem is likely to be myofascial.

- ***Unilateral restriction of anterior rotation of the first rib.*** This dysfunction is seen when the scalene muscles are hypertonic or adaptively shortened and hold the *anterior* aspect of the first rib superiorly or when the *superior glide* of the first rib is restricted at the costotransverse joint. This dysfunction will restrict unilateral elevation of the arm (both arms may be involved). If the dysfunction is intra-articular, rotation and side bending of the head/neck will be limited to the side of the restricted rib (this motion requires a superior glide of the rib at the costotransverse joint). Full expiration will also reveal asymmetry of rib motion. If the restriction is intra-articular, the superior glide of the first rib at the costotransverse joint will be restricted. The presence or absence of pain depends upon the stage of the pathology (substrate, fibroblastic, and maturation) and the irritability of the surrounding tissue. The grade of the mobilization technique is directed by these factors.
- ***Unilateral restriction of posterior rotation of the first rib.*** This dysfunction, also known as an expiratory or anterior sagittal lesion, is seen when the *posterior* aspect of the first rib is held superiorly or when the *inferior glide* of the first rib is restricted at the costotransverse joint. This dysfunction will restrict unilateral elevation of the arm on either side, rotation and side bending of the head/neck to the opposite side of the restricted rib, and full inspiration. If the restriction is intra-articular, the inferior glide of the first rib at the costotransverse joint will be restricted. The presence or absence of pain depends on the stage of the pathology (substrate, fibroblastic, and maturation) and the irritability of the surrounding tissue. The grade of the mobilization technique is directed by these factors.

The intervention for costovertebral dysfunctions involves mobilization and manipulation techniques or local anesthetic injections, or both.

Practice Pattern 4E: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Localized Inflammation

Tietze Syndrome

Tietze syndrome is a local inflammation of the costosternal cartilage, which most commonly affects the second and third costochondral junctions.[27,153] Tietze syndrome may also affect

any of the cartilaginous articulations of the chest wall, including the sternoclavicular joints.[194]

The clinical findings for this condition include a history of a gradual or sudden onset of pain in the involved region, which is increased with deep inspiration, coughing, or sneezing. Upon physical examination, there is often a localized swelling of the costosternal cartilage.

This is a self-limiting condition, which can last from weeks to years. The intervention can involve local injections of corticosteroid and specific joint mobilizations to the costovertebral articulations.

Muscle Strains

Muscle strains, which are common in this region, are characterized by localized pain and tenderness, which is exacerbated with isometric testing or passive stretching of the muscle. Rather than attempt to isolate muscles in this region, the clinician can determine the directions that alleviate the symptoms and those that do not. A gradual strengthening and gentle passive stretching program into the painless directions is initially performed, before progressing as tolerated into the painful directions.

Intercostal Muscles. Injuries to intercostal muscles are mainly caused by direct trauma or after unaccustomed or excessive muscular activity (e.g., lifting a heavy object or persistent coughing).[195] On occasion, the onset of pain or symptoms may be of gradual onset with no obvious inciting event.[196] Intercostal muscle injuries are more likely in activities in which upper body use is extreme, such as regular use of a pickaxe.[196]

The classic presentation is pain between the ribs that is worse on movement, deep inspiration, or coughing, and tender to palpation.

The intervention for intercostals muscle strains includes anti-inflammatory medications, the avoidance of exacerbating activities, and the treatment of any underlying pathology where appropriate.

Contusions

The severity of soft tissue injury to the chest wall is dependent on the mechanism of injury and the degree of protection between the traumatic force and the chest wall.[55] Chest injury is commonly produced by the restraining influence of the diagonal component of a seat belt. Seat belt injuries occur predominantly on the side of the belt and hence occur on different sides in drivers and passengers.[55] These take the form of abrasions, ecchymoses, and friction burns, producing an imprint of the belt.[55]

Trauma to the female breast can be produced by a combination of compression and shearing stress produced by a seat belt, and subcutaneous rupture of breast tissue can occur.[197] The presence of a persistent breast mass after trauma must always be taken seriously, as trauma may draw attention to an unsuspected carcinoma.[55]

Chest trauma can result in disruption of a subcutaneously placed pacemaker generator or leads, long-term indwelling central venous catheter, or subcutaneous portions of arterial bypass grafts.[55]

Severe skeletal trauma to the chest wall can be associated with large chest wall hematomas or collections of air within the chest wall, which can communicate with the intrathoracic space.[55]

The conservative intervention for thoracic cage contusions depends on the severity of the injury and the tissues involved. Typically, the initial intervention for soft tissue injury is cryotherapy with rest. Gentle pain-free active range-of-motion exercises are introduced as tolerated. Once the acute stage is over, thermal modalities are used and the range of motion exercises progressed to strengthening exercises in all planes.

Practice Pattern 4G: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Fractures

Thoracic Vertebral Fractures

Fractures of the thoracic spine account for 25–30% of all spine fractures.[198] These fractures are most often a result of hyperflexion or axial loading injuries[199] and less commonly attributable to rotational stresses, side bending, horizontal shear, and hyperextension. The most common fractures seen in the thoracic spine are anterior wedge compression fractures and burst fractures[200] (see Chap. 5). Most thoracic spine fractures occur between the ninth and 11th vertebral bodies. Multiple fractures are found in 10% of all patients with a spine fracture, and, therefore, evaluation of the entire spine is necessary, because up to 80% of these additional fractures are noncontiguous.[201] Only 12% of patients with fracture–dislocations of the thoracic spine are neurologically intact, and 62% of patients with thoracic spine fracture–dislocations have complete neurologic deficits.[55]

Rib Fractures

Fractured ribs can lacerate the pleura, lung, or abdominal organs. Fractures to upper ribs, clavicle, and upper sternum can signal brachial plexus or vascular injury. Isolated fractures of the ribs, clavicle, or scapula seldom represent significant injuries in and of themselves, but they do reflect the magnitude of force imparted, particularly in older patients with noncompliant chest walls.[202] Fractured rib ends can lacerate the pleura or lung, resulting in hemothorax or pneumothorax.[55] There is a much greater incidence of rib fractures in older patients, whose ribs are relatively inelastic, compared with the incidence of rib fractures in children, whose ribs are more pliable and resilient.[55] For this reason, a posttraumatic pneumothorax in older patients is almost always associated with one or more rib fractures, whereas children can sustain a pneumothorax or major internal thoracic injury after trauma without an associated rib fracture.

Fractures of the first three ribs, in particular, indicate significant energy transfer, because they are well protected by the shoulder girdles and associated musculature.[55] Fractures to the upper ribs, clavicle, and upper sternum are accompanied by brachial plexus or vascular injury in 3–15% of patients.[203] Fractures of the 10th, 11th, or 12th ribs are associated with injury to the liver, kidneys, or spleen and should prompt confirmation of organ injury with CT.[55] Double fractures of three or more adjacent ribs or contiguous combined rib and sternal or costochondral fractures, or single fractures of four or

more contiguous ribs, can produce a focal area of chest wall instability. Paradoxical movement of a "flail" segment during the respiratory cycle can impair respiratory mechanics, promote atelectasis, and impair pulmonary drainage.

The common findings for a rib fracture are described in Chapter 5. A key factor in the intervention of rib fractures is believed to be adequate pain control to allow early aggressive respiratory care and, hence, prevent the development of pulmonary complications.

Early intervention includes assistance with coughing, intracostal nerve blocks, and muscle relaxants. Adhesive strapping or taping should be avoided because it can inhibit deep inspiration and may contribute to atelectasis.[204] Simple rib fractures become stable in 1–2 weeks, with firm healing by callus in approximately 6 weeks.[204]

Scheuermann's Disease

Scheuermann's disease, which is found in approximately 10% of the population and in males and females equally, is typically seen in pubescent athletes.[21]

The disease involves a defect to the ring apophysis of the vertebral body and anterior wedging of the affected vertebrae, as a result of a flexion overload of the anterior vertebral body.[205] The end plate can crack, thus making it possible for disk material to bulge into the vertebral body (Schmorl's node). According to McKenzie,[123] the extension dysfunction develops in patients with Scheuermann's disease as a result of adaptive shortening from poor postural habits, or from derangement or trauma and the healing process.

Clinical findings include evidence of a thoracic kyphosis and pain with thoracic extension and rotation.

The intervention depends on the severity but typically involves postural education, a modification of the aggravating activity, exercise (seated rotation and extension in lying exercises), or bracing. The exercise program involves the stretching of the pectoralis major and minor muscles, and muscle-strengthening exercises for the thoracic spine extensors and the scapular adductors.[38]

Scapular Fractures

Fractures of the scapula are relatively rare due to the thick muscles lying both superficial and deep to the scapula and the energy-absorbing ability of the scapula to move on the chest wall.[206] Because of the large amount of force that is required to fracture a scapula, these fractures are often associated with other major injuries. For example, the incidence of pneumothorax in patients with fracture of a scapula is over 50%.[207] Associated injuries that are directly related to the fractured scapula include injuries of the suprascapular nerve, axillary nerve, axillary artery, and subclavian artery.[55] The body of the scapula is the most frequent site of fracture followed by the neck and glenoid.[208] The spine, coracoid, and acromion are less frequently fractured.[208] Scapular fractures may not be recognized on the initial chest radiograph as they are frequently radiographically obscure and are commonly associated with multiple other regional injuries, such as clavicular and rib fractures, subcutaneous air, pneumothorax, and pulmonary contusion.[55]

Sternal Fractures. The tremendous force necessary to cause a fracture of the sternum has led to the belief that the presence of a sternal fracture is a harbinger of severe associated injuries. The association of seat belt wearing with sternal fractures is well known.[209] A proportional increase in incidence of 100% in drivers and 150% in front-seat passengers has been noted since the enactment of seat belt legislation.[210] Sternal fractures, as such, do not generally cause problems either in healing or by direct damage to adjacent structures. Dislocation of the sternoclavicular joint, however, with posterior displacement of the inner end of the clavicle may cause compression of the trachea and the adjacent great vessels, with significant clinical consequences.[211]

Integration of Practice Patterns 4B and 4F: Impaired Joint Mobility, Motor Function, Muscle Performance, Range of Motion Secondary to Impaired Posture, Systemic Dysfunction (Referred Pain Syndromes), Spinal Disorders, and Myofascial Pain Dysfunction

Referred Pain

Referred pain to this area is extremely common. Referred pain is characterized by a poorly localized pain that is nontender to palpation and does not change with movements or alterations of posture (see Table 27-6).

T4 Syndrome

The name of this syndrome is a bit of a misnomer, because the syndrome can additionally affect any of the T2–7 levels, although it always includes the T4 segment. The T4 syndrome has an unknown etiology, although it is believed to result from a sympathetic reaction to a hypomobile segment, because the symptoms appear to resolve in response to manual therapy techniques to the thoracic segments.[212–214] In the thorax, the sympathetic trunks lie on or just lateral to the costovertebral joints. These trunks may undergo mechanical deformation with abnormal posture (forward head, accentuated thoracic kyphosis, and protracted shoulder girdle), trauma, or pulling and reaching activities, producing pain and sympathetic epiphenomena.[215]

Neurovascular symptoms are not a feature of this syndrome, though a differential diagnosis should consider such conditions.[212] The upper extremity symptoms are glovelike in distribution and are not segmentally related.[213] Nocturnal symptoms are common, usually occurring in the side lying or supine position.[213] More women are affected by this condition than men, in a ratio of more than 3:1.[216]

Clinical findings include local tenderness of bony points, positive slump test, positive upper limb tension tests, depression or prominence of one or more spinous processes, and local thickening and stiffness of one segment,[216] although gross cervical and thoracic motions are usually normal.[212]

The differential diagnosis includes carpal tunnel syndrome, thoracic outlet syndrome (see Chap. 25), cervical disk disease, vascular disease, and neurologic disease.[212]

The intervention for this condition involves mobilization and manipulation of the involved segment, followed by an exercise progression emphasizing upper thoracic flexibility

and muscle strength. Butler[217] recommends using both upper limb tension tests and also the slump test, with combinations of thoracic rotation and side bending.

Notalgia Paresthetica

The name of this condition comes from the Greek root meaning "pain in the back."[218] Clinically, this condition consists of pruritus and localized dysesthesia and hyperesthesia in the distribution of one of the cutaneous posterior (dorsal) rami of the upper thoracic area.

The recommended intervention for this condition is an injection of corticosteroid.

THERAPEUTIC TECHNIQUES

The selection of a manual technique is dependent on a number of factors, including the acuteness of the condition and the restriction to the movement that is encountered. Oftentimes, the same technique that was used to examine the segment can be used for the intervention, the difference being the intent of the clinician and the goal of the intervention. For example, if stretching of the mechanical barrier rather than pain relief is the immediate objective of the intervention, a mobilization technique is carried out at the end of the available range.

To achieve this, the antagonist muscle must be relaxed, and this is most easily accomplished using a hold–relax technique. After this has been gained (and sometimes before and after), there is some minor pain to be dealt with, using grade IV oscillations, after which the joint capsule can be stretched, using either grade IV++ or prolonged stretch techniques. The prolonged stretch or the strong oscillations are continued for as long as the clinician can maintain good control. At the point where control is about to be lost, several isometric contractions to the agonists and the antagonists are demanded of the patient's muscles in the new range, to give the central nervous system information about the newly acquired range. To complete the reeducation, concentric and eccentric retraining is carried out throughout the whole range of the joint. Active exercises are continued at home and at work on a regular and frequent basis, to reinforce the reeducation.

Techniques to Increase Joint Mobility

Joint Mobilizations and High-Velocity Thrust Techniques

Mobilization and high-velocity thrust techniques have traditionally been used routinely in this region to[29,86,219,220]:

- restore thoracic mobility;
- reduce stresses through both the fixation and the leverage components of the spine;
- reduce stresses through the hypermobile segments;
- reduce the overall force needed by the clinician, thus giving greater control.

CLINICAL PEARL

Cleland et al.[221] developed a clinical prediction rule (CPR) to identify a subgroup of patients with neck pain who were considered more likely to benefit from a high-velocity thrust technique of the thoracic spine. However, more recent evidence has questioned its validity.[222] A recent study that included 24 consecutive patients,[223] tested two different forms of high-velocity thrust techniques to the thoracic spine based on this CPR. The study found that patients who were treated with a combination of cervical spine high-velocity thrust techniques and exercises showed significantly greater improvement in pain and disability compared to those treated with thoracic spine high-velocity techniques and exercises.

A number of studies have demonstrated clinical success with high-velocity thrust techniques to the thoracic spine.[135,139,224,225] However, it must be remembered that the isolation of a particular segment in the thoracic spine is extremely difficult, if not impossible because of the number of articulations that exist at each segmental level. In addition, there are a number of concerns that the clinician must be aware of prior to considering using high-velocity thrust techniques in this region. These include the following:

- A number of studies have demonstrated that the meninges may be vulnerable to thoracic manipulative thrust techniques.[226,227]
- The narrow dimensions of the mid-thoracic spinal canal.
- The poor blood supply to this region as compared to other areas of the spine.[53]
- The potential fragility of the bones in this area due to such conditions as osteoporosis, and rheumatoid arthritis.

It is, therefore, recommended that the clinician performs the slump test (see Chap. 11) and a premanipulative hold (see Chap. 10) prior to any technique.

Long Sit Superior Distraction (T5–6). The patient is positioned on the treatment table in the long sit position, with the buttocks on the edge of the back of the table and the hands on the back of the neck, fingers interlocked. The clinician stands behind the patient and places a small towel roll at the T6 level. The towel roll is held in place by the clinician's chest (made easier if the clinician turns slightly so that the side of the chest is used). The clinician threads his or her arms under the patient's armpits and places the heel of the palms under the patient's forearms. The patient is asked to flex the neck. A stride stance (one foot in front of the other) is adopted by the clinician (Fig. 27-23), and, while keeping the elbows close together, the clinician gently rocks the patient backward and forward. After two or three rocks, the traction force is applied, as the clinician shifts his or her body weight from the forward leg to the back, while lifting the patient and pushing the patient's forearms toward the ceiling.

Exercises to Increase Soft Tissue Extensibility

Shoulder Sweep. This exercise is used to mobilize the chest wall and to integrate upper extremity function with thoracic spine and rib cage motion.[61]

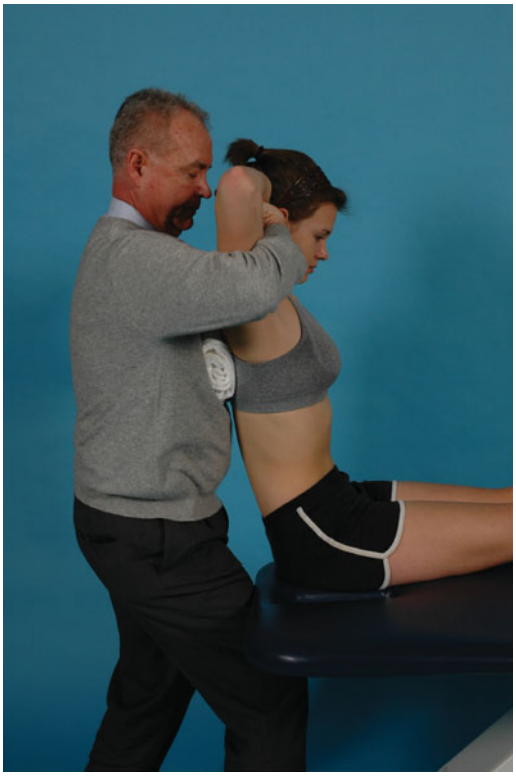

FIGURE 27-23 Long sit superior distraction thrust technique.

The patient is positioned supine on the floor or on a mat table, with the hips and knees flexed to about 90 degrees (Fig. 27-24). The patient is asked to reach sideways and place the back of the hand as far out to the side as is comfortable. While maintaining contact with the floor, the patient moves the hand above the head and to the other side of the body, making a large circle around his or her body (see Fig. 27-24). Manual assistance applied to the scapula or rib cage can be used as can deep breathing, in order to move into the restricted ranges.

Thoracic Spine Flexion. The patient kneels in front of a Swiss ball. The patient positions themselves over the Swissball so that weight is applied through the feet and the forearms (Fig. 27-25). While applying some body weight through the forearms, the patient arches the thoracic spine as far as is comfortable. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated 8–10 times.

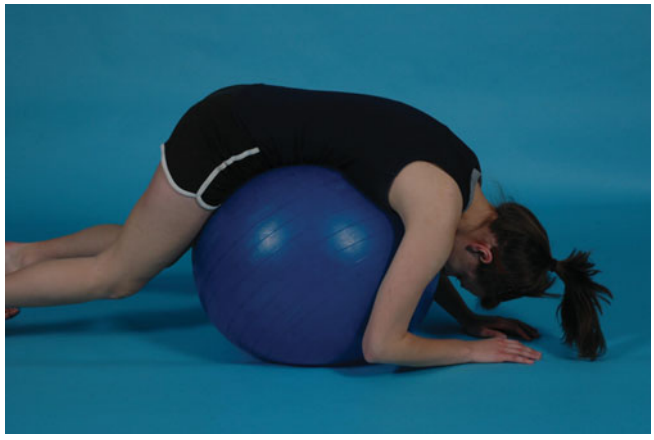

FIGURE 27-25 Thoracic spine flexion over Swiss ball.

Thoracic Spine Extension. It is advised that the clinician monitor this exercise in case the patient loses his or her balance. The patient sits on a Swiss ball, with the feet on the ground. Once the patient has good sitting balance, he or she attempts to lie supine on the ball and then places the hands on the ball (Fig. 27-26). The patient is then instructed to move the top of the head toward the floor, in an attempt to fully extend the thoracic spine. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated eight to 10 times. This exercise can be made more challenging by moving the hands from beside the body, out to the sides (Fig. 27-27) while maintaining the balance.

If the patient is unable to maintain his or her balance on the Swiss ball, a foam roll may be used. The foam roll also allows the clinician to focus the extension exercise on a specific segment.

Thoracic Spine Rotation. The following Swiss ball exercises to improve thoracic rotation range of motion and strength are recommended for the athletic population, only. The patient kneels with his or her back facing the Swiss ball. Using one leg at a time, the patient reaches back with the foot and places it on top of the Swiss ball. Once both feet are on the ball, the legs are

FIGURE 27-24 Shoulder Sweep exercise.

FIGURE 27-26 Thoracic spine extension over Swiss ball.

FIGURE 27-27 Thoracic spine extension over Swiss ball—arms out to the side.

straightened and the weight of the body is primarily borne through the arms. Using the dorsum of the feet and the anterior legs, the patient induces a rotation to the thoracic region by twisting at the waist (Fig. 27-28), while maintaining balance through the arms. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated 8–10 times. By alternatively moving the legs into hip flexion and extension, rotation of the thoracic spine can be achieved, while maintaining balance with the arms (see Fig. 27-28).

For the nonathletic population, thoracic rotation exercises can be performed using a firmer base of support. The patient kneels in front of a wobble board and places both hands on the board. Once good balance is achieved, the patient is asked to raise one arm out to the side as high as is comfortable, while keeping both knees on the floor. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated eight to 10 times.

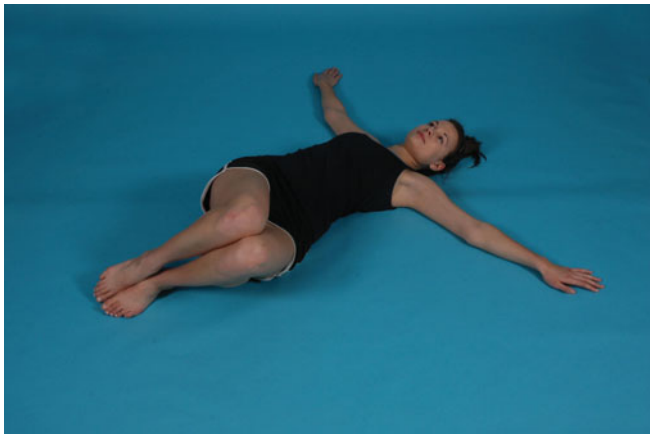

FIGURE 27-29 Hooklying rotations with arms abducted.

Thoracic rotation exercises can also be performed in the supine position. The patient lies supine with both knees bent and feet placed on the floor. The arms are abducted to approximately 90 degrees (Fig. 27-29). Keeping the trunk against the floor, the patient lowers the thighs to one side and then the other (see Fig. 27-29), as far as is comfortable. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated eight to 10 times.

Thoracic Spine Side Bending. The patient kneels to the side of a Swiss ball. The patient is asked to lean sideways over the ball and, with the arm closest to the ball, to attempt to touch the floor on the other side of the ball (Fig. 27-30) without losing balance. This position is held for 8–10 seconds, after which the patient relaxes. The exercise is repeated eight to 10 times.

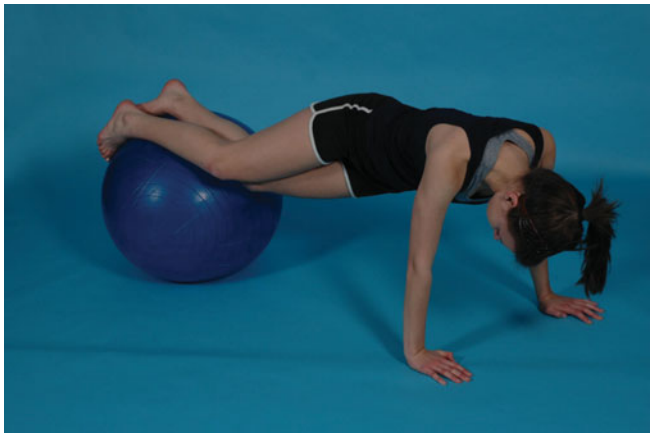

FIGURE 27-28 Thoracic spine rotation with trunk on Swiss ball.

FIGURE 27-30 Thoracic side bending over Swiss ball.

Rib Techniques for the Mid-Lower Thoracic Spine

Myofascial Stretch into Extension. The patient is positioned supine, and the clinician stands at the head of the bed. The patient elevates both arms over the head and reaches around the back of the clinician's thighs. By having the patient hold a towel in this position, the clinician can place both of his or her hands under the patient's rib cage and pull the rib cage in an anterior and cranial direction, thereby encouraging thoracic extension (Fig. 27-31). A belt wrapped around the patient at the correct level can make this technique more specific.

FIGURE 27-31 Supine myofascial stretch into extension.

CASE STUDY

RIGHT ANTERIOR CHEST PAIN

HISTORY

A 25-year-old man presented at the clinic complaining of pain in his right anterior chest. About 1 month previously, the patient had experienced a sudden and sharp pain in his right posterior chest at the midscapular level during a tug of war game at his company's picnic. The posterior chest pain subsided very quickly and did not bother him for the rest of the game. However, the next morning, pain was felt in the anterior aspect of the chest. This anterior chest pain eased off over the next few days with rest, but recurred as soon as the patient returned to weight lifting.[87]

Questions

1. Given the mechanism of injury, what structure(s) could be at fault?
2. Should the report of anterior chest pain concern the clinician in this case?
3. What is your working hypothesis at this stage? List the various diagnoses that could present with anterior chest pain, and the tests you would use to rule out each one.
4. Why do you think the pain shift from posterior thoracic to anterior thoracic?
5. Does this presentation/history warrant a scan? Why or why not?

CASE STUDY

BILATERAL AND CENTRAL UPPER THORACIC PAIN

HISTORY

A 30-year-old housewife presents at the clinic with a 3-day history of constant central and bilateral upper thoracic pain that is deep and dull and can be felt in the front of the chest when the pain is aggravated. The pain is reported to be worse with flexion motions but is improved with lying on a hard surface. Further questioning revealed that the patient had a history of minor back pain but was otherwise in good health and had no report of bowel or bladder impairment.

Questions

1. What structure(s) could be at fault with central and bilateral upper thoracic pain as the major complaint?
2. Should the report of anterior chest pain concern the clinician in this case?
3. Why was the statement about "no reports of bowel or bladder impairment" pertinent?
4. What is your working hypothesis at this stage? List the various diagnoses that could manifest with central and bilateral upper thoracic pain and the tests you would use to rule out each one.
5. Does this presentation/history warrant a scanning examination? Why or why not?

CASE STUDY

NECK SPRAIN

HISTORY

A 42-year-old right-handed female was referred by her primary-care physician with a diagnosis of neck sprain. [228] The patient reported a 10-year history of intermittent neck pain (right greater than left), which had worsened over the past 6 months. More recently, the patient reported developing right shoulder (right upper trapezius) and arm pain, as well as infrequent (about twice a week) paresthesia in the right arm and hand involving the fourth and fifth digits. The patient described the pain as a sharp stabbing pain at the right side of the neck and a dull aching pain in the right upper trapezius region. She indicated that the neck pain was independent of the upper trapezius pain. At the time of the evaluation, the neck and upper trapezius pain were a 3/10 and 4/10, respectively. The symptoms improved when she positioned herself supine or left side lying with a pillow under the head. The upper trapezius pain was reduced when she side bent the head toward the side of pain and worsened as the day progressed, especially when she was at work and performing elevated arm activities. She reported that the paresthesias of the ulnar aspect of a right forearm, as well as digits 4 and 5, appeared more often during the afternoon and occasionally at night. When inquiring about the irritability of the condition, the patient reported that between a few hours and 1 day were required for the pain to decrease after it was provoked. The patient worked as a faculty member at a local college, which involved spending prolonged periods of time on the computer and extensive reading. The patient's past medical history was negative for dizziness, diplopia, unexpected weight change, drop attacks, dysarthria, dysphagia, tinnitus, and night pain unrelated to position.

Questions

1. List the structure(s) that could be at fault with these complaints.
2. Does this sound like a neuromusculoskeletal condition?
3. Are there any other questions you would ask this patient?
4. What is your working hypothesis at this stage? List the various diagnoses that could manifest with central and bilateral upper thoracic pain and the tests you would use to rule out each one.
5. Does this presentation/history warrant a scanning examination? Why or why not?

CASE STUDY

INTERSCAPULAR PAIN

HISTORY

A 21-year-old woman presented with a 1-week history of left-sided interscapular pain that started at work. The patient worked as a computer operator. The pain was reported to be aggravated by lying prone, deep breathing in, and standing or sitting erect. Further questioning revealed that the patient had a history of this pain over the past few months but that it had not been as intense as it was currently. The patient was otherwise in good health and had no reports of bowel or bladder impairment.

Questions

1. List the structures that can produce interscapular pain.
2. Given the fact that this patient works at a computer, what could be the cause of her pain?
3. What is your working hypothesis at this stage? List the various diagnoses that could manifest with interscapular pain and the tests you would use to rule out each one.
4. Does this presentation/history warrant a scan? Why or why not?

REVIEW QUESTIONS*

1. In the thoracic region, in which plane are the zygapophyseal (facet) joints oriented?
2. Which of the ribs are considered atypical ribs, and why?
3. What is the joint where the rib and the vertebra meet called?
4. Which structures modify and restrict rotation in the thoracic region?
5. Which ribs demonstrate bucket handle movement and which display pump handle motions?

*Additional questions to test your understanding of this chapter can be found in the Online Learning Center for *Orthopaedic Assessment, Evaluation, and Intervention* at www.duttononline.net.

CHAPTER 28 Lumbar Spine

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the vertebrae, ligaments, muscles, and blood and nerve supply that comprise the lumbar intervertebral segment.
2. Outline the coupled movements of the lumbar spine, the normal and abnormal joint barriers, and the reactions of the various structures to loading.
3. Perform a detailed examination of the lumbar musculoskeletal system, including history, observation, palpation of the articular and soft tissue structures, specific passive mobility and passive articular mobility tests for the intervertebral joints, and stability testing.
4. Evaluate the results from the examination and establish a diagnosis.
5. Describe the common pathologies and lesions of this region.
6. Describe intervention strategies based on clinical findings and established goals.
7. Design an intervention based on patient education, manual therapy, and therapeutic exercise.
8. Apply mobilization techniques to the lumbar spine, using the correct grade, direction, and duration, and explain the mechanical and physiologic effects.
9. Evaluate intervention effectiveness to progress or modify intervention.
10. Plan an effective home program, including spinal care, and instruct the patient in this program.
11. Help the patient to develop self-reliant intervention strategies.

OVERVIEW

Over the past few decades, low-back pain (LBP) has become increasingly problematic, placing significant burdens on health systems and social-care systems.[1,2] The findings in the literature seem to suggest the seemingly contradictory notion that acute back conditions are self-limiting and have an excellent natural history, but there is a good chance that a problem remains. According to these studies, the first episode of back pain can have differing results: 80–90% will be asymptomatic in 6 weeks, 98% in 24 weeks, and 99% in 52 weeks,[3] leading to the assumption that most cases of LBP are benign in nature.[4–6] However, the small percentage of people who do become disabled with chronic LBP account for 75–90% of the cost associated with LBP.[7] This group of patients has been the focus of much research to determine factors associated with chronicity and the pathologic processes responsible.

Given the numerous causes and types of LBP, it is imperative that any clinician examining and treating the lower back have a sound understanding and knowledge of the anatomy and biomechanics of this region. Although this knowledge is not the sole determinant of the approach to LBP, it does provide a solid framework on which to build successful management. There have also been moves toward the design of clinical prediction rules (see Chap. 5) on how best to treat patients with LBP (see "Intervention" section).

It is worth noting that trunk strength, flexibility, aerobic conditioning, and postural education have all been found to have a significant preventative effect on the occurrence and recurrence of back injuries.[8–15] Thus, physical therapy, with its emphasis on the restoration of functional motion, strength, and flexibility, should be the cornerstone of both the intervention and the preventative processes in LBP.

ANATOMY

The lumbar spine (Fig. 28-1) consists of five lumbar vertebrae, which, in general, increase in size from L1 to L5 to accommodate progressively increasing loads. Between each of the lumbar vertebrae are the intervertebral disks (IVD).

VERTEBRAL BODY

The anterior part of each vertebra is called the vertebral body. The pedicles, which project from the posterior aspect of the

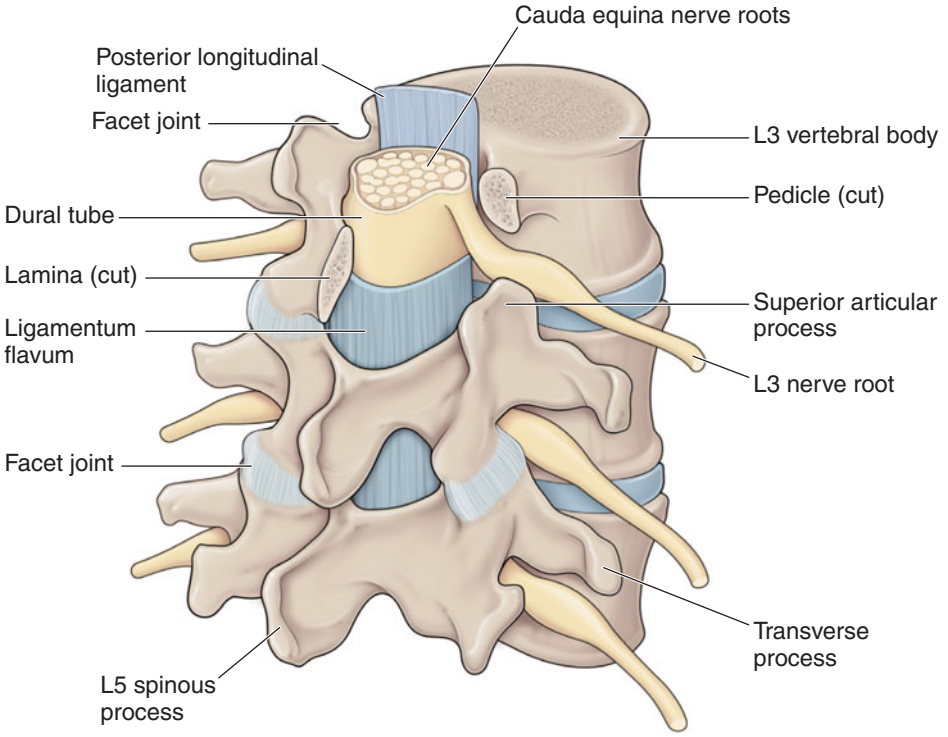

FIGURE 28-1 Structures of the lumbar spine.

vertebral body, represent the only connection between the posterior joints of the segment and the vertebral bodies, both of which deliver tensile and bending forces. Noticeably, the muscles that act on a lumbar vertebra pull downward, transmitting the muscular action to the vertebral body. This muscular action is borne through the pedicles, which act as levers, and thus are subjected to a certain amount of bending.[16] If the vertebral body slides forward, the inferior articular processes of that vertebra abut against the superior articular processes of the next lower vertebra and resist the slide.[16] These resistive forces are transmitted to the vertebral body along the pedicles.

The lamina (see Fig. 28-1) functions to absorb the various forces that are transmitted from the spinous and articular processes. The pars interarticularis connects the vertically oriented lamina and the horizontally extending pedicle, which exposes it to appreciable bending forces.[16] The two laminae meet and fuse with one another, forming an arch of bone aptly called the vertebral, or neural arch, which serves as a bony tunnel for the spinal cord. Both the transverse and the spinous processes of the vertebral body provide areas for muscle attachments.

The first sacral segment, the point at which the sacrum joins the lumbar spine, is usually included in discussions of the lumbar spine. In most cases, this is a fixed segment but, in some cases it may be mobile (lumbarization of S1). At other times, the fifth lumbar segment may be fused to the sacrum or ilium, resulting in a sacralization of that vertebra. It is unclear how these anomalies affect the biomechanics of the spine.

Intervertebral Disk

Annulus Fibrosis

In the lumbar spine, the superior and inferior surfaces of the vertebral bodies are comparatively large and flat, reflecting their load-transfer function. The lumbar disk is approximately cylindrical, its shape being determined by the integrity of the annulus fibrosis (AF). The AF consists of approximately 10–12 (often as many as 15–25) concentric sheets of predominantly type I collagen tissue,[17] bound together by proteoglycan gel.[18] The number of annular layers decreases with age, but there is a gradual thickening of the remaining layers.[19] The fibers of the AF are oriented at approximately 65 degrees from vertical. The fibers of each successive sheet or lamella maintain the same inclination of 65 degrees, but in the opposite direction to the preceding lamella, resulting in every second sheet having the same orientation. Thus, only 50% of the fibers are under stress with rotational forces at any given time. This alteration in the direction of fibers in each lamella is vital in enabling the disk to resist torsional (twisting) forces.[20]

Each lamella is thicker anteriorly than posteriorly, leading to the lumbar disks being thinner, but more tightly packed, posteriorly than anteriorly.[21] Consequently, the posterior part of the annulus will have thinner but stronger fibers, and it is capable of withstanding tension applied to this area during flexion activities and postures, which occur more frequently than with extension.[16] However, because of the predominance of flexion activities in life, fatigue damage may occur in the posterior aspect of the disk, making it a common site of injury.[22] The wedge-shaped appearance of the disk produced by the configuration of the lamellae contributes to the normal lordosis of this region.[22]

The outermost lamellae insert into the ring apophysis of the upper and lower vertebrae by mingling with the periosteal fibers (fibers of Sharpey). These fibers, attaching them to bone, may be considered as ligaments and as such are designed primarily to limit motion between adjacent vertebrae.[23] The inner portions of the lamellae are attached to the superior and

inferior cartilaginous end plates, and form an envelope around the NP.[16]

Nucleus Pulposus

The lumbar IVDs of a healthy young adult contain a nucleus pulposus (NP) that is composed of a semifluid mass of mucoid material. This material is clear, firm, and gelatinous.[16]

CLINICAL PEARL

The overall consistency of the NP changes with increasing age, as the water content of the NP diminishes and subsequently becomes drier.

At birth, the water content of the NP is approximately 80%. In the elderly, the water content is approximately 68%. Most of this water content change occurs in childhood and adolescence, with only approximately 6% occurring in adulthood.[24] The portion of the NP that is not water is made up of cells that are largely chondrocytes and a matrix consisting of proteoglycans, collagen fibers, other noncollagenous proteins, and elastin.[22,25,26]

With the exception of early youth, there is no clear boundary between the NP and AF, and it resembles a transitional zone.[27] The biomechanical makeup of the NP is similar to that of the AF, except that the NP contains mostly type II collagen, as opposed to type I.[17] The collagen interacts with the ground substance to form a concentration proportional to the viscoelastic requirements of the AF.

CLINICAL PEARL

The IVDs are able to distribute compressive stress evenly between adjacent vertebrae because the NP and inner AF act like a pressurized fluid, in which the pressure does not vary with location or direction.[28,29] Biomechanical studies of the IVD seem to indicate that the disk acts to provide flexibility at low loads and stability at high loads.[30,31]

An unequal load distribution to the IVD is a major predisposing factor in radial tearing of the AF.[32] The tearing can be caused by the torsional effect of the superior vertebra rotating in a constant direction with sagittal movements. The posterolateral aspect of the AF tends to weaken first.[33] If the inner layers of the posterior AF tear in the presence of the NP that is still capable of bulging into the space left by the tear, the symptoms of disk disease are likely to be experienced, with the spinal canal location of disk trespass determining the type of neural compromise, clinical pain pattern, and often the outcome.[33] It must be remembered that the degree of neural compromise and potential for pain cannot be judged accurately by the size or type of disk material. Large, free fragments can often cause no neurologic deficit or pain.[34]

Vertebral End Plates

Each vertebral end plate consists of a layer of hyaline and fibrocartilage approximately 0.6–1-mm thick,[35] which covers the top or bottom aspects of the disk and separates the disk from the adjacent vertebral body. Peripherally, the end plate is surrounded by the ring apophysis.[16]

At birth, the end plate is part of the vertebral body growth plate, but by approximately the 20th year, it has been separated from the body by a subchondral plate. During this time, the plate is bilaminar, with a growth zone and an articular area.[36] With aging, the growth zone becomes thinner and disappears, leaving only a thickened articular plate.

Nutrition of the disk comes via a diffusion of nutrients from the anastomosis over the AF and from the arterial plexi underlying the end plate. Although almost the entire AF is permeable to nutrients, only the center portions of the end plate are permeable. Over approximately 10% of the surface of the end plate, the subchondral bone of the centrum is deficient. At these points, the bone marrow is in direct contact with the end plate, thereby augmenting the nutrition of the disk and end plate.[37] It is possible that a mechanical pump action produced by spine motion could aid with the diffusion of the nutrients.

The two end plates of each disk, therefore, cover the NP in its entirety but fail to cover the entire extent of the AF.

CLINICAL PEARL

Because of the attachment of the AF to the vertebral end plates on the periphery, the end plates are strongly bound to the IVD. In contrast, the vertebral end plates are only weakly attached to the vertebral bodies[38] and can be completely torn from the vertebral bodies by trauma. It is for this and other morphologic reasons that the end plates are regarded as constituents of the IVD, rather than as a part of the lumbar vertebral body.[36]

Between the ages of 20 and 65 years, the end plate thins and the vascular foramina in the subchondral bone become occluded, resulting in decreased nutrition to the disk. At the same time, the underlying bone becomes weaker, and the end plate gradually bows into the vertebral body, becoming more vulnerable centrally, where it may fracture into the centrum.[16] The presence of damage to a vertebral body end plate reduces the pressure in the NP of the adjacent disk by up to 57%, and doubles the size of so-called stress peaks in the posterior aspect of the AF.[39]

Nerve Root Canal

The nerve root canal is located at the lateral aspect of the spinal canal (Fig. 28-1). The dural sac forms the medial wall of the canal, the internal aspect of the pedicle, and the lateral wall. The posterior border of the nerve root canal is formed by the ligamentum flavum, superior articular process, and lamina. The anterior border of the canal is formed by the vertebral body and IVD.

The nerve root canal can be described according to its location[40]:

- The entrance zone is medial and anterior to the superior articular process.
- The middle zone is located under the pars interarticularis of the lamina and below the pedicle.
- The exit zone is the area surrounding the intervertebral foramen.

A decrease in the dimension of this canal results in a condition called lateral stenotic syndrome.[41]

Innervation

The outer half of the IVD, the posterior longitudinal ligament (PLL), and the dura are innervated by the sinuvertebral nerve,[42] which is considered to arise from the anterior (ventral) ramus and the sympathetic trunk.[43] The nerve endings are simple or complex, are encapsulated and nonencapsulated, and exist as free nerve endings. It has been suggested that apart from a nociceptive function, these nerve endings may also have a proprioceptive function.[44,45]

Alterations in Disk Structure

Although the lumbar IVD appears destined for tissue regression and destruction, it remains unclear why similar age-related changes remain asymptomatic in one individual yet cause severe LBP in others. The basic changes that influence the responses of the disk to aging appear to be biochemical and may concern the collagen content levels in the NP.

There is, with age, an increase in the collagen content of both the NP and the AF and a change in the type of collagen present.[46] The elastic collagen of the NP becomes more fibrous, whereas the type 1 collagen of the AF becomes more elastic.[46] Eventually, they come to resemble each other. In addition, the concentration of noncollagenous proteins increases in the NP. The change of the makeup of the collagen alters the biomechanical properties of the disk, making it less resilient, perhaps leading to changes from microtrauma.[46]

CLINICAL PEARL

In general, the IVD becomes drier, stiffer, less deformable, and less able to recover from creep with age.

It was traditionally thought that the loss of height that occurs with aging resulted from a loss in the height of the IVD. More recently, it has been demonstrated that between the ages of 20 and 70 years, the disk actually increases its height by approximately 10%, and that the loss of height with age is more likely to be caused by the erosion of the vertebral end plate.[47]

As the NP becomes more fibrous, its ability to handle compressive loading becomes compromised and more weight is taken by the AF, resulting in a separation of the lamellae and the formation of cavities within it.[46]

Zygapophyseal Joint

The articulations between two consecutive lumbar vertebrae form three joints. One joint is formed between the two vertebral bodies and the IVD. The other two joints are formed by the articulation of the superior articular process of one vertebra and the inferior articular processes of the vertebra above it. These latter joints are known as the zygapophyseal joints.

In the intact lumbar vertebral column, the primary function of the zygapophyseal joint is to protect the motion segment from anterior shear forces, excessive rotation, and flexion.[48] Additional functions include

- the production of spinal motions including coupling movements;
- a minimal restrictor of the physiologic movements of extension and side bending.[49]

From an anteroposterior perspective, the zygapophyseal joints of the lumbar spine appear straight, but when viewed from above, they are seen to be curved into a J or C shape. Their orientation varies both with the level and with the individual subject.[50] It is thought that this orientation serves to maximally restrict anterior and rotary movements and that the C-shaped joints do better in preventing anterior displacement than the J-shaped joints, because of the curvature of the joint surfaces.[16,51] Both shapes competently prevent rotation. The area of the zygapophyseal joints most involved in resisting anterior shear forces is the anteromedial part of the superior zygapophyseal joint. It is this area that is most vulnerable to fibrillation.[16] The tangential splitting and vertical tearing of the cartilage that occur with aging are believed to reflect these forces and appear to be a part of the normal degeneration of the joint.[16]

CLINICAL PEARL

At the thoracolumbar junction, the morphologic configuration of the zygapophyseal joints is extremely variable. In general, there is a change from a relatively coronal orientation at T10–11 to a more sagittal orientation at L1–3, before returning to the more coronal orientation at L5 and S1. Davis[52] compared the thoracolumbar junction to a carpenter's mortise and tenon joint, which, when approximated, would have the effect of impeding all motion except flexion.[52] This appears to be particularly true with respect to axial rotation, in which there is a high degree of torsional stiffness.[53,54]

A fibrous capsule surrounds the joint on all of its aspects except the anterior aspect, which consists of the ligamentum flavum (LF). Posteriorly, the capsule is reinforced by the deep fibers of the multifidus.[55] In lumbar extension, there is a potential for the posterior capsule to become pinched between the apex of the inferior facet and the lamina below. To prevent this, some fibers of the multifidus blend with the posterior capsular fibers and appear to keep the capsule taut.[56]

Superiorly and inferiorly, the capsule is very loose. Superiorly, it bulges toward the base of the next superior transverse process, whereas, inferiorly, it does so over the back of the lamina. In both the superior and the inferior poles of the joint capsule, there is a very small hole that allows the passage of fat from within the capsule to the extracapsular space.[57]

Within the zygapophyseal joints, three types of intra-articular meniscoids have been noted[16]:

1. A connective tissue rim
2. An adipose tissue pad
3. A fibroadipose meniscoid

It is thought that the function of these intra-articular meniscoids is to

- fill the joint cavity;
- increase the articular surface area without reducing flexibility;
- protect the articular surfaces, as they become exposed during extreme flexion and extension.

These menisci have been inculpated in the cause of some types of LBP, when they fail to return to their original position on recovery from a flexion or extension movement and block the joint toward the neutral position.[58]

Ligaments

Anterior Longitudinal Ligament

The anterior longitudinal ligament (ALL) covers the anterior aspects of the vertebral bodies and IVD (Fig. 28-2). The ALL extends from the sacrum along the anterior aspect of the entire spinal column, becoming thinner as it ascends.[59] The ALL is connected only indirectly with the anterior aspect of the IVD by loose areolar tissue.[16] Some of the ligament fibers insert directly into the bone or periosteum of the centrum.[60] Because of these attachments, and the pull on the bone from the ligament, it is proposed that the anterior aspect of the vertebral body becomes the site for osteophytes. The remaining ligament fibers cover two to five segments, attaching to the upper and lower ends of the vertebral body.

The ALL of the lumbar spine is under tension in a neutral position of the spine and functions to prevent overextension of the spinal segments. In addition, the ALL functions as a minor assistant in limiting anterior translation and vertical separation of the vertebral body.

The ALL receives its nerve supply from recurrent branches of the grey rami communicans.[61]

Posterior Longitudinal Ligament

The PLL is found throughout the spinal column, where it covers the posterior aspect of the centrum and IVD (see Fig. 28-2). Its deep fibers span two segments, from the superior border of the inferior vertebra to the inferior margin of the superior. These fibers integrate with the superficial annular fibers to attach to the posterior margins of the vertebral bodies.[16] The more superficial fibers span up to five segments. In the lumbar spine, the ligament becomes constricted over the vertebral body and widens out over the IVD. It does not attach to the concavity of the body but is separated from it by a fat pad, which acts to block the venous drainage through the basivertebral vein during flexion, as the ligament presses it against the opening of the vein. Although the PLL is rather narrow and is not as substantial as the ALL, it is thought to be important in preventing IVD protrusion.[62] Both the ALL and the PLL have the same tensile strength per unit area.[63]

The PLL tends to tighten in traction and in posterior shearing of the vertebral body. It also acts to limit flexion over a number of segments, although because of its proximity to the center of rotation, it is less of a restraint than the LF.[59]

The PLL is innervated by the sinuvertebral nerve.

Ligamentum Flavum

The LF connects two consecutive laminae (see Fig. 28-2). This is a bilateral ligament. The medial aspect of the ligament attaches superiorly to the lower anterior surface of the lamina and the inferior surface of the pedicle.[64] The LF attaches inferiorly to the back of the lamina and the pedicle of the next inferior vertebra.[64]

Its lateral portion attaches to the articular process and forms the anterior capsule of the zygapophyseal joint.

The LF is formed primarily from elastin (80%), with the remainder (20%) being collagen.[65] Thus, it is an elastic ligament that is stretched during flexion and recovers its neutral length with the neutral position, or extension.

The function of the LF is to resist separation of the lamina during flexion, but there is also appreciable strain in the ligament with side bending.[16,66] Although it seems unlikely that the ligament contributes to an extension recovery from flexion, it does appear to prevent the anterior capsule from becoming nipped between the articular margins as it recoils during extension.[16] The LF is innervated by the medial branch of the posterior (dorsal) ramus.[67]

Interspinous Ligament

The interspinous ligament (see Fig. 28-2) lies deeply between two consecutive spinal processes. The ligament is important for stability, as it represents a major structure for the posterior column of the spine. Unlike the longitudinal ligaments, it is not a continuous fibrous band but, instead, consists of loose tissue that fills the gap between the bodies of the spinous processes.[16,68] The interspinous ligament is often disrupted in traumatic cases, which results in the posterior column becoming unstable. An extensive anatomic study on the interspinous ligament showed that degenerative changes start as early as the late second decade, with ruptures occurring in more than 20% of the subjects older than 20 years, particularly at L4–5 and L5–S1.[69]

The ligament has three distinct parts—anterior (ventral), middle, and posterior (dorsal)—of which the middle has the most clinical significance, because it is the part where ruptures tend to occur.[68]

The interspinous ligament most likely functions to resist separation of the spinous processes during flexion.[70] This ligament is supplied by the medial branch of the posterior (dorsal) rami.[67]

Supraspinous Ligament

The supraspinous ligament (SSL) (see Fig. 28-2) is broad, thick, and cord like, but it is only well developed in the upper lumbar region.[16,71] Although it joins the tips of two adjacent spinous processes, the SSL is not considered by some to be a true ligament. This is because part of it is derived from the posterior part of the interspinous ligament, although it also merges with the insertions of the lumbar posterior (dorsal) muscles.[68] Because this ligament is the most superficial of the spinal ligaments and the farthest from the axis of flexion, it has a greater potential for sprains.[72] The SSL is supplied by the medial branch of the posterior (dorsal) rami.[67]

Iliolumbar Ligament

The iliolumbar ligament is one of the three vertebropelvic ligaments, the others being the sacrotuberous and the sacrospinous ligaments. The ligament is variously believed to be a degenerate part of the quadratus lumborum or the iliocostalis and does not fully develop until approximately age 30 years.[73]

The iliolumbar ligament functions to restrain flexion, extension, axial rotation, and side bending of L5 on S1.[74] Motions at the lumbosacral joint increase by approximately 20% in all directions when the ligament is missing or transected.[59] The incidences of degenerative instability and isthmic lumbar spondylolisthesis have also been shown to increase in its absence.[75,76]

Pseudoligaments

These ligaments, the intertransverse, transforaminal, and mamilloaccessory, resemble the membranous part of the fascial system separating paravertebral compartments and do not have any mechanical function.

Intertransverse Ligaments. These ligaments are more membranous than ligamentous. The ligament splits into posterior (dorsal) and anterior (ventral) portions, between which is a fat-filled recess. During flexion and extension movements, the fat can be displaced to accommodate the repositioning of the articular zygapophyseal joint. The main function of the ligament appears to be to compartmentalize the anterior and posterior musculature.[16]

Transforaminal Ligaments. Occurring in approximately 47% of subjects, the transforaminal ligaments traverse the lateral end of the intervertebral foramen.[77] The most significant of these ligaments is the superior corporotransverse ligament. At L5, the fifth lumbar nerve root runs between the ligament and the ala of the sacrum. With marked forward slip and downward descent of L5, or with a loss of IVD height, the corporotransverse ligament can have a guillotine effect on the fifth nerve root, resulting in symptoms that can mimic an IVD herniation or a foraminal occlusion.[78]

Mamilloaccessory Ligament. This ligament runs from the accessory process of one vertebra to the mammillary process of the same vertebra.[79] The ligament forms a tunnel for the medial branch of the posterior (dorsal) ramus, thereby preventing it from lifting off the neural arch. In approximately 10% of adults, the tunnel becomes ossified.[79]

Muscles

Quadratus Lumborum

The quadratus lumborum muscle is large and rectangular, with fibers that pass medially upward. The fibers attach to

- the inferior anterior surface of the 12th rib;
- the anterior surface of the upper four transverse processes;
- the anterior band of the iliolumbar ligament;
- the iliac crest lateral to the attachment of the iliolumbar ligament.

The muscle is active during inspiration, fixing the lowest rib to afford a stable base from which the diaphragm can act. The importance of this muscle from a rehabilitation viewpoint is its contribution as a lumbar spine stabilizer.[80] Working unilaterally, it is typically involved with side bending of the lumbar spine, especially with eccentric control of contralateral side bending. The quadratus lumborum is an important, yet often underappreciated, lateral lumbar spine stabilizer that has been shown to be very active in sustained postures and when a heavy weight is held in the opposite hand.[81,82] The quadratus lumborum is supplied by the anterior (ventral) rami of T12–L2.[83,84]

Multifidus

The lumbar multifidus is the largest of the intrinsic back muscles to cross the lumbosacral junction and lies most medially in the spinal gutter (Fig. 28-3).[56] It is a fascicular muscle, with each fascicle being layered on another, giving it a laminated appearance.[16] The lumbar multifidus originates in three groups, which arise from the same vertebra.

1. Laminar fibers arise from the inferoposterior edge of the lamina.
2. Basal fibers arise from the base of the spinous process.
3. Common tendon fibers arise from a common tendon attached to the inferior tip of the spinous process.

The lumbar multifidus has a complicated insertion (Table 28-1).

Over the past several decades, there has been much research regarding the lumbar multifidus, with particular reference to its relationship to LBP, and its importance in lumbar spine stabilization. In vitro biomechanical studies have shown that the lumbar multifidus is an important muscle for lumbar segmental stability through its ability to provide segmental stiffness and to control motion.[85–87] Wilke et al.[88] concluded that the multifidus is responsible for two-thirds of the stiffness of the lumbar spine. The multifidus is active in nearly all antigravity activities and appears to contribute to the stability of the lumbar spine by compressing the vertebrae together.[46] Hides et al.[89] found reductions in ipsilateral multifidus cross-sectional area in patients with unilateral LBP and speculated that this may be a direct result of reflex inhibition.[90] This loss of multifidus cross-sectional area was shown to persist after remission of LBP.[84] Isolated multifidus strengthening has

been shown to restore the muscle size at the segmental level of the dysfunction.[90]

MacIntosh and Bogduk[56] analyzed the lumbar multifidus to determine the possible actions of the muscle and its individual fibers. The study revealed that working bilaterally, the multifidus muscles can produce the rocking component of extension, but because of the muscle's vertical orientation, it cannot produce the accompanying translation.[56] In addition, the muscle, by "bow stringing" over a number of segments, can increase the lumbar lordosis, working in a postural role.[91]

Although not considered a primary lumbar rotator,[92] the multifidus is consistently active during both ipsilateral and contralateral spinal rotation, and both multifidi are simultaneously active regardless of which way the spine is turning.[56,57]

The major function of the multifidus from a biomechanical perspective is one of arthrokinematic control. It is believed that the lumbar multifidus acts as an antagonist to flexion and opposes the flexing moment of the abdominals as they rotate the trunk.[56,91,93] This synergistic function may be compromised with injury to the multifidus. Using magnetic resonance imaging, the signal intensities of the multifidus during lumbar hyperextension have been found to be markedly diminished in patients with chronic LBP compared with normal patients.[94]

Unilaterally, the multifidus muscle should also be able to produce side bending. However, its horizontal vector is very small, and it is unlikely to be an efficient side bender of the spine.[16,56]

The multifidus shares a close association with the gluteus maximus and the sacrotuberous ligament, factors that are thought to enhance sacroiliac joint and lumbar spine stability.[95–97]

The lumbar multifidus has the distinction of being innervated segmentally by the medial branch of the posterior (dorsal) ramus of the same level or the level below the originating spinous process.[98,99] Because the multifidus is segmental in origin and innervation, any impairment of this muscle can produce palpable changes in the muscle, thus directing the clinician to the segment that is dysfunctional.[100]

Erector Spinae

The erector spinae is a composite muscle consisting of the iliocostalis lumborum and the thoracic longissimus (Fig. 28-3). Both of these muscles are subdivided into the lumbar and thoracic longissimi and iliocostallii.[16] As a group, the muscles of the erector spinae play an important role in lumbar stabilization by providing compressive forces along the spine that stabilize the spinal curvatures.[101] The nerve supply to the erector spinae muscles is by the medial branch of the posterior (dorsal) ramus of the thoracic and lumbar spinal nerves.

Longissimus Thoracis Pars Lumborum. This is a fascicular muscle that arises from the accessory processes of the lumbar vertebrae to insert into the posterior-superior iliac spine

(PSIS) and the iliac crest lateral to it. The upper four tendons converge to form the lumbar aponeurosis that inserts lateral to the L5 fascicle.

The longissimus thoracis pars lumborum muscles have both a vertical and a horizontal vector. The vertical vector is much the larger of the two and can produce extension or side bending, depending on whether it is functioning bilaterally or unilaterally.[102] Because of its attachment to the transverse rather than the spinous process, which results in reduced leverage, the longissimus thoracis pars lumborum is much less efficient than the lumbar multifidus in producing posterior sagittal rotation, due to its reduced leverage.[99,103] Indeed, mathematical analysis of the lumbosacral portion of the muscle suggests that the net effect of its pull would be to produce an anterior, and not a posterior, shear.[16]

Iliocostalis Lumborum Pars Lumborum. There are four overlying fascicles arising from the tip of the upper four transverse processes and the adjoining middle layer of the thoracolumbar fascia. The fibers insert onto the iliac crest, with the lower and deeper fibers attaching lateral to the PSIS.[103]

There is no muscular fiber from L5, but it is believed that this is represented by the iliolumbar ligament, which is completely muscular in children, becoming collagenous by approximately 30 years of age.

The vectors and actions of this muscle are similar to those of the longissimus. However, the lower and deeper fibers produce strong axial rotation and act with the multifidus as synergists to produce rotation during abdominal muscle action.[103]

Longissimus Thoracis Pars Thoracis. This muscle group consists of 11–12 pairs of muscles, which extend from the transverse processes of T2 and their ribs and run inferomedially to attach to the spinous processes of L3–5 and the sacral spinous processes, as well as the PSIS.

The orientation and various attachments of this muscle group allow it to act indirectly on the lumbar spine. The main action of the muscle appears to be the extension of the thoracic spine on that of the lumbar. An anatomic-mathematical study[104] suggests that 70–80% of the force required to extend the upper lumbar spine is produced from the thoracic fibers of the erector spinae, which also generate 50% of the force in the lower levels.

Iliocostalis Lumborum Pars Thoracis. The thoracic iliocostalis serves as the thoracic part of the iliocostalis lumborum and not the iliocostalis thoracic. It is a layered muscle consisting of inferomedially orientated fascicles attached to the following points[103]:

- lateral part of the lower eight rib angles;
- PSIS;
- posterior (dorsal) surface of the sacrum, distal to the multifidus.

This muscle completely spans the lumbar spine and is in an excellent position to extend and side bend the spine, as well as to increase the lumbar lordosis. It is a weak rotator, because the amount of rib separation on ipsilateral rotation is minor, but on contralateral rotation, it is better. It is, therefore, possible that the muscle is an effective derotator of the spine.[16]

Abdominal Muscles

Rectus Abdominis. The rectus abdominis (Fig. 28-4) originates from the cartilaginous ends of the fifth through seventh ribs and xiphoid and inserts on the superior aspect of the pubic bone. The linea alba (Fig. 28-4) is the anterior abdominal aponeurosis or rectus sheath in the midline. It is formed by the interlacing of aponeurosis of the external oblique, internal oblique, and transverse abdominis muscles from both sides. It is broader superiorly, where the recti are separated at a considerable interval, and narrower inferiorly, where the recti are closely packed (Fig. 28-4). Above the umbilicus, the linea alba is a single layer, whereas below the umbilicus it has a double layer.[105]

CLINICAL PEARL

A split between the two rectus abdominis to the extent that the linea alba may split under strain is known as a diastasis recti (see Chap 30 and "Practice Pattern 4E: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Localized Inflammation" section).[105–110]

The rectus abdominis muscle functions to produce torque during flexion of the vertebral column, as it approximates the thorax and pelvis anteriorly.[111] The muscle appears to serve a beneficial role of helping to stabilize the lumbar spine in the sagittal plane.[90]

Transversus Abdominis. The transverse abdominis muscle (Fig. 28-4) originates from the lateral one-third of the inguinal ligament, the anterior two-thirds of the inner lip of the iliac crest, the lateral raphe of the thoracolumbar fascia, and the internal aspects of the lower six costal cartilages, where it interdigitates with the diaphragm.[112] Its upper and middle fibers run transversely around the trunk and blend with the fascial envelope of the rectus abdominis muscle, while the lower fibers blend with the insertion of the internal oblique muscle on the pubic crest.[113]

Although much emphasis has traditionally been placed on the strengthening of the rectus abdominis during lumbar spine rehabilitation, recent research has suggested that it is the contraction of the hoop-like transversus abdominis (TrA) that creates a rigid cylinder, resulting in enhanced stiffness of the lumbar spine and stabilization of the lumbar motion segment (see "Biomechanics" section).[46,81,82,114–117] Since the midportion of the TrA attaches to the cross-hatch arrangement of the middle layer of the thoracolumbar fascia (see later), contraction of the TrA has been thought to increase spinal stability via tensioning of the thoracolumbar fascia in the middle and lower regions of the lumbar spine or by producing a mild stabilizing compressive force on the lumbar vertebrae.[90,112,116] The thoracolumbar fascia creates a pressurized visceral cavity anterior to the spine when the TrA contracts. This force is theorized to increase the stability of the lumbar spine during a variety of postures and movements.[118]

Internal Oblique. The internal oblique (see Fig. 28-4), which forms the middle layer of the lateral abdominal wall, is located between the TrA and the external oblique muscles.[113] It has multiple attachments to the inguinal ligament, lateral raphe,

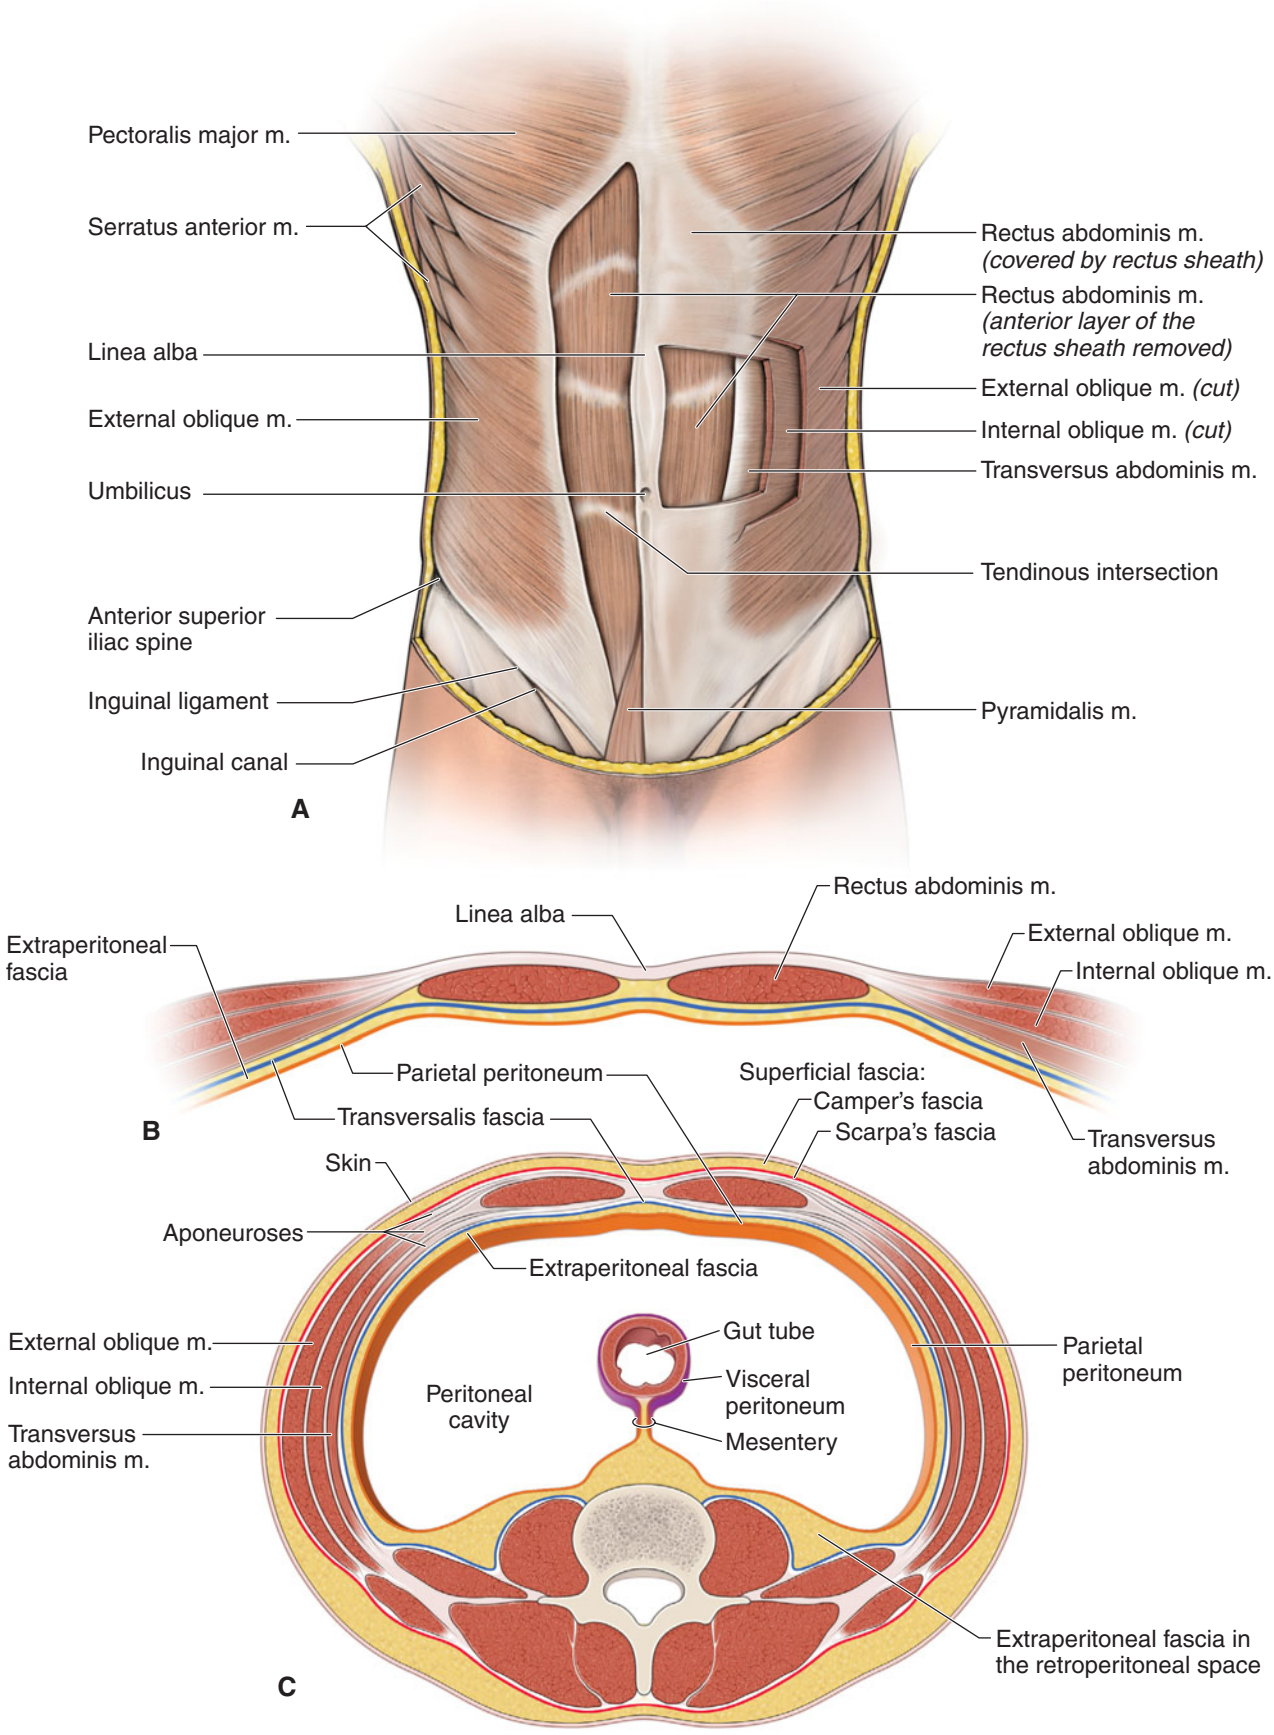

FIGURE 28-4 Abdominal muscles. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

iliac crest, pubic crest, transverse abdominis, and costal cartilages of the seventh through ninth costal cartilages. Because of these multiple attachment sites, the different fascicles of the muscle can have very different force vectors.

The internal oblique is active during a number of functions, including gait (most often close to initial contact[119]) and erect sitting and standing postures.[120] Acting bilaterally, the internal obliques flex the vertebral column and assist in respiration. Acting in unison, the muscle, in conjunction with the external obliques, can produce rotation of the vertebral column, bringing the thorax backward (when the pelvis is fixed) or the pelvis forward (when the thorax is fixed).[111,121]

External Oblique. The external oblique (see Fig. 28-4) originates from the lateral aspect of the fifth through 12th ribs, and through interdigitations with the serratus anterior and latissimus dorsi. The muscle travels obliquely, medially, and inferiorly to insert into the linea alba, inguinal ligament, anterior superior iliac spine (ASIS), iliac crest, and pubic tubercle.

Acting bilaterally, the external obliques flex the vertebral column and tilt the pelvis posteriorly. Acting in unison, the muscle, in conjunction with the internal obliques, can produce side bending of the vertebral column, approximating the thorax and the iliac crest laterally.[111]

Researchers have suggested that the internal obliques, and to a lesser extent the external obliques, may contribute to the production of intra-abdominal pressure and thus stability of the lumbar spine.[122]

Psoas Major

Although traditionally viewed as a muscle of the hip, the psoas major muscle combines with the iliacus muscle to directly attach the lumbar spine to the femur.[123] The psoas major originates from

- anterolateral aspects of the vertebral bodies;
- intervertebral disks of T12–L5;
- transverse processes of L1–5;
- tendinous arch spanning the concavity of the sides of the vertebral bodies.

The iliacus is attached superiorly to the iliac fossa and the inner lip of the iliac crest. Joining with the psoas major, the combined tendon passes over the superior lateral aspect of the pubic ramus and attaches to the lesser trochanter of the femur.

Taken individually, the iliacus and psoas major serve different functions.

- The psoas major is electromyographically active in many different positions and movements of the lumbar spine, and its activity can add a stabilizing effect on the lumbar spine with compressive loading.[124] With the foot fixed on the ground (closed chain), contraction of the psoas major increases the flexion of the lumbar-pelvic unit on the femur.[125]
- With the foot fixed on the ground, contraction of the iliacus produces an anterior torsion of the ilium and extension of the lumbar zygapophyseal joints. If there is a decrease in the length of the iliopsoas as a result of adaptive shortening or increased efferent neural input to the muscle, the result is an anteriorly rotated pelvis and an increase in lordosis. This may increase the anterior shear stress on the lumbosacral junction in any posture.[124]

From a clinical perspective, the iliacus and psoas major usually are considered together as the iliopsoas. Working bilaterally (insertion fixed), the iliopsoas can produce flexion of the trunk on the femur as in the sit-up from supine position, or in bending over to touch one's toes. The iliopsoas muscle also side bends the spine ipsilaterally.[124]

Working from a stable spine above (origin fixed), the iliopsoas muscle flexes the hip joint by flexing the femur on the trunk.

The iliopsoas is innervated by the anterior (ventral) rami of L1 and L2.

Thoracolumbar Fascia

The thoracolumbar fascia travels from the spinous process of T12 to the PSIS and iliac crest. The thoracolumbar fascia consists of three layers of connective tissue that envelop the lumbar muscles and separate them into anterior, middle, and posterior compartments or layers[126]:

1. The anterior layer covers the anterior surface of the quadratus lumborum muscle. It is attached to the anterior transverse processes and then to the intertransverse ligaments. On the lateral side of the quadratus lumborum, it blends with the other layers of the fascia.
2. The middle layer is posterior to the quadratus lumborum, with its medial attachment to the tips of the transverse processes and the intertransverse ligaments. Laterally, it gives rise to, or is attached to, the transverse abdominal aponeurosis.
3. The posterior layer covers the lumbar musculature and arises from the spinous processes, wrapping around the muscles. It blends with the other layers of the fascia along the lateral border of the iliocostalis lumborum in a dense thickening of the fascia called the *lateral raphe*.[126] This layer consists of two laminae, a superficial one with its fibers orientated inferomedially, and a deep lamina whose fibers are inferolateral. The superficial fibers are derived from the latissimus dorsi.

The functions of the TFL are varied. The TFL

- provides muscle attachment for the transversus abodominis;
- stabilizes the spine against anterior shear and flexion moments;
- resists segmental flexion via tension generated by the transverse abdominis on the spinous process;
- assists in the transmission of extension forces during lifting activities. The posterior ligamentous system has been proposed as a model to explain some of the forces required for lifting. It is believed to transmit forces by passive resistance to flexion, from the joint capsule and extracapsular ligaments, and from the more dynamic effects of the thoracolumbar fascia.[127]

Nerve Supply of the Lumbar Segment

The nerve supply to the lumbar spine follows a general pattern. The outer half of the IVD is innervated by the sinuvertebral

nerve[42] and the grey rami communicants,[128] with the posterolateral aspect innervated by both the sinuvertebral nerve[61] and the grey rami communicants. The lateral aspect receives only sympathetic innervation.

The zygapophyseal joints are innervated by the medial branches of the posterior (dorsal) rami.[42,67,129] Each joint receives its nerve supply from the corresponding medial branch above and below the joint.[42,67] For instance the L4–5 joint receives its nerve supply from the medial branches of L3 and L4. The lateral branches cross the subjacent transverse process and pursue a sinuous course inferiorly, laterally, and posteriorly through the iliocostalis lumborum.[67] They innervate that muscle, and eventually the L1–3 lateral branches pierce the posterior (dorsal) layer of thoracolumbar fascia and become cutaneous, supplying the skin over the lateral buttock as far as the greater trochanter.[42,67] The intermediate branches run posteriorly and inferiorly from the intertransverse spaces. They form a series of intersegmental communications within the longissimus thoracis.[42,67]

At the L1 and L2 levels, the nerves exit the intervertebral foramen above the disk. From L2 downward, the nerves leave the dura slightly more proximally than the foramen through which they pass, and at a decreasing angle of obliquity and an increasing length within the spinal canal. The L3 nerve root travels behind the inferior aspect of the vertebral body and the L3 disk. The L4 nerve root crosses the whole vertebral body to leave the spinal canal at the upper aspect of the L4 disk, at an angle of approximately 60 degrees. The L5 nerve root emerges at the inferior aspect of the fourth lumbar disk at an angle of approximately 45 degrees and crosses the fifth vertebral body to exit at the upper aspect of the L5 disk. The S1 nerve root emerges at a 30-degree angle and crosses the L5–S1 disk.

Lumbar Spine Vascularization

The blood supply for the lumbar spine is provided by the lumbar arteries (Fig. 28-5), and its venous drainage occurs via the lumbar veins (Fig. 28-5).

Biomechanics

Physiologic motions at the lumbar spine joints can occur in three cardinal planes: sagittal (flexion and extension), coronal (side bending), and transverse (rotation). Including accessory motions, six degrees of freedom are available at the lumbar spine.[62]

The amount of segmental motion at each vertebral level varies. Most of the flexion and extension of the lumbar spine occurs in the lower segmental levels, whereas most of the side bending of the lumbar spine occurs in the midlumbar area.[112,130,131] Rotation, which occurs with side bending as a coupled motion, is minimal and occurs most at the lumbosacral junction.[112,130,131] The amount of range available in the lumbar spine generally decreases with age.[132]

Flexion

The lumbar spine is well designed for flexion, which is its most commonly used motion in daily activities. Flexion of the lumbar spine from erect standing involves an unfolding or straightening of the lumbar lordosis, followed by, at most, a small reversal of the lordotic curve.[133] The flexion–extension range of the lumbar spine that occurs between vertebral segments is approximately 12 degrees in the upper lumbar spine, increasing by 1–2 degrees per segment to reach a maximum motion of 20–25 degrees between L5 and S1.[16,131]

During lumbar flexion in standing, which normally is initiated by the abdominal muscles, the entire lumbar spine leans forward, and there is a posterior sway of the pelvis as the hips flex.

CLINICAL PEARL

Flexion of the lumbar spine can also occur with a posterior pelvic tilt. The posterior pelvic tilt can be performed voluntarily, or it may occur as a result of weak paraspinal extensor muscles or adaptively shortened hamstring and gluteal muscles.[134]

At the segmental level, lumbar flexion produces a combination of an anterior roll and an anterior glide of the vertebral body, and a straightening, or minimal reversal, of the lordosis.[112,131] At L4–5, reversal may occur, but at the L5–S1 level, the joint will straighten but not reverse[135] unless there is pathology present. During the anterior rocking motion of the segment that occurs with flexion, the inferior facets of the superior vertebra lift upward and backward, opening a small gap between the facets. The superior vertebra translates anteriorly by approximately 5–7 mm, closing the gap and enhancing stability through increased tension of the joint capsule.[57] The anterior sagittal translation, or shear, is also resisted by

- the superoanterior orientation of the lateral fibers of the AF;
- the iliolumbar and SSLs at the L5 to S1 segment, with the longitudinal ligaments helping to a lesser extent;
- the semisagittal and sagittal orientation of the zygapophyseal joints, which cause the superior facet to come against the inferior one during an anterior shear, with the highest pressure occurring on the anteromedial portion of the superior zygapophyseal joint surface. The zygapophyseal joints are, therefore, vital in the limitation of this anterior shear.[136]
- the horizontal vector of the erector spinae and the multifidus, which acts to pull the vertebrae posteriorly.

Flexion is also limited by the compressibility of the anterior structures, such as the IVD, and by the extensibility of the posterior structures of the segment (ligaments, IVD, and muscles). These structures have varying contributions to the resistance of segmental flexion, depending on the degree of flexion[137]:

- The joint capsule resists approximately 39%.
- The supraspinous and interspinous ligaments resist approximately 19%.
- The LF ligament resists approximately 13%.
- The IVD resists approximately 29%.

Extension

Extension movements of the lumbar spine produce a converse of those that occur in flexion. Theoretically, true extension of

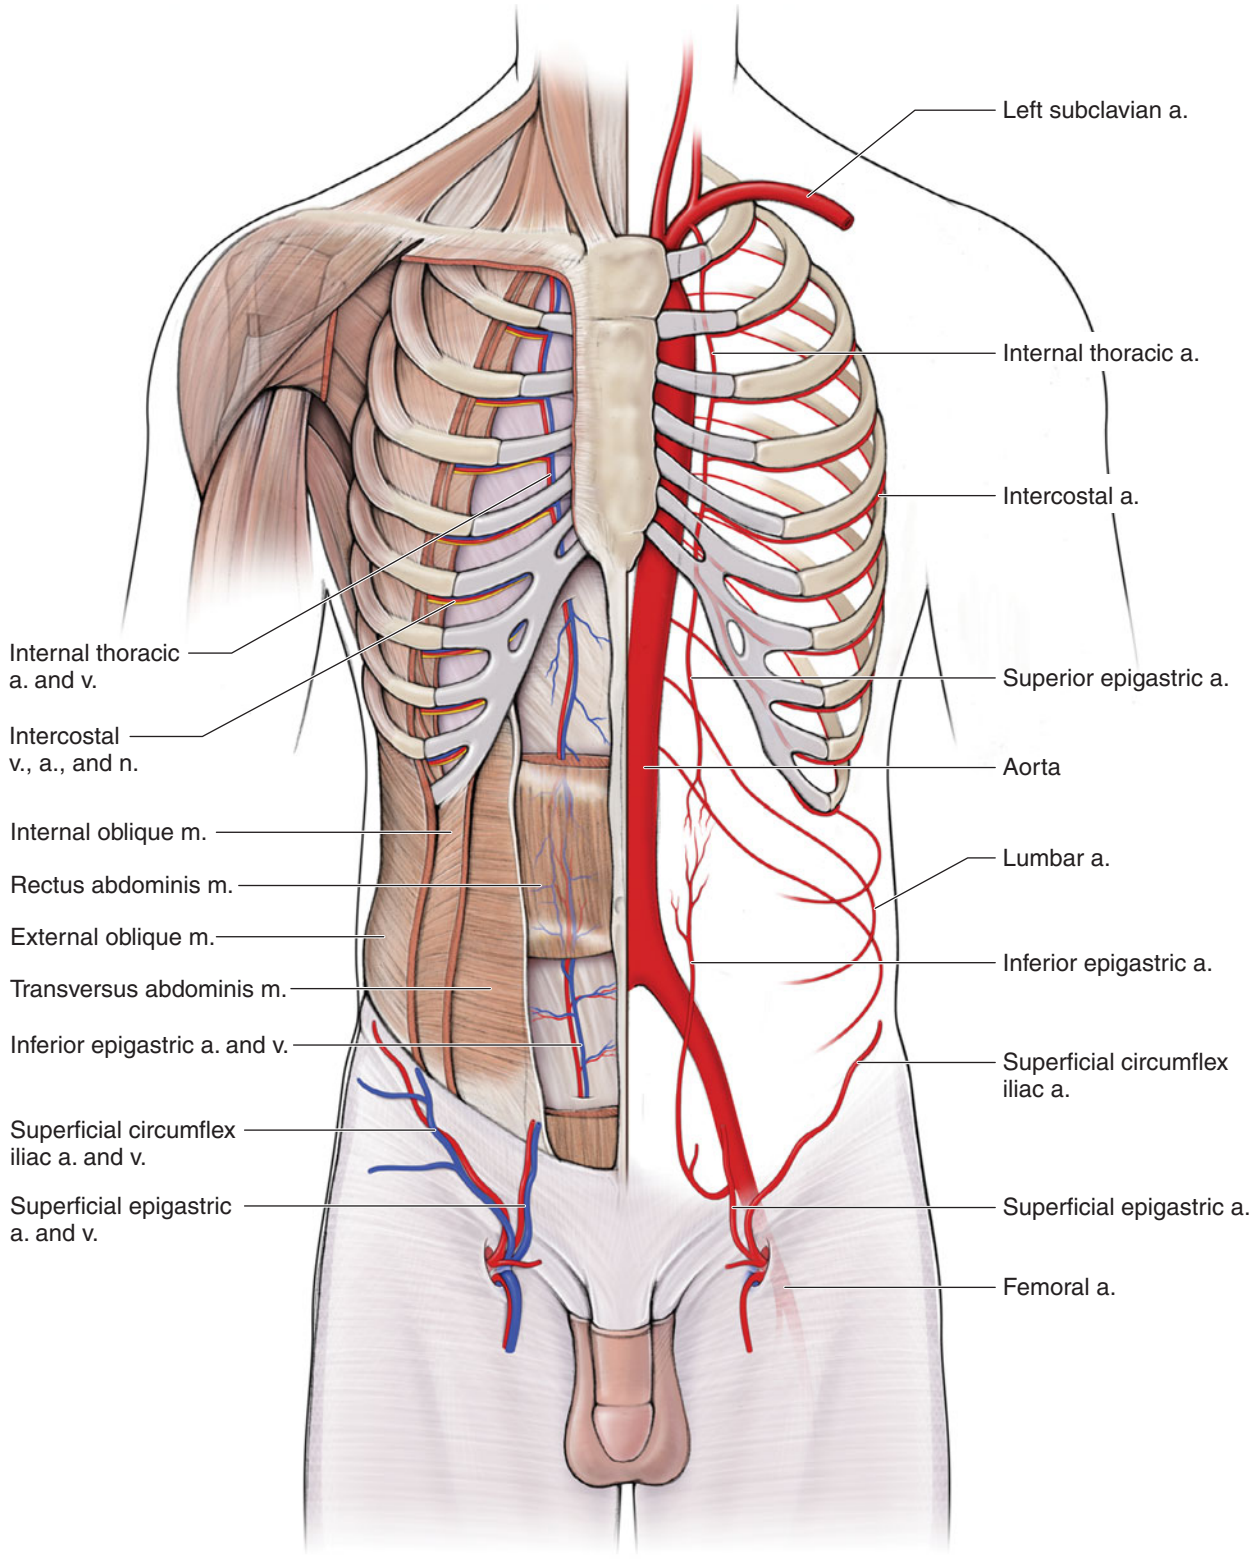

FIGURE 28-5 Vasculature of the spine. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

the lumbar spine is pathologic and depends on one's definition: pure extension involves a posterior roll and glide of the vertebra and a posterior and inferior motion of the zygapophyseal joints, but not necessarily a change in the degree of lordosis.[131] During lumbar extension, the inferior zygapophyseal joint of the superior vertebra moves downward, impacting with the lamina below and producing a buckling of the interspinous ligament between the two spinous processes. This impaction is accentuated when the joint is subjected to the action of the back muscles.[138] If the extending force continues to be applied, especially unilaterally, the superior facets can pivot on their inferior counterparts, producing a

strain on the opposite zygapophyseal joint, and potentially damaging or tearing the capsule.[16]

CLINICAL PEARL

Repetitive contact of the spinous processes during the extremes of lumbar extension can lead to a periostitis called *kissing spine* or *Baastrup's disease*,[139] with resulting ligamentous laxity and hypermobility of the segment.[140]

An anterior pelvic tilt increases the lumbar lordosis and results in an anterior motion of the vertebrae and their associated structures. Although the differing terminology between true extension and the extension created by increasing the lordosis is seemingly esoteric, there are clinical implications during the examination, when the clinician is assessing the ability of the patient to assume the extended position of the lumbar spine.

Pure lumbar extension is limited by

- the ability of structures anterior to the fulcrum to be elongated;
- the ability of the IVD to allow compression;
- joint capsule tension;
- passive tension of the psoas major muscle.

AXIAL ROTATION

Intervertebral Disk

Approximately 65% of the resistance to IVD torsion is resisted by a combination of tension and impaction of the contralateral zygapophyseal joint, and tension of the supraspinous and interspinous ligaments, with the disk contributing approximately 35% of the resistance.[141] During axial rotation, which produces torsion of the IVD, those collagen fibers of the AF that are orientated in the same direction as the twist are stretched and resist the torsional force, while the others remain relaxed, thereby sharing the stress of twisting.

During forced segmental torsion, the first structure to fail is the zygapophyseal joint, which normally occurs at approximately 1–2 degrees of segmental rotation.[141] As collagen can only elongate approximately 4% before damage, the maximum segmental rotation at each segmental level is typically limited to approximately 3 degrees.[20,62] Macroscopic failure of the IVD is likely to occur only in the presence of extreme trauma, with accompanying fracture of the zygapophyseal joint.[32] However, surgical incision of the zygapophyseal joint, or facetectomy, which increases the amount of rotation the segment is capable of handling, also significantly increases the stress in the posterior AF fibers.[32,141]

In the absence of zygapophyseal joint damage, surgical or otherwise, axial rotation must be coupled with other motions to cause disk injury.[51] For example, the combination of maximal lumbar flexion and rotation, which increases the amount of rotation before the contralateral zygapophyseal joint makes contact, has been associated with trauma to the AF.[142,143]

Other Structures

Rotational movements of the lumbar spine do appear to produce the appropriate motor patterns for optimal trunk muscle cocontraction and spinal stability.[114,144] The axis of rotation in the sagittal plane passes through the anterior aspect of the IVD and vertebral body.[145] For axial displacements, the axis of rotation tends to be located within the posterior annulus.[145] Axial rotation of the lumbar spine amounts to approximately 13 degrees to both sides. The greatest amount of segmental rotation, approximately 5 degrees, occurs at the L5 and S1 segments. Axial rotation of the segment involves

- twisting, or torsion, of the IVD fibers;
- compression of the contralateral zygapophyseal joint, for example, with left axial rotation, the right inferior zygapophyseal joint will impact on the superior zygapophyseal joint of the bone below;
- stress on those annular fibers inclined toward the direction of rotation.

In normal segments, the zygapophyseal joints protect the IVD from torsional injuries by coming into contact before microfailure of the IVD can occur. During axial rotation, tension is built in the interspinous and SSLs, and the contralateral joint becomes impacted after 1–2 degrees of rotation.[141] Further movement is accommodated by compression of the articular cartilage. If this range is exceeded, any further rotation that occurs is impure. Impure rotation of the segment forces the upper vertebra to pivot backward on the impacted joint, around the newly created axis of rotation. This causes the vertebra to swing laterally and backward, increasing the potential for a lateral shear force on the annulus. At this extreme, the IVD is vulnerable to either torsional or shear forces, and the other joint capsule is placed under severe tension.[32] This combination can result in a failure of any one of these structures, resulting in any or all of the following: compression fractures of the contralateral lamina, subchondral fractures, fragmentation of the articular surface and tearing, avulsion of the ipsilateral joint capsule, or a pars interarticularis fracture.[16]

The ipsilateral joint does not normally gap during normal axial rotation, except during therapeutic manipulation.[146] Abnormal gapping has been found to occur in segments with degenerative or traumatic instability, questioning the role of therapeutic manipulation in such cases.[146]

SIDE BENDING

Side bending is a complex and highly variable movement involving side bending and rotatory movements of the interbody joints and a variety of movements at the zygapophyseal joints.[133] The means of how this is achieved has been the subject of debate for many years, and it is difficult to ascertain how an impaired segment would behave, compared with a healthy one.[147] The general pattern of coupled motion is for side bending to be associated with contralateral axial rotation at the mid and upper lumbar levels but ipsilateral axial rotation at L5–S1.[133] However, there is at present little evidence for strict rules of coupled motion that determine whether an

individual has abnormal ranges or directions of coupling in the lumbar spine.[133,148]

Bending motions can occur in any direction, producing both a rocking motion and a translation shearing effect on the IVD. The NP tends to be compressed and the AF buckles in the direction of the rocking motion,[149] and there is a tendency for the AF to be stretched in the opposite direction, while the pressure on the posterior aspect of the NP is relieved. Although the deformation can occur in a healthy disk, displacement of the NP is prevented by the AF that encapsulates it. The AF will buckle at its compressed aspect because it is not braced by the NP, which is exerting that effect on the AF fibers at the opposite side of the disk.[20]

AXIAL LOADING (COMPRESSION)

Axial compression or spinal loading occurs in weight bearing, whether in standing or sitting.

Intervertebral Disk

It has been demonstrated experimentally that the AF, even without the NP, can withstand the same vertical forces that an intact disk can for short periods,[150] provided that the lamellae do not buckle. However, if the compression is prolonged or if the lamellae are not held together, the sheets buckle and the system collapses on itself.

The extent and magnitude of the compression depend on the amount of applied compressive force, the disk height, and the cross-sectional area of the disk. Variations in disk height can be divided into two categories: primary disk height variations and secondary disk height changes.

1. Primary disk height variations are related to intrinsic individual factors such as body height, gender, age, disk level, and geographic region.[151,152]
2. Secondary disk height changes are associated with extrinsic factors, such as degeneration, abnormality, or clinical management. Surgical procedures, such as nucleotomy, diskectomy, and chemonucleolysis cause a decrease in disk height, resulting from the removal of a portion of the NP or damage to the water-binding capacity of the extracellular matrix.[153–155] In addition, there are diurnal changes in disk height, which are caused by fluid exchange and creep deformation.[156]

With variations in disk height, one would expect changes in mechanical behavior of the disk. An important result to emerge from a recent study is that axial displacement, posterolateral disk bulge, and tensile stress in the peripheral AF fibers are a function of axial compressive force and disk height.[157] Under the same axial force, disks with a higher height-to-area ratio generate higher values of axial displacement, disk bulge, and tensile stress on the peripheral AF fibers.

The NP is deformable but relatively incompressible. Therefore, when a load is applied to it vertically, the nuclear pressure rises, absorbing and transmitting the compression forces to the vertebral end plates and the AF.[16]

- The resistance of the end plate is dependent on the strength of the bone beneath and the blood capacity of the vertebral body.
- The AF bulges radially,[158] delaying and graduating the forces.

The peripheral pressure increases the tension on the collagen fibers, which resist it until a balance is reached, at the point when the radial pressure is matched by the collagen tension.[112]

This equilibrium achieves two things:

1. Pressure is transferred from one end plate to another, thus relieving the load on the AF.
2. The NP braces the AF and prevents it from buckling under the sustained axial load.

Other structures provide resistance to axial loading of the spine:

- The ALL offers resistance if the spine is in its normal lordosis. The lumbar lordosis while standing is approximately 50% greater than when seated.[159]
- The inferior articular process can impact on the lamina below during strong lordosis.

During axial compression of the IVD the following occur:

1. Water is squeezed out of disk. The water loss is 5–11%[160]
   a. Rapid creep occurs (1.5 mm in the first 2–10 minutes)[161] and then slows (to approximately 1 mm per hour).[150]
   b. The creep plateaus at 90 minutes.[162]
   c. Over a 16-hour day, a 10% loss in disk height occurs.
   d. A person's height is restored with unloading. The best unloading position is in the supine knees-up posture (better than the extended supine posture).[163]
2. The intradiskal pressure increases.

Breakdown of the System

Under normal circumstances, the NP acts like a sealed hydraulic system. Within this system, the fluid pressure rises substantially when volume is increased (by fluid injection or by imbibing[153]) and falls when volume is decreased (by surgical excision or axial compression loading).[155] By a similar mechanism, the age-related degenerative changes reduce the water content of the NP by 15–20%,[156] causing a 30% fall in the NP pressure.[164] In effect, the load is being transferred from the NP to the AF. The posterior AF is affected most, because it is the narrowest part of the disk and the least able to sustain large compressive strains.[157]

The end plate is also susceptible during compression, being able to withstand only approximately one-tenth of the stress that the AF can handle.[20] Even though axial loading occurs evenly over the surface of the end plate, failure of this structure typically occurs over the NP, indicating that this central part of the end plate is weaker than the periphery.[165]

Until approximately 40 years of age, as much as 55% of the compressive load through the centrum is borne by the cancellous bone,[166] the remainder being borne by the cortical bone. After this age, horizontal trabeculae are absorbed in the center of the vertebral body, thereby

weakening the part of the centrum overlying the NP. This results in only approximately 35% of the axial stress being taken by the cancellous bone, with the greater proportion now going through cortical bone.[166] Because cortical bone fails with a smaller degree of deformation than cancellous bone, compressive failure occurs much more readily in the cortical bone.[166]

Pain originating from this failure would be expected to increase during the course of a day, especially in an individual who had spent a considerable amount of time with the lumbar spine flexed (e.g., a truck driver).[167]

CLINICAL PEARL

It is well known that during periods when the osmotic pressure within the IVD is greater than the hydrostatic pressure from axial loading (for example, when lying in bed) the disks imbibe fluid, causing the spine to increase in length.[156,168,169] Patients should thus be advised to avoid performing full-range spinal motions (bending) shortly after rising from bed.[156,168,169]

Other Structures

Although the IVD bears most of the compressive load of the spine in the neutral position and in the very early ranges of flexion and extension, the zygapophyseal joints bear up to 25% of the compressive load in the middle ranges of extension.[170] The contribution of the zygapophyseal joints becomes more significant during prolonged weight bearing, in the presence of IVD space narrowing, or if lumbar extension is combined with rotation.[170] In intradiscal pressure studies and electromyographic measurements of trunk muscles, in conjunction with mathematical models, investigators have estimated the compressive load on the lumbar spine to reach 1,000 N during standing and walking.[171] The compressive load on the lumbar spine is substantially higher in many lifting activities. Large extensor moments about the joints of the lumbar vertebral column are produced by the paravertebral musculature during lifting. These moments result in large compressive and shear forces acting between each pair of vertebrae, as high as several thousand newtons.[172,173] Conflicting evidence exists on what strategy is most effective in preventing back injury during lifting. Although lifting from a squat position with the lumbar spine maintained in lordosis is a commonly taught strategy, there is little evidence to support that this posture reduces compressive and shear forces acting on the spinal segments.[174] Existing evidence suggests that compressive and shear forces acting on the lumbar spine are most influenced by load moment, lifting speed, and acceleration.[175] A study by Kigma et al.[174] showed that the width of an object and the height from which an object is lifted are more important determinants of forces acting on the lumbar spine than the strategy used to perform the lift. The study further suggests that squatting may be an effective technique to reduce compressive forces acting at L5–S1 when lifting narrow loads, but straddling and stooping techniques are more effective at reducing compressive forces when lifting wider loads from the floor.[174]

In the sagittal plane, when a compressive load is applied to a whole lumbar spine specimen along a vertical path, bending moments are induced because of the inherent curvature of the lumbar spine. As a result, the spine undergoes large changes in its curvature at relatively small load levels. Countless studies over the years have demonstrated that a neutral spine under compressive load results in bony failure,[176] specifically end-plate fracture, and damage to the underlying trabeculae,[177] and that repeated loading reduces the ultimate strength of the end plate and can cause damage to other tissues.[178,179] A burst fracture is a vertebral fracture resulting from axial impact.[180]

Distraction

Symmetric distraction of the spine is a rare force in everyday functioning, and, consequently, the disk is less resistant to distraction than it is to compression.[181] Although asymmetric distraction occurs constantly with spinal movement (side bending of the spine causes ipsilateral compression and contralateral distraction), symmetric distraction, in which all points of the one vertebral body are moved an equal distance away from its adjacent body, occurs only at times such as vertical suspension or therapeutic traction.

The AF appears to bear the principal responsibility for restricting distraction, with the oblique orientation of the collagen fibers becoming more vertical as the traction force is applied. For this reason, back pain reproduced with traction may implicate the AF as the source.

Shear

Shear is the movement of one vertebral body across the surface of its neighbor. This movement can occur in any plane. Resistance to the shear forces is provided by a number of structures including the zygapophyseal joints, the AF fibers of the IVD, and the segmental ligaments.

In forward shearing, the AF fibers on the lateral aspects of the disk predominantly resist the movement, because they lie parallel to the movement.[182] Those angled posteriorly will be relaxed during forward shearing but tensed during backward shearing.[182] The anterior and posterior fibers will offer some contribution to anterior and posterior shearing, but this will be much less than that of the lateral fibers.[182]

The anterior and posterior fibers are primarily involved during lateral shearing, again with those orientated in the direction of the shear undergoing tension. As with torsion, only half of the fibers can contribute to the resistance and, as with torsion, shear forces are potentially very disruptive to the IVD.[182] It could be argued that the presence of free nerve endings in the outer part of the AF could indicate a nociceptive ability in the disk, and anything disturbing these endings may then be considered potentially painful, although there is no direct evidence to prove this.

Lumbar Stabilization

From the mechanical point of view, the spinal system is highly complex and statically highly indeterminate. The requirement for muscular control of the spine varies within the range of motion (ROM). The *neutral zone* is a term used by Panjabi[183] to define a region of laxity around the neutral resting position of a spinal segment. The neutral zone (see Chap. 22) is the position of the segment in which minimal loading is occurring

in the passive structures (all of the noncontractile elements of the spine including the ligaments, fascia, joint capsules, IVDs, and noncontractile components of muscle), and the contribution of the active system (the muscles and tendons that surround and control spinal motion) is most critical—within its neutral zone of motion, the restraints and control for bending, rotation, and shear force are largely provided by the muscles that surround and act on the spinal segment.[184,185] The size of the neutral zone is determined by the integrity of the passive restraint and active control systems, which in turn are controlled by the neural system.[183] Studies have demonstrated that a larger than normal neutral zone caused by injury or microtrauma is related to a lack of segmental muscle control and is associated with intersegmental injury and IVD degeneration.[86,183,186–188] Unfortunately, there is as yet no *clinical* method to measure the size of the neutral zone.

The research of Gardner-Morse et al.[189] and O'Sullivan et al.[190] lends support to the hypothesis of a neutral zone. They proposed that the passive system alone is incapable of providing sufficient spinal stabilization during most activities and would buckle under its own weight without sufficient muscular tension.[80,90] In addition, activities such as acute repetitive loading have been shown to have a significant effect on reducing the stiffness of the passive system, because of the viscoelastic nature of the structures of the passive system (e.g., ligaments, and IVDs).[191,192] Thus, in addition to structural integrity, stabilization of the lumbar spine must also rely on muscular support. Muscle activity is available and required throughout the ROM, except in specific situations, such as at the end of lumbar flexion ROM when a reflex reduction in paraspinal muscle activity occurs, the so-called "flexion relaxation phenomenon."[120,185,193] At the end of spinal ROM, the restraints to bending, rotation and shear forces are provided largely by tension and compression on the spine's passive structures.[16] The concept of different trunk muscles playing differing roles in the provision of dynamic stability to the spine was proposed by Bergmark,[194] and later refined by others.[80,81,114,195–197] Bergmark classified the functional role of the muscles of the lumbar spine as either mobilizers or stabilizers.[196,197] Mobilizer muscles, which tend to work over two joints or several segments, are superficial, and have narrow insertions with long tendons.[197] The mobilizer muscles function to produce movement in the sagittal plane using concentric acceleration and are capable of generating a tremendous amount of force. The stabilizer muscles, as their name suggests, provide stabilization. Stabilizers can be further divided into global (spanning several segments) and local stabilizers (located at a single segment).[194]

Global Stabilizers

This system consists of muscles whose origins are on the pelvis and whose insertions are on the thoracic cage. These muscles include

- rectus abdominis;
- internal and external obliques;
- lateral fibers of the quadratus lumborum;
- thoracic part of the lumbar iliocostalis.

The global muscle system acts on the trunk and spine, without being directly attached to it. These muscles appear to provide general trunk stabilization by increasing the stiffness but are not capable of having a direct segmental influence on the spine. Cholewicki and McGill demonstrated that the quadratus lumborum was architecturally best suited to be the major stabilizer of the lumbar spine.[80] However, in general, the specific pattern of global muscle activity is task specific. Global stabilizers have a role in eccentrically decelerating momentum and controlling rotation of the spine as a whole.

Local Stabilizers

The local muscle system consists of a series of deep muscles that have insertions or origins at the lumbar vertebrae or pelvis and are responsible for providing segmental stability and directly controlling the lumbar segments and the sacroiliac joint (see Chap. 29). These muscles include

- lumbar portions of the iliocostalis and longissimus thoracis muscles;
- medial fibers of the quadratus lumborum;
- lumbar multifidus;
- TrA;
- posterior fibers of the internal oblique that attach to the tensor fascia latae.

CLINICAL PEARL

- **Transversus abdominis:** the deepest abdominal muscle, may have a presetting role, because it is the first trunk muscle to become active before movement initiation[115] or perturbation.[198] Together with the internal oblique, the TrA is primarily active in providing rotational and lateral control to the spine, while maintaining adequate levels of intra-abdominal pressure and imparting tension to the thoracolumbar fascia, thereby increasing the stiffness of the lumbar spine.[199] Hodges et al.[200] found that a coactivation of the diaphragm and abdominal muscles produces a sustained increase in intra-abdominal pressure. Activity of the diaphragm and TrA is initiated before rapid limb movements[201] and is tonic during repetitive movements of the arm[202,203] and walking.[204] In addition the TrA contributes to control of sacroiliac motion (see Chap. 29).
- The lumbar multifidus is considered to have the greatest potential to provide dynamic control to the motion segment, particularly in its neutral zone.[85,205] In a biomechanical study, Wilke et al. found that the lumbar multifidi are responsible for more than two-thirds of the stiffness at the L4–5 segmental level.[188]

The local muscle system is important for the provision of segmental control to the spine and provides an important stiffening effect on the lumbar spine, thereby enhancing its dynamic stability.[101] The local stabilizers also function to maintain a continuous low-force activity at joints in all positions and directions and thus provide segmental joint support.

CLINICAL PEARL

The lumbar multifidus, TrA, and the posterior fibers of the internal oblique are known to be tonically active during upright postures and active motions of the trunk,[206] with the TrA capable of tonic activity irrespective of trunk position, direction of movement, or loading of the spine.[199]

Two prominent and similar theories for active lumbar stabilization are the bracing mechanism, proposed by McGill,[207] and the deep corset mechanism, proposed by Richardson et al.[114]

- **Bracing mechanism:** muscles act similar to guy wires when stabilizing the spine and that a loss of tension can result in unstable buckling of the spinal structures. The muscles of the trunk function via a complex interaction of agonist/antagonist spinal muscles, both segmentally and regionally to provide tension (active stiffness). According to this theory lightly pretensioning, or bracing, the abdominal muscles using an isometric contraction is a way to enhance the guy wire affect by taking up the slack prior to activities that may destabilize the spine.[208] The external oblique, internal oblique, and TrA overlay each other to create the abdominal wall and act through attachments to the abdominal and thoracolumbar fascia to create a cylinder. As the intra-abdominal pressure increases, the three-dimensional force per unit area exerted on the spine also increases, potentially constraining spinal movement in all directions.
- **Deep corset mechanism:** Richardson et al.[114] have proposed that a pressure corset is formed by the muscles of the lumbar spine. Under this proposal, the TrA forms the wall of the cylinder and the muscles of the pelvic floor and diaphragm form the base and lid, respectively. Within this system, the intra-abdominal pressure group is maintained at a level that provides spinal support.[97,114,200,209] Since the abdominal cavity has a finite volume, the intra-abdominal pressure (force/area) will increase if the abdominal cavity volume is reduced (contraction of the muscles in the pelvic floor, abdominal muscles and diaphragm, and the wearing of a lumbar corset) In addition, the increase in intra-abdominal pressure is thought to provide a mild distractive force to the spinal segments, due to separation of the pelvic floor and diaphragm. Because intra-abdominal pressure and fascial tension are important for the control of intervertebral motion, the muscles that surround the abdominal cavity, such as the diaphragm and the pelvic floor muscles (see Chap. 29), provide an additional contribution. These two muscle groups also have important respiratory and continence functions. Theoretically, reduced contribution of the diaphragm to spinal stability may occur during periods of increased respiratory demand. As the diaphragm descends during inspiration, intra-abdominal pressure increases provided that the musculature of the abdominal and pelvic floor maintains its respective tension. Although current training programs for lifting focus on maintaining the load's proximity to the body's center of gravity (COG), minimizing trunk rotation, matching the load magnitude to the lifter's capacity, and avoiding fatigue, it remains unclear the role that breath control may play in achieving lumbar segmental control during lifting tasks.[210] An intriguing study by Hagins and Lamberg[210] reported that individuals with LBP performed a lifting task with more inhaled lung volume than individuals without LBP.

CLINICAL PEARL

Cholewicki and McGill[80] reported that lumbar stability is maintained in vivo by increasing the activity (stiffness) of the lumbar segmental muscles, and they highlighted the importance of motor control to coordinate muscle recruitment between large trunk muscles and small intrinsic muscles during functional activities, to ensure stability is maintained. These muscle activations are not restricted to the motion of the spine. For example studies of arm movement suggest that when the limb is moved, the nervous system does not simply stiffen the trunk; rather, the spine and pelvis are moved in the direction opposite to the perturbation.[211]

Lumbar instability is considered to be a significant factor in patients with chronic LBP.[212] Because of the close relationship between the passive anatomical restraints of the lumbar spine and the muscles that control it, it would seem logical to assume that any pain-provoking injury, or any condition that alters the structural integrity of the lumbopelvic complex (muscle strain, ligament sprain, disk herniation, etc.) is by definition a "clinical instability." Growing evidence is emerging to support this hypothesis.[213–215] Various studies have demonstrated that coordinated patterns of muscle recruitment are essential between the global and local system muscles of the trunk to compensate for the changing demands of daily life and to ensure that the dynamic stability of the spine is preserved.[80,185,216,217] In normal subjects with no history of LBP, the TrA, erector spinae, and obliquus internus abdominis are recruited just prior to any limb movement.[218] Several studies indicate that the deep abdominal muscles undergo changes in their functional performance in populations with LBP.[81,218,219] These studies have shown that it is the local system that is particularly vulnerable to breakdown. In particular, the prevalence of LBP is being attributed to inhibition and atrophy of the multifidi and transverse abdominis, and the resultant poor neutral zone stabilization, although the reasons as to why these two muscles become inhibited and atrophied is unclear.[81,116,216,220,221] Cholewicki and McGill[80] reported that the lumbar spine is more vulnerable to instability in its neutral positions, at low load and when the muscle forces are low. They confirmed that under these conditions, lumber stability is maintained in vivo by increasing the activity (stiffness) of the lumbar segmental muscles (local muscle system). Furthermore, they highlighted the importance of motor control to coordinate muscle recruitment between large trunk muscles (the global muscle system) and small intrinsic muscles (the local muscle system) during functional activities to ensure that mechanical stability is maintained.[185]

The scientific literature reports varying disruptions in patterns of recruitment and cocontraction within and between different muscles synergies.[185] Studies also have described subtle changes or shifts in the pattern of abdominal muscle activation and righting responses in subjects with chronic LBP.[84,222] These changes in the activation patterns result in altered patterns of

synergistic control or coordination of the trunk muscles.[219,223] In addition to pain, generalized changes to the trunk musculature such as a loss of strength, endurance, and muscle atrophy are also believed to produce changes in the neural control system, affecting the timing of patterns of cocontraction.

CLINICAL PEARL

It is important to note that reports on the changes that occur in the control of trunk muscles in the presence of LBP vary considerably with an increase,[224] a decrease,[225] and no change[226] being reported. What is clear is that enormous variability is seen in the adaptation of the trunk muscles in people with lumbopelvic pain.

EXAMINATION

LBP can arise from a number of local structures in the lumbar spine and a number of sources more distal (see Chap. 5). A number of local structures have been found to cause LBP when stimulated. Theoretically any innervated structure in this area can cause symptoms so the distributions and descriptions of referred symptoms must always be considered in relation to the neurologic supply of the lumbar segment. For example, McCullogh and Waddell[227] studied the effects of electrical stimulation of spinal ligaments, muscles, the AF, and the NP and found that these structures referred pain to the buttock and upper leg, but rarely below the upper calf. The reported pain was dull and poorly localized. In contrast, stimulation of the nerve roots produced a sharper, more localized pain, often with some paresthesia. Stimulation of the L5 and S1 nerve roots nearly always radiated to or below the ankle.

Idiopathic and *nonspecific* LBP have emerged as catchall terms in the diagnosis of low-back dysfunction. Indeed, up to 85% of patients cannot be given a definitive diagnosis because of weak associations among symptoms, pathologic changes, and imaging results.[37,228] Muscle aches, muscle sprains, tendinitis, sacroiliac and low-back strain, lumbago, mechanical LBP, and lumbar strain are just some of the diagnoses currently in clinical use. This difficulty in determining a specific diagnosis stems from a variety of reasons, including the fact that multiple structures in one or more segments may be involved. These structures include the interconnecting ligaments, the outer fibers of the annulus fibrosus, zygapophyseal joints, vertebral periosteum, paravertebral musculature and fascia, blood vessels, and spinal nerve roots.[228]

A number of associated occupational, psychosocial, and environmental factors can be used to help predict the development of a complicated course of LBP.[229–235] These include the following:

- ***Genetics.*** A number of studies[236–238] have suggested that genetic factors play an important role in the development of lumbar disk degeneration, but their role in the cause of clinical LBP is unclear.
- ***Age older than 40 or 50 years.*** The relation between chronic LBP and age over 40 or 50 years, with a decrease of occurrence over 60 years, is considered as an established fact in many reviews.[239,240] The link between spinal degeneration and chronic LBP often has been assumed, because the severity of the radiographic abnormalities makes it logical to infer a cause-and-effect correlation.[241–243] Conditions such as osteoarthrosis, congenital anomalies, and postural misalignments have often been assumed to relate to LBP, but the evidence to support these assumptions (with the exception of some degenerative changes) has been inconclusive.[241–243] Indeed, given the low correlation of radiographic findings and clinical signs and symptoms, some physicians feel that radiographs are not necessary initially in the workup of acute nontraumatic LBP.[242]
- ***Low level of formal education and social class.*** For back pain, specifically, some studies have found an inverse relation of formal education, social class, or both to the prevalence of back pain symptoms.[244–246] A tentative conclusion, although not based on an extensive literature review, indicates that lower levels of socioeconomic status and education are better predictors of adverse prognosis for occupational disability from back pain than are risk factors per se.[247]
- ***Physical workload.*** From a number of studies that examined the relation between physical and psychosocial load at work and the occurrence of LBP, it has been concluded that both work-related physical factors of flexion and rotation of the trunk and lifting at work, and low job satisfaction, are risk factors for sickness absence resulting from LBP.[248,249] Physical load on the back has commonly been implicated as a risk factor for LBP and, in particular, for work-related LBP. Certain occupations and certain work tasks seem to have a higher risk of LBP.[250–253] Repeated lifting of heavy loads is considered a risk factor for LBP,[27] especially if combined with side bending and twisting.[254,255] A study of static work postures found that there was an increased risk of LBP if the work involved a predominance of sitting.[256] Kelsey[257] and Kelsey and Hardy[167] found that men who spend more than half their workday driving have a threefold increased risk of disk herniation. A growing body of evidence indicates that exposure to vibration and jolting in workers who operate tractors, excavators, bulldozers, forklift trucks, armored vehicles, lorries, helicopters, and many other vehicles and machines may cause an increased risk of LBP.[257–261]
- ***Sciatic pain.*** LBP radiating to a leg (i.e., sciatic pain) seems to be a more persistent and severe type of pain than nonspecific LBP. Sciatic pain also causes more disability and longer absence from work.[34] In patients with sciatic pain (sciatica) from disk herniation, radiographic examinations such as myelograms, computed tomographic (CT) scans, and magnetic resonance imaging (MRI) scans demonstrate nerve root compression by a herniated disk. However, sciatica can have a number of causes (Table 28-2).

CLINICAL PEARL

Approximately 20–30% of individuals without any history of sciatic pain have abnormal findings in radiographic examinations.[262]

Diabetes mellitus
Syphilis

Data from Judge RD, Zuidema GD, Fitzgerald FT: Musculoskeletal system. In: Judge RD, Zuidema GD, Fitzgerald FT, eds. *Clinical Diagnosis*, 4th ed. Boston, MA: Little, Brown and Company, 1982:365–403

- ***Smoking.*** In some epidemiologic studies, smoking has been associated with LBP.[263,264] Several possible pathophysiologic mechanisms have been proposed to explain the association. It has been suggested that smoking accelerates degeneration by impairing the blood supply to the vertebral body and nutrition of the IVD.[265] Smoking also increases coughing activity, which causes an increase in intradiscal pressure.[266] Also, it has been hypothesized that the high serum proteolytic activity in the blood of cigarette smokers gains access to a previously degenerated neovascularized disk and accelerates the degenerative process. Increased proteolytic activity may also weaken the spinal ligaments, resulting in spinal instability.[267] However, besides its direct harmful effects, and its link to other health risk factors as well as lifestyle and behavioral patterns, no substantive evidence appears to support smoking as a definitive cause of LBP.[263]
- ***Obesity.*** There are several hypotheses relating to a link between obesity and LBP. Increased mechanical demands resulting from obesity have been suspected of causing LBP through excessive wear and tear,[151,152,268,269] and it has been suggested that metabolic factors associated with obesity may be detrimental.[268] An interesting study by Fransen et al.[270] reported that although obesity does not appear to be causative, it may have a meaningful impact on how long LBP persists.
- ***Psychological factors.*** It has been established that people who are simultaneously subjected to demanding physical and psychosocial conditions have more LBP than people with only demanding physical or only demanding psychosocial conditions.[271] Four explanations for the association between psychosocial work characteristics and musculoskeletal symptoms have been suggested[272] (1) psychosocial work characteristics can directly influence the biomechanical load through changes in posture, movement, and exerted forces; (2) these factors may trigger physiologic mechanisms, such as increased muscle tension or increased hormonal excretion, that may, in the long term, lead to organic changes and the development or intensification of musculoskeletal symptoms or may influence pain perception and thus increase symptoms; (3) psychosocial factors may change the ability of an individual to cope with an illness, which, in turn, could influence the reporting of musculoskeletal symptoms; and (4) the association may well be confounded by the effect of physical factors at work. It seems plausible that psychosocial factors in private life also could affect musculoskeletal symptoms through the second and third mechanism.[272] Studies have also found an effect of low workplace-social support and low job satisfaction. However, the effect found for low job satisfaction may be a result of insufficient adjustment for psychosocial work characteristics and physical load at work.[272] Although psychological factors, like obesity, appear to have a meaningful effect on the duration of LBP, they do not cause LBP.
- ***Comorbidity.*** Comorbidity may slow or interfere with normal recovery from back pain and may affect an individual's general sense of health, leading to a decreased self-perception of capability.[273]

A recent report issued by the Agency for Health Care Policy and Research,[274] now known as the Agency for Healthcare Research and Quality, suggests grouping back pain into five broad categories:[275]

- potentially serious spinal conditions such as spinal tumor, infection, fracture, and cauda equina syndrome. Although the likelihood of a low-back syndrome due to a serious condition is low, the consequences of a missed diagnosis or delayed treatment can be quite costly in terms of prolonged morbidity and, in the extreme, mortality.[275]
- nonspinal causes secondary to abdominal involvement (gallbladder, liver, renal, pelvic inflammatory disease, prostatic carcinoma, ovarian cyst, uterine fibroids, aortic aneurysm, or thoracic disease);
- sciatica and dural tissue compromise;
- nonspecific back symptoms, the majority of which are mechanical in nature;
- psychological causes such as stress and work environment (disability, workers' compensation, and secondary gain).

The physical examination of the lumbar spine must include a thorough assessment of the neuromuscular, vascular, and orthopaedic systems of the hip, lower extremities, low back, and pelvic region.[276] Figure 28-6 depicts a simple algorithm for decision making during the examination of the lumbar spine.

History

The clinician should establish the chief complaint of the patient, in addition to the location, behavior, irritability, and severity of the symptoms. Although dysfunctions of the lumbar spine are very difficult to diagnose, the history can provide some very important clues (Table 28-3). Applying the principles and rationale outlined in Chapters 4 and 5, the clinician uses the history to help with differential diagnosis. A useful organizational acronym for this purpose is LOP4QRST, which represents the following descriptors[275]:

- location;
- onset;
- prior history/treatment;

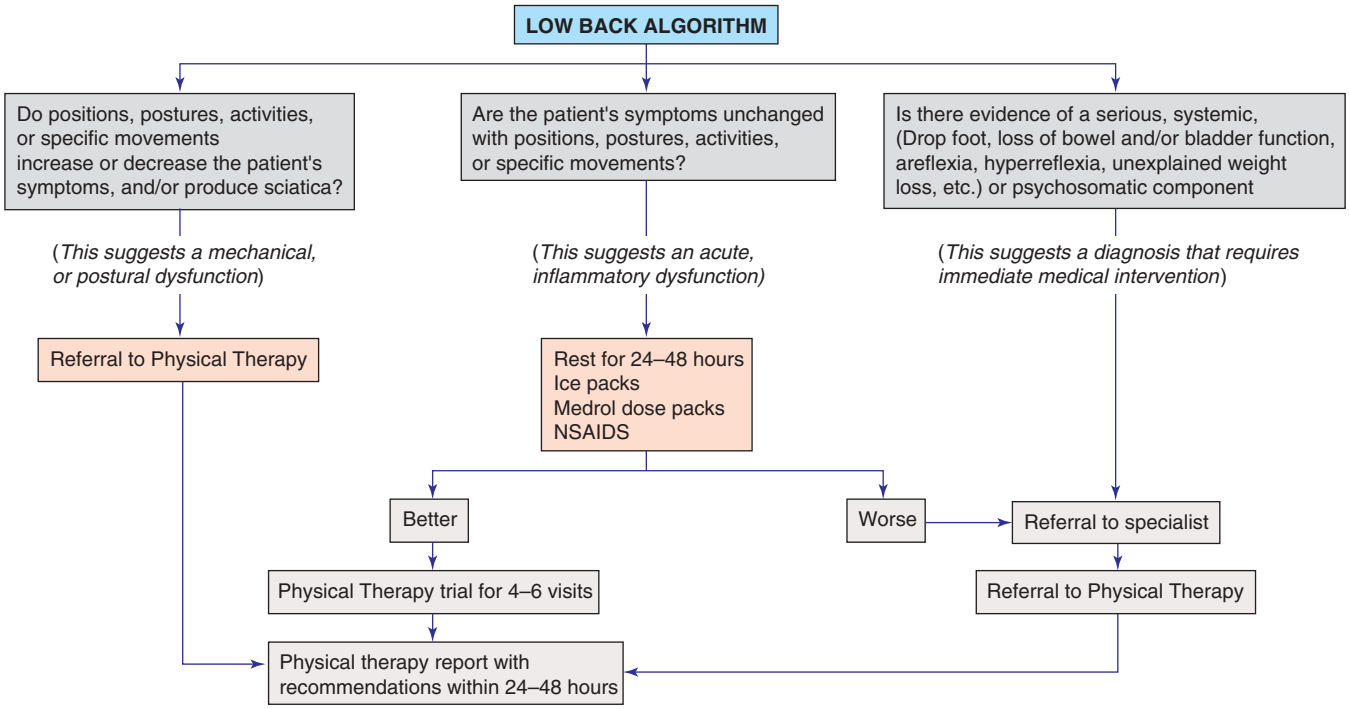

FIGURE 28-6 Examination algorithm for the low back.

- palliative measures (including medications);
- provocative factors (including movement/positional factors);
- progression/course;
- quality of symptoms;
- referral patterns;
- severity;
- temporal factors.

A lower back medical screening questionnaire is provided in Table 28-4.

- ***Location.*** Back pain may be localized centrally, unilaterally, or bilaterally. Generally speaking, the stronger the pain stimulus, the larger the area of pain reference will be. As the stimulus intensity decreases, the referred pain area becomes smaller, and localization of the pain by the patient becomes easier. The distribution of the pain should be described by the patient and outlined on a pain diagram. Central back pain is unlikely to be caused by a unilateral structure, such as a zygapophyseal joint or the sacroiliac joint, and bilateral pain hardly ever has a central origin (one of the exceptions being a central IVD protrusion).[277]
- An inflammation of the zygapophyseal joints can cause local back pain or buttock pain,[278] but it also has been associated with pain referred to the buttocks and even below the knee.[129,227,279]

CLINICAL PEARL

Various research studies have been undertaken to establish the validity of history taking for use in diagnosing a lumbar disk herniation.[228,280–282] Deyo et al.[228] reported a sensitivity for sciatic distribution of pain in the diagnosis of lumbar disk herniation of 95%, and calculated that the likelihood of a disk herniation being present in the absence of sciatic pain as 0.1%. Similarly high degrees of sensitivity have been found in other studies.[280–282] Radiculopathy is such a sensitive finding (95%) that its absence almost rules out a clinically important disk herniation, although it is only 88% specific for herniation.[283] In contrast, the sensitivity of pseudoclaudication in detecting spinal stenosis is 60%, whereas the combination of pseudoclaudication and age greater than 50 years has a sensitivity of 90% (specificity, 70%).[283] One study[284] showed that taking the history and MRI findings into account, elderly patients with protruded herniation were considered to be more likely to experience groin pain, with the rate of L4–5 disk involvement being higher than that of L5–S1 involvement. These results support conclusions drawn from a study by Murphey,[285] which found that groin and testicular pain are rare with L5–S1 disk disease but are fairly common with L4–5 disk disease.

- Groin pain, although also associated with hip pathology and other conditions, is a complaint often present in patients with a high lumbar IVD herniation.[284] On questioning, patients with this form of groin pain often describe the pain as a dull ache lying deep beneath the skin, which they usually find difficult to localize with any degree of accuracy. Although the patient with a high lumbar IVD herniation often reports pain and numbness on physical examination, the clinician is often unable to discern any specific findings, such as tenderness, muscle weakness, or hypesthesia, except perhaps occasionally a slight hyperalgesia.[284]
- Leg pain reported by the patient may indicate a radiculopathy or a pseudoradiculopathy. Conditions that

TABLE 28-3 Reliability of the Historical Examination[a]

Historical Question	Population	Kappa Value or % Agreement
Patient report of (McCombe et al.)[b]	Group 1:50 patients with low-back pain	Interexaminer reliability

may result in radicular symptoms include inflammatory irritation due to tissue injury, disk herniation and subsequent nerve root irritation. In general, with a disk protrusion, the presence of leg pain indicates a larger protrusion than does back pain alone.[286] Coughing, sneezing, or a Valsalva maneuver typically exacerbates the symptoms. Other conditions capable of producing radicular-like symptoms include arthrosis involving the

TABLE 28-4 Medical Screening Questionnaire for the Low-Back Region

	Yes	No
Have you recently had a major trauma, such as a vehicle accident or a fall from a height?		
Have you ever had a medical practitioner tell you that you have osteoporosis?		
Do you have a history of cancer?		
Do you have pain at night that wakes you up?		
Does your pain ease when you rest in a comfortable position?		
Have you recently had a fever?		
Have you recently lost weight even though you have not been attempting to eat less or exercise more?		
Have you recently taken antibiotics or other medications for an infection?		
Have you been diagnosed as having an immunosuppressive disorder?		
Have you noticed a recent onset of difficulty with retaining your urine?		
Have you noticed a recent need to urinate more frequently?		
Have you noticed a recent onset of numbness in the area where you would sit on a bicycle seat?		
Have you recently noticed your legs becoming weak while walking or climbing stairs?

facet joints or vertebral body–disk interface, spinal hematoma, and congenital or acquired central or lateral canal stenosis.[275] A pseudoradiculopathy, as its name suggests, is pain that is radicular in distribution but is caused by something other than those conditions mentioned. Examples of a pseudoradiculopathy include referred pain and symptoms produced by a facilitated segment.[287] Despite the obvious differences in pathology, pseudoradiculopathy and radiculopathy have the common elements of dermatomal pain, diminished reflexes, muscle weakness, and positive nerve provocation tests.[129,287,288] Distinguishing between the two is, therefore, difficult. In general, unilateral pain with no referral below the knee may be caused by the lumbosacral structures other than the spinal nerves, whereas irritation of a spinal nerve may cause radicular symptoms below the knee.[289] On occasion, the patient may report feeling back pain more than leg pain or vice versa. Patients who report a dominance of leg pain over back pain and whose symptoms are worsened with flexion of the lumbar spine most likely have nerve root irritation caused by an IVD herniation.[289] The clinician should also ask the patient about any difficulty with coughing, sneezing, or abdominal straining (Dejerine's triad), each of which causes an increase in intrathecal pressure that may provoke radicular symptoms.[275] Patients with bilateral root pain should be suspected of having a central disk protrusion, spondylolisthesis, bilateral stenosis of the lateral spinal recesses, a narrowed spinal canal, or malignant disease.[290]

- ***Onset.*** When did the problem begin, how long has the patient had the problem, and have similar episodes occurred in the past? Low-back disorders may be acute, chronic, or recurrent. If possible, the clinician should attempt to order the onset of symptoms chronologically and then determine what has occurred to the symptoms since the onset. The mechanism of injury for the lumbar spine usually involves lifting, bending, or twisting, or a combination of all three.[257] However, postural ligamentous pain tends to be more frequent in patients who stand or sit for long periods at work.[291] If an obvious cause is reported, the clinician should confirm the direction, amount, and duration of any forces involved. The forces applied to the lumbar spine and IVD vary according to the task or position of the body (Table 28-5). In general, a sudden onset of pain associated with an activity or movement suggests a ligament, muscle, or IVD as the source, whereas a gradual onset of symptoms suggests a degenerative process or a lesion that is increasing in size, such as a neuroma or neoplasm.[290] While pain is suggestive of mechanical or chemical irritation, paresthesia, anesthesia, and weakness are attributed to decreased nerve or arterial function due to compression, constriction, or other blockage.[275]

The frequency of the episodes often can give the clinician an indication of severity. Stable episodes of symptoms (e.g., symptoms that only occur every few years and do not change much in severity with each episode) are generally easier to treat than episodes that occur daily or weekly and appear to be worsening.

TABLE 28-5 Intradiscal Pressures and Forces Generated by Common Tasks

Task	Total Load (kg)[a]
Lying supine	25
Side lying	75
Standing	150
Bending at waist in standing position	200
Sitting	175
Bending at waist in sitting position	225

- ***Prior history/intervention.*** Patients should be asked if they have experienced similar complaints or problems in the past, even if the current complaint feels differently. If so, it is helpful to determine what intervention was provided, whether self-administered or by a health-care provider, over what length of time and if that treatment was effective.[275]
- ***Palliative measures.*** It is important to determine what attempts have been made to alleviate the symptoms and what effect, if any, was achieved. Depending on the nature of the pathology, certain body positions may bring relief, although it is important to remember that patients often present with symptoms more complex than classic textbook examples allow[275]:
  - Lying supine with knees flexed decreases pressure on the spinal column and tension of neural elements. Similar relief may be felt in the side-lying position; however, patients with a neurocompressive disk herniation may find this position unsustainable on one side and tolerable on the other side.
  - Standing or extension may be less provoking than seated or flexed positions in patients with disk pathology, whereas the opposite is typically true of patients with spinal stenosis. A classic example of positional relief involves the stenotic patient who leans on a shopping cart while walking to alleviate back and lower extremity symptoms.

Pathology of nonmechanical origin is usually nonresponsive to provocative movement and may be negatively responsive to positional changes, as in the case of sepsis within the abdominal cavity and neoplastic activity.[275,292]

- ***Provocative factors (Table 28-6).*** Information about the activities or positions that aggravate or relieve the symptoms provides the clinician with an insight as to whether the patient has a mechanically related disorder or one that is nonmechanical. In postural syndromes, the symptoms are usually increased by maintenance of a particular posture and relieved by altering the position. For example, if the patient complains of pain with standing with the feet together, the cause of the pain could be stresses on the structures caused by an increased lordosis, especially if the pain is reduced by placing one foot in front of the other, or if the pain is reduced when the lumbar lordosis is reduced with an active posterior pelvic tilt. Pain that is relieved by sitting and forward bending but aggravated by walking may indicate a zygapophyseal joint problem, spondylolisthesis (in the younger patient), or lateral recess or spinal stenosis (in the elderly patient). Pain that is aggravated by sitting, stooping, or lifting, but is relieved by recumbency and is not increased by brief periods of standing and walking may indicate an IVD lesion such as a protrusion or an annular tear.[293] In addition to those patients with an IVD protrusion, pain with coughing and sneezing also occurs in patients with active sacroiliitis, because the sudden increase in intra-abdominal pressure produces a painful distraction of the sacroiliac joints.[277] Once the motion or position that reduces the symptoms is identified, the initial focus of the intervention is teaching the patient strategies that encourage this motion or posture.
- ***Progression and course of symptoms.*** Questions related to the type and behavior of symptoms can help determine the structure involved and the stage of healing. It is important to determine whether the condition is improving or worsening. Constant pain indicates an inflammatory process. Steadily increasing pain, especially in elderly patients, may indicate malignancy.[290] Pain that is gradually expanding and increasing is associated with a lesion that is increasing in size, such as a neuroma or neoplasm.[290] Pain with movement suggests a mechanical cause of pain. If the muscles and ligaments are involved, activity will tend to decrease the pain, but the pain will worsen with repeated movements or sustained positions as the structures become fatigued or overstressed.[286,294] Dural pain tends to be diffuse, vague, and spreads upward to the chest or downward to the thighs.[277]

Symptoms of lumbosacral pathology can demonstrate a phenomenon of centralization and peripheralization.[286,295,296] Centralization of symptoms is the progressive retreat of the most distal extent of referred or radicular pain toward the lumbar spine midline in response to standardize movement testing during evaluation of the effect of repeated movements on pain location and intensity. Peripheralization of symptoms indicates movement in the opposite direction. Centralization of the symptoms normally indicates improvement in the patient's diskogenic condition (see "Special Tests" section).[297]

- ***Quality of symptoms.*** Pain is the most common initial complaint involving the low back. Descriptors used by the patient to characterize his or her pain can provide valuable clues to the origin of the problem (Table 28-7).
- ***Radiation/referral of symptoms.*** LBP that emanates from the bony structures, soft tissues, or neural elements often demonstrates an associated pattern of referral or radiation.[275] At a given spinal level, the similar pain patterns of dermatomal, myotomal, and sclerotomal pain represent the distributions of a single nerve root. However, based on the pattern alone, it is difficult to determine the offending structure involved.[275] Radicular and dermatomal pain are often used interchangeably although their meanings are distinct:
  - Radicular pain refers to pain initiated by nerve root irritation and presents itself along the pathway of the root.

TABLE 28-6 Relieving Positions or Movements

Relieving Position or Movement	Probable Cause
Flexion	Facet joint involvement Low-back strain Lateral stenosis
Extension	Disk involvement Nerve root irritation (disk herniation)
Rest	Neurogenic claudication

TABLE 28-7 Common Descriptors of Pain and Their Origin

Descriptor	Origin
Deep ache, and boring	Bony tissues
Dull, achy, sore, burning, and cramping	Muscle/fascia
Sharp, life like, shooting, lancinating, tingling, burning, numbness, and weakness	Nerve
Burning, stabbing, throbbing, tingling, and cold	Vascular
Deep pain, cramping, and stabbing	Visceral

- Dermatomal pain is defined as pain within the distribution of a single sensory nerve root that innervates the skin and presents itself at the surface.

Two additional definitions are pertinent. A myotome consists of groups of muscles supplied by a single spinal segment, whereas a sclerotome is an area of bone or fascia supplied by a single spinal segment.[275]

- ***Severity.*** The most frequently used tool to assess severity is a numerical rating scale, with 0 representing the absence of pain and either 10 or 100 representing the most extreme intensity of pain that the patient has experienced or can imagine. There are several other tools that provide quantification of the patient's symptoms to greater or lesser degree[275]:
- The visual analog scale is frequently used, particularly with new patients and during reexaminations. The scale consists of a 10-cm unmarked line, with indicators of "no pain" at the left end of the line and "extreme pain" at the right end of the line. Patients are asked to mark the line at the point corresponding to their pain level.
- Color charts are useful for young patients and patients who have difficulty communicating information due to language barriers. The colors extend from red to violet, with red representing extreme pain and violet representing the absence of pain.
- Verbal descriptors, such as minimal, slight, moderate, and severe, may also be used to categorize pain levels, although can be subject to misinterpretation. It is important to quantify a patient's pain intensity at its current level, when it is at its lowest and highest points, and an average estimate over a selected period of time, for example 1 week.[275] This information may then be used as outcome measures for subsequent treatment.
- ***Temporal factors—diurnal or nocturnal variation in symptoms.*** Determining the connection between time of day and onset of symptoms may help differentiate between mechanical and inflammatory disorders. For example, muscle strains may feel slightly sore in the morning on waking but typically result in greater intensity of pain at the end of the day following activity.[275] A patient with an inflammatory condition such as ankylosing spondylitis, an IVD lesion, osteoarthritis, ankylosing spondylitis, or Scheuermann's disease tend to experience the greatest symptoms in the morning, after the joints and surrounding tissues have had ample time to stiffen. In addition, patients with mechanically based pain often report an increase in symptoms during the evening hours, when their attention is not diverted by work or daily activities.[275] This may also be true when looking at pain patterns during the week when much activity occurs at home and work versus during the weekends when rest is more likely.[275] Night pain that wakes a patient may be an indicator of neoplastic activity or infection ("Red Flags") (Table 28-8) and should be addressed immediately. In contrast, a patient who awakens following movement, such as changing positions while sleeping, would be less of a risk for "Red Flags."[275] The same is true of the patient who has difficulty returning to sleep after getting up, for example, to visit the restroom.[275] Depending on the size of the patient, prone lying tends to compress the posterior structures and aggravate a zygapophyseal extension dysfunction. Persistent or progressive pain in supine lying may indicate a neurogenic or space-occupying lesion, such as an infection, swelling, or tumor. It may also indicate a zygapophyseal extension dysfunction, especially if the patient has marked adaptive shortening of the hip flexors and rectus femoris. For women, back pain may show a monthly periodicity related to the menstrual cycle.

TABLE 28-8 Red Flags for the Low-Back Region

Condition	Red Flags
Back-related tumor	Age over 50 yr History of cancer Unexplained weight loss Failure of conservative therapy
Back-related infection (spinal osteomyelitis)	Recent infection (e.g., urinary tract or skin infection) Intravenous drug user/abuser Concurrent immunosuppressive disorder
Cauda equina syndrome	Urine retention or incontinence Fecal incontinence Saddle anesthesia Global or progressive weakness in the lower extremities Sensory deficits in the feet (i.e., L4, L5, and S1 areas)

Data from: DuVall RE, Godges J: Introduction to physical therapy differential diagnosis: The clinical utility of subjective examination. In: Wilmarth MA, ed. *Medical Screening for the Physical Therapist. Orthopaedic Section Independent Study Course 14.1.1.* La Crosse, WI: Orthopaedic Section, APTA, Inc, 2003:1–44.

In addition to this list of basic questions, the clinician should also address the following areas:

- ***Patient's general health and past medical history.*** This component includes checking for a family history of

rheumatoid arthritis, IVD lesions,[298] diabetes, osteoporosis, and vascular disease. When collecting information about the patient's health history, a useful acronym is "FAOMASHL": family health history, accidents, other associated/unassociated complaints, medications, allergies, surgeries, hospitalizations, and lifestyle factors.[275] The clinician should solicit information from the patient regarding the presence or past existence of any major illnesses, including, but not limited to, diabetes, heart disease, cancer, and hypertension. Any allergies should be documented. The dates, provider contact information, and outcomes of hospitalizations and surgical procedures should be noted.[275] It is also vital, from a diagnostic as well as treatment viewpoint, to determine the patient's level of conditioning.

- ***Patient age.*** Spondylolisthesis is more common among 10–20-year olds.[290,299] Cancer, compression fractures (see Chap. 5), spinal and lateral recess stenosis, and aortic aneurysms are more common among patients older than 65 years of age.[300,301] Inflammatory spondyloarthropathy is most common in the 15–40-year-old age group,[228] and IVD lesions are more common in this group as well.[290] Osteoarthritis and spondylosis are more common in the 45 years and older age group.[290]
- ***Occupation.*** Information regarding the patient's job description should include the estimated level of activity, from sedentary to strenuous.[275] Also, elements such as lifestyle factors, hobbies, and exercise routines can provide useful information. Flexion and rotation of the trunk, lifting, axial loading, sustained flexed postures, vibration, and low job satisfaction are all considered as risk factors for back pain.[302–304] The level of impairment or disability that a lesion produces is related to the type of work performed. For example, diskodural back pain produces more disability in a truck driver who has to sit the whole day than in a patient who has light and varying work. For some patients, normal activities are unrestricted but their favorite sport is impossible.[290] The clinician should determine if there are any work stressors that may either physically or emotionally delay recovery or increase the likelihood of chronicity.[275] This necessitates a full understanding of the patient's job description and workplace environment. Depending on the circumstances, lifestyle factors may be a source of either physical or psychosocial irritation for the patient or can be used as a motivational force during treatment.[275] Additionally, the patient's participation in hobbies may be negatively impacted by back pain. Recovery and return to these activities can also be used as a motivational device.[275]
- ***Impact of symptoms.*** The effect the symptoms have on the patient's work, daily activities, and recreational pursuits can be assessed using the functional assessment tests outlined later. With this information, the clinician can set a baseline with which to measure progress that is meaningful to the patient. In addition, the clinician can determine whether the need for assistive devices is warranted.
- ***Medication use.*** Pain medications can mask symptoms. If the patient reports taking pain medication prior to the examination, the clinician may not obtain a true response to pain from the patient. It is important to ask the patient about dosage and frequency of the over-the-counter preparations, prescription medications, particularly corticosteroids and anticoagulants, vitamins, and herbal supplements.

CLINICAL PEARL

In general, pain that is worse in the lower extremity than in the low back indicates a nerve root irritation, whereas pain that is worse in the low back than in the lower extremity is probably referred from a spinal structure.[280]

- ***Psychosocial factors and nonorganic signs.*** During the initial history, it is important to document any psychosocial factors or nonorganic signs and symptoms, as these may directly affect the clinician's ability to accurately and completely diagnose the patient (see "Examination Conclusions" section). The patient's response to treatment and prognosis will be impacted as well.

Systems Review

It must always be kept in mind that pain can be referred to the lumbar spine area from pathologic conditions in other regions. For example, reports of pain in the upper lumbar region could suggest the possibility of aortic thrombosis, neoplasm, chronic appendicitis,[305] ankylosing spondylitis, or visceral disease (see Chap. 5) (Table 28-8).

The clinician should determine whether there has been any recent and unexplained weight loss, night pain that is unrelated to movement, or changes in bowel and bladder function.

Any one of these findings may indicate the presence of a serious pathology:

- Unexplained weight loss or night pain not associated with movement may indicate a malignancy. In many patients whose LBP is caused by infection or cancer, the pain is not relieved when the patient lies down.[306] However, this finding is not specific for the presence of these conditions.[228]
- Bowel or bladder dysfunction may be a symptom of severe compression of the cauda equina (cauda equina syndrome). This rare condition usually is caused by a tumor or a massive midline IVD herniation. Urinary retention with overflow incontinence is usually present, often in association with sensory loss in a saddle distribution, bilateral sciatica, and leg weakness.[228] This condition constitutes a medical emergency.
- Unexplained abdominal pain and backache. Fielding et al.[307] in a review of 528 cases with abdominal aortic aneurysms reported that 91% had symptoms at their first presentation, with abdominal pain and backache being most common symptoms. In the same study, it was found that the diagnosis can be made by careful routine palpation deep and left to the midline keeping the hands steady in one position until the aortic pulse is felt, and then carefully evaluating the lateral extent of the pulse with the pads of the fingers.[308]

CLINICAL PEARL

An intriguing study by Roche et al.[309] that examined the sensitivity and specificity of historical questions to identify

patients with serious pathology in the lumbar spine found the following questions to have the best positive likelihood ratios:

- inability to urinate or to hold urine;
- sleep disturbances;
- current smoking history.

It is important to note that although these questions were found to have very high specificity, they also had a very low true positive rate indicating that many of the patients with serious pathology did not answer "yes" to the historical questions. To improve sensitivity, while attempting to maintain moderate specificity in this study, a number of symptoms were considered in parallel. The highest combination of sensitivity (0.87) and specificity (0.50) was obtained by combining in parallel the symptoms of unable to sleep, awakened and unable to fall back to sleep, medication required to sleep, and pain worsened by walking.

Tests and Measures

Observation

Observation involves an analysis of the entire patient in terms of how he or she moves and responds, in addition to the positions the patient adopts. Whether the clinician chooses to greet patients personally in the waiting room or in the examination room, the examination should begin with the initial contact.[275] The patient's gait pattern and any antalgia can provide some important clues. Upper lumbar or thoracolumbar instability or hypermobility often can lead to facilitation of the upper lumbar segments, with resulting psoas hypertonicity.[287,310] This may lead to reduced hip extension during gait, resulting in a shortened stride length on the involved side.[95] Body weight and ground reaction forces, generated by rapid walking, can equalize the stride length by hypermobilizing or destabilizing the lumbosacral junction or the ipsilateral sacroiliac joint.[95] The process is reinforced by the mechanical pull of the shortened iliopsoas, and this increases the stress on the upper lumbar spine, increasing the facilitation.

CLINICAL PEARL

Muscle weakness and reduced walking capacity are among several functional deficits associated with a lumbar herniated NP.[311,312] Weakness of the gastrocnemius is a clinical sign associated with involvement of the L5–S1 disk (neurologic level S1), whereas weakness of the extensor hallucis longus is a positive sign for involvement of the L4–5 disk (neurologic L5).

Once in the examination room, the patient should be gowned appropriately to allow complete inspection of the lumbar spine and lower extremities. Although spinal alignment provides some valuable information, a positive correlation has not been made between abnormal alignment and pain.[255,313] "Good posture" is a subjective term based on what the clinician believes to be correct, and it is highly variable (see Chap. 6).

Posterior Aspect. The shoulders and pelvis should appear fairly level, and the bony and soft tissue contours should appear symmetric. A horizontal line through the highest points of the iliac crests passes also through the spinous process of the fourth lumbar vertebra. The transtubercular plane to the tubercles on the iliac crest cuts the body of the fifth lumbar vertebra, and the upper margin of the greater sciatic notch is opposite spinous process of the first sacral vertebra. There should be no differences in the muscle bulk between both sides and regions of the erector spinae. Atrophy of the paraspinals is rare but may indicate a chronic inflammatory disease, such as ankylosing spondylitis or tuberculosis, or point to poliomyelitis or a myopathy.[277] If atrophy of the paravertebral or extremity muscles is present, the clinician must determine whether it follows a segmental or nonsegmental pattern. A predominance of the thoracolumbar portion of the erector spinae may indicate poor stabilization of this area,[134] or a rotational asymmetry.[314] Asymmetric spasm of the paraspinals or gluteal muscles can make them appear more prominent compared with the normal side. The presence of spasm should alert the clinician to the presence of sciatica or a serious disease.[277]

The inferior angles of the scapulae should be level with the seventh thoracic spinous process; the iliac crests should be level.[315] The PSISs, medial malleoli, and lateral malleoli should all be level with their counterparts on the opposite side. Differences between the two sides may indicate a functional limb-length discrepancy (see Chap. 29). This discrepancy can be caused by altered bone length, altered mechanics, or joint dysfunction[316] (Table 28-9).

The thoracic and lumbar vertebrae should be vertically aligned. Curvature of the spine is referred to as *scoliosis* (see Chap. 6).

Deformity, birthmarks, and hairy patches are all evidence of congenital deficits of the integumentary system and can indicate underlying anomalies in the systems derived from the same embryologic segments.[317] A hairy patch or tuft that is located at the base of the lumbar spine may indicate spina bifida occulta or diastematomyelia.[318]

Lateral Pelvic Shift. Structural asymmetry in the lumbar region often is associated with pain. For example, patients with

TABLE 28-9 Causes of Functional Limb-Length Difference

Joint	Apparent Lengthening	Apparent Shortening
Sacroiliac	Anterior rotation	Posterior rotation
Hip	Lowering Extension External rotation	Hiking Flexion Internal rotation
Knee	—	Flexion Valgus Varus
Foot	Supination	Pronation

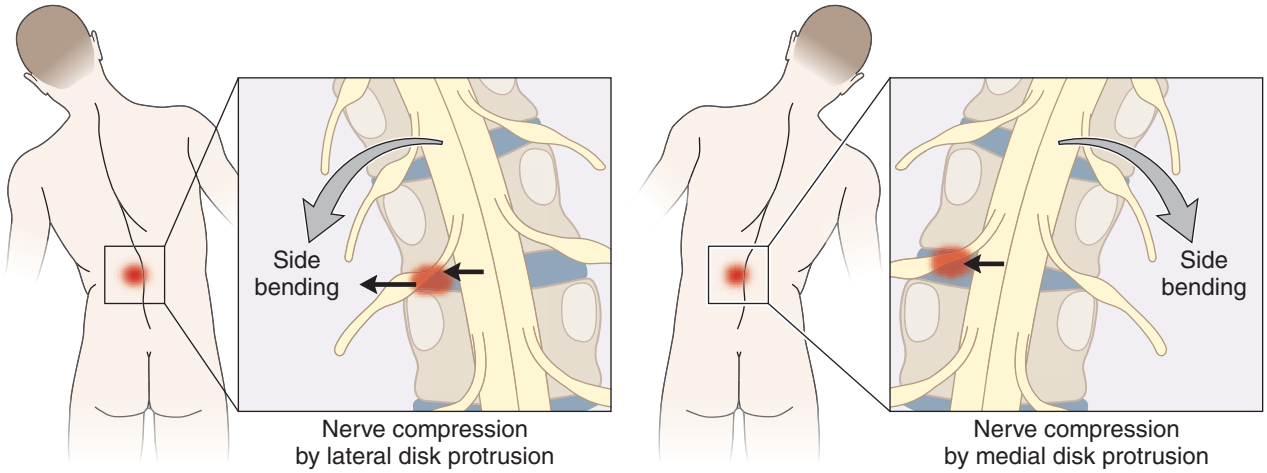

FIGURE 28-7 Direction of the lateral list in relation to disk herniation.

disk-related LBP commonly present with a pelvic shift or list when acute sciatica is present. In these cases, the patient may list away from the side of the sciatica, producing a so-called sciatic scoliosis.[319] The lateral pelvic shift is perhaps the most commonly encountered. Under the McKenzie classification system (see Chap. 22), a derangement requires the presence of a relevant lateral shift deformity.[286] Determining the presence of a lateral shift deformity may help speed up the recovery from a derangement by first correcting the lateral shift deformity.[286] The direction of the list, although still controversial, is believed to result from the relative position of the disk herniation to the spinal nerve (Fig. 28-7). Theoretically, when the disk herniation is lateral to the nerve root, the patient may deviate the back away from the side of the irritated nerve, which has the effect of drawing the nerve root away from the disk fragment (Fig. 28-7). This movement is demonstrated dramatically in patients with extreme lateral disk herniations, whose efforts at side bending to the side of the herniation markedly exaggerate the pain and paresthesia.[320] When the herniation is medial to the nerve root, the patient may list toward the side of the lesion, in an effort to decompress the nerve root[321] (Fig. 28-7). It is also theorized that this is a protective position resulting from

- irritation of a zygapophyseal joint;
- irritation of a spinal nerve or its dural sleeve, caused by disk herniation[262] and the resulting muscle spasm[322];
- spasm of the quadratus lumborum muscle and, occasionally, the iliacus muscle;
- the size of the disk protrusion. In a prospective study of 45 patients with a sciatic scoliotic list (Cobb's angle >4 degrees), Suk et al.[320] found that the direction of sciatic scoliosis was not observed during surgery to be associated with the location of nerve root compression, but rather it was related to the side of disk herniation. Porter and Miller[323] analyzed the mechanism of sciatic scoliosis and concluded that the herniated disk was thought to be reduced in size by stretching or inward bulging at the convex side of the scoliosis, and called this phenomenon autonomic decompression.[323]

The clinician must first determine the presence of the shift and then determine its relevance to the presenting symptoms. To determine its relevance, a side-glide test sequence can be used. The side-glide test sequence is performed by manually correcting the shift by pushing the pelvis into its correct position[286] (Fig. 28-8). **VIDEO** If the side-glide produces either a centralization or peripheralization of the patient's symptoms, the test is considered positive for a relevant lateral shift.[324] In addition, for a lateral shift to be significant, the patient must exhibit an inability to self-correct past midline when asked to shift in the direction opposite the shift.[325] The relevant lateral shift must be corrected, using side-glides, before the patient attempts the McKenzie extension

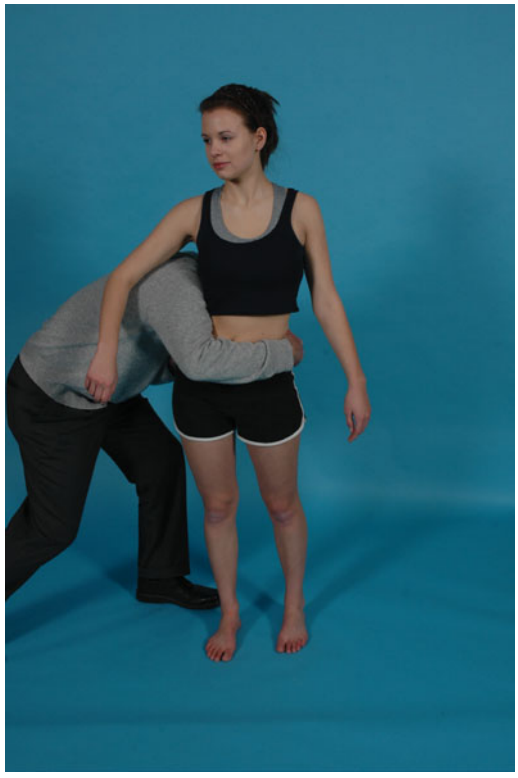

FIGURE 28-8 Side-glide test.

exercises.[326] A lateral shift that is not deemed to be relevant or to be a deformity, per McKenzie's criteria, may be treated with only sagittal plane movements (e.g., extension principles).[286]

CLINICAL PEARL

Riddle and Rothstein found that therapists agreed 60% of the time on the presence and direction of the lateral shift. A κ value of 0.26 was determined, indicating poor reliability.[327] A similar study by Donahue et al. of 49 patients with LBP examined the amount of intertester agreement when assessing only the lateral shift. The amount of agreement was found to be 47%, statistically similar to that obtained by pure chance.[325]

Lateral Aspect

From the side, the clinician should observe that the ear lobe should be in line with the tip of the shoulder, and the peak of the iliac crest. The amount of lumbar lordosis is noted as to whether it is excessive or reduced. The lumbar lordosis should appear as a smooth and gentle curve, and there should be a gradual transition at the thoracolumbar junction.

- An excessive lordosis may result in the pelvic crossed syndrome.[134] In this syndrome, the erector spinae and the iliopsoas are found to be adaptively shortened, and the abdominal and gluteus maximus muscles are found to be weak. As a result, this syndrome can produce adaptive shortening of the PLL, lower back extensors, and hip flexor muscles and lengthening of the ALL and lower abdominals. An excessive lordosis may also indicate that the patient has a spondylolisthesis. With this condition, the whole spine often lies in a plane anterior to the sacrum. There may also be an associated mid or low lumbar shelf at the spinous processes, which, if not visible, can be palpated. An anterior pelvic tilt posture may also be caused by weakness of the abdominal muscles or an adaptively shortened iliopsoas or thoracolumbar fascia, with subsequent lengthening of the hamstring and gluteal muscles.[134]
- A flattened back may indicate that the patient has either a lumbar spinal stenosis or a lateral recessed stenosis. A flattened lordosis is caused by a posterior pelvic tilt, adaptive shortening of the hamstrings, and weakness of the hip flexor muscles.[134]
- A reversed lordosis, often referred to as a *sway back*, is caused by a thoracic kyphosis and a posterior pelvic tilt. This posture results in a stretching of the anterior hip ligaments, back extensors, and hip flexors; hip hyperextension; and compression of the vertebrae posteriorly.[134] Kyphosis of the lumbar spine may also indicate damage to the SSL complex.

The type of footwear that the patient habitually wears can be a factor. For example, high-heeled footwear has a tendency to modify the pelvic angle and increase the lordosis.[328]

Palpation

There is some disagreement as to when in the examination the palpation assessment should occur, with some authors preferring to perform this portion at the end.[329] The order of examination procedures should reflect awareness of the patient's potential discomfort and proceed from least to most invasive.[275] For instance, a patient who reports difficulty when lying on his or her stomach should be examined in the prone position only if necessary, saving this position for the end of the examination. For patients who are able to attain all positions without significant distress, it is most convenient for the clinician to perform procedures as gravity suggests, moving from the standing position to seated, supine, side-lying, and then prone.[275]

Whenever it is performed, palpation of the lumbar spine area should be performed in a systematic manner, and in conjunction with palpation of the pelvic area, which is described in Chapter 29, and the hip area, which is described in Chapter 19. Palpation of the lumbar region is best performed with the patient in a prone position but may also be performed on a seated patient. The examiner should begin by assessing the soft tissues for an increase in focal temperature.[275]

CLINICAL PEARL

A study by Deyo et al.[228] found that palpation of soft tissue and bony tenderness had both poor reproducibility and specificity.

As previously mentioned, in most individuals, the midpoint of an imaginary line drawn between the iliac crests represents the L4–5 interspace and the level of the L4 transverse process. The transverse processes of L3, L2, and L1 each lie two fingerbreadths superior to the vertebra, respectively.[330] Alternatively, they can be found at the level of the lower pole of the spinous process of the vertebra immediately above or below. The lumbar zygapophyseal joints of each motion segment are located approximately 2–3 cm (0.8–1.2 inches) lateral from the spinous processes. The reference point indicating the position of L4 is marked on the patient. The spinous process of L5 is just inferior to this point. The L5 spinous process is short, sharp, and thick compared with those of L4 and L3. The clinician should move superiorly from the L5 spinous process, carefully palpating each segmental level. Evidence of tenderness, altered temperature, muscle spasm, or abnormal alignment during palpation can highlight an underlying impairment.

Posterior Aspect. Palpation of the posterior aspect of the lumbar spine is best achieved by placing the patient in a relaxed prone position, or bent over the treatment table.

- The clinician moves the index and middle fingers quickly down the spine, feeling for any abnormal projections or asymmetries of the spinous processes. Any alterations in the alignment of the spinous processes in a posteroanterior (P-A) direction, particularly at the L4–5 or L5–S1 segmental level, may indicate the presence of a spondylolisthesis.[331] Specific pain elicited with P-A pressure over the segment serves as further confirmation. Asymmetry of the spinous processes in a P-A direction may also indicate wedging of a vertebral body or a complete loss of two adjacent IVD spaces.[277] Absence of a spinous process may be associated with spina bifida. Side-to-side alterations in the spinous process may indicate the presence of a rotational asymmetry of the vertebra.[314]

- The SSLs should be palpated. The ligament is usually supple, springy, and nontender. Because this ligament is the most superficial of the spinal ligaments and farthest from the axis of flexion, it has a greater potential for sprains.[72]
- Palpation of the transverse processes of T12 and L5 presents difficulties. That of L3 is easy to feel, being usually the longest of all transverse processes; it is usually possible to feel those of L1, L2, and L4. That of L5 is covered by the posterior ilium.[332]
- Patients with localized tenderness over the zygapophyseal joints without other root tension signs or neurologic signs may have zygapophyseal joint pain.[333] This source can be confirmed if the patient responds well to intra-articular joint injections or to blocks of the medial branches of the posterior (dorsal) rami.[333,334]
- A well-localized and tender point at the gluteal level of the iliac crest, 8–10 cm from the midline, may indicate the presence of Maigne's syndrome.[322] Maigne's syndrome is characterized by sacroiliac joint, low lumbar, and gluteal pain, with occasional referral to the thigh, laterally or posteriorly.
- Normally, the skin can be rolled over the spine and gluteal region with ease. Tightness or pain produced with skin rolling may indicate some underlying pathology.[335] The source of the signs and symptoms is an irritation of the medial cutaneous branch of posterior (dorsal) rami of the T12 or L1 spinal nerves, as it passes through a fibro-osseous tunnel at the iliac crest.[322]

Anterior Aspect.

- The inguinal area, located between the ASIS and the symphysis pubis, should be palpated carefully for evidence of tenderness, which may be indicative of a hernia, an abscess, sprain of the ligament, or an infection, if the lymph nodes are swollen and tender.
- In some patients, the anterior aspect of the vertebral bodies may be palpable when the patient is positioned supine with the hips flexed and feet flat on the bed. Tenderness of the anterior aspect of the vertebral bodies may indicate an irritation of the ALL, which may indicate the presence of an anterior instability.[13]

CLINICAL PEARL

Evaluation of the abdominal, inguinal, popliteal arteries, and distal pedal pulses is dependent on the patient's profile and presentation.[275] As a general rule, the abdominal aorta should be assessed for possible enlargement via auscultation and palpation in any patient over the age of 50 with acute onset of LBP.[275]

Active Range of Motion

Normal active motion, which demonstrates considerable variability (Table 28-10) between individuals, involves fully functional contractile and inert tissues and optimal neurologic function.[147,336–339] It is important to note that ROM may be affected by age and sex, whereas occupation and body mass index have little or no influence on motion.[340] In addition it has also been determined that total sagittal ROM, flexion angle, and extension angle decline as age increases.[341] However, it is the quality of motion and the symptoms provoked, rather than the quantity of motion, that are more important. The reproducibility (precision) of an individual's effort is one indicator of optimum effort. Measurements should not change significantly (<5 degrees) with repeated efforts.[342] The capsular pattern for the lumbar spine is normal trunk flexion, a decrease in lumbar extension with rotation, and side bending equally limited bilaterally.[343]

TABLE 28-10 Normal Active ROM of the Lumbar Spine

Movement	Range (Degrees)
Flexion	50–70
Extension	10–30
Side bending	25–35
Axial rotation	20–40

Data from: Ng JK, Kippers V, Richardson CA, et al: Range of motion and lordosis of the lumbar spine: Reliability of measurement and normative values. *Spine* 26:53–60, 2001.

A good view of the spine is essential during motion testing. External measurement of vertebral motion may not reflect the true intervertebral movement because of skin movement error,[344] but it is less invasive than a radiograph and more practical. Although limited spinal motion is not strongly associated with any specific diagnosis, this finding may help in the planning or monitoring of the physical therapy intervention.[228]

CLINICAL PEARL

Among the spinal motion tests, rotation, side bending, and fingertip-to-floor distance show the strongest associations with the severity of back pain.[344]

While standing, the patient performs flexion, extension, and side bending to both sides (Fig. 28-9A–D). If full active ROM is attained without the production of symptoms, combined motions are introduced (see the next section). If these motions fail to reproduce the symptoms, the clinician need not assess passive motions. However, resisted motions may produce further clinical findings.[275] Pain induced by active ROM may implicate a number of tissues including muscle and tendon, ligament and capsule, and bone and nerve. The key to deciphering which offending structure is involved lies in determining the type of pain produced and whether active, passive, and/or resisted motions are provoking. Injuries involving noncontractile tissues such as ligaments, facet capsules, and IVDs are provoked by loading the structure actively or passively, whereas resisted isometric muscle contraction is typically unprovoking, unless, in the case of disk herniation, "abdominal canister" (i.e., transversus, obliques, rectus, multifidi, pelvic floor, and diaphragm) contraction increases intrathecal pressure.[275]

The active ROM tests should be observed in front of and behind the patient. At the end of each of the active motions,

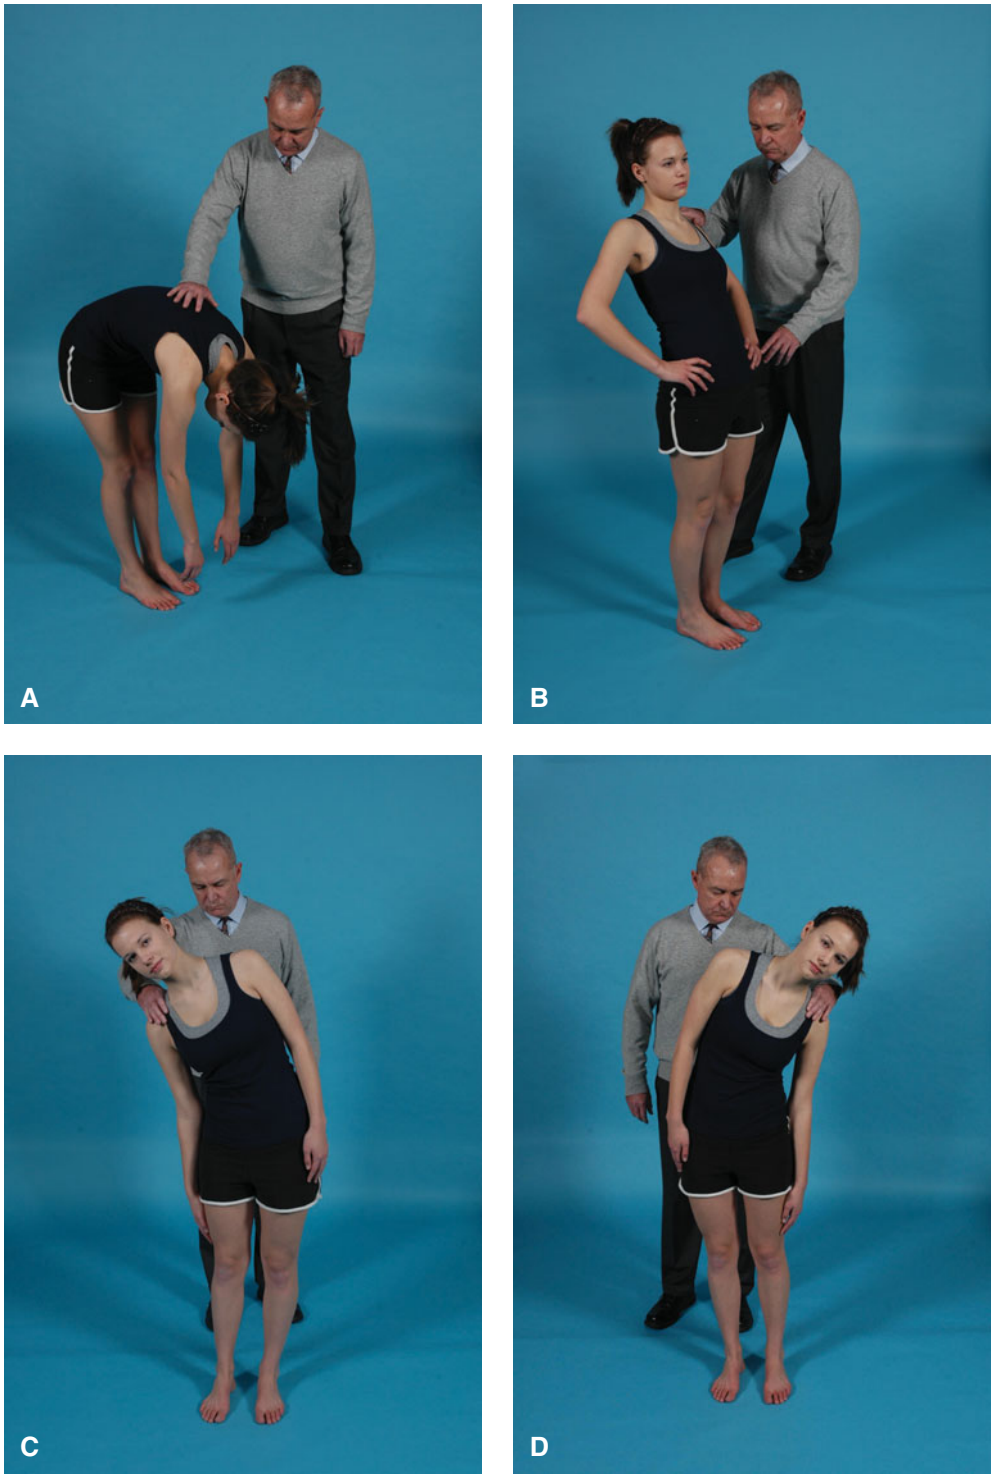

FIGURE 28-9 Active ROM of the lumbar spine with overpressure. (**A**) Flexion. (**B**) Extension. (**C**) Side bending right. (**D**) Side bending left.

passive overpressure is applied to assess the end-feel, and resistance tests are performed with the muscles in the lengthened positions.

The clinician should consider having the patient remain at the end range of each of the motion tests for 10–20 seconds, if sustained positions were reported to increase the symptoms. If repetitive or combined motions were reported in the history to increase the symptoms, the patient is asked to perform repeated motions. McKenzie[286] advocates the use of sustained or repeated movements of the spine in an attempt to affect the nuclear position. These movements are performed either to peripheralize the symptoms lateral from the midline or distally down the extremity or ideally to centralize the symptoms to a point more central or near midline. One study of 87 patients with leg and LBP[295] found that those patients who demonstrated excellent outcomes with the McKenzie-based interventions had reported centralization during the initial examination. Another study[296] found a significant correlation between positive diskograms and peripheralization and centralization, with the incidence of an adequate annulus being

significantly greater in the centralizing patients with positive diskograms than in their peripheralizing counterparts.

During the active motions, the clinician notes the following:

- ***Curve of the spine.*** The curve of the spine in flexion, extension, and side bending should be smooth. An angulation occurring during flexion or extension could indicate an area of instability or hypomobility. In side bending, an angulation indicates hypomobility below the level or hypermobility above the level in the lumbar spine.[335]
- ***Presence of any deviations during or at the end of range.*** Failure to recover from flexion smoothly may indicate instability.[345] This typically occurs at the endpoint of flexion, as the patient begins to return to the erect stance and has to extend the lumbar spine by walking the hands up the thighs or by using a series of jerking motions. Trunk deviation during flexion is believed to be associated with a disk herniation, with the direction of the deviation being determined by the relative position of the compression on the nerve. How the disk responds to movements depends on the activity. For example, walking appears to move the NP into a more central location, whereas prolonged sitting appears to displace the disk into a less advantageous position.[346]
- ***Provocation of symptoms.*** The clinician should determine whether the symptoms are neurologic or nonneurologic, and how far the distribution of pain extends. Leg pain provoked by any motion other than flexion is not a good prognostic sign[343]; neither is posterior leg pain, reproduced with extension, rotation, or side bending, as this usually indicates a significant prolapse or extrusion.
- ***Any gross limitations of motion.*** Gross limitation of both side bends may indicate ankylosing spondylitis or significant osteoarthritis.
- ***Any dysfunctional movement patterns.*** This involves an assessment of the typical pattern and muscle activation strategies. Active spinal movement, commonly reveals good ranges of spinal mobility but with aberrant quality of motion commonly associated with a sudden acceleration, hesitation, or lateral movement within the midrange of spinal motion.[185] Both O'Sullivan[13] and Sahrmann[347] have devised classification schemes to categorize movement patterns:

O'Sullivan classifies instabilities according to directional patterns of clinical instability, although he admits that these classifications have not been scientifically validated.[13]

- ***Flexion pattern.*** The flexion pattern is the most common. It is characterized by complaints of central back pain that is aggravated during flexion–rotational movements, and an inability to sustain semiflexed positions. On observation, there is often a loss of segmental lordosis at the level of the "unstable" motion segment, which is more noticeable in standing. This loss of lordosis is increased in flexed positions. Movements into forward flexion are associated with a tendency to flex more at the symptomatic level than at adjacent levels and, usually, are associated with an arc of pain into flexion and an inability to return from flexion to neutral without use of the hands to assist in the movement. During backward bending, extension above the symptomatic segment, with an associated loss of extension at the involved segment, often is observed. Functional activities, such as squatting, sitting with knee extension or hip flexion, and sit to stand, reveal an inability to control a neutral lordosis and a preponderance to segmentally flex at the unstable motion segment. Specific muscle tests reveal an inability to perform the abdominal hollowing maneuver (see "Clinical Instability of the Lumbar Spine" section) at the unstable motion segment. The patient may also be unable to actively produce a neutral lordotic lumbar spine posture.
- ***Extension pattern.*** The extension pattern is characterized by complaints of central back pain that is aggravated during extension–rotational movements, and an inability to sustain positions such as standing, overhead activities, fast walking, running, and swimming. On observation, there is often an increase in segmental lordosis at the level of the "unstable" motion segment in standing, which is often associated with an increase in segmental muscle activity at this level. Extension activities reveal segmental hinging at the involved segment, with a loss of segmental lordosis above this level and an associated postural sway. Forward bending movements often reveal a tendency to hold the lumbar spine in lordosis, with a sudden loss of the lordosis midway through the flexion range and an arc of pain. On returning from the flexed position, there is often a tendency to hyperextend the lumbar spine segmentally before the upright posture is achieved, with pain on returning to the upright position. Specific muscle testing reveals an inability to perform the abdominal hollowing maneuver. The patient also is often unable to initiate a posterior pelvic tilt independent of hip flexion and activation of the gluteals, rectus abdominis, and external obliques.
- ***Recurrent lateral shift pattern.*** The lateral shift is usually unidirectional, occurs recurrently, and is associated with unilateral LBP. The patient typically stands with a loss of lumbar segmental lordosis at the involved level and an associated lateral shift at the same level. The lateral shift is accentuated when standing on the foot ipsilateral to the shift and is observed during gait as a tendency to transfer weight through the trunk and upper body rather than through the pelvis. Sagittal spinal movements reveal a shift further laterally at midrange flexion, which is commonly associated with an arc of pain. Sit to stand and squatting are associated with a tendency toward lateral trunk shift during the movement, with increased weight bearing on the lower limb ipsilateral to the shift. Specific muscle testing reveals an inability to perform the trunk raise, with dominance of activation of the quadratus lumborum, lumbar erector spinae, and superficial multifidus on the side ipsilateral to the shift and an inability to activate the segmental multifidus on the contralateral side to the lateral shift.
- ***Multidirectional pattern.*** This pattern is the most serious and debilitating of the patterns and is frequently characterized by high levels of pain and functional disability. All weight-bearing positions are normally painful, and locking of the spine occurs frequently with positions of sustained flexion, rotation, and extension. These patients exhibit great difficulty in assuming neutral lordotic spinal

positions, and an inability to perform the abdominal hollowing maneuver.

Sahrmann categorizes a number of movement impairment syndromes that can present in the lumbar spine as a result of an imbalance of flexibility and strength. The intervention for each of the syndromes involves a correction of these imbalances.

- ***Flexion syndrome.*** This syndrome is characterized by lumbar flexion motions that are more flexible than hip flexion motions. The syndrome is typically found in the 8–45-year-old age range and results in pain with positions or motions associated with lumbar flexion, because of adaptive shortening of the gluteus maximus, hamstrings, or rectus abdominis.
- ***Extension syndrome.*** This syndrome is characterized by lumbar extension motions that are more flexible than hip extension motions. Patients with this syndrome are usually older than 55 years of age, and the symptoms are increased with positions or motions associated with an increase in lumbar lordosis, because of adaptive shortening of the hip flexors and lumbar paraspinals and weakness of the external oblique muscles.
- ***Lumbar rotation.*** This syndrome is characterized by pain that is unilateral or greater on one side and is increased with rotation to one side. No attempt is made to equate the side of rotation with the side of the symptoms. It is theorized that this syndrome is produced when one segment of the lumbar spine rotates, side bends, glides, or translates more easily than the segment above or below it. This syndrome is associated with spinal instability and can result from habitual motions or positions that involve rotation to one side, a leg-length discrepancy (see Chap. 29), or a muscle imbalance between the oblique abdominal muscles.
- ***Lumbar flexion with rotation.*** This syndrome is characterized by pain that is unilateral or greater on one side and is increased with the combined motion of lumbar flexion and rotation. Many of the characteristics of the lumbar flexion and lumbar rotation syndromes can be applied to this syndrome.
- ***Lumbar extension with rotation.*** This syndrome is characterized by pain that is unilateral or greater on one side and is increased with the combined motion of lumbar extension and rotation. Many of the characteristics of the lumbar extension and lumbar rotation syndromes can be applied to this syndrome.

There is no gold standard to measure ROM of the lumbar spine. The majority of published data concerning normal ranges of motion exists without concomitant data on the subjects' demographic background, specifically with respect to age, gender, and occupation. Methods to objectively measure lumbar motion have included[337]

- Measuring the ROM visually (eyeballing). This method is endorsed by the American Academy of Orthopaedic Surgeons.[348] Although this seems to be the fastest and easiest method, its validity is questionable.[349]
- Using a tape measure, measuring the distance from a bony landmark to the floor at the end of available motion. This test provides only a gross measurement of the lumbar motion.[350]
- Goniometric measurement. The goniometer, also known as the universal goniometer, is the most accessible and least costly device. It should be noted that goniometric measurement of the lumbar spine often incorporates some thoracolumbar motion. It should also be noted that researchers have found poor intra- and interrater reliability for all goniometric measurements of the thoracolumbar spine.[351–353] Table 28-11 lists the suggested landmarks used when assessing lumbar ranges of motion with a goniometer.
- Schöber technique. This technique is used only to measure flexion. The first sacral spinous process is marked, and a mark is made about 10 cm above this mark. The patient then flexes forward, and the increased distance is measured. If there is normal motion of the lumbar spine with absence of disease, there should be an increase of 4–5 cm. The obvious limitation with this technique is that it only measures flexion.
- The modified Schöber technique,[354] which measures the change in distance between two skin markings over the lumbar spine during flexion or extension. A point is marked midway between the two PSISs, which is the level of S2. Points at 5 and 10 cm above that level are marked, and the distance between the three points is measured. The patient is

TABLE 28-11 Goniometric Landmarks, Normal Motion Values, and End-Feel Descriptors for the Lumbar Spine

Motion	Axis of Rotation	Arm Landmarks	Normal Values (Degrees)	Normal End-Feel
Flexion	Coronal/axillary line at L5 level	Stationary arm: along thigh Active arm: axial line to L1 spinous process	70–90	Tissue stretch (firm elastic resistance)
Extension	Coronal/axillary line at L5 level	Stationary arm: along thigh Active arm: axial line to L1 spinous process	30–50	Bone to bone (hard, painless) or tissue stretch
Side bending	Midline at S1 spinous process	Stationary arm: midline inferiorly Active arm: L1 spinous process	30	Tissue stretch
Rotation	Visual estimation only		35	Tissue stretch

asked to bend forward or backward, and the distance is remeasured. The distance between the two measurements is an indication of the amount of motion occurring in the lumbar spine. This method also is prone to error, because it can measure only lower lumbar levels and may not reflect the amount of motion available in the whole lumbar spine.[355] Various studies have shown this technique to have overall good interrater reliability.[355,356]

- The fluid (bubble) goniometer. This device consists of a fluid-filled circular tube attached to or embedded in a flat platform with a 360-degree scale. With the joint in a neutral position, the device is either strapped to the distal aspect of an extremity or manually held in place on the patient, as can be the case when measuring trunk movement. Although many clinicians appreciate the ease of use and elimination of landmark estimation required by the universal goniometer, this device still exhibits problems with reliable positioning, particularly if attached with a strap or when used on obese patients.[275] Landmarks used are similar to those of the goniometer's active arm.
- The inclinometer technique recommended by the American Medical Association.[342] Inclinometers are small angle measuring devices that work like a plumb line, operating on the principle of gravity. An appropriate inclinometer should include a large enough dial to allow easy reading of 2-degree increments. The inclinometer technique can record regional movement of the lumbar spine rather than the combined movement of the spine and hip[357] and has been proved to correlate well with measurements taken from a radiograph.[351,358] For example, to measure lumbar flexion, two inclinometers are used, aligned in the sagittal plane. The center of the first inclinometer is placed over the T12 spinous process. The center of the second one is placed over the sacrum, midway between the PSISs. The patient is asked to flex the trunk as far as possible, and both inclinometer angles are recorded. The lumbar flexion angle is calculated by subtracting the sacral (hip) from the T12 inclinometer angle.

Whatever technique is chosen, the same technique must be used subsequently when reassessing ROM.

Flexion. The first 60 degrees of forward bending typically result from flexion of the lumbar motion segments, which is followed by an additional movement at the hip joints of approximately 25 degrees.[62] The patient is instructed to tuck the chin toward the chest and bend forward at the waist, keeping the knees extended, while attempting to touch the toes.[275] The clinician should note any change in an existing scoliotic curve, deviation away from the midline which may suggest guarding due to disk pathology, patient apprehension or assistance (use of hands on knees), which may suggest instability, lack of motion between spinal segments, and whether the normal lordosis decreases as expected.

The lumbar flexion movement can be repeated with the patient sitting, as this test can help screen for the presence of rotoscoliosis.[359]

McKenzie[286] advocates the testing of lumbar flexion motion in supine as well as in the standing position. In the standing position, flexion of the lumbar spine occurs from above downward, so pain at the end of the range is likely to indicate that L5–S1 is affected. Bringing the knees to the chest in the supine position (Fig. 28-10) produces a flexion of the lumbar spine from below upward, so that pain at the beginning of the movement may indicate that L5–S1 is affected.[286]

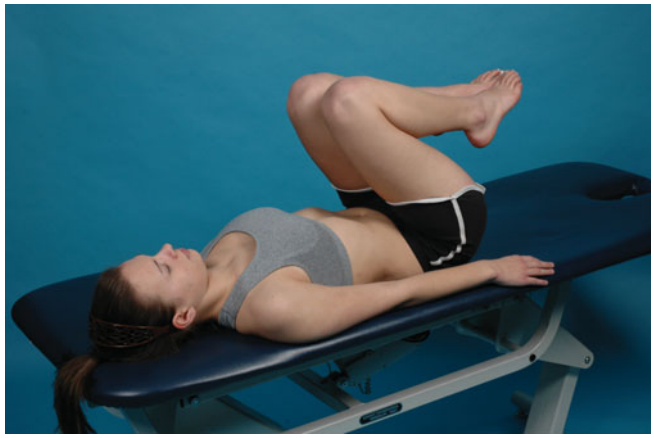

FIGURE 28-10 Lumbar flexion from below.

Trunk deviation during flexion is believed to be associated with an IVD herniation, with the direction of the deviation determined by the relative position of the compression on the nerve.[360] Deviations during flexion may also result from neuromeningeal adhesions, hypomobile segment(s) on the contralateral side, hypermobile segment(s) on the ipsilateral side, a structural scoliosis, and a shortened leg on the ipsilateral side.[360] Passive ROM is tested with the patient seated on the examination table. The patient is instructed to keep the arms to the side, while the clinician grasps his or her shoulders and flexes the patient forward at the waist, keeping the pelvis firmly on the table. The clinician should note the end-feel and any change in an existing scoliotic curve, lack of motion between spinal segments, and whether the normal lordosis decreases as expected.

Extension. The patient is instructed to place his or her hands on the posterior iliac crests to provide support and then extend backward from the waist, keeping the knees extended and the gaze toward the ceiling (Fig. 28-9B). The clinician notes if the arc of extension is even throughout the lumbar spine or more pronounced at a specific spinal segment.[275] Pure lumbar extension in standing involves the patient leaning back at the waist. Lumbar extension is often the stiffest and most uncomfortable movement for the patient. Thus, patients with LBP tend to use the protective guarding mechanism against the compression and shearing forces, generated by simply hyperextending the hips. By applying a compressive force through the patient's shoulders during the backward bending, the clinician can induce a small increase in the lumbar lordosis. Passive ROM is tested with the patient seated on the examination table. The patient is instructed to place his or her hands across the chest. The clinician supports the upper back with one arm and the sacrum with the other hand and then extends the patient backward in an arching motion rather than a leaning motion. The clinician notes the end-feel or any altered symptoms.

Side Bending. The standing patient is instructed to lean to the side by sliding the palm of the hand down the outside of the thigh, without flexing forward or extending backward, and keeping the palm on the lateral thigh or hip. The clinician notes if the arc of bending is even or more pronounced at a specific spinal segment as well as whether the patient unintentionally rotates the torso to accommodate motion.[275] Side-bending ROM has been found to be a good indicator of the degree of LBP[234] and disability.[235] In acute spinal derangements, such as a unilateral posterolateral IVD protrusion or unilateral zygapophyseal joint derangement, lumbar side bending may be significantly reduced or absent on one side (usually toward the involved side). Arthritic conditions of the spine tend to demonstrate a symmetric loss of side bending to both sides.

The common method of measuring the amount of side bending is to record the distance between the fingertip and the floor at the end of the side bend, but this is merely an estimation of the flexibility of the whole spine rather than the lumbar spine.[337] Thus, it is recommended that lumbar spine movement in side bending be measured using the inclinometer technique.[342]

The patient may be seen to lift one foot or bend the knees during the side-bending movements and should be reminded to maintain the feet on the floor during measurement. At the end of the side-bending motion, overpressure is applied on the shoulder (see Figs. 26-9C–D). Passive ROM is tested with the patient seated on the examination table. The patient is instructed to cross the arms across the chest. The clinician places one arm across the upper back and the other hand on the contralateral iliac crest. The clinician then bends the patient to each side, keeping the opposite crest from rising off the table. As with extension, an arching motion rather than a leaning motion is desired. The end-feel is noted or any altered symptoms.

Axial Rotation. Axial rotation of the spine usually is assessed in the sitting position to eliminate motion occurring from the hips. The patient, keeping the knees together, twists at the waist to each side. Patients frequently tend to side bend or extend the torso, so the clinician must take care in preventing such motion. Axial rotation of the trunk commonly includes movement of both thoracic and lumbar segments of the spine. Overpressure may be applied at the end of range (Fig. 28-11). Normal range could indicate normalcy, hypermobility, or instability. Restricted range will be in either a capsular or a noncapsular pattern. Pain with this maneuver can implicate a nonorganic source, an annular tear, a ligament tear, or a zygapophyseal joint dysfunction.[360] Passive ROM is tested with the patient seated on the examination table. The patient is instructed to place his or her hands across the chest, and the clinician grasps the shoulders and rotates the patient's torso. Alternately, the clinician may use a shoulder–scapula contact. End-feel is noted or any altered symptoms.

Combined Motion Testing. The combined motion tests of the lumbar spine are used to detect biomechanical impairments. Although combined motion tests do not provide information as to which segment is at fault, they may provide information as to which motion or position reproduces the pain.[361]

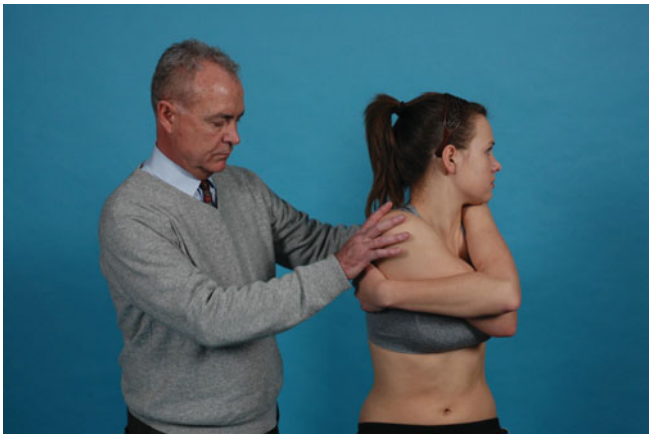

FIGURE 28-11 Lumbar rotation.

Combined motion tests can reproduce the pain in a structure that is either being compressed or stretched[362]:

- A reproduction or increase in symptoms with flexion and side bending away from the side of the symptoms may implicate pain in a structure that is being stretched.
- A reproduction or increase in symptoms with extension and side bending toward the side of the symptoms may implicate pain in a structure that is being compressed.

Combined motions can be performed as repetitive motions or as sustained positioning. For example, the patient can be asked to repetitively perform the combined motion of flexion and right side bending to assess for what McKenzie describes as a derangement syndrome, or the clinician can position the patient in flexion and right side bending (Fig. 28-12) to assess

FIGURE 28-12 Lumbar flexion and right side flexion.

FIGURE 28-13 Supine lying.

FIGURE 28-15 Double knees to chest.

for what McKenzie describes as a dysfunction syndrome. Alternatively, the clinician can ask the patient to maintain the position of flexion and right side bending to assess for a postural dysfunction.[286]

Six-Position Test

The six-position test is a screening tool that I have found to be particularly useful with the acute patient, in helping to determine the position of comfort for the patient and for focusing the examination and intervention. The reliability or validity of these tests has yet to be established, but they are based on applied anatomy and biomechanics. The patient is placed in the following positions:

1. Supine with the hips and knees extended (Fig. 28-13). In individuals with adaptive shortening of the rectus femoris and the iliopsoas (a common finding), this position is manifested by an inability of the posterior thighs to rest on the table. Pain in this position may indicate a lumbar extension or lumbar rotation syndrome (see "Intervention Strategies" section), especially if the next position relieves the symptoms.[347]
2. Supine in the hook-lying position, with the hips and knees flexed and the feet flat on the bed (Fig. 28-14). This is typically the most comfortable position for the patient with acute LBP, except in cases of severe stenosis or spondylolisthesis.
3. Supine with both knees held against the chest (Fig. 28-15). This position rotates the pelvis posteriorly and widens the intervertebral foramina of the lumbar segments.[294] This is normally a comfortable position for patients who have spinal stenosis, lateral recess stenosis, or a lumbar extension syndrome.
4. Supine with one hip and knee extended, the patient raises the other knee to the chest without using the arms (Fig. 28-16). Once the leg is elevated, the patient grasps it with both hands and pulls it toward the chest. Holding the left knee against the chest invokes a position of lumbar flexion and left side bending, which widens the intervertebral foramen on the right and narrows the

FIGURE 28-14 Hook lying.

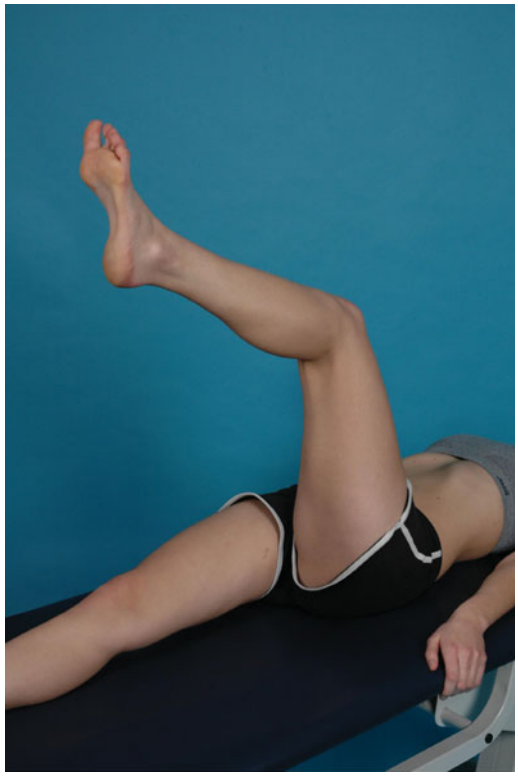

FIGURE 28-16 Single knee to chest.

FIGURE 28-17 Prone lying.

intervertebral foramen on the left. Holding the right knee against the chest invokes a position of lumbar flexion and right side bending, which widens the intervertebral foramen on the left and narrows intervertebral foramen on the right.[294] Given the amount of rotation induced with this maneuver, this test is often positive even when the position of both knees to the chest does not provoke symptoms. Occasionally though, one side may be pain free and can be used as an introductory exercise.

5. Prone lying with the legs straight (Fig. 28-17). This is typically comfortable for patients with an IVD protrusion, but uncomfortable for patients with spinal stenosis, spondylolisthesis, and an extension or a rotation syndrome[347] (see "Intervention Strategies" section).
6. Prone lying with passive knee flexion applied by the clinician (Fig. 28-18). This is a confirmatory test for the previous position, if it increases the symptoms in patients with spinal stenosis, spondylolisthesis, and an extension or a rotation syndrome[347] (see "Intervention Strategies" section).

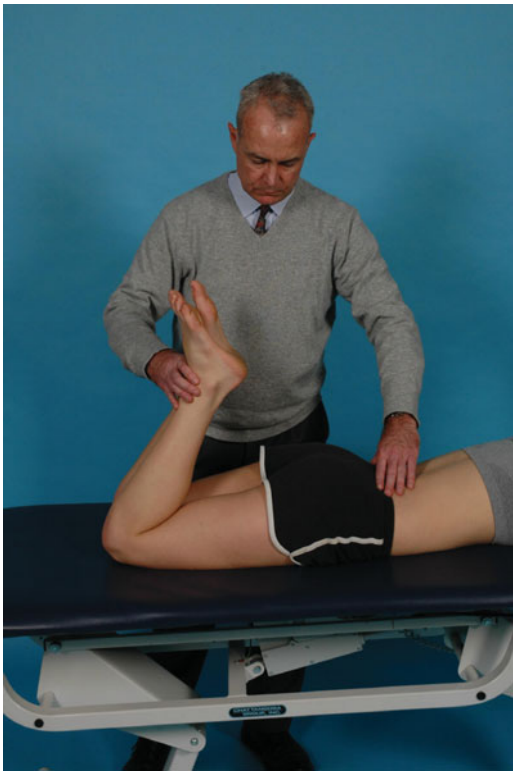

FIGURE 28-18 Prone double knee bend.

The results from these tests should provide the clinician with information on the effect that pelvic tilting in a non–weight-bearing position has on the symptoms. If anterior pelvic tilting appears to aggravate the patient's symptoms, initial positions and exercises that promote posterior pelvic tilting are advocated. If posterior pelvic tilting appears to aggravate the patient's symptoms, initial positions and exercises that promote an anterior pelvic tilt are advocated.

Muscle Strength. Optimum control of the spine and pelvis requires a carefully controlled, dynamic system where the strategy of activation of the trunk muscles matches the functional task. Resisted motions of the lumbar spine can be categorized into those that provide valuable information regarding the origin of lumbar pathology (key muscle testing) and those that assess basic strength parameters, such as dynamic and static motor control.[275]

Gross strength of the trunk can also be assessed by applying a resisting force to the patient's upper back during resisted extension and the shoulders during flexion, lateral bending, and rotation.[275] The clinician notes the presence and type of pain produced and the degree of effort exerted.

Key Muscle Testing. The key muscle tests are used as part of the lower quarter scanning examination (see Chap. 4), because they examine the integrity of the neuromuscular junction and the contractile and inert components of the various muscles.[343] With the isometric tests, the contraction should be held for at least 5 seconds to demonstrate any weakness. If the clinician suspects weakness, the test is repeated two to three times to assess for fatigability. The larger muscle groups, such as the quadriceps, hip extensors, and calf muscles, must be tested by repetitive resistance against a load to sufficiently stress the muscle–nerve components.

Standing up on the Toes (S1–2). The patient raises both heels off the ground (Fig. 28-19). The key muscles tested during this maneuver are the plantar flexors. These are difficult muscles to fatigue, so the patient should perform 10 heel raises unilaterally, with the arms supported by the clinician. In addition to observing for fatigability, the clinician should look for Trendelenburg's sign. A positive Trendelenburg's sign occurs when, during unilateral weight bearing, the pelvis drops toward the unsupported limb; this can indicate a number of conditions, including a hip impairment (coxa vara) or a gluteus medius weakness (see Chap. 19).

Unilateral Squat While Supported (L3–4). The patient performs unilateral squats while supported (Fig. 28-20). The key muscles being tested during this maneuver are the quadriceps and hip extensors. Neurologic weakness of the quadriceps (L3–4) is relatively rare and often suggests a nondiskogenic lesion, such as a neoplasm, especially if the weakness is bilateral.[360]

Heel Walking (L4). The patient walks toward, or away from, the clinician while weight bearing through the heels (Fig. 28-21). The key muscles being tested during this maneuver are the dorsiflexors (L4). Approximately 40% of IVD lesions affect this level, about an equal amount as those that affect the L5 root.[33] An IVD protrusion of the L4–5 disk can irritate the

FIGURE 28-19 Standing up on toes.

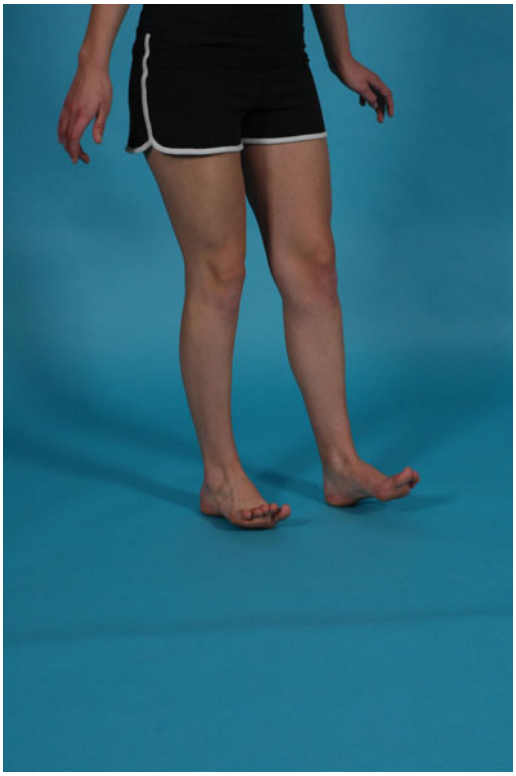

FIGURE 28-21 Heel walking.

fourth root, the fifth root, or, with a larger protrusion, both roots. The dorsiflexors can also be tested in supine (Fig. 28-22).

Hip Flexion (L1–2). With palsy, the patient is unable to raise the thigh off the table. Palsy at this level should always serve as a red flag for the clinician, because IVD protrusions at this level are rare, but this is a common site for metastasis.[363] Painful weakness of hip flexion may indicate the presence of a fractured transverse process, metastatic invasion, acute spondylolisthesis, acute segmental articular dysfunction, a major contractile lesion of the hip flexors (rare), or a hip joint

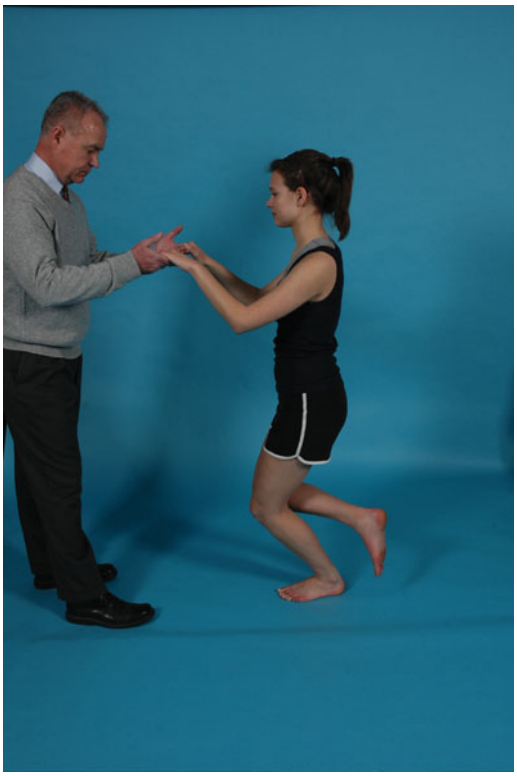

FIGURE 28-20 Unilateral squat.

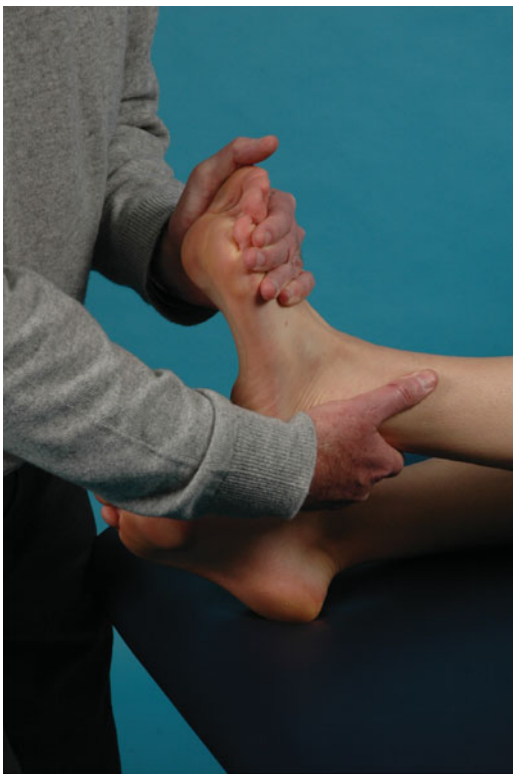

FIGURE 28-22 Key muscle testing of the dorsiflexors with the patient supine.

FIGURE 28-23 Resisted hip flexion.

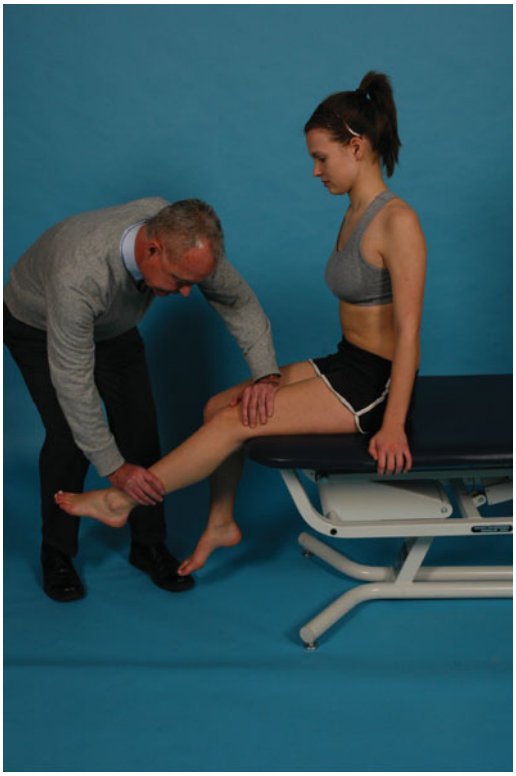

FIGURE 28-24 Resisted knee extension.

pathology. The patient's hip is actively raised off the treatment table to approximately 30–40 degrees of flexion. The clinician then applies a resisted force proximal to the knee into hip extension (Fig. 28-23), while ensuring that the heel of the patient's foot is not contacting the examining table. Both sides are tested for comparison.

Knee extension (L3–4). The clinician positions the patient's knee in 25–35 degrees of flexion and then applies a resisted flexion force at the middistal shaft of the tibia (Fig. 28-24). Both sides are tested for comparison. Alternately, knee extension can be tested with the patient prone. The patient's leg is positioned in approximately 120 degrees of knee flexion, taking care to do this passively. The clinician rests the superior aspect of his or her shoulder against the posterior aspect of the patient's ankle and grips the edges of the examining table. A force to flex the patient's knee is applied while the patient resists. Both sides are tested for comparison.

Hip extension (L5–S1). The patient's knee is flexed to 90 degrees, and his or her thigh is lifted slightly off the examining table by the clinician, while the other leg is stabilized. A downward force is applied to the patient's posterior thigh (Fig. 28-25), while the clinician ensures that the patient's thigh is not in contact with the table. Both sides are tested for comparison.

Knee flexion (S1–2). The patient's knee is flexed to 70 degrees, and an extension isometric force is applied just above the ankle (Fig. 28-26). Both sides are tested for comparison.

Great toe extension (L5). The patient is asked to hold the big toe in a neutral position. The clinician then applies resistance to the toe (Fig. 28-27) and compares the two sides.

Ankle eversion (L5–S1). The patient is asked to place the feet at 0 degree of plantar and dorsiflexion relative to the leg. A resisted force is applied by the clinician to move each foot into inversion (Fig. 28-28), and a comparison is made.

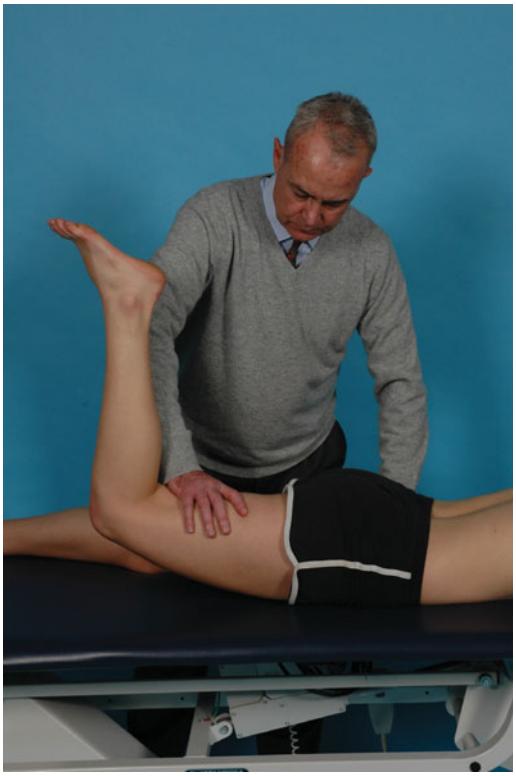

FIGURE 28-25 Resisted hip extension with knee flexed.

FIGURE 28-26 Resisted knee flexion.

Muscle Stretch Reflexes

The reflexes should be assessed and graded accordingly, with any differences between the two sides noted. The tendon should be struck directly once the patient's muscles and tendons are relaxed.

Patellar Reflex (L3). The patient is positioned sitting, with the legs hanging freely. Alternatively, both knees can be supported in flexion, with the patient placed in supine (Fig. 28-29).

Hamstring Reflex (Semimembranosus: L5, S1; and Biceps Femoris: S1–2). The patient is positioned prone, with the knee flexed and the foot resting on a pillow. The clinician places a thumb over the appropriate tendon and taps the thumbnail with the reflex hammer to elicit the reflex.

FIGURE 28-28 Resisted ankle eversion.

FIGURE 28-29 Patellar reflex.

Achilles Reflex (S1–2). The patient is positioned so that the ankle is slightly dorsiflexed with passive overpressure (Fig. 28-30).

Pathologic Reflexes

Pathologic reflexes occur in the presence of motor cortex, brain stem, or corticospinal tract lesions (upper motor neuron lesions), wherein the motor response to a sensory stimulus is not modulated. The following pathologic reflexes are described in Chapter 3:

FIGURE 28-27 Resisted great toe extension.

FIGURE 28-30 Achilles reflex.

- Babinski;
- Clonus;
- Oppenheim.

Sensory Testing

A thorough evaluation of the sensory system is quite an involved process, due to the number of ascending pathways carrying information to the brain.[275] The clinician checks the dermatome patterns of the nerve roots, as well as the peripheral sensory distribution of the peripheral nerves (see Chap. 3). Dermatomes vary considerably between individuals.

Superficial Reflexes

There are a number of reflexes that occur in response to stimulation of the skin, known as the *superficial reflexes*. Three of these, the cremasteric (L1–2), Geigel (L1–2), and anal (S2–5), are pertinent to nerves exiting the lumbar spine.[275] Performance of these superficial reflex tests involves either stroking or pricking the skin of the upper inner thigh (cremasteric and Geigel) or perianal tissue and noting the presence of muscle contraction by the cremasteric (elevation of the testicles), iliopuepartal (elevation of the clitoral prepuce), or external sphincter muscles (also known as anal wink), respectively. It is important to remember that without correlation from the history and physical examination findings, absence of a superficial reflex may not ultimately be clinically significant.

Neurodynamic Mobility

The neurodynamic mobility tests to help confirm a lumbar disk herniation include straight leg raising (SLR), bilateral SLR, crossed SLR sign, slump test, prone knee bend (femoral nerve stretch), and bowstring tests, which are described in Chapter 11.

The lower the angle of a positive SLR test, the more specific the test becomes and the larger the disk protrusion found at surgery.[228,364] A limited SLR at 60 degrees is moderately sensitive for herniated lumbar disks but nonspecific, because limitation often is observed in the absence of disk herniations.[228,365,366] Crossed SLR is less sensitive but highly specific.[365–367] Thus, the crossed SLR test suggests concordance with the diagnosis, whereas ipsilateral SLR is more effective in ruling out the diagnosis.

The femoral nerve stretch test (see Chap. 11) is probably the single best screening test to evaluate for a high lumbar radiculopathy. This test has been shown to be positive in 84–95% of patients with high lumbar disks,[154,368,369] although the test may be falsely positive in the presence of an adaptively shortened iliopsoas or rectus femoris or any pathology in or about the hip joint, sacroiliac joint, and lumbar spine.

Differing Philosophies

The next stage in the examination process depends on the clinician's background. Clinicians who are heavily influenced by the muscle energy techniques of the osteopaths use position testing to determine the segment on which to focus. Other clinicians omit the position tests and proceed to the combined motion and passive physiologic tests.

FIGURE 28-31 Position testing in neutral.

Position Testing. Position testing in the lumbar spine is an osteopathic technique used to determine the level and type of zygapophyseal joint dysfunction.[100,332,335,370–372] Position testing is performed with the patient in three positions: neutral (Fig. 28-31), flexion (Fig. 28-32), and extension (Fig. 28-33). The transverse processes are then layer palpated (Fig. 28-34). The findings and possible causes for the position testing are outlined in Tables 28-12 and 28-13.

FIGURE 28-32 Position testing in flexion.

FIGURE 28-33 Position testing in extension.

FIGURE 28-34 Layer palpation of the transverse processes. May also be used for P-A pressures.

Passive Physiologic Intervertebral Mobility Tests. The passive physiologic intervertebral mobility (PPIVM) tests are most effectively carried out if the combined motion tests locate a hypomobility, or if the position tests are negative, rather than as the entry tests for the lumbar spine.[373,374] Judgments of stiffness made by experienced physical therapists examining patients in their own clinics have been found to have poor reliability.[375]

The passive physiologic movement tests are performed into

- flexion;
- extension;
- rotation;
- side bending.

TABLE 28-12 Causes and Findings for a Flexed Rotated Side Bent Right

Causes of an FRSR	Associated Findings
Isolated left joint extension	PPIVM and PPAIVM tests in hypomobility (FRSR) left extension quadrant are reduced
Tight left flexor muscles (FRSR)	PPIVM test in left extension quadrant is decreased; PAIVM test is normal
Arthrosis or arthritis of left joint in capsular pattern (ERSL < FRSR)	PPIVM and PPAIVM tests in right flexion quadrant are more reduced than in left extension quadrant
Fibrosis of left joint (ERSL = FRSR)	PPIVM and PPAIVM tests are equally reduced in right flexion and left extension quadrants
Left posterolateral disk protrusion (ERSR < FRSR)	PPIVM tests in left extension quadrant are reduced with springy end-feel; both flexion quadrants are normal

ERSL, extended rotated side bent left; ERSR, extended rotated side bent right; FRSR, flexed rotated side bent right; PPAIVM, passive physiologic accessory intervertebral movement; PPIVM, passive physiologic intervertebral mobility.

TABLE 28-13 Causes and Findings of an Extended Rotated Side Bent Left

Causes of an ERSL[a]	Associated Findings
Isolated left joint flexion hypomobility (ERSL); tight left extensor muscles (ERSL)	PPIVM and PPAIVM tests in right flexion quadrant are reduced; PPIVM test in right flexion quadrant is decreased; PPAIVM is normal
Arthrosis or arthritis of left joint in capsular pattern (ERSL < FRSR)	PPIVM and PPAIVM tests are equally reduced in right flexion and left flexion quadrants
Fibrosis left joint (ERSL = FRSR)	PPIVM and PPAIVM tests are equally reduced in right and left flexion quadrants
Right posterolateral disk protrusion (ERSL < FRSL)	PPIVM tests in right extension quadrant are reduced with springy end-feel; both flexion quadrants appear normal

ERSL, extended rotated side bent left; ERSR, extended rotated side bent right; FRSL, flexed rotated side bent left; FRSR, flexed rotated side bent right; PPAIVM, passive physiologic accessory intervertebral movement; PPIVM, passive physiologic intervertebral mobility.
[a]An ERSR would have the same causes and findings, but on the opposite side.

The adjacent spinous processes of the segment are palpated simultaneously, and movement between them is assessed as the segment is passively taken through its physiologic range.

The test is used for acute and subacute patients who have pain in the cardinal motion planes. For these tests, the patient is in the side-lying position, facing the clinician. The clinician may locate the patient's lumbosacral junction using one of the following methods:

- by locating the L5 spinous process and then moving inferiorly;
- by locating the PSIS and moving superiorly and medially;
- by locating the spinous process of T12 and counting down to the correct level using the spinous processes.

Once located, the neutral position of the spine for flexion and extension is found by palpating the L5 spinous process and alternatively flexing and extending the hips until it is felt to rock around the flexion and extension point.

Flexion. The patient is close to the clinician, with the underneath leg slightly flexed at the hip and knee. A small pillow or roll can be placed under the patient's waist to maintain the lumbar spine in a neutral position with respect to side bending. The test can be performed by flexing one or both of the patient's legs, but it is generally easier to use one leg. The clinician, facing the patient, palpates between two adjacent lumbar spinous processes in the interspinous space (Fig. 28-35) with the cranial hand, while the other hand grasps the patient's lower legs (Fig. 28-36).

The patient's lower extremities are moved into hip and lumbar flexion and returned to neutral by the clinician, as the

FIGURE 28-35 Intersegmental palpation.

motion between segments is palpated. Using this general technique, the clinician works up and down the lumbar spine, getting a sense of the overall motion available.

Although there is a high degree of variability in patients, segmental motion should decrease from L5 to L1.[62] A generalized hypermobility demonstrates more motion in all of the segments, whereas an isolated hypermobile segment demonstrates more motion at only that level. Each segment is checked sequentially, while moving the lumbar spine passively from neutral to full flexion.

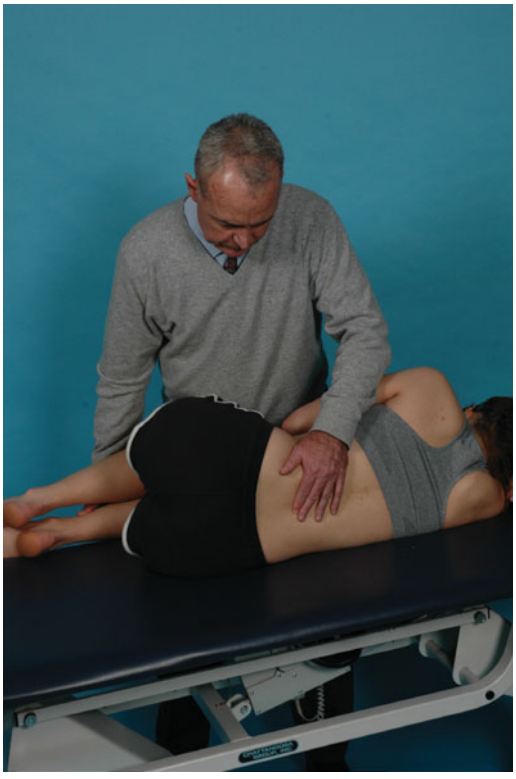

FIGURE 28-36 Passive mobility testing—flexion.

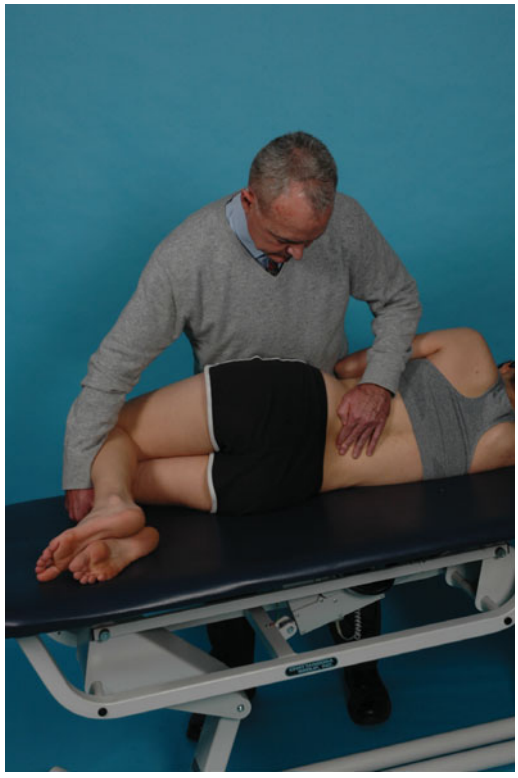

FIGURE 28-37 Passive mobility testing—extension.

For the mid and upper lumbar segments, this technique can be modified for the larger patient by performing it with the patient sitting up.

Extension. Although flexion and extension can be tested together, it is more accurate to assess them separately. The patient is positioned as for flexion testing but is oriented diagonally on the bed so that the pelvis is close to the edge, and the shoulder further from the edge. A small pillow or roll can be placed under the patient's waist to maintain the lumbar spine in a neutral position with respect to side bending. The clinician locates two adjacent spinous processes with his or her cranial hand, while the caudal arm flexes the patient's knees as much as possible before extending the patient's hips (Fig. 28-37). As the patient's knees move off the table, the clinician supports them on his or her thighs. When the patient's legs are on the table, the clinician's caudal arm is used to produce the hip and the lumbar extension. The pelvis motion is felt, and the spine is returned to its neutral position each time.

Side bending. The patient is placed in the side-lying position, with the knees and hips flexed, the thighs supported on the table and the lower legs off the table. The lumbar spine should be in a neutral position in relation to flexion and extension. The clinician, facing the patient, places his or her cranial arm between the patient's arm and body and palpates the interspinous spaces, while the caudal hand grasps under the patient's body (Fig. 28-38). As the patient's trunk is lifted toward the ceiling, the superior spinous process should be felt to move away from the table, as the lumbar spine is side bent toward the table. The opposite direction of sidebend is tested with the patient side-lying on the opposite side. The technique can also be performed using the patient's legs with the direction of the leg lift representing the direction of the side

FIGURE 28-38 Passive mobility testing—side bending.

bending. For example, with the patient in the right side-lying position, right side bending (and left rotation) is introduced by lowering the feet and ankles off the table. The procedure is repeated for the other side, and the two sides are compared.

Rotation. The patient is positioned as described for extension testing in spinal neutral, with both knees being just off the table. A small pillow or roll can be placed under the patient's waist to maintain the lumbar spine in a neutral position. The interspinous spaces are palpated with the cranial hand, which is placed along the lower thoracic spine, with a reinforced index finger resting against adjacent spinous processes from underneath (Fig. 28-39).

The patient's pelvis is stabilized by the caudal hand, while the patient's thorax is rotated toward and away from the clinician, using the cranial hand. As the patient's thorax is rotated away, the spinous process of the upper segment should be felt to rotate toward the table, compared with the spinous process of the lower segment.

The spine is returned to neutral each time, and the clinician progresses up the spine. The process is repeated with the patient side lying on the opposite side.

Unfortunately, the PPIVM tests do not completely exclude such intersegmental impairments as minor end-range asymmetric hypo- or hypermobilities, because the application of side bending or rotation in neutral does not fully flex or extend the zygapophyseal joints, nor is it possible to fully flex or extend both zygapophyseal joints simultaneously. In order to completely flex a particular joint, the opposite joint has to move out of the fully flexed position by using side bending and allowing the increased superior glide of the superior zygapophyseal joint on the opposite joint.

Passive Physiologic Accessory Intervertebral Mobility Tests. The passive physiologic accessory intervertebral mobility (PPAIVM) tests investigate the degree of linear or accessory glide that a joint possesses and are used on segmental levels where there is a possible hypomobility, to help determine if the motion restriction is articular, periarticular, or myofascial in origin. In other words, they assess the amount of joint motion, as well as the quality of the end-feel. The motion is assessed in relation to the patient's body type and age and the normal range for that segment and the end-feel is assessed for pain, spasm or hypertonicity, or resistance to motion.

Several techniques have been proposed over the years to assess segmental mobility of the T10–L5 segments, including P-A pressure techniques (see later discussion). The PPAIVM techniques outlined here are used to confirm the findings of the PPIVM tests, by testing the joint glides of that segmental level, to confirm or refute whether a hypo- or hypermobility exists. Spinal locking techniques may be used to help localize these techniques to a specific level, or to a specific side of the segment. Descriptions of the symmetric techniques follow.

A pillow or towel roll should be placed under the lumbar spine of the patient if side bending of the lumbar spine appears to be occurring when the patient is placed in the side lying position.

Flexion. The patient is in the side lying position, close to the edge of the bed, with the spine supported in the neutral position, the thighs on the table, and the head resting on a pillow. The clinician faces the patient and locates the suspected segment using palpation. The superior segment is stabilized using the cranial hand (see Fig. 28-40). The clinician now flexes the patient's lumbar spine, using the patient's legs, as in the PPIVM test, until motion is felt at the superior spinous process of the monitored segment.

Using the index and middle fingers of the caudal hand, the clinician straddles the transverse processes of the inferior segment and pulls the segment inferiorly, using the caudal

FIGURE 28-39 Passive mobility testing—rotation.

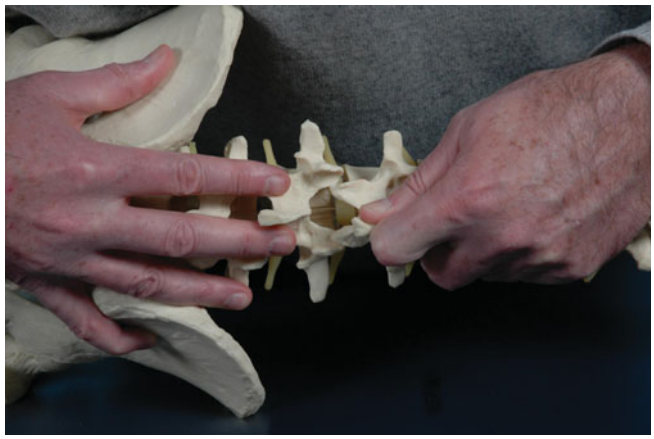

FIGURE 28-40 Passive articular mobility testing for flexion showing stabilization.

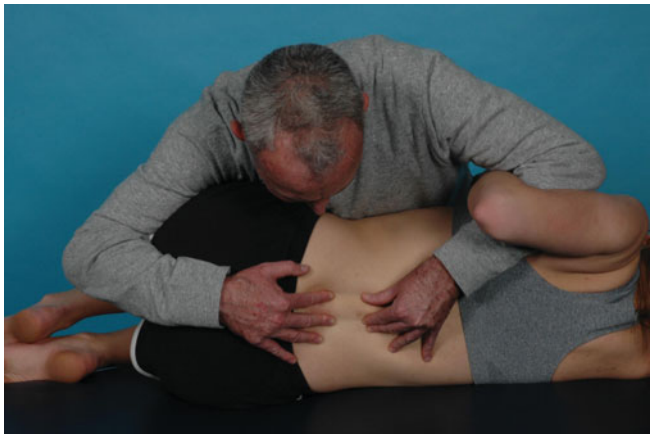

FIGURE 28-41 Passive articular mobility testing for flexion.

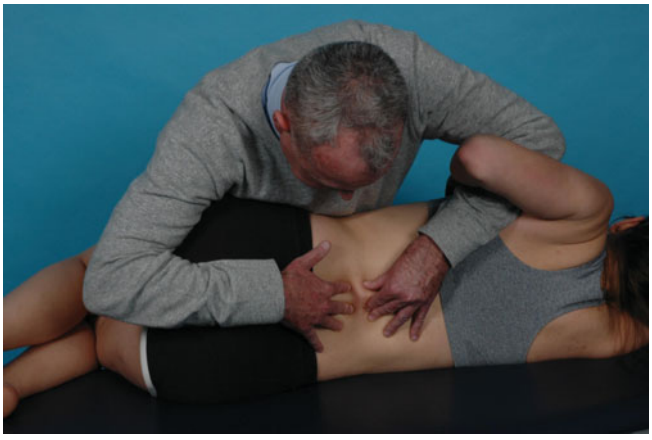

FIGURE 28-43 Passive articular mobility testing for extension.

hand and forearm (Fig. 28-41), thereby indirectly assessing the full superior linear glide of the superior segment. The quality and quantity of the joint glide are assessed.

Extension. The patient and clinician are positioned as in the PPIVM test, with the patient being positioned diagonally on the bed, hips forward, knees well flexed, and head resting on a pillow.

Having located the suspected level, the clinician extends the patient's spine to that level by pushing the patient's legs across the table until the monitoring finger detects motion at the superior spinous process. The superior spinous process of the segment is pinched (see Fig. 28-42) and the joint complex is passively taken into full extension by straddling the transverse processes, as for the flexion technique, and pushing the caudal vertebra anteriorly (see Fig. 28-43). At the end of the available range, the transverse processes of the inferior segment are glided in a cranial direction to test the full linear glide. The quality and quantity of the joint glide are assessed.

Side bending. The patient and clinician are positioned as in the PPIVM test, with the patient's hips forward, knees well flexed, and head resting on a pillow. The side on which the patient lies is determined by the intent of the technique.

- To test the ability of the segment to side bend ipsilaterally (close), the patient lies on the side to be tested.
- To test the ability of the segment to side bend contralaterally (open), the patient lies with the side to be tested uppermost.

Having located the suspected level, the clinician extends or flexes the patient's spine to that level by pushing the patient's legs across the table until the monitoring finger detects motion at the superior spinous process.

The clinician places the axilla of his or her caudal arm over the iliac crest of the patient, while the index and middle fingers of the hand are placed over the spinous processes of the inferior vertebra (Fig. 28-38). The clinician firmly squeezes the patient's pelvis and upper thigh with the caudal arm and applies a force in an inferior direction toward the patient's feet, while the middle finger of the caudal hand pushes the spinous process superiorly.

The quality and quantity of the joint glide are assessed and compared with the other side.

Rotation. The patient is positioned as in the PPIVM test. A small pillow or roll can be placed under the patient's waist to maintain the lumbar spine in a neutral position. The patient's pelvis and the inferior aspect of the caudal spinous process are fixed using the caudal arm and hand, respectively (Fig. 28-44). The thumb of the other hand is placed on the superior aspect of the cranial spinous process.

As the patient's thorax is rotated away, the spinous process of the upper segment should be felt to rotate toward the table,

FIGURE 28-42 Passive articular mobility testing for extension showing stabilization.

FIGURE 28-44 Passive articular mobility testing for rotation.

compared with the spinous process of the lower segment. The quality and quantity of the joint glide are assessed. The spine is returned to neutral each time, and the clinician progresses up the spine. The process is repeated with the patient side lying on the opposite side.

Functional Assessment Tools

Disability and the patient's ability to function may actually be more significant to health care costs than pain alone.[376] Several instruments have been produced in the past 30 years, which can provide reliable and valid methods to quantify a patient's functional status.[377]

Overall, no instrument is probably used more often for assessment of the low back than the Oswestry Low Back Disability Questionnaire (OLBDQ),[378] which has been widely researched and validated by investigators of spinal disorders (see Chap. 5).

The Roland–Morris Disability Questionnaire (RDQ)[379] (Table 28-14) is a health status measure, designed to be completed by patients to assess physical disability due to LBP. The RDQ was derived from the Sickness Impact Profile (SIP), which is a 136-item health status measure covering all aspects of physical and mental function.[380] Twenty-four items were selected from the SIP, and each item was qualified with the phrase "because of my back pain" to distinguish back pain disability from disability resulting from other causes—a distinction that patients are, in general, able to make without difficulty.[380,381]

Patients are asked to place a check mark beside a statement if it applies to them that day, and the score is calculated by adding up the number of items checked. Scores, therefore, range from 0 (no disability) to 24 (maximum disability). RDQ scores have been found to correlate well with other measures of physical function, including the physical subscales of 36-item Short Form Health Survey (SF-36), the SIP, and the OLBDQ.[380]

The Physical Impairment Index (PII), designed by Waddell et al.[235] is a series of seven tests, each scored positive or negative based on published cutoff values (Table 28-15) that tend to provide a measurement of physical impairment in patients with LBP. The final score of the PII ranges between zero and seven, with higher numbers indicating greater levels of impairment. Fritz and Piva[382] in a study of 78 patients with acute (<3 weeks duration) LBP found the PII to have a high interrater reliability (intraclass correlation coefficient = 0.89), and its validity was generally supported by the pattern of correlations. The minimum detectable change on the index was approximately one point.

Fear Avoidance Beliefs Questionnaire (FABQ)[383] (see Chap. 4) was developed, based on theories of fear and avoidance behavior, and focused specifically on patients' beliefs about how physical activity and work affected their LBP. Each item of the FABQ is scored 0–6, with higher numbers indicating increased levels of fear avoidance beliefs. Two subscales are contained within the FABQ: a seven-item work subscale (score range 0–42) and a four-item physical activity subscale (score range 0–24). The subscales of the FABQ have shown good reliability,[384] and previous studies have found the FABQ work subscale to be associated with current and future disability and work loss in patients with chronic[383,385,386] and acute[387] LBP.

TABLE 28-14 The Roland–Morris Disability Questionnaire

When your back hurts, you may find it difficult to do some things you normally do

This list contains sentences that people have used to describe themselves when they have back pain

When you read them, you may find that some stand out because they describe you *today*

As you read the list, think of yourself *today*. When you read a sentence that describes you today, put a tick against it. If the sentence does not describe you, then leave the space blank and go on to the next one

Remember, only tick the sentence if you are sure it describes you today

- ☐ I stay at home most of the time because of my back
- ☐ I change position frequently to try and get my back comfortable
- ☐ I walk more slowly than usual because of my back
- ☐ Because of my back I am not doing any of the jobs that I usually do around the house
- ☐ Because of my back, I use a handrail to get upstairs
- ☐ Because of my back, I lie down to rest more often
- ☐ Because of my back, I have to hold on to something to get out of an easy chair
- ☐ Because of my back, I try to get other people to do things for me
- ☐ I get dressed more slowly than usual because of my back
- ☐ I only stand for short periods of time because of my back
- ☐ Because of my back, I try not to bend or kneel down
- ☐ I find it difficult to get out of a chair because of my back
- ☐ My back is painful almost all the time
- ☐ I find it difficult to turn over in bed because of my back
- ☐ My appetite is not very good because of my back pain
- ☐ I have trouble putting on my socks (or stockings) because of the pain in my back
- ☐ I only walk short distances because of my back
- ☐ I sleep less well on my back
- ☐ Because of my back pain, I get dressed with help from someone else
- ☐ I sit down for most of the day because of my back
- ☐ I avoid heavy jobs around the house because of my back
- ☐ Because of my back pain, I am more irritable and bad tempered with people than usual
- ☐ Because of my back, I go upstairs more slowly than usual
- ☐ I stay in bed most of the time because of my back

Special Tests

Centralization. The patient either stands or lies prone depending on the intent of a loaded or unloaded assessment. Multiple directions of repeated end-range lumbar testing is targeted. Movements may include extension, flexion, or side flexion. Movements are repeated generally for 5–20 attempts until a definite centralization or peripheralization occurs. Centralization of symptoms is considered a positive finding for diskogenic symptoms. In a study by Donelson et al.,[296] the presence of centralization had a sensitivity of 92% and

TABLE 28-15 Physical Impairment Index Along with Scoring Criteria

Test	Performance	Scoring	
		Positive	Negative
Total flexion range of motion	The patient stands erect. The inclinometer is held at T12–L1, and the patient is asked to reach down as far as possible toward the toes, while keeping the knees straight.	Less than 87 degrees	Greater than or equal to 87 degrees
Total extension range of motion	The patient stands erect. The inclinometer is held at T12–L1. The patient is asked to arch backward as far as possible. The clinician may support the patient with one hand on the shoulder for balance.	Less than 18 degrees	Greater than or equal to 18 degrees
Average lateral flexion range of motion	The patient stands erect, with the inclinometer aligned vertically in line with the spinous processes of T9 and T12. The patient is asked to lean straight over to one side as far as possible, with the fingertips reaching straight down the side of the thigh. The clinician may support the patient's shoulder with one hand. The patient repeats the motion to the opposite side. Average lateral flexion is computed.	Less than 24 degrees	Greater than or equal to 24 degrees
Average straight leg raised range of motion	The patient is supine. In inclinometer is positioned on the tibial crest just below the tibial tubercle. The leg is raised passively by the clinician, whose other hand maintains a knee in extension. The leg is raised slowly to the maximum tolerated straight leg raise (not the onset of pain). The opposite leg is tested in the same manner. Average straight leg raising computed.	Males: less than 66 degrees Females: less than 71 degrees	Males: greater than or equal to 66 degrees Females: greater than or equal to 71 degrees
Spinal tenderness	The patient is prone with the back muscles relaxed. Palpation is done slowly without sudden pressure. Superficial tenderness to light-skinned pinch is a test first. The patient is asked "is that painful?" Any response other than "no" is a positive. If superficial tenderness is not present, deep tenderness is assessed by placing firm pressure with the ball of the thumb over the spinous processes and interspinous ligaments within 1 cm of the midline from T12 to S2. Again the patient is asked, "is that painful?" Any response other than "no" is a positive test.	Positive superficial or deep spinal tenderness	Negative superficial or deep spinal tenderness

(Continued)

TABLE 28-15 Physical Impairment Index Along with Scoring Criteria *(Continued)*

Test	Performance	Scoring	
		Positive	Negative
Bilateral active straight leg raise	The patient is supine with the knees extended. The patient is asked to lift both legs together 6 inches off the examining surface and hold that position for 5 s. The clinician should not count aloud or offer encouragement. The patient may not use the hands to lift the legs. If the patient is unable to maintain the lifted position for 5 s, the test is positive.	Positive test	Negative test
Active sit-up	The patient is supine with the knees flexed to 90 degrees and the feet flat. The clinician should hold the patient's feet with one hand. The patient is instructed to reach out with the fingertips to touch (not hold) both knees and hold that position for 5 s. The clinician should not count aloud or offer encouragement. If the patient is unable to maintain the position for 5 s, the test is positive.	Positive test	Negative test

Data from Waddell G, Somerville D, Henderson I, et al: Objective clinical evaluation of physical impairment in chronic low back pain. *Spine* 17:617–628, 1992; Fritz JM, Piva SR: Physical impairment index: Reliability, validity, and responsiveness in patients with acute low back pain. *Spine* 28:1189–1194, 2003.

specificity of 64% (LR+ 2.6; LR− 0.12) as a predictor for symptomatic disks.

The Single-Legged Squat. The single-legged squat (Fig. 28-20) can be used as an indicator of lumbopelvic–hip stability. The test is functional, requires control of the body over a single weight-bearing lower limb and is frequently used clinically to assess hip and trunk muscular coordination and/or control.[388]

Loss of Extension. The patient lies in the prone position. The patient is asked to extend his or her lumbar spine while keeping the pelvis in contact with the treatment table. A positive test for diskogenic symptoms is moderate or major loss of extension. In a study by Laslett et al.[389] using visual observation only found that a loss of extension in predicting symptomatic disks had a sensitivity of 27% and specificity of 87% (LR+ 2.01; LR− 0.84).

Neurodynamic Mobility Testing. The slump, straight (Well) leg raise, bowstring, double straight leg raise, and prone knee flexion tests are described in Chapter 11.

Milgram's Test. Milgram's test is as much an assessment of abdominal muscle strength as it is intrathecal irritability.[275] With legs fully extended, the supine patient is asked to actively raise both feet approximately 2 inches off the table and maintain this position for at least 10 seconds and up to 30 seconds (Fig. 28-45). The inability to perform this test due to muscle weakness is not considered a positive finding within the context of this test, but should nevertheless still be charted.[275]

Posteroanterior Pressures. P-A pressures, advocated by Maitland,[390] are applied over the spinous, mammillary, and transverse processes of this region. The clinician should apply the P-A force in a slow and gentle fashion using the index and middle fingers of one hand, while monitoring the paravertebrals with the other hand (see Fig. 28-46).

Although these maneuvers are capable of eliciting pain, restricted movement, or muscle spasm, or a combination, they are fairly nonspecific in determining the exact level involved, or the exact cause of the symptoms, and have been found to

FIGURE 28-45 Milgram's test.

FIGURE 28-46 P-A pressures.

have poor interrater reliability in the absence of corroborating clinical data.[391,392] In a single-group repeated-measures interrater reliability study by Hicks et al.[393] to determine the interrater reliability of common clinical examination procedures proposed to identify patients with lumbar segmental instability, a consecutive sample of 63 subjects (38 women, 25 men; 81% with previous episodes of LBP) with current LBP was examined by three pairs of raters. The results of the study agreed with other studies, suggesting that segmental mobility testing is not reliable. In fact, in this study, the prone instability test (see later), Beighton–Horan Ligamentous Laxity Scale, and the presence of aberrant motion with trunk ROM demonstrated higher levels of reliability.

CLINICAL PEARL

The Beighton–Horan Ligamentous Laxity Scale[394] measures the following five elements:

- passive opposition of the thumb to the flexor aspect of the forearm (one point per hand);
- passive hyperextension of the fifth metacarpophalangeal joint beyond 90 degrees (one point per hand);
- hyperextension of the elbows by 15 degrees or more (one point per arm);
- hyperextension of the knees (one point per leg);
- forward flexion of the trunk with the knees extended and palms flat on the floor (one point).

All elements are added together to give an overall ligamentous laxity score ranging from 0 (*tight*) to 9 (*hyperlax*).

As a screening tool, the P-A pressures have their uses and can help detect the presence of excessive motion or spasm. However, caution should be exercised when making clinical decisions related to the assessment of motion at a specific spinal level using P-A accessory motion testing. Consider the following example with the patient positioned prone:

- A P-A pressure is applied simultaneously to both transverse processes of the L3 segment. Biomechanically, this produces a relative extension movement of the L2–3 segment, while producing a flexion movement of the L3–4 segment.
- If the spinous process of L3 is pushed to the right, inducing a left rotation of L3, this produces a relative right rotation of L2 on L3, but a left rotation of L3 on L4.

Anterior Stability Test. The patient is in the side-lying position. To test the lower three segments (L3–5), the patient's hips are placed in approximately 70 degrees of flexion and the knees are flexed (Fig. 28-47A). This position is to prevent tightening of the posterior lumbar ligaments, particularly the SSL, which could stabilize the lower three segments and produce a false-negative test result.[373] The clinician stands facing the patient, resting his or her thighs against the patient's knees. The upper segments are stabilized using the cranial hand and the other hand over it. The inferior interspinous space is palpated. The clinician pushes with the thighs, through the patient's knees, along the line of the femur (Fig. 28-47B). This produces a posteriorly directed force to the pelvis, sacrum, and lumbar spine. Any posterior movement of the inferior segment, which is actually a relative anterior movement of the superior segment on the inferior segment, is noted and compared with the next segmental level. There should be little or no movement. To test the upper two segments (L2 and L1), the lumbar spine is flexed by flexing the hips to approximately 100 degrees, and the procedure is repeated. A positive test is one in which there is excessive movement or pain, or both.

Lateral Stability Test. This test does not rely on the objectivity of the end-feel. Instead, an indirect shearing maneuver is used, and the reproduction of pain is considered a positive test.[360,373] The patient lies in the side-lying position facing the clinician, with the lumbar spine positioned in neutral and the hips and knees flexed to approximately 45 degrees. The clinician, using the fleshy part of one forearm, applies a downward pressure to the lateral aspect of the patient's trunk at the level of the L3 transverse process (Fig. 28-48). This produces a lateral translation of the entire lumbar spine in the direction of the bed. The pressure is applied until an end-feel is detected. The test is repeated with the patient side lying on the opposite side.

Prone Instability Test.[393] The patient is positioned prone so that the trunk rests on the bed and their feet rest on the floor, with the hips flexed and the trunk muscles relaxed. The clinician applies a P-A pressure (approximately 4 kg or thumbnail blanching) over the most symptomatic spinous process and any reproduction of symptoms is noted. The clinician then releases the P-A pressure, and the patient is asked to hold onto the sides of the table and to slightly lift his or her feet off the floor (Fig. 28-49). This maneuver produces a cocontraction of the global abdominal, gluteal, and erector

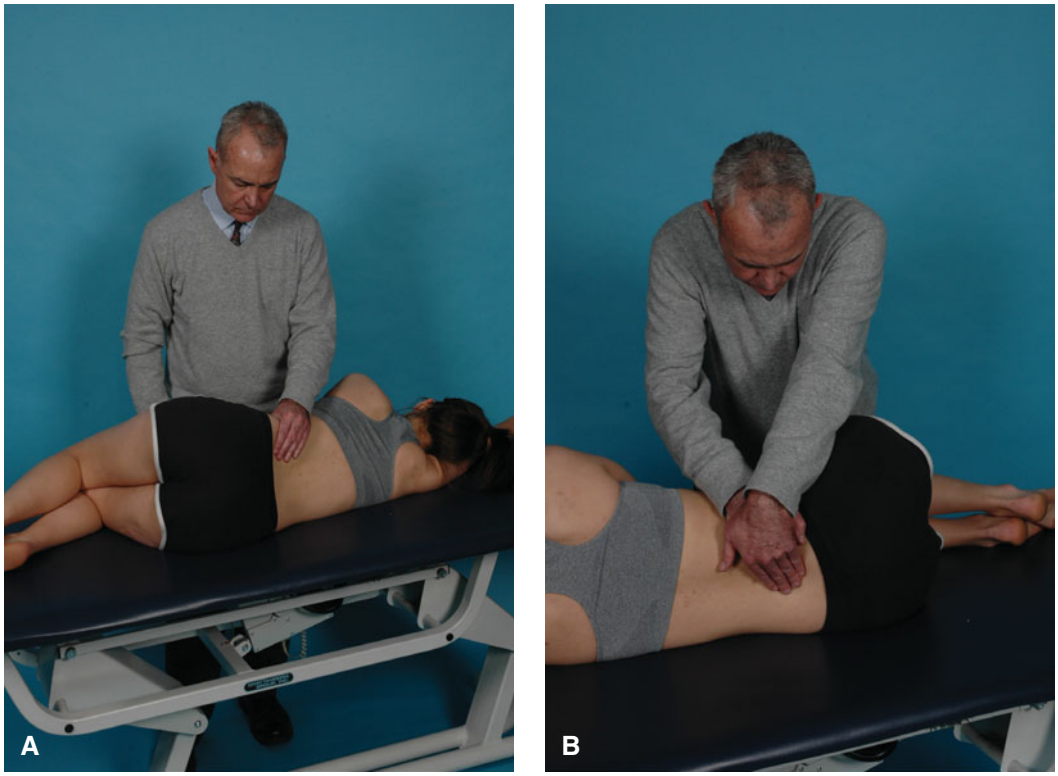

FIGURE 28-47 Anterior stability test. (**A**) Patient position. (**B**) Technique.

spinae muscles. While the patient maintains their feet off the floor, the clinician reapplies the P-A pressure over the same spinous process level. If a dramatic reduction or the complete elimination of the symptoms compared to the first application of P-A pressure is noted (the muscle activity must be able to effectively stabilize the segment), it is considered a positive prone instability test. According to Hicks et al.,[393] patients with LBP, who present with a *negative* prone instability test, are unlikely to respond to a stabilization exercise program.

Passive lumbar extension test.[395] The passive lumbar extension test is used to help detect lumbar spinal instability. The patient lies in the prone position, with the clinician standing at the foot of the bed. The clinician grasps the patient's ankles and, while applying a gentle traction force, raises both of the patient's lower extremities concurrently to a height of approximately 30 cm from the bed, while maintaining the knees extended (Fig. 28-50). Pain, apprehension, or a sense of heaviness in the low back are considered positive findings for this test. The test has been shown to have a sensitivity of 84.2% and a specificity of

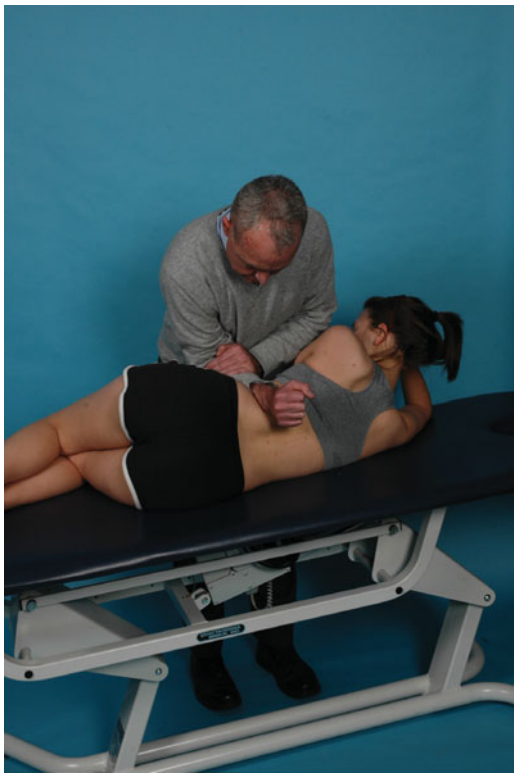

FIGURE 28-48 Lateral stability test.

FIGURE 28-49 Prone instability test.

FIGURE 28-50 Passive lumbar extension test.

90.4%.[395] The positive likelihood ratio of the test was 8.84 (95% confidence interval = 4.51–17.33).[395]

CLINICAL PEARL

A recent systematic review[396] found that the majority of clinical tests routinely employed to diagnose structural lumbar segmental instability demonstrated only limited ability to do so. However, the same study reported that the passive lumbar extension test may be useful in orthopaedic clinical practice to diagnose structural lumbar segmental instability.

Imaging Studies

Plain radiography should be limited to patients with clinical findings suggestive of systemic disease or trauma. Guidelines recommend plain radiography for patients with fever, unexplained weight loss, a history of cancer, neurologic deficits, alcohol or injection–drug abuse, an age of more than 50 years, or trauma.[397] A major diagnostic problem with LBP is that many anatomic abnormalities seen on imaging tests, including myelography, CT, and MRI, are common in healthy individuals.[398,399] The high prevalence of these abnormalities in the absence of symptoms suggests that making causal inferences may be hazardous. In the absence of corresponding clinical findings (from the history and physical examination), these anatomic derangements seem to be irrelevant and inconsequential.[400]

Bulging disks viewed on MRI are commonly implicated as the cause of symptoms. However, bulging disks are more common than not after the age of 50 years and often have little, if any, association with symptoms.[400]

Examination Conclusions

Following the examination, a working hypothesis, or diagnosis, can be established based on a summary of all of the findings. For example, the tests and measures can help to determine

- the presence of a medical diagnosis, such as a spinal stenosis, ankylosing spondylitis, or an IVD protrusion;
- the presence of nonorganic signs. Inconsistencies occurring during the history and examination, which seem to be lacking in any somatic or organic base, have become known as *nonorganic* findings (see "Psychogenic Pain" section in Chap. 5). Nonorganic findings do not necessarily imply a nonexistent or fictitious condition. Waddell[401] developed a series of tests designed to elicit nonorganic responses from patients in whom psychosocial factors are suspected (see Chap. 5).

A pathology-based or biomechanical approach to LBP is based on the notion that LBP results from a deviation of the lumbopelvic complex from its normative physiologic and anatomic state and that by identifying a structural fault, and then correcting that fault, will lead to a dissipation of the signs and symptoms. Tables 28-16 through 28-18 summarize the typical findings in a patient with a biomechanical diagnosis, highlighting both the similarities and the differences between each. The difficulty in identifying a pathoanatomic cause for most patients with LBP has prompted efforts to identify alternative methods of subgrouping, or classifying, affected individuals based on clusters of examination findings. In 1995, Delitto et al.[402] published a treatment-based classification system (see Chap. 22) which proposed four classifications for patients with higher levels of disability, each with a distinct set of examination findings and an associated intervention strategy thought to optimize outcomes for patients in the category. The information gathered from the physical examination and patient self-reports of pain (pain scale and pain diagram) and disability (modified Oswestry Questionnaire) was used to determine whether the patient's condition would be amenable to physical therapy or whether care from another practitioner would be required. The problem with this classification system was that the clusters of examination findings used to make classification decisions and intervention strategies were principally derived from expert opinions and limited available evidence. In 2006, Fritz et al. published a report in an effort to update this decision-making algorithm. Inclusion criteria were age 18–65 years, referred to physical therapy with a primary complaint of LBP less than 90 days in duration with or without referral of symptoms into the lower extremity, and an Oswestry score greater than or equal to 25%. Patients were excluded if a lateral shift or acute kyphotic deformity was visible, if symptoms could not be reproduced with lumbar ROM or palpation, or when signs of nerve root compression were present (positive SLR test and reflex or strength deficits). Patients who were pregnant or had undergone prior surgery to the lumbosacral region were also excluded. A total of 123 patients were included in the trial. The goal of this RCT study was to test the hypothesis that a patient with LBP who received interventions matched to the patient's classification would have

better outcomes than those receiving unmatched interventions. The individual examination items used in the study included standing AROM, repeated extension in standing, repeated flexion in sitting, sustained extension in prone, a recording of the presence of centralization and/or peripheralization, SLR findings, assessment of aberrant movements during flexion/extension, prone instability test with P-A forces applied (see "Special Tests" section), and prone P-A glides. After completion of the baseline examination, patients were randomized into one of three intervention groups (manipulation, specific exercise, or stabilization) and referred to physical therapy. Reliability of ROM, centralization/peripheralization judgments with flexion and extension and the instability test was moderate to excellent. Reliability of centralization/peripheralization judgments with repeated or sustained extension or aberrant movement judgments was fair to poor. Overall agreement on classification decisions was 76% ($\kappa = 0.60$, 95% confidence interval 0.56, 0.64), with no significant differences based on level of experience (Table 28-19).

INTERVENTION STRATEGIES

A number of clinical studies have failed to find consistent evidence for improved intervention outcomes with many intervention approaches.[403] However, recent studies have demonstrated increasing evidence that the subacute-stage postinjury (4–12 weeks) is a critical period in preventing disability.[404]

It is essential that the impairments, functional limitations, and disability found during the examination guide the intervention and that the intervention should be dynamic, should direct the responsibility of the rehabilitative process toward the patient, and should have two principal objectives: to relieve

TABLE 28-18 Interpretation of Findings: Excessive Movement

Hypermobility	Instability
Causes Cumulative stress resulting from neighboring Hypomobility Low level but prolonged overuse Sudden macrotrauma that is not enough to produce instability	*Causes* Sudden macrotrauma (ligamentous) Hypermobility allowed to progress (ligamentous) Degeneration of interposing hyaline or fibrocartilage (articular)
Findings Subjective complaints of "catching" Good days and bad days Symptoms aggravated with sustained positions Negative lower quarter scan	*Findings* Subjective complaints of "catching" Good days and bad days Symptoms aggravated with sustained positions Negative lower quarter scan

Intervention Educate patient to avoid excessive range Take stress off joint (mobilize hypomobility) Anti-inflammatory modalities, if necessary Stabilize, if absolutely necessary	*Intervention* Falls into three areas: 1. Global stabilization a. Educate patient to avoid activities likely to produce instability b. Total body neuromuscular movement pattern reeducation c. Work or sports conditioning and rehabilitation 2. Local stabilization a. Muscular splinting of region (lifting techniques, twisting on feet, and chin tucking when lifting) b. Bracing with supports (collars, corsets, splints, and braces) c. Regional neuromuscular movement pattern reeducation 3. Segmental stabilization: PNF and active exercises to segment

PNF, proprioceptive neuromuscular facilitation; PPIVM, passive physiologic intervertebral mobility.

TABLE 28-19 Decision Making in Classification Patients into Interventions

Classification Group	Factors Favoring	Factors Against
Manipulation	More recent onset of symptom Hypomobility with spring testing LBP only (no distal symptoms) Low FABQ scores (FABQ < 19)	Symptoms below the knee. No pain with spring testing Increasing episode frequency Peripheralization with motion testing
Stabilization	Younger age Positive prone instability test Aberrant motions present Greater SLR ROM Hypermobility with spring testing Increasing episode frequency Three or more prior episodes	Discrepancy in SLR ROM (>10 degrees) Low FABQ scores (FABQA < 9)
Specific exercise	Strong preference for sitting or walking Centralization with motion testing Peripheralization in direction opposite to centralization	LBP only (no distal symptoms) Status quo with all movements

FABQ, Fear Avoidance Beliefs Questionnaire.

the acute pain and to attempt prevention of transition to chronicity.[405]

ACUTE PHASE

In the acute phase of rehabilitation for the lumbar spine, the intervention goals are to

- decrease pain, inflammation, and muscle spasm;
- promote healing of tissues;
- increase pain-free range of segmental motion;
- regain soft tissue extensibility;
- regain neuromuscular control;
- allow progression to the functional phase.

The recommendations concerning bed rest for common, acute LBP have changed over the years.[406] In a 1986 study by Deyo et al.,[407] primary care physicians in the walk-in clinic of a public hospital found that the prescription of 2 days rest was equivalent to a prescription of 7 days in terms of pain and function. Moreover, a prescription of 2 days rest was associated with fewer days of sick leave. In 1995, Malmivaara et al.[408] showed that continuation of daily activity to the extent tolerable resulted in a more rapid recovery than either bed rest or back-mobilizing exercises. The most recent guidelines (2000), based on the results of several randomized studies, advise avoiding bed rest to the extent possible.[409] A study by Rozenberg et al.[405] found that for patients with acute LBP, normal activity is at least equivalent to bed rest. These authors recommended that prescriptions for bed rest, and thus for sick leaves, should be limited when the physical demands of the job are similar to those for daily life activities.[405]

Tissue loading during walking has been found to be below levels caused by many specific rehabilitation tasks, suggesting that walking is a wise choice as an initial aerobic exercise for general back rehabilitation.[483]

Pain relief may be accomplished initially by the use of modalities such as cryotherapy, electrical stimulation, and gentle exercises and occasionally by the temporary use of a spinal brace. Thermal modalities, especially ultrasound, with its ability to penetrate deeply, may be used after 48–72 hours. Patient education should be emphasized during this phase. Information about activities to avoid should be given, in addition to advice about adopting positions of comfort. Once the pain and inflammation are under control, the intervention can progress toward the restoration of full strength, ROM, and normal posture.

Manual techniques during this phase may include myofascial release, grade I and II joint mobilizations, massage, gentle stretching, and muscle energy techniques. Manual or mechanical traction may be used for patients with IVD herniations. Conflicting results from randomized trials and systematic reviews on the effectiveness of manipulation suggest that while some patients respond rather dramatically, others may not experience much improvement.[410] The variety of conclusions in trials of manipulation may be attributable to the failure of researchers to adequately consider the importance of classification. Studies by Flynn et al.[411] and Childs et al.[410] have identified a clinical prediction rule for classifying whether a patient will benefit from spinal manipulation. The five variables identified include

- current episode of LBP less than 16 days duration;
- no symptoms distal to the knee;
- less than 19 points on the FABQ;
- at least one hypomobile segment in the lumbar spine;
- at least one hip internal rotation greater than 35 degrees.

The spinal manipulation used was described as follows. The patient lies in the supine position with their hands clasped behind the neck, and the clinician stands on the side opposite to the site to be manipulated. The patient is passively side bent away from the clinician, by sliding the patient's pelvis toward the clinician. While stabilizing the pelvis against the table with one hand, the clinician then passively rotates the patient's trunk toward them using the other hand. A quick posterior and inferior thrust is then applied by the clinician to the ASIS.

In the Flynn et al. study, the presence of four out of five variables in the CPR increased the likelihood of success with spinal manipulation from 45% to 95%.[411] Using the same CPR, the Childs et al.[410] study compared with patients who were negative on the CPR and received exercise, the odds of a successful outcome among patients who were positive on the CPR and received manipulation were 60.8 (95% CI, 5.2–704.7). The odds were 2.4 (CI, 0.83–6.9) among patients who were negative on the CPR and received manipulation and 1.0 (CI, 0.28–3.6) among patients who were positive on the CPR and received exercise. A patient who was positive on the CPR and received manipulation has a 92% chance of a successful outcome, with an associated number needed to treat for benefit at 4 weeks of 1.9 (CI, 1.4–3.5).

Cleland et al.[412] used this CPR in a case series of patients with LBP, to assess its accuracy for predicting outcomes using other manipulation techniques. Eleven of the 12 patients (92%) in this case series, who satisfied the CPR and were treated with an alternative lumbar manipulation technique, demonstrated a successful outcome in two visits.[412] The study concluded that patients with LBP who satisfy the CPR may obtain a successful outcome with either manipulation technique directed at the lumbopelvic region.[412] The alternative lumbar manipulation technique used in this study was described as follows. The patient is positioned in side lying, and the clinician stands facing the patient. The clinician then flexes the patient's top leg until there is movement detected at the selected segmental interspinous space, at which point the patient's foot is placed in the popliteal fossa of the bottom leg. Next, the clinician grasps the patient's bottom shoulder and arm and introduces trunk side bending toward the table and contralateral rotation until motion is again felt at the specified interspinous space. Maintaining the patient's positional setup, the patient is rolled toward the clinician. Using the arm and body, the clinician applies a high-velocity, low-amplitude thrust of the pelvis in an anterior direction.

A few studies have included flexibility training.[413–415] Only one has showed that flexibility training in an increase in trunk extensor flexibility, [413] although this functional gain was only temporary.

FUNCTIONAL/CHRONIC PHASE

The goals of this phase are

- to achieve significant reduction or to complete resolution of the patient's pain;
- restoration of full and pain-free vertebral ROM;
- full integration of the entire upper and lower kinetic chains;
- complete restoration of respiratory function;
- restoration of thoracic and upper quadrant strength and neuromuscular control.

The number of physical therapy sessions required to provide relief for nonspecific LBP varies widely. The factors provided to explain this variance include the medical diagnosis, duration of the complaint, prior therapy, and the patient's age and gender.[416] Evidence on the effectiveness of physical therapy for the management of chronic spine disorders is limited. A systematic review by the Philadelphia Panel[417] suggested there was "good evidence to include stretching, strengthening, and mobility exercises" in treatment programs directed toward the management of chronic LBP. In the past decade, the results of randomized clinical trials on meta-analysis have provided various degrees of support for the efficacy of specific, nonsurgical physical interventions (that may be delivered by physical therapists) for the management of spine disorders. A number of studies have reported that intensive exercise reduces pain and improves function in patients with chronic LBP.[403,418,419] In addition, exercise programs that combine aerobic conditioning with specific strengthening of the back and legs can reduce the frequency of recurrence of LBP.[420] However, evidence on the efficacy of care specifically provided by physical therapists is more limited.[421–434] Although there is evidence to suggest that some interventions (e.g., exercise, spinal manipulation, massage) that may be delivered by a physical therapist are efficacious in the management of spine conditions, evidence on the efficacy of care specifically provided by physical therapist is less conclusive.[435] The RCTs that have been conducted are all limited because of small sample sizes, heterogeneous samples, or lack of standardized treatments.[435]

Three major exercise protocols for the management of LBP have emerged over the past 40 years: Williams flexion exercises,[436,437] McKenzie exercises,[286,438] and spinal stabilization exercises.[114,439–441] Despite the fact that these exercise protocols are commonly used in clinical practice to treat LBP, very few randomized control trials as to their effectiveness exist to date.[442]

WILLIAMS FLEXION EXERCISES

Dr. Paul Williams first published his exercise program in 1937 for patients with chronic LBP, in response to his clinical observation that the majority of patients who experienced LBP had degenerative vertebrae secondary to degenerative disk disease. According to Williams, "Man, in forcing his body to stand erect, severely deforms the spine, redistributing body weight to the back edges of the intervertebral disks in both the low back and neck."[436]

Conceptually, Williams believed that the goal of exercise was to reduce the lumbar lordosis or to flatten the back through strengthening exercises for the abdominal muscles (to lift the pelvis from the front) and strengthening exercises for the gluteal muscles (to pull the back of the pelvis down). Williams designed a group of six exercises to address these issues:

1. ***Trunk flexion or sit-up.*** Although the instructions that Williams gave to perform this exercise were erroneous, a variation of this exercise, the crunch, forms the cornerstone of many modern exercise protocols.
2. ***Posterior pelvic tilt.*** With the exception of patients with IVD lesions,[443] the posterior pelvic tilt exercise, outlined later, is still widely recommended. However, due to the fact that they can cause increased compression loads on the lumbar spine,[444] they should be prescribed with caution.
3. ***Trunk flexion or bilateral knees to chest.*** Like the posterior pelvic tilt exercise, this exercise is not recommended for patients with IVD lesions. However, it may provide comfort to patients with spinal stenosis.
4. ***Long sit and reach.*** This exercise is no longer recommended because of the stress it places on the soft tissues of the low back. Williams himself acknowledged that this exercise would not be appropriate for patients with sciatica.
5. ***Iliotibial band stretch in the front lunge position.*** Although adaptive shortening of the iliotibial band may be a contributing factor in LBP, as suggested by Williams, better stretches for this structure exist.
6. ***Stand to squat or stand to sit.*** This exercise was recommended because of its ability to strengthen the gluteal muscles. This exercise has since been incorporated into many spinal stabilization protocols.

Although the use of William's exercises has decreased over the years, the exercises are still indicated for those patients who experience an increase in symptoms when moving into spinal extension, and in those cases where the goal is to temporarily widen the intervertebral foramina and gap the zygapophyseal (facet) joints, thereby reducing nerve root compression.

McKenzie Approach

In many respects, the McKenzie approach (see also Chap. 22) contradicts Williams' basic assertions that the lumbar lordosis is harmful. McKenzie initially theorized that the development of LBP is primarily due to three predisposing factors: prolonged sitting in the flexed position, the frequency of flexion, and a lack of extension range.[286] As a result, the early versions of the McKenzie approach focused on regaining spinal extension. The McKenzie approach has since developed into a system that uses physical signs, symptom behavior, and their relation to end-range lumbar test movements to determine appropriate classification and intervention.

The physical examination component of the McKenzie method involves a comprehensive assessment of the patient, performed in a series of active and passive movements performed in the beginning, middle, and end ranges of trunk flexion, extension, and combinations of side bending and

rotation called *side gliding*.[286] The same maneuvers are repeated with the trunk in the neutral position, shifted toward the side of pathology, and away from pathology. The intent is to gauge the responses, reactions, or effects of spinal loading, and for the presence of the centralization phenomenon. The patient's response to the examination determines a classification and the direction of preference for therapeutic exercise, with the direction chosen being based on the ability of the position or movement to centralize the patient's symptoms. The end-range exercises theoretically move the NP away from the side of compression loading, with flexion exercises moving the NP posteriorly and extension exercises moving the NP anteriorly.[286,445–450] The midrange exercises are better suited for patients with symptoms of neural compression.[451] Postural correction and maintenance of a normal lordosis are also integral parts of the McKenzie program.

The three major classifications or syndromes are postural, dysfunction, and derangement. Strategically speaking, when utilizing McKenzie protocols, one should rule out a derangement first before treating anything else.

Postural Syndrome

The key characteristics of the postural syndrome are[452]

- intermittent pain;
- time factor;
- pain produced by maintenance of posture/position;
- symptoms provoked by position, but not by movement;
- no deformity (relevant to pain);
- no loss of movement;
- no provocative signs/no pathology;
- aged 30 years and under (usually);
- sedentary workers (underexercised);
- often have cervical and thoracic pain also;
- often have days at a time without pain;
- no pain while active and moving;
- pain is local to the spine (not referred).

As the postural syndrome is not generally affected by mechanical maneuvers performed by the clinician or the patient, the focus of the intervention is to isolate and subsequently instruct the patient to avoid the offending position(s). The "slouch/overcorrect" maneuver is taught to the patient. The patient should sit on the edge of the chair and allow the lumbar spine to slouch into a fully flexed position and allow the head and chin to protrude. He or she must then smoothly move into a fully erect sitting position, achieving a maximal lumbar lordosis, with the head held directly over the spine and with a retracted chin.[452] This postural motion should be repeatedly performed from the position of "poor" (slouch) posture to the overcorrect position VIDEO.

Dysfunction Syndrome

The key characteristics of the dysfunction syndrome include[452]

- intermittent pain;
- no time factor;
- pain produced at end position or movement of shortened structures;
- pain relief with relief of stress/unloading shortened tissue;
- always a loss of function/movement;
- no deformity (not rapidly reversible);
- test movements reproduce pain but pain does not worsen as a result;
- over 30 years old except where trauma or derangement is causative factor;
- poor posture often underexercised.

The symptoms related to the dysfunction syndrome tend to be related to movement and become evident in the difficulty or inability of the patient to accomplish end range of movement, most frequently in the extremes of flexion and extension. The intervention goal for the dysfunction syndrome is the restoration of function or movement of the adaptively shortened tissue using frequent repetition of restricted end-range exercises. To achieve the lengthening of adaptively shortened soft tissues, the stretches need to be performed daily every 2–3 hours. This usually needs to be continued for a 4–6-week period or until the patient can fully stretch without any end-range pain. The following instructions must be given to the patient[452]:

- Stretch in the direction of movement loss and end-range pain.
- Allow elongation without microtrauma.
- Pain produced by stretching must stop shortly after release of stress (persisting pain afterward indicates overstretching).
- Peripheralization of symptoms should never occur.
- Stretching must be strong enough to reproduce discomfort or some pain.
- Must be performed regularly during the day (15 times/2 hours).

Derangement Syndrome

The key characteristics of the various derangement syndromes are

- often constant pain;
- time factors (diurnal cycle);
- pain brought on or increased by certain movements/positions (repetition/sustaining usually worsens pain);
- pain decreased or abolished by other movements/positions (repetition/sustaining usually improves the condition);
- always a loss of movement/function;
- deformity of kyphosis/scoliosis is common (derangements 2 and 4, respectively—see Chap. 22);
- deformity of accentuated lordosis uncommon (derangement 7—see Chap. 22).

McKenzie classifies derangement of the lumbar spine into seven categories on the basis of the location of symptoms and the presentation of fixed antalgias responsive to end-range loading in directions other than that within which complaints

are caused.[286,453] Derangements that are considered to be *anterior* require strategies containing a flexion component, whereas those that are considered to be *posterior* involve strategies incorporating an extension component. In most cases, these may be conducted within the sagittal plane, but flexion and extension strategies may, in other cases, be combined with coronal or transverse motions for the best mechanical and symptomatic responses.[452] The theoretical model of the derangement syndrome involves the concept of displacement of the nucleus pulposus/annulus.

The intervention goal for the derangement syndrome is to reduce the derangement by altering the position/shape of the nucleus pulposus/annulus using restricted end-range loading for a prolonged period of time and then to maintain the reduction and aid recovery of function.[452] Mechanical treatment is dependent on the mechanical diagnosis for derangements. The interventions for derangements 1–7 are outlined in Table 28-20. The sequential extension progression advocated by McKenzie, initiated once the patient is able to tolerate prone lying (Fig. 28-17), involves prone on elbows (Fig. 28-51), prone push-up (Fig. 28-52) **VIDEO**, and extension in standing (Fig. 28-53) **VIDEO**.

The McKenzie method has been tested for intraobserver variability, with differing results.[297,327,454] In a recent study by Long et al.,[455] the McKenzie approach using exercise prescription based on a directional preference demonstrated significantly better outcomes than comparison groups performing exercise away from a directional preference.

Several outcome studies have examined the effectiveness of the McKenzie method compared with that of other approaches.[456–459] Ponte et al.[456] compared the effectiveness of the McKenzie method with that of the Williams approach and found that the McKenzie method demonstrated greater improvements in pain intensity and lumbar ROM than the Williams protocol. However, this study had a small sample size (22 subjects), and subjects were not randomly assigned but rather assigned by the referring physician to a treatment group.

Nwuga and Nwuga[457] also compared the effectiveness of the McKenzie method with that of the Williams approach. Sixty-two females, aged 20–40 years and all diagnosed with a prolapsed IVD in the lumbar spine, were assigned to either the McKenzie group or the Williams group. Similar conclusions were drawn from this study as from the Ponte study, namely that the McKenzie method demonstrated greater improvements in pain intensity and lumbar ROM than the Williams protocol.[457]

Stankovic and Johnell performed two separate outcome studies (1989 and 1994) that compared long-term patient outcomes following treatment with either the McKenzie approach or with patient education alone in a mini back school.[458,459] A mini back school involves education of the patient in the mechanics of the spine, proper posture, and safe lifting techniques. The 1989 study assessed six variables in 100 employed patients with acute LBP: return to work, sick leave during recurrences, recurrences of pain during the year of observation, pain, movement, and the patient's ability to self-help. The McKenzie method was found to be superior in four of the six variables. The two variables that showed no significant difference were sick leave during recurrences and patient's ability to self-help.[459] The 1994 study was a continuation of the 1989 study and used the same subjects. The later study showed that subjects who received McKenzie treatment had significantly fewer recurrences of pain and current episodes of sick leave compared with the subjects who received mini back school education.[458]

A randomized controlled comparative trial with an 8-month follow-up period was conducted by Petersen et al.,[432] which compared the effect of the McKenzie treatment method with that of intensive dynamic strengthening training in patients with subacute or chronic LBP. Two-hundred and sixty consecutive patients with LBP and at least 8 weeks duration of symptoms (85% of the patients had more than 3 months duration of symptoms) were randomized into two groups: Group A was treated with the McKenzie method ($n = 132$) and Group B was treated with intensive dynamic strengthening training ($n = 128$). The treatment period for both groups was 8 weeks at an outpatient clinic, followed by 2 months of self-training at home. Treatment results were recorded at the end of the treatment period at the clinic, then 2 and 8 months after. The study concluded that the McKenzie method and intensive dynamic strengthening training seem to be equally effective in the treatment of patients with subacute or chronic LBP.

The reasons for the positive measure changes observed in the McKenzie treatments remain unclear.[460] Schnebel et al.[451] suggested that the positive results might be related to activation of the gate control mechanisms or relaxation and/or decompression of neural tissues. Porterfield and DeRosa[461] believed that the application of controlled forces to the spine through active exercise or manual techniques might temporarily reduce pain levels by altering the fluid dynamics of injured tissue.

Spinal Stabilization Exercises

The basic premise in spinal stabilization (core strengthening, dynamic stabilization, trunk stabilization, and lumbopelvic stabilization) exercises is to teach the patient with LBP how to maintain functional levels by dynamically stabilizing the involved segments with increased muscular support. This increased muscular support can then be used to help maintain the neutral zone.

There is evidence suggesting that therapeutic exercise is effective in the treatment of nonspecific back pain,[462–465] although there is insufficient evidence to conclude with absolute certainty which theoretical mechanism of lumbar stabilization would be most beneficial in the management of patients with segmental lumbar instability.[90]

Before the stabilization progression can begin, the involved structures must be permitted to heal beyond the acute stage of healing. This can be achieved with patient education and with exercises that involve only lower and/or upper extremity motion, while avoiding specific trunk exercises and excessive trunk motion (see "Clinical Instability of the Lumbar Spine" section).

Stretching Exercises

Muscle flexibility should be addressed according to patient tolerance. In individuals suspected to have instability, stretching exercises should be used with caution, particularly ones

TABLE 28-20 Intervention of Derangements 1–7

Derangement	Description	Intervention
1	Central or symmetrical pain across L4–5, with rarely buttock or thigh pain and no deformity This indicates a minor posterior disk disturbance	1. Reduction by application of extension principle 2. Maintenance of reduction by a. maintenance of lordosis b. sitting with lumbar support c. frequent performance of extension exercises 3. Recovery of function by a. flexion procedures (lying first), followed by extension procedures: prone lying (Fig. 25-20), prone on elbows (Fig.__new photo), prone push-up (Fig. __new photo), and extension in standing (Fig. __new photo). 4. Prophylaxis: a. Continuation of exercises as directed. Patients can self-treat b. Follow advice (especially regarding the avoidance of, or proper mechanics associated with, prolonged bending and sitting)
2	Central or symmetric pain across L4–5, with or without buttock and or thigh pain, with deformity of lumbar kyphosis Indicates a major posterior-central disk disturbance. A progression of derangement 1 and can easily worsen to a derangement 4 or 6	1. Reduction of deformity until the prone position can be obtained easily 2. Further treatment as for derangement 1
3	Unilateral or asymmetrical pain across L4–5 with or without buttock or thigh pain and no deformity A minor posterolateral disk disturbance A progression of derangement 1	1. Reduction as for derangement 1 2. If no centralization or reduction of pain occurs, the application of unilateral procedures is indicated. 3. Once centralization or reduction of pain is achieved, further treatment as for derangement 1
4	Unilateral or asymmetrical pain across L4–5 with or without buttock or thigh pain and with deformity of lumbar scoliosis Typically a major posterolateral disk disturbance and can be considered a progression of derangement 2 or 3	1. Reduction of derangement: a. Lateral shift correction for lateral component of derangement b. Extension procedures for reduction of posterior component c. Maintenance of lordosis for stabilization of reduction 2. If fol1owing reduction of deformity no centralization occurs the application of unilateral technique is necessary 3. Once centralization is achieved, further treatment as for derangement 1
5	Unilateral or asymmetrical pain across L4–5 with or without buttock or thigh pain. There is leg pain extending below the knee The pathogenesis is a posterolateral disk disturbance with impingement on nerve root and dural sleeve Progression of derangement 3 or 4 Intermittent sciatica may be caused by a disk bulge. Flexion in both standing and lying enhance pain; repetition worsens symptoms. It may be caused by an adhesive or tethered nerve root. This is labeled as an adherent nerve root and flexion in standing enhances pain but repetition does not necessarily worsen the symptoms	Treatment of an adherent nerve root: 1. Stretching by flexion procedures 2. Followed by extension procedures to prevent recurrence of derangement Treatment of disk bulge: reduction of derangement as treatment of derangements 1 or 3

(Continued)

TABLE 28-20 Intervention of Derangements 1–7 *(Continued)*

Derangement	Description	Intervention
6	Unilateral or asymmetrical pain across L4–5 with or without buttock or thigh pain. There is leg pain extending below the knee and a deformity of sciatic scoliosis The most frequent cause is a major posterolateral disk disturbance with impingement on the nerve root and dural sleeve	If movement or postures/positions does not reduce sciatica: no treatment utilizing movement or positions is possible at this stage If sciatica is reduced by movement or positions then proceed with a reduction of deformity as with derangement 2 or further reduction as for derangements 3 and 1
7	A symmetrical or asymmetrical pain across L4–5 with or without buttock and/or thigh pain and a deformity of accentuated lordosis Involves an anterior or anterolateral disk disturbance	Reduction of derangement utilizing flexion procedures

The aim of the intervention in derangement syndrome is to reverse derangement 2–6 by shift correction or extension principle to resemble derangement 1 (centralization).
Data from Heffner SL, McKenzie R, Jacob G: McKenzie protocols for mechanical treatment of the low back. In: Morris C, ed. *Low Back Syndromes: Integrated Clinical Management.* New York, NY: McGraw-Hill, 2006:611–622.

encouraging end-range lumbar flexion.[388] Poor flexibility may cause excessive stresses to be borne by the lumbar motion segments. For example, adaptively shortened hip flexors and rectus femoris muscles can cause an extension and rotation hypermobility in the lumbar spine. Occasionally, stretching both the anterior and the posterior thigh muscles is beneficial. However, most of the time, only one should be stretched, and the decision is based on the diagnosis:

- The patient with spinal stenosis or a painful extension hypomobility, and who responds well to lumbar flexion exercises, should be taught how to stretch the hip flexors and rectus femoris while protecting the lumbar spine from excessive lordosis.
- The patient with a painful flexion hypomobility or IVD herniation, and who responds well to lumbar extension

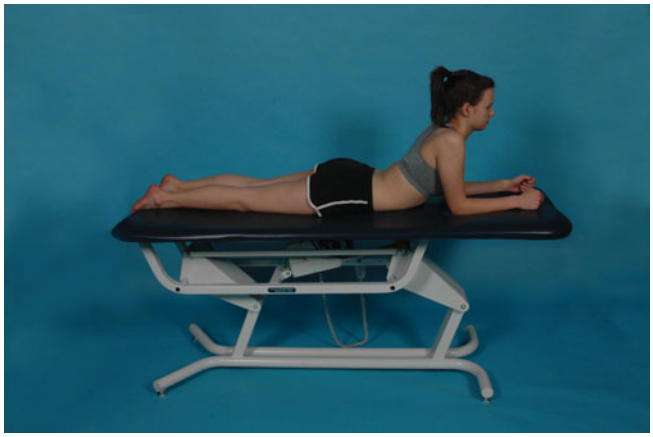

FIGURE 28-51 Prone on elbows.

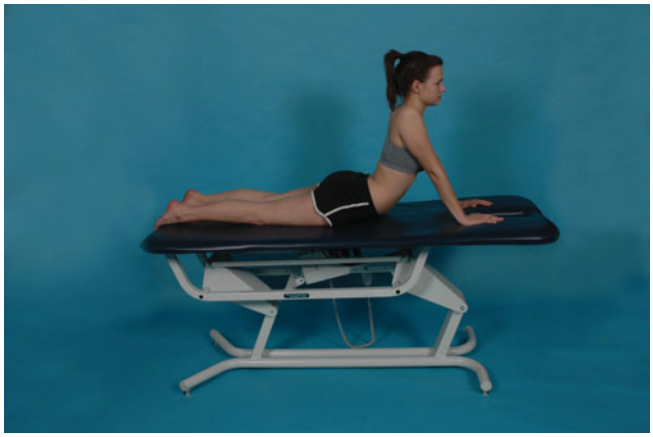

FIGURE 28-52 Prone push-up.

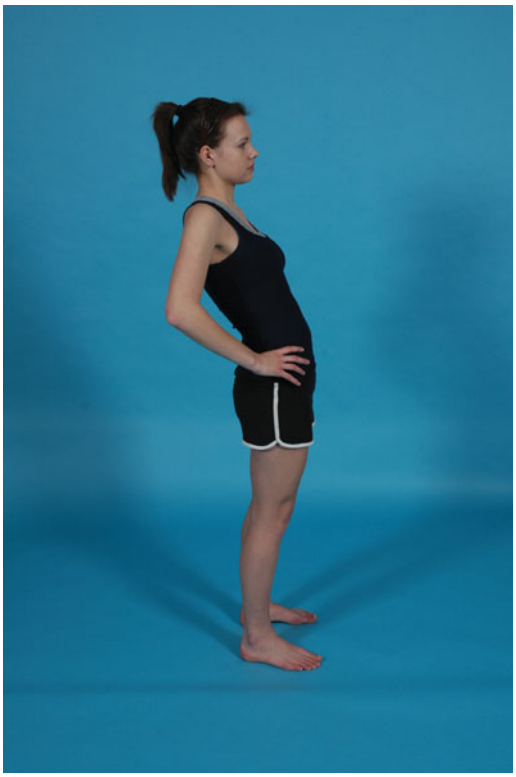

FIGURE 28-53 Extension in standing.

exercises, should be taught how to stretch the hamstrings while protecting the lumbar spine from flexing.

Stretches should be applied and then taught. The goal of stretching is to perform the technique, while maintaining the pelvis in its neutral zone, to avoid excessive anterior or posterior pelvic tilting.

Aerobic Exercise

The importance of aerobic exercise cannot be overemphasized, both in reducing the incidence of LBP[466] and in the intervention for patients who have LBP.[467] Aerobic fitness should be maintained. The following aerobic exercises may be used as tolerated:

- walking and jogging on soft, even ground;
- upper body ergonometer;
- indoor cross-country skiing machines;
- water aerobics.

Proprioceptive Neuromuscular Facilitation

Two of the more commonly used forms of proprioceptive neuromuscular facilitation (PNF) exercises in lumbar spine rehabilitation are rhythmic stabilization training (RST) and combination of isotonic (COI) exercises[468]:

- ***RST technique.*** Uses isometric contraction of antagonist pattern resulting in cocontraction of the antagonist if the isometric contraction is not broken by the clinician. It is used mainly to manage conditions in which weakness is a primary factor and in which stabilization provides stimulation of the agonistic pattern.[469]
- ***COI technique.*** Used to evaluate and develop the ability to perform controlled purposeful movements. It involves the performance of alternating concentric, eccentric, and isometric contractions and is used to treat deficiencies in strength and ROM.[470]

Although previous studies have shown that isometric training can have positive effects on back pain,[468,471] information on the effectiveness of dynamic and combined dynamic–static contraction exercises for trunk muscle stabilization and strength is scarce. Kofotolis and Kellis[468] examined the effects of RST and COI on trunk muscle endurance, flexibility, and functional performance in subjects with chronic LBP. Eighty-six women (40.2 ± 11.9 [mean ± SD] years of age) who had complaints of chronic LBP were randomly assigned to three groups: RST, COI exercises, and control. Subjects were trained with each program for 4 weeks, with the aim of improving trunk stability and strength. The exercises were performed with the patient in sitting over the edge of the treatment table and consisted of the subject flexing and then extending the trunk against the clinician's variable manual resistance and maintaining static positions for 5 seconds. Multivariate analysis of variance indicated that both training groups demonstrated significant improvements in lumbar mobility (8.6–24.1%), static and dynamic muscle endurance (23.6–81%), and Oswestry Index (29.3–31.8%) measurements, suggesting that static and dynamic PNF programs may be appropriate for improving short-term trunk muscle endurance and trunk mobility in patients with chronic LBP.

Back School

Several back schools and back rehabilitation programs have been developed to teach people proper lifting technique and body mechanics. These programs are aimed at groups of patients. They include the provision of general information on the spine, recommended postures and activities, preventative measures, and exercises for the back.

The efficacy of back schools, however, remains controversial.[472,473] Cohen et al.[474] concluded that there is insufficient evidence to recommend group education for people with LBP.

PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM ASSOCIATED WITH LOCALIZED INFLAMMATION

Ligament Tears

As with those elsewhere in the body, ligament tears of the lumbar spine are normally traumatically induced. Knowledge of the various restraints to the various motions of the lumbar spine can aid in determining which ligament has the potential to be sprained with a given mechanism.

Iliolumbar Ligament Sprain

The iliolumbar ligament, an extremely important structure that stabilizes the lumbar spine on the sacrum and functions to anchor the L5 vertebra onto the S1 vertebral body,[73] is commonly injured.

The iliolumbar ligament sprain, also known as the iliac crest syndrome, has a classic presentation of lower lumbar pain just at or above the medial iliac crest area, with radiation sometimes down the leg. On examination, the SLR and Patrick (FABER) sign are both usually negative; there is no weakness or sensory impairment, and no radicular signs. The diagnosis is confirmed by deep palpation of the iliolumbar ligament in an attempt to reproduce the patient's discomfort. Njoo et al.[475] have provided evidence of good interobserver validity in the diagnosis of this problem in a prospective manner. A single injection of lidocaine and steroid provides effective and sustained treatment to this readily accessible area.[476]

Muscle Contusions, Strains, and Tears

Muscle injuries are associated with a history of trauma and are capable of producing a significant degree of discomfort. Two sites are commonly involved in the lumbar region, and strains and tears can occur with relatively little trauma there[477]

1. The point where the erector spinae group of muscles joins to their common tendon just above and medial to the posterior superior iliac spines.
2. At the gluteal origin on the ala of the ilium, just lateral to the posterior superior iliac spines.

However, muscle pain can also be produced from excessive muscle activity or muscle guarding, which follows an injury to the spine. The intervention for muscle tears involves a gradual and controlled resumption of movements and activities.

Diastasis Recti Abdominis

The female anatomy undergoes tremendous changes during the childbearing year.[478] The musculoskeletal changes that may occur during this time include increased ligament laxity, pelvic floor dysfunction, and diastasis recti abdominis (DRA) (see Chap. 30).[109]

It is important for physical therapists to learn the screening skills and know that a DRA has a potential impact on the stability of the pelvis on a long-term basis.

PRACTICE PATTERN 4F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM OR REFLEX INTEGRITY SECONDARY TO SPINAL DISORDERS

Piriformis Syndrome

The sciatic nerve usually travels below the piriformis. In approximately 15% of the population, however, either the tibial part of the sciatic nerve passes through the belly of the piriformis muscle or the piriformis has two muscle bellies and the nerve passes between the two bellies. Consequently, contraction or tightness of the muscle can often produce radicular symptoms (see Chap. 5).

Piriformis syndrome usually is a diagnosis of exclusion once the more common causes of sciatica have been ruled out.[479] Robinson[480] listed six cardinal features of piriformis syndrome: (1) a history of trauma to the sacroiliac and gluteal regions; (2) pain in the region of the sacroiliac joint, greater sciatic notch, and piriformis muscle, extending down the lower limb and causing difficulty in walking; (3) acute exacerbation of the symptoms by lifting or stooping; (4) a palpable, sausage-shaped mass over the piriformis muscle, during an exacerbation of symptoms, which is markedly tender to pressure (this feature is pathognomonic of the syndrome); (5) a positive result on the SLR test; and (6) gluteal atrophy, depending on the duration of symptoms.[479]

The intervention for piriformis syndrome depends on the suspected pathology. If muscular spasm and tightness is the suspected etiology, then an aggressive stretching and massage of the piriformis program should be instituted.[481] If this conservative approach fails, a local anesthetic block to the muscle should be considered. Surgical neurolysis is considered for recalcitrant cases.

Entrapment Neuropathy of the Medial Superior Cluneal Nerve

The cutaneous innervation of the lower lumbar and gluteal regions has been attributed to the posterior (dorsal) rami of L1–L3. Maigne and Maigne[482] observed that the cutaneous innervation of the gluteal region is derived from higher levels of the thoracolumbar region, that is, from T11 to L1. Anastomoses between these nerves are also common. Superior cluneal nerve injury is a well-known cause of chronic pain complicating bone graft harvesting from the posterior iliac crest for spinal fusion.[483,484] The medial superior cluneal (MSC) nerve is the most medial nerve of these nerves. The MSC usually crosses the posterior iliac crest at a distance of approximately 7 cm from the midline.[485] At that point, it becomes superficial by passing through an osseofibrous tunnel, formed by the thoracolumbar fascia cranially and the rim of the posterior iliac crest caudally.[485] This tunnel is occasionally a site of compression for the MSC nerve.[482]

According to Maigne,[485] MSC nerve entrapment can be diagnosed and treated using the following criteria:

- a trigger point over the posterior iliac crest, located 7 cm from the midline (corresponding to the nerve compression zone);
- relief of symptoms by nerve block.

INTEGRATION OF PRACTICE PATTERNS 4H AND 4I: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, ROM ASSOCIATED WITH FRACTURES, JOINT ARTHROPLASTY, AND SOFT TISSUE SURGICAL PROCEDURES

Spondylolysis

Spondylolysis is a defect of the pars interarticularis of the spine. The actual defect in the pars covers a broad range of etiologies, from stress fracture to a traumatic bony fracture with separation.[486] Patients with bilateral pars defects can progress to spondylolisthesis (see the next section).

The exact cause of spondylolysis is unknown, but it is likely related to congenital, acquired (repeated microtrauma), or developmental causes. Spondylolysis commonly is asymptomatic, making diagnosis extremely difficult. Those patients with symptoms often have pain with extension and/or rotation of the lumbar spine. Patients with suspected spondylolysis should be evaluated initially with plain radiography, consisting of anteroposterior, lateral, and oblique views of the lumbar spine. The lateral views are most sensitive for detection of pars fractures, and the oblique views are the most specific.[486,487] If plain radiographs are negative or inconclusive, further imaging may be warranted. Currently, controversy surrounds the questions as to whether MRI, CT, and single-photon emission CT bone scintigraphy are best to further evaluate these patients.[488–490]

The initial management of a patient with spondylolysis is conservative. In a meta-analysis performed by McNeely et al.,[491] the efficacy of physical therapist intervention in the treatment of spondylolysis and spondylolisthesis was systematically reviewed. Of the 71 potential studies, only two of the studies met the relevance criteria of the critical appraisal.[486]

Spratt et al.[492] examined the efficacy of trunk extension and flexion treatment programs on 56 patients with radiographic instability (retrodisplacement or spondylolisthesis).[486] Subjects were randomly assigned to one of three groups: a flexion, an extension, or a control group. The flexion and extension groups performed exercises biased into flexion or extension, respectively.[486] At the 1-month follow-up, no treatments were shown to alter ROM or trunk strength. However, patients in the extension group reported less pain, as compared with patients in the flexion and control groups.[486,492] In a study by O'Sullivan et al.,[190] 45 subjects with spondylolysis or spondylolisthesis were divided into two groups: a group that underwent 10 weeks of rehabilitation, with a focus on training of the deep abdominal muscles, and a control group that underwent treatment as directed by their treating practitioner.[486] The group that underwent specific abdominal exercise training had a reduction in pain and disability levels, which was maintained at a 30-month follow-up.[486] The control group showed no significant change throughout the study.[190]

Based on these studies, the physical therapy intervention should strive to correct any muscle imbalances (adaptively shortened hip flexors), increase trunk muscle strength, and educate the patient to avoid activities involving excessive impact and activities involving lumbar hyperextension. Bracing may also be advocated.

Surgical intervention is indicated only after patients have failed conservative management.

Spondylolisthesis

The term spondylolisthesis refers to an anterior slippage and inability to resist shear forces of a vertebral segment in relation to the vertebral segment immediately below it, which usually occurs in the lumbar spine. The most common site for spondylolysis and spondylolisthesis is L5–S1.[423] Frequently, spondylolisthesis leads to spinal instability—the inability of the spine to maintain its normal pattern of displacement when placed under physiologic load.[31] Under normal conditions, the anterior slippage of the vertebra is resisted by the bony block of the posterior facets, by an intact neural arch and pedicle, and, in the case of the L5 vertebra, by the iliolumbar ligament. Age appears to be an important factor in the natural history of spondylolisthesis. Children younger than 5 years of age rarely present with spondylolysis, and severe spondylolisthesis is equally rare. The period of most rapid slipping is between the ages of 10 and 15 years, with no more slipping occurring after the age of 20.[299] In the adolescent spine, the zygapophyseal joints are more horizontal than in the adult's allowing more side flexion and rotation, and causing the lumbar disk and posterior column structures to sustain a greater responsibility for mobility control.[493] Higher grade spondylolisthesis is twice as common in girls as in boys, and is approximately four times more common in women than men.[494]

The etiology of spondylolisthesis has been discussed extensively in the literature.[76,190,299,487,495–505] Newman[502] described five groups represented by this deformity, based on etiology:

1. ***Congenital spondylolisthesis.*** This type results from dysplasia of the fifth lumbar and sacral arches and zygapophyseal joints.
2. ***Isthmic spondylolisthesis.*** This type is caused by a defect in the pars interarticularis, which can include a fracture or elongation of the pars.
3. ***Degenerative spondylolisthesis.*** This type usually affects older people and occurs most commonly at the L4–5 level. This type is perhaps the most commonly encountered by the orthopaedic physical therapist.
4. ***Traumatic spondylolisthesis.*** This type occurs with a fracture or acute dislocation of the zygapophyseal joint and is fairly rare.
5. ***Pathologic spondylolisthesis.*** This type can result from a pathologic process causing a weakening of the pars, pedicle, or zygapophyseal joint.

Spondylolisthesis acquisita, a sixth etiologic category, was added to represent the slip caused by the surgical disruption of ligaments, bone, and disk.

There are two prevailing theories as to the etiology of degenerative spondylolisthesis:

1. ***Dysfunction of the IVD.***[504] The IVD at the level of the spondylolisthesis is subjected to considerable anteriorly directed shear forces and is the main structure that opposes these shear forces, functioning to prevent against further slippage and keeping the spinal motion segment in a stable equilibrium. It is postulated that slip progression after skeletal maturity is almost always related to IVD degeneration at the slip level. As the biochemical integrity of the IVD is lost, the lumbosacral slip becomes unstable and progresses. Disk degeneration at the slip level and adult slip progression are likely to develop during the fourth and fifth decades of life. This unstable mechanical situation leads to symptoms of low back and sciatic pain and may necessitate spinal instrumentation and fusion.
2. ***Horizontalization of the lamina and the facets or sacrum morphology.***[506] A more trapezoidal shape of the vertebral body, or a dome-shaped contour of the top of the sacrum, or both, are found in individuals with slipping. There is also a greater anterior flexion of the lumbar spine than in "normal" individuals of comparable age.[500] A sagittal orientation of the facet joints also could predispose the vertebra to slip.[497]

Other factors such as the lumbosacral angle, ligamentous laxity, previous pregnancy, and hormonal factors impose an increased stress on the L4–5 facet joints, and, as most of the stress is placed anteriorly on the inferior facet of L4, the wear pattern is concentrated at this point, creating a more sagittally orientated joint by way of remodeling.[499]

Whatever the cause, if the syndesmosis maintains the bonds between the two halves of the neural arch, there is no mechanical instability and the patient is asymptomatic, whereas if the syndesmosis is loose, separation occurs during flexion. Repetitive motions that cause fatigue may advance to an acute, spontaneous pars interarticularis weakening, stress fracture, or fracture and a predilection for spondylolisthesis.[493]

Spondylolisthesis is graded according to the percentage of slip. Slip percentage is the distance from a line extended along the posterior cortex of the S1 body to the posteroinferior corner of the L5 vertebra,[507] divided by the anteroposterior

diameter of the sacrum. Grading is then performed using the Meyerding classification[508] as follows: grade I, 1–25%; grade II, 26–50%; grade III, 51–75%; grade IV, 76–100%; and grade V (spondyloptosis) more than 100%.

The possible pathologic changes at the adjacent instability segment include instability of the motion segment, IVD space narrowing, and stenosis caused by facet degeneration and ligament flavum hypertrophy.[509] Degeneration of the IVD above or below a surgical fusion, and damage to the posterior ligament complex, may also contribute to the development of the lesions, by reducing resistance to shearing forces at the intervertebral level next to the fusion.[509]

The symptoms, if they do occur, usually begin in the second decade. However, there is often no correlation with the degree of slip and the level of symptoms. This is because the anterior slippage of the vertebral body usually results in intervertebral foramen enlargement initially. It is only when the neural arch rotates on the pivot formed by its articulation with the sacrum, or there are anterior osteophytes, that encroachment occurs, resulting in nerve root irritation. Onset during adolescence is often accompanied by an insidious clinical manifestation, exacerbated with lumbar extension and rotation activities and is usually painful but not disabling.[510] Clinically, these patients complain of chronic midline pain at the lumbosacral junction, which is mechanical in nature. Mechanical pain is worsened with activity and alleviated with rest. The symptoms can be exacerbated by repetitive extension and torsion activities.[510] Patients may also complain of leg pain, which can have a radicular-type pattern or, more commonly, will manifest as neurogenic claudication. The spectrum of neurologic involvement runs from rare to more common in the higher grade slips, with the majority of neurologic deficits being an L5 radiculopathy with an L5–S1 spondylolisthesis, but cauda equina impairments can occur in grade III or IV slips. If neurogenic claudication is present, the patient may complain of bilateral thigh and leg tiredness, aches, and fatigue.[498] ROM for flexion of the lumbar spine frequently is normal with both types of claudication. Some patients are able to touch their toes without difficulty. Strength and sensation are usually intact in the lower extremities. The muscle stretch reflexes generally will be normal or diminished. If hyperreflexic symptoms and other upper motor neuron signs, such as clonus or a positive Babinski test, are found, the cervical, thoracic, and lumbar spine should be investigated to rule out a lesion of the spinal cord or cauda equina. Questions regarding bicycle use versus walking can help the clinician to differentiate neurogenic from vascular claudication. Both cycling and walking increase symptoms in vascular claudication due to the increased demand for blood supply. However, patients with neurogenic claudication worsen with walking but are unaffected by cycling due to the differing positions of the lumbar spine adopted in each of these activities. Patients with neurogenic claudication are far more comfortable leaning forward or sitting, which flexes the spine, than walking.[503] The position of forward flexion increases the anteroposterior diameter of the canal, which allows a greater volume of the neural elements and improves the microcirculation. A check of distal pulses is important to rule out any coexisting vascular insufficiency. Findings such as hairless lower extremities, coldness of the feet, or absent pulses are signs of peripheral vascular disease. Sensory defects in a stocking–glove distribution are more suggestive of diabetic neuropathy.

A common clinical manifestation is increased lumbar and hamstring muscular tone, which may be associated with a compensatory response secondary to ineffective stabilization of the painful spinal segment.[510]

Differential diagnosis includes coexisting osteoarthritis of the hip, myelopathy, spinal tumors, and infections.

Differential diagnosis of clinical instability associated with spondylolisthesis often requires several clinical and diagnostic tests.[510] Radiographic findings for these patients can be misleading. Multiple scans including different radiographic views are necessary to avoid imaging era, and failure to investigate lateral and oblique views may lead to misdiagnosis in 20% of cases.[511] In a lateral view, taken while the patient is supine, the forward displacement often appears trivial, because it is only when the patient is standing that the true degree of slip is appreciated. Consequently, if spondylolisthesis is suspected, a lateral spot view of the lumbosacral junction must be taken while the patient stands upright, and during flexion and extension of the trunk.[501] However, a patient with LBP who demonstrates a spondylolisthesis on radiograph may have an asymptomatic spondylolisthesis, and therefore the source of the back pain requires further investigation. Some authors have suggested that manual palpation is effective in detecting spine instability, simply by determining if the motion is greater than that found with hypermobility.[512,513] However, little evidence exists to support the reliability of palpation mechanisms for spinal instability assessment.[510,514,515]

The intervention for spondylolisthesis depends on the presenting symptoms, rather than the degree of slip, and ranges from conservative to surgical. Conservative intervention is more likely to be successful in the case of a limited slip and sparse clinical findings. Such an approach includes pelvic positioning initially to provide symptomatic relief, followed by an active lumbar stabilization program (Table 28-21), and stretching of the rectus femoris and iliopsoas muscles to decrease the degree of anterior pelvic tilting.

In those cases where conservative measures do not provide adequate relief, or the neurological signs and symptoms appear to be progressing, surgery may be required. During the past decade, numerous patients with lumbar degenerative spondylolisthesis have been treated with decompression and fusion with or without instrumentation.[509] A high fusion rate and satisfactory clinical outcome have been reported. However, a few patients present with recurrent back pain and sciatica after surgery. The possible causes of postoperative pain include inadequate decompression, fibrosis, recurrent IVD herniation, adjacent stenosis.[509] Ironically, another cause of postoperative pain is instability of those segments above and below the fusion site.[87]

Lumbago

The term *lumbago* is used to describe local back pain of a diskogenic origin but also can be used to describe a sudden onset of persistent LBP, marked by a restriction of lumbar movements and reports of "locking." The mechanism of mechanical locking is still a contentious issue.[58,129,516] The severity of each episode varies, from incapacitating to minor

TABLE 28-21 A Three-Phase Rehabilitation Program for a Grade 1 Spondylolisthesis

Phase 1	Phase 2	Phase 3
Abdominal isometrics (in neutral, diagonal, and straight planes)	Continued progression of exercises from Phase 1	Continued progression of exercises from Phase 1 and 2
Cocontraction of multifidi and abdominals in flexion	Contralateral arm and leg raises in prone Prone trunk lifts on the Physioball	Increase in distal weighting and lever length using resistance
Isometric abdominal exercises in hook lying	Rhythmic marching during supine stabilization on Physioball	Multifidi exercises in prone
Multifidi contraction in a flexed position		Sitting and standing exercises with outside resistance to target cocontraction during functional activities
Resisted isometrics using cane (to isolate transverse abdominis) in supine	Abdominal crunches on the Physioball Abdominal stabilization during oblique lever changes	Nonlocal muscle strengthening
Cocontraction of the spine during ADLs	Cocontraction of the spine during ADLs	

Data from Cook C, Cook A, Fleming R: Rehabilitation for clinical lumbar instability in a female adolescent competitive diver with spondylolisthesis. *J Man Manip Ther* 12:91–99, 2004.

discomfort. Although it can occur at any age, lumbago typically affects patients between the ages of 20 and 45 years. The mechanism of injury usually involves a sudden unguarded movement of the lumbar spine, involving either flexion or extension combined with rotation or side bending.

Hypomobilities can be classified as symmetric or asymmetric. If both sides of the joint are involved, the lesion is symmetric, whereas if only one side is involved, the lesion is asymmetric.

INTEGRATION OF PREFERRED PATTERNS 4BAND 4F: IMPAIRED JOINT MOBILITY, MOTORFUNCTION, MUSCLEPERFORMANCE, ROM SECONDARY TO IMPAIRED POSTURE, SYSTEMIC DYSFUNCTION (REFERRED PAIN SYNDROMES), SPINAL DISORDERS, AND MYOFASCIAL PAIN DYSFUNCTION

Postural Syndromes of the Lumbar Region

Symmetric impairments of the lumbar spine occur as a result of either acute pain or myofascial and articular tissue shortening from a fixed postural impairment.[86,134,183,187]

A symmetric impairment will not be apparent in the flexion and extension position tests, because, as both are equally impaired, there is no deviation from the path of flexion or extension, but rather the path is shortened or lengthened, depending on which type of impairment (hypomobility or hypermobility) is present. In addition, there is no apparent loss of side bending or rotation, and both sides appear equally hypomobile or hypermobile, with no change in the axis of rotation, except in the case where it ceases to exist, as in bony ankylosis.

Lower Crossed Syndrome[134,517]

In this syndrome, the erector spinae and the iliopsoas are tight, and the abdominal and gluteus maximus are weak (see Chap. 6). This syndrome results in an anterior pelvic tilt, an increased lumbar lordosis, and a slight flexion of the hip. A number of muscles are adaptively shortened in this syndrome, including the gastrocnemius, soleus, hip adductors, and hip flexors. The hamstrings also are frequently shortened in this syndrome, and this may be a compensatory strategy to lessen the anterior tilt of the pelvis[518] or a result of the weak glutei. Common injuries associated with this syndrome include hamstring strains, anterior knee pain, and LBP.

INTEGRATION OF PRACTICE PATTERNS 4D AND 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, ROM ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION, AND LOCALIZED INFLAMMATION

Lumbar Disk Pathology

Back pain, with or without radiculopathy, is a significant clinical problem. A large percentage of the mechanical causes of back pain, particularly LBP, are attributed to pathologies of the IVD. IVD herniation in the lumbar spine may occur from adolescence into old age. Degenerative changes are the body's attempts at self-healing as the body ages. If part of this healing

TABLE 28-22 Comparison of Degeneration and Degradation of the Disk

Degeneration	Degradation
Changes occur to biochemistry in early adulthood and middle age	Vasculogenic degradation of nucleus
Circumferential clefting and tearing of anulus	Circumferential and radial tearing of annulus
No migration of nucleus	Nucleus migrates through radial fissures
Undisplaced	Nucleus herniates through anulus
Disk maintains or increases height	Disk is reabsorbed

involves the stabilization of an unstable joint, the joint motion can be reduced by muscle spasms or by increasing the surface area of the joint.[519] The biology of IVD degeneration is not well understood, but is thought to be a normal process, as opposed to the pathologic process that occurs with degradation (see Table 28-22 and later discussion).

The diagnoses associated with degenerative disk disease include

- idiopathic LBP;
- lumbar radiculopathy;
- myelopathy;
- lumbar stenosis;
- spondylosis;
- osteoarthritis;
- degenerative disk disease;
- zygapophyseal joint degeneration.

Disk degeneration appears to involve a structural disruption of the AF and cell-mediated changes throughout the IVD and subchondral bone.[520] Kirkaldy-Willis proposed a system to describe the spectrum of degeneration involving three stages or levels.[75] The three stages, which have essentially withstood the test of time, are defined as early dysfunction, intermediate instability, and final stabilization.

1. ***Early dysfunction.*** This stage is characterized by minor pathologic changes resulting in abnormal function of the posterior elements and IVD.[521] Autopsy results show that disk degeneration begins as early as 20–25 years of age.[291] Disk herniation most commonly occurs at the end of this stage, as splits and clefts develop in the annulus, but may also occur during the last stage. Degeneration seems to start early in the upper lumbar spine, with end plate fractures and Schmorl's nodes related to the vertical loading of those segments.[46] A Schmorl's nodule represents a dislocation of cartilage tissue through the end plate into the vertebral body. One study[522] provided evidence that a family history of operated lumbar disk herniation has a significant implication in lumbar degenerative disk disease, indicating that there may be a genetic factor in the development of lumbar disk herniation as an expression of disk degeneration.
2. ***Intermediate instability.*** This stage is characterized by laxity of the posterior joint capsule and AF. Disruption of the AF is associated with back pain.[523] All skeletal tissues adapt to increased mechanical demands, but they may not always adapt quickly enough. People who suddenly change to a physically demanding occupation may subject their tissues to an increase in repetitive loading, causing fatigue damage to accumulate rapidly. The ability of spinal tissues to strengthen in response to increased muscle forces may be restricted by health and age, so that fatigue damage accumulates most rapidly in sedentary middle-aged people who suddenly become active.[524]
3. ***Final stabilization.*** This stage is characterized by fibrosis of the posterior joints and capsule, a loss of disk material, the formation of radial tears of the AF, and osteophyte formation.[525] Osteophyte formation around the three-joint complex increases the load-bearing surface and decreases the amount of motion, producing a stiffer and thus less painful motion segment.[520]

Clinical experience has shown that it is possible for the three-joint complex to go through all of these phases with few symptoms generated.

Disk Degradation

Disk degradation is a more aggressive process than the degenerative changes that occur with aging, and although the macroscopic changes are similar to those of age-related degeneration, degradation is a more accelerated process.

Under normal conditions, the NP is contained by the AF. Any disturbance of the balance of these tissue structures may lead to tissue destruction, functional impairment, and LBP.[32] Three main types of lumbar disk herniation are recognized:

1. ***Contained (protrusion).*** With a contained herniation, the nuclear material bulges outward through the tear to strain, but not escape from, the outer AF or the PLL. Contained herniations are confined to the central canal. The disk bulges against the dura and the PLL, producing a dull, poorly localized somatic-type pain in the back and sacroiliac region. Regarding the modes of lumbar disk herniation, Yasuma et al.[526] described the degenerative process of the matrix and concluded that most herniations are protrusions of the NP that occur before the age of 60 years, whereas after that age, prolapse of the AF predominates. Eckert and Decker[527] and Taylor and Akeson,[528] however, found cartilaginous end-plate fractures in 60% of herniated masses, and in approximately 50% of sequestrated fragments, respectively. Because the NP is usually still contained, the patient is likely to feel more pain in the morning after the NP has imbibed more fluid, because of the added volume and the subsequent increase in pressure on pain-sensitive structures. Recent attention has been given to the internal disruption of the NP in a contained herniation.[529] In this condition, the NP becomes inflamed and invaginates itself between the annular layers. Compression of the disk during sitting and bending

increases the pain, because the nociceptive structures within the AF are further irritated. There is usually no, or minimal, leg pain and no, or minimal, limitation in the SLR test (see Chap. 11).[529]

2. ***Extrusion (prolapse).*** With extrusion, the nuclear material remains attached to the disk but escapes the AF or the PLL to bulge posterolaterally into the intervertebral canal. Once a tear to the periphery is opened for the NP, it would seem logical that further stresses can force it to migrate through the tear. However, under normal conditions, the nuclear material is intrinsically cohesive and does not herniate through the AF, even if the AF fibers are weakened by a radial incision.[530]
3. ***Sequestration.*** The migrating nuclear material escapes contact with the disk entirely and becomes a free fragment in the intervertebral canal.

As part of its unnatural history, the disk may or may not travel through each stage of herniation sequentially, producing symptoms that range from backache to bilateral radiculopathy.

Nerve Compression

Extrusions and sequestrations impinge on nerve tissue. Central prolapses, although relatively rare, may produce upper motor neuron impairments if they are sufficiently large to compress the cervical or thoracic spinal cord, and bowel or bladder impairments if they occur in the lumbar spine (cauda equina syndrome).[531] A substantial compression of the root affects the nerve fibers, producing paresthesia and interference with conduction. In 1934, Mixter and Barr suggested that tissue of the IVD extrudes into the spinal canal, compressing and therefore irritating the nerve root and causing sciatic pain.[532] Although this concept was widely accepted for many years, it has now been demonstrated that mechanical compression of the nerve root alone does not explain sciatic pain and radiculopathy.[533–535] The operative finding that mechanically compressed nerve roots become tender, and results of recent histologic and biochemical studies on herniated lumbar disk tissue, led to the notion of inflammatory induced sciatic pain.[533–536] More recent models of lumbar radiculopathy suggest that the underlying mechanisms probably result, in part, from a local chemical irritant such as proteoglycans released from a disk and creating an inflammatory reaction, an autoimmune reaction from exposure to disk tissues, an increased concentration of lactic acid or a lower pH around the nerve roots.[534,537] Investigators have repeatedly demonstrated inflammatory cells, proinflammatory enzyme phospholipase A2, immunoglobulins, and various inflammatory mediators in herniated disk tissues.[533,538] It is also thought that neovascularization in herniated disk tissue could promote the formation of granulation tissue,[535,536,539] and in association with blood vessels, deposits of immunoglobulins have been reported.[534]

The presence of inflammation in disk herniations could explain the clinical findings of improvement in radicular pain following the administration of corticosteroid or nonsteroidal anti-inflammatory drugs (NSAIDs).

The diagnosis of a disk herniation is based largely on the history and physical examination findings and, on occasion, imaging test results. The patient's complaints of pain usually are related to the following factors:

- Whether excessive imbibition or excessive dehydration has occurred to the disk.[346] Excessive imbibition, which results from a prolonged absence from compressive forces, may place a mechanical stress on the innervated outer AF, or other posterior structures, resulting in pain and decreased mobility following recumbency. Dehydration of the disk results from the application of prolonged compressive forces, which reduces the size of the disk and allows for excessive translational segmental mobility and compression on normally unloaded segmental structures.[346] This mechanism results in increased symptoms and decreased mobility as the day progresses.
- Whether the nerve root is involved. An ischemic nerve root responds with an increase in symptoms if a movement increases compression to the nerve root.[346] Such movements include lumbar extension and ipsilateral side bending. This is probably why patients with nerve root involvement adopt a posture of flexion and contralateral side bending, although occasionally this posture can result in an increase in symptoms because of an increase in tension and a decrease in intraneural circulation.[346] In these cases the patient is likely to adopt a posture of flexion and ipsilateral side bending.

The ability of the disk to maintain its hydrostatic pressure is a factor of previous extrusions or sequestrations, disk surgery, and the degree of disk degeneration.[157,520] Theoretically, if the hydrostatic pressure is maintained following a posterolateral disk protrusion, the patient will have increased pain with flexion, flexion with contralateral rotation, or side bending.[346] These symptoms tend to be increased with repetition of those motions but improved with motions in the opposite directions, although initially those symptoms may increase, depending on the position of the NP.[346]

Imaging results can be misleading. Anatomic evidence of a herniated disk is found in 20–30% of imaging tests (myelography, CT, and MRI) among normal persons.[228,398,399] Conventional physical examination for a suspected disk herniation consists of tests for key muscle strength and lumbar ROM, and muscle stretch reflex and sensory testing, and dural mobility tests such as the SLR test. It must be remembered that no single test in the physical examination has a high diagnostic accuracy alone for disk herniation.[280]

Several plausible diagnoses, depending on the distribution of symptoms, must be eliminated before a lumbar radiculopathy can be confirmed. These include

- hip joint pathology (degenerative joint disease, avascular necrosis, synovitis, etc.)[540];
- meralgia paresthetica. This syndrome, also known as Bernhardt–Roth syndrome, is characterized by pain or dysesthesia in the anterolateral thigh, caused by entrapment of the lateral cutaneous (femoral) nerve of the thigh at the ASIS (see Chap. 5). Trummer et al.[541] reported that lumbar disk herniation could mimic meralgia paresthetica, and Kallgren and Tingle[542] noted that meralgia paresthetica

could mimic lumbar radiculopathy because of the similarity of the symptoms.

- irritation of the spinal nerve root by osteophytic spurs;
- sacroiliac or pelvic dysfunction;
- intermittent claudication of the iliac or iliofemoral arteries;
- spondylolisthesis;
- lateral recess stenosis;
- muscle strain;
- stress fracture of the lumbar/thoracic vertebra (burst and compression);
- neoplasm;
- isolated peripheral nerve injury or neuritis;
- diabetic amyotrophy, which is relatively uncommon but can occasionally be the presenting symptom of uncontrolled diabetes mellitus.[543]

The differential diagnosis can be aided by a description of the distribution of the patient's symptoms and the results of the physical examination.

High Lumbar Disk Lesions

From 1% to 11% of herniated disks originate from the L1–2, L2–3, or L3–4 levels.[544–546] Reduced motion and stress at the upper lumbar spine and the protective influence of the PLL may account for the disparity.[546]

CLINICAL PEARL

A number of studies have shown that with increasing age, lumbar disk herniation is more cranially localized so that higher level disk injuries are more common in advanced age.[547] Because of the nerve root anatomy previously discussed, a herniation at these high levels may occur without compromise to the nerve root, and may thus go undetected.

If symptoms are present, the high lumbar radiculopathy typically does not radiate pain down the back of the leg but, instead, causes an insidious onset of pain in the groin or anterior thigh that is often relieved in a flexed position and worsens with standing.[548] The superficial cremasteric reflex is also invariably present.[315]

The differential diagnoses for upper lumbar nerve root symptoms include spondylolisthesis and an infective cause, such as diskitis or an epidural abscess.

Third Lumbar Nerve Root Compression

The clinical findings with a lesion at this level may include

- pain in the midlumbar area, upper buttock, whole anterior thigh and knee, medial knee, and just above the ankle;
- dural signs of prone knee flexion and, occasionally, a positive SLR;
- significant motion loss of extension;
- slight weakness of iliopsoas and grosser loss of quadriceps;
- hypoesthesia of the medial aspect of the knee and lower leg;
- absent or reduced patellar reflex.

TABLE 28-23 Common Radicular Syndromes of the Lumbar Spine

Disk Level	Nerve Root	Motor Deficit	Sensory Deficit	Reflex Compromise
L3–4	L4	Quadriceps	Anterolateral thigh	Knee Anterior knee Medial leg and foot
L4–5	L5	Extensor hallucis longus	Lateral thigh	Medial hamstrings Anterolateral leg Mid posterior (dorsal) foot
L5–S1	S1	Ankle plantar flexors	Posterior leg	Ankle Lateral foot

Data from American Medical Association: *Guides to the Evaluation of Permanent Impairment*, 5th ed. Chicago: American Medical Association, 2001.

Fourth Lumbar Nerve Root Compression

Approximately 40% of IVD impairments affect this level, about an equal amount as those that affect the L5 root.[33] A disk protrusion at this level can irritate the fourth root, the fifth root, or, with a larger protrusion, both roots (Table 28-23). The clinical findings with a lesion at this level may include

- pain located in the lumbar area or iliac crest, inner buttock, outer thigh and leg, and over the foot to the great toe;
- positive dural signs of SLR, bilateral and crossed SLR, and neck flexion (see Chap. 11)[311];
- marked lateral deviation of the lumbar spine and gross limitation of one side flexion (both common findings);
- weak dorsiflexion of the ankle;
- hypoesthesia of the outer lower leg and great toe;
- diminished tibialis posterior, patellar, and tibialis anterior muscle stretch reflexes.

Fifth Lumbar Nerve Root Compression

This level is affected as often as the fourth nerve root and is frequently compressed by the L4–5 disk as well as the L5–S1 disk (see Table 28-23). The clinical findings with a lesion at this level may include

- pain in the sacroiliac area, lower buttock, lateral thigh and leg, inner three toes, and medial sole of the foot;
- positive unilateral SLR and neck flexion[311];
- lateral deviation during flexion;
- weakness of peroneal, extensor hallucis, and hip abductor muscles;
- hypoesthesia of outer leg and inner three toes and medial sole;
- diminished fibularis (peroneus) longus, Achilles, and extensor hallucis muscle stretch reflexes.

First, Second, and Third Sacral Roots

According to Cyriax, the first, second, and third sacral roots can be compressed by a fifth lumbar disk protrusion. The clinical findings with a lesion at the S1 level (see Table 28-23) may include[343]

- pain in the low back to buttocks to sole of the foot and heel;
- limited SLR;
- weakness of the calf muscles, peronei, and hamstrings;
- atrophy of the gluteal mass (but weakness is not always detectable);
- hypoesthesia in the outer two toes, outer foot, and outer leg as far as the lateral aspect of the knee.

With a second sacral root palsy, the signs are the same as for the first sacral nerve root, except that the fibularis (peroneal) muscles are spared and the hypoesthesia ends at the heel. With third sacral root palsy, the SLR is generally normal and no palsy is detectable. However, the patient may report pain in the groin, and pain down the inner aspect of the thigh to the knee.[531]

Fourth Sacral Nerve Root Compression

A lesion of this nerve root is always a concern, because a permanent palsy may lead to incontinence and impotence.[531,549] The clinical findings with a lesion at this level may include

- pain in the lower sacral, peroneal, and genital areas;
- saddle area paresthesia;
- no positive dural signs;
- possible gross limitation of all lumbar movements;
- bladder, bowel, or genital dysfunction;
- positive superficial anal reflex and reduced anal wink.[315]

Vertical Prolapse (Schmorl's Node)

A Schmorl's node is the herniation of disk substance through the cartilaginous plate of the IVD into the body of the adjacent vertebra.[550] These vertical prolapses of the disk are often asymptomatic and occur as incidental findings on radiographs. Indeed, a chronic Schmorl's node has been reported to be the most common impairment of the IVD and of the whole spine.[551] Schmorl's nodes tend to be more common in men than in women, a factor attributed to the greater spinal loads in men.[550] Theories proposed to explain the pathogenesis of Schmorl's nodes include origins that are

- developmental, in which embryonic defects such as ossification gaps, vascular channels, and notochord extrusion defects form points of weakness where Schmorl's nodes may occur[26];
- degenerative, in which the aging process produces sites of weakness in the cartilaginous endplate, resulting in formation. of Schmorl's nodes[551,552];
- pathologic, where diseases weaken the IVD and/or vertebral bodies[553,554];
- traumatic, in which acute and chronic trauma destroy the cartilaginous end plates, resulting in disk herniation.

Although most orthopedists accept that Schmorl's nodes occur because of trauma, no studies have shown a direct causal relation between a traumatic episode and the formation of an acute Schmorl's node.

Once the Schmorl's node has occurred, subsequent proliferation of cartilage and reactive ossification may develop in the vicinity of the dislocated tissue.[132] This ossification encloses the dislocated tissue and segregates it from the spongiosa of the vertebral body. The formation of this cartilaginous cap, or calcification of the protrusion, may act to resist its expansion.[22]

Intervention

The natural history of radiculopathy and disk herniation is not quite as favorable as for simple LBP, but it is still excellent, with approximately 50% of patients recovering in the first 2 weeks and 70% recovering in 6 weeks.[555] Prognostic factors for positive outcome with conservative intervention for lumbar disk herniation are depicted in Table 28-24.

CLINICAL PEARL

Intervention focuses on a return to normal activities as soon as possible, patient education and involvement, and therapeutic exercises.

Complete bed rest is not recommended in the first 4–6 weeks after onset of symptoms.[556,557] Surgery is often recommended after 4–6 weeks, if the symptoms persist, following MRI and CT scan findings.[558] However, of those who opt for surgery, 10–40% will complain of pain, motor dysfunction, or reduced activity of daily-living performance after surgery.[559,560] Ito et al.[558] showed that if patients with herniated lumbar disk could tolerate the symptoms of disk herniation for 2 months after onset of symptoms, it was possible to treat them with conservative approaches.[559] Using CT scan techniques, it was shown that 66% of herniated disk cases may normalize or recover either totally or partially with time and that large lumbar herniated nucleus propulsions can decrease and even disappear in some patients treated successfully with conservative care.[559,561] The McKenzie exercise program can be valuable to the overall intervention strategy and, if centralization of pain occurs, a good response to physical therapy can be anticipated.[297,459] In addition to the usual history taken, the McKenzie method makes particular inquiries regarding

- whether the symptoms are constant or intermittent;
- the topography of the symptoms;
- whether the symptoms are better or worse with bending forward, sitting, rising from sitting, standing, walking, lying, rising from lying, when still, and/or on the move. Much of this information can be gained by asking the patient which activities of daily living produce the symptoms.

In cases of radiculopathy, the goal is to decrease radiating symptoms into the limb and, thus, to centralize the pain by using specific maneuvers or positions, such as the lateral shift correction (Fig. 28-8) VIDEO. Once this centralizing position is identified, the patient is instructed to perform these

TABLE 28-24 Prognostic Factors of Positive Outcome with Conservative Intervention for Lumbar Disk Herniation

Outcome	Factor
Favorable	Absence of crossed SLR
	Spinal motion in extension that does not reproduce leg pain
	Relief or >50% reduction in leg pain within first 6 wks of onset
	Limited psychosocial issues
	Self-employed
	Educational level >12 yr
	Absence of spinal stenosis
	Progressive return of neurologic deficit within first 12 wks
Unfavorable	Positive crossed SLR
	Leg pain produced with spinal extension
	Lack of >50% reduction in leg pain within first 6 wks of onset
	Overbearing psychosocial issues
	Worker's compensation
	Educational level <12 yr
	Concomitant spinal stenosis
	Progressive neurologic deficit
	Cauda equina syndrome
Neutral	Degree of SLR
	Response to bed rest
	Response to passive care
	Gender
	Age
Questionable	Actual size of lumbar disk herniation
	Canal position of lumbar disk herniation
	Spinal level of lumbar disk herniation
	Lumbar disk herniation material

SLR, straight leg raising.
Data from Saal JA: Natural history and nonoperative treatment of lumbar disc herniation. *Spine* 21:2S–9S, 1996.

maneuvers repetitively or sustain certain positions for specific periods throughout the day.[535]

In addition, the patient is instructed in a lumbar stabilization program, in which neutral zone mechanics are practiced in various positions to decrease stress to the lumbosacral spine. Lumbar-stabilizing exercises have been recommended to improve lumbar function in patients with low back injury so that these patients may improve their activities of daily living.[559] It is theorized that these types of exercise may strengthen the stabilizer muscles, which control and limit the free movement of one vertebra on the other, thereby accelerating the recovery process of the herniated disk.

The intervention program is only as good as the concomitant home exercise program, and the clinician must continually monitor the home exercise program, evaluating the patient's knowledge of the exercises and upgrading the program when appropriate.

Surgery for Lumbar Radiculopathy

Several characteristics of patients with sciatica appear to predict the eventual need for surgery. These include a mentally demanding job (as opposed to a mentally nondemanding job or no job); a gradual onset of pain; an increase of pain on coughing, sneezing, or straining; and difficulty putting on socks or stockings.[562]

The aims of lumbar surgery for radiculopathy are to relieve pain and to restore neural function. Considerable literature reflects the evolution of lumbar disk surgery, the most commonly performed neurosurgical procedure. Oppenheim and Krause in 1909 were the first to remove what was thought to be a lumbar spinal tumor (enchondroma, chordoma).[563] Other surgeries followed, leading to Mixter and Barr who systematized the diagnosis and operative treatment of lumbar disk prolapse in 1934.[532]

Lumbar disk herniation is one of the few causes of spinal pain that can be successfully treated surgically.[564] Several surgical options are available. The more common ones are described here.

Enzymatic Intradiskal Therapy (Chemonucleolysis)

Enzymatic intradiskal therapy is advocated as a minimally invasive, intermediate stage between conservative management and open-surgical intervention for a contained lumbar IVD prolapse.

Two enzymes are used in vivo: chymopapain and collagenase. The therapeutic concept behind intradiskal therapy is to produce a decrease in the water-binding capacity of the polysaccharide side chains. This is supposed to result in a lowering of the pressure in the IVD, with a subsequent reduction in the size of the IVD protrusion and relief of the tension on the nerve root.

The success rate of chemonucleolysis with chymopapain or collagenase has been found to be approximately 72% and 52%, respectively.[565,566] However, the final outcome from chemonucleolysis, followed by surgery if chemonucleolysis fails, remains poorer than the outcome from primary diskectomy.[4] Consequently, although chemonucleolysis is an excellent procedure in principle, it is rarely performed. The complications associated with this procedure include allergic reactions, lumbar subarachnoid hemorrhage, and paraplegia.

Diskectomy

Diskectomy is a commonly performed surgical procedure in the general population, with high success rates reported in the literature.[567] There is now strong evidence on the relative effectiveness of surgical diskectomy versus chemonucleolysis versus placebo.[4]

Hemilaminectomy and Diskectomy

These diskectomies are usually approached posteriorly. Posterolateral diskectomy is used to treat herniated lumbar IVDs. The aim of a diskectomy is to decompress the involved nerve root or roots, while minimizing scar tissue formation and avoiding iatrogenic nerve damage.

Percutaneous Diskectomy

Percutaneous diskectomy is a minimally invasive procedure that uses a probe for automatic aspiration of the NP material from the IVD. Because the probe is inserted using a cannula, the procedure causes minimal damage to the muscles, bones, and joints of the back and no adherences in the epidural space. A short convalescence is, therefore, to be expected. This procedure is indicated for patients with radicular pain, positive SLR, and positive neurologic signs and symptoms (atrophy, weakness, and sciatica) who have not responded to at least 6 weeks of conservative therapy. It also is advocated for patients with pure IVD herniation without stenosis or any other additional factors. These factors include IVD fragments in the spinal cord, severe spinal arthritis, and LF hypertrophy.

Microdiskectomy

A microdiskectomy is designed to decompress neural tissues by removing the IVD material that is causing the compression and irritation of the nerve root. Microdiskectomy is reported to have a high success rate, more than 90% in some studies.[567] Following a diskectomy, patients are generally able to return to their previous levels of activity, including participation in recreational sports. This surgery, however, can be associated with a long recuperation and a protracted period of disability.[568,569]

Laser Diskectomy

As its name suggests, laser diskectomy uses a laser to remove diskal tissue and thereby alleviate the pressure on the nerve root. However, because it does not address the actual pathology, its success rate is dramatically inferior to that of standard diskectomy.[570]

Laminectomy

A laminectomy is defined as the removal of a lamina. A complete laminectomy involves the removal of the entire lamina, together with the spinous process and the LF caudal and cranial to the lamina. The disadvantage of a complete laminectomy is that it may produce a destabilizing effect on the motion segment.[509]

Decompression

Decompression of the lumbar spine is defined as a laminectomy with partial facetectomy. Decompression may also be accompanied by partial laminectomy and canal enlargement, expansive lumbar laminoplasty, unilateral laminotomy for bilateral decompressions, or partial pediclectomy.

Fusion

There is little consensus among spine surgeons regarding the optimal indications for lumbar fusion surgery. Some surgeons believe that most patients with spinal stenosis are appropriate candidates for spinal fusion. Others believe that most of these patients should undergo only a laminectomy, because the degenerative changes that have occurred produce an inherent stability of the motion segment.

Controversy also exists regarding the use of fusion surgery versus nonsurgical approaches for degenerative disk disease with no herniation or stenosis.[571] Spinal fusion is associated with wider surgical exposure, more extensive dissection, and longer operation times than laminectomy.

As an adjunct to the excision of recurrent lumbar IVD herniations, lumbar fusion provides several theoretical advantages[572]:

- reduction or elimination of segmental motion;
- reduction of mechanical stresses across the degenerated disk space;
- reduction of the incidence of additional herniation at the affected disk space;

Circumferential fusion has been advocated to improve fusion rates and clinical outcomes in intervention of the lumbosacral spine. Circumferential lumbar fusion can be challenging, however, requiring either thecal sac retraction and bilateral facet disruption or a posterior lumbar interbody fusion.[573]

Alternative options have included either sequential anterior and posterior fusions or a posterior lumbar interbody fusion at the time of simultaneous posterolateral fusion. In 1982, Harms and Rolinger[573] suggested the placement of bone graft and titanium mesh, via a transforaminal route, into the disk space that previously had been distracted using pedicle screw instrumentation (transforaminal lumbar interbody fusion [TLIF]).

Other options for fusing the lumbar spine include bone grafting with a posterolateral approach without instrumentation (facet fusion or intertransverse fusion), a posterolateral approach with pedicle screws, or posterior lumbar interbody fusion or anterior lumbar interbody fusion (ALIF) with bone grafts, cages, or dowels.[572]

Complications of ALIF include postoperative ileus, vascular and visceral injury, retrograde ejaculation in males, and venous thrombosis.[574] Complications of TLIF include epidural bleeding, neural injury, postsurgical instability, epidural fibrosis, and arachnoiditis.[574] Most of the complications reported for the ALIF and TLIF procedures are approach rather than device related.

Lumbar Artificial Disk Replacement

The use of lumbar artificial disk replacement for the treatment of symptomatic lumbar disk disease has recently been approved by the US Food and Drug Administration (FDA). The artificial disk is an alternative to fusion procedures and offers the advantage in its ability to restore pain-free motion while protecting adjacent segments from increased loading and failure. Candidates for this procedure include patients who are18–60 years and in whom nonoperative treatment for at least 6 months has failed and who have

- single level degenerative disk disease confirmed by MRI and diskography;
- no previous lumbar fusion;
- no instability, and;
- no extruded disk material.

Postsurgical Intervention

Patients who undergo spinal surgery may receive physical therapy as part of their rehabilitation. Although there is a large

amount of information from evidence-based clinical practice guidelines for the management of many musculoskeletal conditions, there is relatively little information available on the physical therapy management of patients who have undergone spinal surgery.

The randomized controlled trials comparing various physical activity programs[10,575–577] have demonstrated the benefits of these programs. These benefits have included less pain and disability, improved ROM, and greater satisfaction with care.

Before the surgery, the patients may receive advice on spine care, postsurgical precautions, and instructions on basic exercises.

The postsurgical intervention following surgery is as varied as the number of types of surgery. The following are guidelines for postsurgical rehabilitation. The primary goals for the initial period following the surgery are

- reduction of pain and inflammation;
- prevention of postsurgical complications;
- protection of the surgical site;
- prevention of a recurrent herniation;
- maintenance of dural mobility;
- improvement of function;
- minimizing of the detrimental effects of immobilization [578–583];
- early return to appropriate functional activities. Patients usually are permitted to shower 1 week after the surgery.
- safe return to occupational duties. Patients with a sedentary occupation may return to work within 7–10 days after the surgery. Prolonged positions and postures are to be avoided.
- patient education on correct body mechanics and independent self-care.

The patient is given guidance on the gradual resumption of daily activities. Immobilization or prolonged rest should be avoided. Instead, the patient is encouraged to walk for short periods and distances several times a day.

Outpatient physical therapy, if appropriate, usually begins in the second or third week. The physical therapy examination includes

- a thorough history;
- inspection of the wound site;
- anthropometric data;
- postural examination;
- neural examination, including neurodynamic mobility, and strength testing.

The components of the physical therapy intervention include a graded exercise program, with gentle ROM, submaximal isometrics, and arm and leg exercises as appropriate.

Additional interventions may include electrotherapeutic modalities, physical agents, and scar massage. Patient education is very important, particularly postural education and information on body mechanics.

Progressive strengthening exercises for the spinal stabilizers usually are initiated by the fourth postoperative week.

Cardiovascular conditioning exercises are introduced at the earliest opportunity based on patient tolerance. These include riding a stationary bicycle, using an upper body ergonometer and a stair-stepper, and swimming in a pool. The sessions for these exercises are initially brief (5–10 minutes) and are gradually increased up to 30–60 minutes.

Activities such as jogging are usually permitted at 6–8 weeks if there is minimal pain. When the patient does resume these activities, they should be done in the morning hours when the IVD is maximally hydrated.[584] High-impact sports such as basketball and soccer are usually permitted after the 12th week.

Degenerative Spinal Stenosis

Degenerative spinal stenosis (DSS), a narrowing of the spinal canal, nerve root canal (lateral recess), or intervertebral foramina of the lumbar spine, is predominantly a disorder of the elderly—it is the most common diagnosis associated with lumbar spine surgery in patients older than 65 years.[585]

DSS is being diagnosed more frequently. The reasons for this are the widespread use of sophisticated noninvasive imaging techniques and the increasing elderly population. Lumbar spinal stenosis may be classified as central or lateral.[586]

- Central stenosis is characterized by a narrowing of the spinal canal around the thecal sac containing the cauda equina. The causes for this type of stenosis include facet joint arthrosis and hypertrophy, thickening and bulging of the LF, bulging of the IVD, and spondylolisthesis.
- Lateral stenosis is characterized by encroachment of the spinal nerve in the lateral recess of the spinal canal or in the intervertebral foramen. Initially the depth of the canal that constituted narrowing was identified as an anteroposterior measurement,[587] but more recently the lateral width of the spinal canal has been studied.[346] The causes for this type of stenosis include facet joint hypertrophy, loss of IVD height, IVD bulging, and spondylolisthesis.

A compression of the nerve within the canal can result in a limitation of the arterial supply or claudication resulting from the compression of the venous return. Neurogenic claudication, or pseudoclaudication, can result in nerve root ischemia and symptomatic claudication, which is brought on by walking and relieved by sitting.[588] Compressive loading of the spine can also exacerbate symptoms, such as those that occur with prolonged standing. Central stenosis, which can result in symptoms related to cauda equina compression, may occur more often with certain movements or changes in posture[589]:

- The length of the canal is shorter in lumbar lordosis than kyphosis.
- Extension and, to a lesser degree, side bending of the lumbar spine toward the involved side produces a narrowing of the canal.
- Flexion of the lumbar spine reverses the process, returning both the venous capacity and the blood flow to the nerve.

Both the history and the examination findings are very specific.

Patients with lumbar spinal stenosis who are symptomatic often relate to a long history of LBP. Unilateral or bilateral leg

pain is usually a predominant symptom. Approximately 65% of patients with lumbar spinal stenosis present with neurogenic claudication.[588] Subjectively, the patient reports an increase in symptoms with lumbar extension activities such as walking, prolonged standing, and, to a lesser degree, side bending. On observation, the patient presents with a flattened lumbar lordosis.

The physical examination usually reveals evidence of reduced flexibility or shortening of the hip flexors (iliopsoas and rectus femoris). The hip extensor muscles (gluteus maximus and hamstrings) usually are lengthened. This lengthening places them at a mechanical disadvantage, which leads to early recruitment of the lumbar extensor muscles and may lead to excessive lumbar extension.[590]

Therapeutic exercise is one of numerous interventions that have been proposed for the conservative management of patients with lumbar spinal stenosis. Several authors advocate only the use of Williams flexion exercises because of the neuroforaminal narrowing that occurs with lumbar extension.[591,592] However, the prescribed program may need to be modified so that it does not exacerbate any coexisting orthopaedic conditions, such as osteoarthritis of the hips or knees, while still being effective.[8] In a randomized clinical trial by Whitman et al.,[593] two physical therapy programs were compared for 58 patients with lumbar spinal stenosis:

- manual therapy (eclectic, consisting of techniques such as those described by Maitland,[594] Greenman,[335] and Whitman et al.[595]), body-weight-supported treadmill walking, and exercise group;
- lumbar flexion exercises, a treadmill-walking program, and subtherapeutic ultrasound group.

A greater proportion of patients in the first group reported recovery at 6 weeks compared with the flexion exercise and walking group ($P = 0.0015$), with a number needed to treat for perceived recovery of 2.6 (confidence interval, 1.8–7.8). At 1 year, 62% of the first group and 41% of the flexion exercise and walking group still met the threshold for recovery.[593]

The therapeutic exercise progression is based on the underlying impairments and should include postural education; hip flexor, rectus femoris, and lumbar paraspinal stretching; lumbar (core) stabilization exercises targeting the abdominals and gluteals; aerobic conditioning; and positioning through a posterior pelvic tilt. There is some controversy as to whether the hamstrings should be stretched, as lengthening of these muscles may allow the pelvis to rotate anteriorly, resulting in an increased lordosis and further stenosis.

Failure to respond to a conservative approach is an indication for nerve root and sinuvertebral nerve infiltration.[596] Permanent relief in lateral recess stenosis has been reported with an injection of local anesthetic around the nerve root.[597] When nerve root infiltration fails, surgical decompression of the nerve root is indicated.

Zygapophyseal Joint Dysfunction

The term *Facet joint syndrome* refers to a pain-provoking dysfunction of the zygapophyseal joint.[129] This pain is the result of a lesion to the joint and its pain-sensitive structures. Zygapophyseal movement dysfunctions can result from a hypomobility or a hypermobility instability (see "Clinical Instability of the Lumbar Spine" section).

Hypomobility

Hypomobility in the lumbar spine can have a variety of causes including ligament tears,[598] muscle tears or contusions,[599] lumbago,[343] intra-articular meniscoid entrapment,[516] zygapophyseal joint capsular tightness, and zygapophyseal joint fixation or subluxation.[600]

Theoretically, the signs and symptoms that present with a hypomobility include unilateral LBP that is aggravated with certain movements. Given that the joint is only capable of flexion and extension movements, it is assumed that flexion or extension movements can provoke pain, particularly at the end of these ranges. These movements are tested with active ROM and the combined motion tests and confirmed with the position tests of the PPIVM and PPAIVM tests.[373]

Hypomobility of the zygapophyseal joint can have an extra-articular, periarticular, or pathomechanical cause, with the distinction being made by the results of the end-feel obtained by the clinician during the PPIVM and PPAIVM tests.[373]

- ***Extra-articular.*** Decreased range with the PPIVM, but normal PPAIVM.
- ***Periarticular.*** Restriction of range in both PPIVM and PPAIVM tests, with a hard capsular end-feel.
- ***Pathomechanical.*** Restriction of range in both PPIVM and PPAIVM tests, with an abrupt, slightly springy end-feel.

The conservative intervention for a zygapophyseal dysfunction includes specific joint mobilizations, postural education, correction of muscle imbalances, and core stabilization exercises.

CLINICAL INSTABILITY OF THE LUMBAR SPINE

There is considerable controversy as to what, exactly, constitutes spinal instability. Traditionally, the radiographic diagnosis of increased translation or angulation of a spinal segment during flexion–extension or side bending in patients with chronic LBP was considered to be one of the most obvious manifestations of lumbar instability.[185,601] However, lumbar segmental instability in the absence of radiographic findings has also been cited as a significant cause of chronic LBP.[602,603] The limitation in the clinical diagnosis of lumbar segmental instability lies in the difficulty of accurately detecting abnormal or excessive intersegmental motion, either radiographically or through palpation.[13] One of the limitations in the radiographic diagnosis of clinical instability is that the testing is static and assesses the spinal segment mobility at its end of range (outside the neutral zone of motion), rather than accurately assessing the functional control of the spinal segment within its neutral zone.[185] Hypermobility, a close relative of instability, is usually the most difficult movement impairment to diagnose in the spine, because it is not a matter of stiffness, but rather of a relative degree of looseness.[373] Because of a lack of sensitivity and specificity of any one test, or

combination of tests, to accurately identify clinical instability, its diagnosis requires the presence of a concurrent number of diagnostic criteria based on findings from the subjective and physical examination.[185]

The following clinical findings (anywhere in the spinal joints) may indicate the presence of instability and its pertinence to the presenting complaints of the patient:

- back pain that is most commonly described as recurrent, constant, catching, locking;
- repeated unprovoked episode(s) of feeling unstable or giving way, following a minor provocation;
- inconsistent symptomatology. The most frequently reported aggravating postures are sustained sitting, prolonged standing and semi flexed postures.[604] The most common aggravating movements are typically forward bending, sudden unexpected movements, returning in an upright position from forward bending, lifting, and sneezing.[604]
- minor aching for a few days after a sensation of giving way;
- compression symptoms (vertebrobasilar, spinal cord), which are not associated with a history of an IVD herniation or stenosis;
- consistent clicking or clunking noises;
- protracted pain (with full ROM);
- creases posteriorly or on abdomen (spondylolisthesis);
- spinal ledging;
- spinal angulation on full ROM;
- inability to recover normally from full ROM, commonly flexion;
- excessive active ROM. Active spinal movement, commonly reveals good ranges of spinal mobility but with aberrant quality of motion commonly associated with a sudden acceleration, hesitation, or lateral movement within the midrange of spinal motion.[185]

Intervention

Instability of the spine is perhaps the most difficult of the motion impairments to treat. A stiff or jammed joint is a relatively simple problem that requires selecting and applying a mobilization or manipulation technique. Instability is a permanent, or at best, a semipermanent state. The intervention for a hypermobility or instability involves the removal of any abnormal stresses from the joint. If the underlying cause of the articular hypermobility is deemed to be a localized joint hypomobility, then this dysfunction must logically be dealt with first using joint mobilizations or stretching techniques.[373] The techniques to increase joint mobility and the techniques to increase soft tissue extensibility are described later in "Therapeutic Techniques" section. Following the diagnosis, and the correction of any articular hypomobility, the focus shifts to retraining muscles that are involved in the dynamic stabilization and segmental control of the spine.

Whereas conventional exercises generally work to increase the strength of the global muscles, a more specific approach, which aims to improve the dynamic stability role of the segmental muscles during functional postures and movements, is recommended in conjunction with the focus on the global muscles. This approach has proven beneficial in a number of LBP conditions. For example, O'Sullivan et al.[190] have demonstrated decreased pain and disability in patients with chronic LBP who have a radiologically confirmed diagnosis of spondylolysis or spondylolisthesis.

While stressing the low-back tissues may enhance their health, too much loading can be detrimental. Choosing the optimal exercise requires judgment based on clinical experience and scientific evidence.[443] Training should begin in non–weight-bearing positions depending on patient response, in prone lying, in the quadriped position, or in supine lying before progressing to weight-bearing postures. It is important to note that the quadriped position has a significantly higher COG and smaller base of support (BOS) than the prone position, making it a more challenging position. Initially, the exercises prescribed are those that were found to provide relief during the examination. Usually, either flexion or extension movements demonstrate benefit. Contractions initially are held for 5 seconds and gradually are increased to 60 seconds. Training is performed a minimum of once a day for 10–15 minutes, with emphasis on proper cocontraction of the local muscle system. Depending on the severity of the condition, this range may initially be small, permitting only upper or lower extremity motions and gentle isometrics of the spinal muscles.

- ***Transversus abdominis exercise.*** This exercise, also known as the abdominal drawing-in maneuver, is known to result in preferential activation of the internal oblique and TrA, with little contribution by the rectus abdominis in the pain-free population.[605] The patient, placed in hook-lying (with knees 70–90 degrees and feet resting on the floor), quadriped, prone, or the semireclined position (based on comfort), is asked to take a relaxed breath in and out and then draw the waist-line in (towards the spine) without taking a breath (Fig. 28-54).[388] The contraction must be performed in a slow and controlled manner. Assessment of optimal recruitment of the TrA can be done through palpation just distal to the ASIS and lateral to the rectus abdominis (Fig. 28-54) or with the use of biofeedback.[388] When performed correctly, the clinician should feel flat tension of the muscle, rather than a bulge if the internal oblique contracts, and should see no substitute patterns (no movement of the pelvis, no flaring or depression of the lower ribs, no inspiration or lifting of the rib cage, no bulging out of the abdominal wall, and no increased pressure through the

FIGURE 28-54 Abdominal drawing-in with palpation.

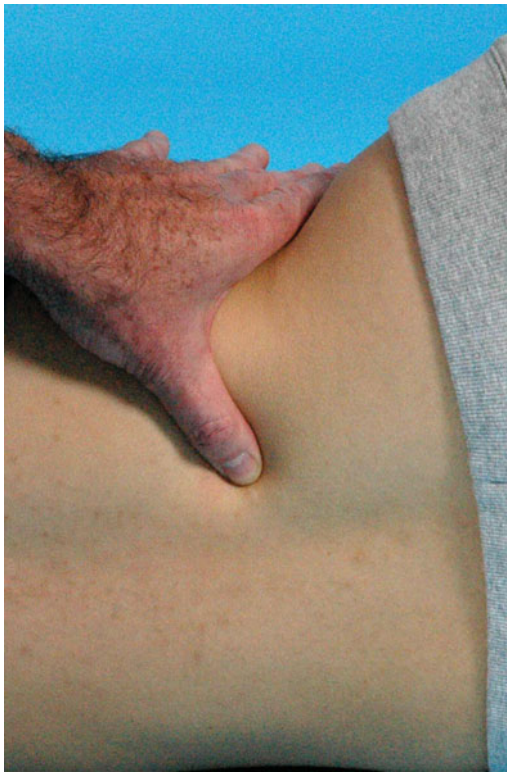

FIGURE 28-55 Multifidus activation.

feet).[81,114,606] Activation of the pelvic floor muscles or multifidus can be used to initiate activity in the TrA. Once the technique is successfully learned, the patient is encouraged to perform the exercise while in the sitting and standing positions while self-palpating.[81,114,388,606]

- ***Spinal bracing.*** McGill[207] advocates bracing of the spine, which has been shown to activates all three layers of the abdominal musculature, not just the TrA. The patient lies in supine position with the hips and knees flexed with the feet resting on the bed.[207,388] The patient is asked to activate the abdominal musculature and back extensors simultaneously so that both areas feel firm.
- ***Multifidus activation.*** The patient lies in the prone or side-lying position. The clinician uses the thumbs or index fingers to palpate immediately lateral to the spinous processes of the lumbar spine and the patient is asked to bulge the muscle out against the palpating digits (Fig. 28-55). Emphasis is placed on slow and gentle tension or swelling of the muscle as the goal is to increase control not strength. So that the patient can practice at home, a small piece of tape can be placed on the skin over the muscle to help patients find the correct level easily.

Pelvic Floor Muscle Activation

The pelvic floor muscles can be activated in isolation or in conjunction with activation of the TrA or multifidus. If activated in isolation the following instruction is given: "Contract as if you are stopping the flow of urine while you attempt to pull the ischial tuberosities together."

Once these techniques are mastered in the position of comfort, they are performed with the head, and lower and upper extremity movements (arm raises, bent leg raises) to improve muscular endurance depending on the emphasis of the intervention.[216,607]

FIGURE 28-56 Unilateral shoulder flexion.

Diaphragm Activation

The patient is in the supine hook-lying, side-lying, or prone over a pillow to relax the paraspinal muscles and place the patient's lumbar spine in neutral. The patient is asked to focus on active inspiration using contraction of the diaphragm (movement of the abdominal wall and basal rib cage) and relaxed expiration. Manual contact by the clinician can be used to encourage basal rib cage expansion.

Once these muscle activations can be performed in isolation and in the controlled position, the clinician then attempts to promote static coordination between the local and global muscles using the following progression:

- **Extremity loading**: Superimposing upper and then lower extremity movements while maintaining the position of the spine and pelvis (Fig. 28-56).
- **Rhythmic stabilization**: The clinician applies various low forces to the body with slow alternations while the patient maintains a neutral position. These techniques are performed in supine initially and then in sitting.
- **Unstable base**: The patient holds the neutral spine position during extremity loading and rhythmic stabilization.
- **Functional movements**: The patient holds the neutral spine position during a variety of functional activities such as walking, weight shifting, and trunk rotations.

A variety of exercises that emphasize specific muscle groups, depending on the clinical findings, can be introduced. All of the following exercises are superimposed on the neutral spine (midrange or functional position), making sure the patient maintains control while performing the exercises:

Emphasis on Abdominals

- ***Bent-leg fall out.*** The patient is placed in the supine hook-lying position (knees at 90 degrees of flexion) and is asked to separate the knees while preventing pelvic rotation (Fig. 28-57).[608]
- ***Progressive limb loading.*** From the supine hook-lying position the patient is asked to do the following:

FIGURE 28-57 Bent-leg fall out.

- lift one of the legs to 90 degrees of hip and knee flexion (Fig. 28-58), then
- slide the heel of the raised leg away from the body to extend the knee (Fig. 28-59), and then finally
- to lift the straight leg to 45 degrees (Fig. 28-60).

The exercise is then repeated using the other leg.

The exercise progression then follows a series of levels of increasing difficulty while performing the same three methods of progressive limb loading:

- The opposite leg is held at 90 degrees of hip flexion using both upper extremities (Fig. 28-61).
- The opposite leg is held at 90 degrees of hip flexion with no upper extremity assistance (Fig. 28-62).

FIGURE 28-59 Progressive limb loading 2.

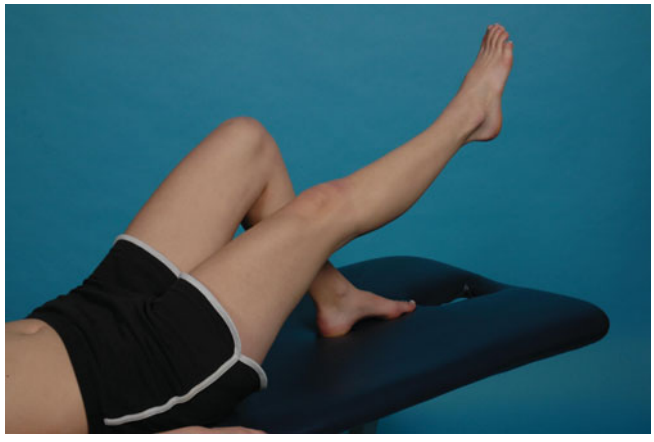

FIGURE 28-60 Progressive limb loading 3.

- Both legs perform the series of progressive limb loading simultaneously (Fig. 28-63).

At this stage external resistance in the form of weights, elastic resistance, or pulleys can be added for strengthening.

- ***Abdominal crunch.*** The patient lies in the supine position with the knees flexed to approximate 90 degrees and the feet resting on the table. The patient folds his or her hands across the chest. The patient is asked to perform the abdominal drawing-in maneuver, and then to raise the head and

FIGURE 28-58 Progressive limb loading 1.

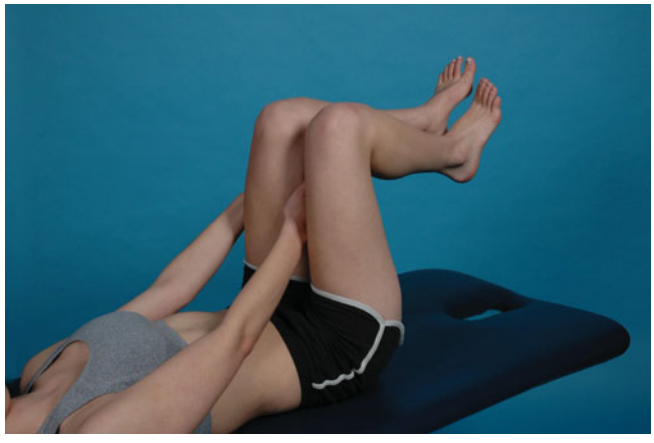

FIGURE 28-61 Progressive limb loading 4.

FIGURE 28-62 Progressive limb loading 5.

FIGURE 28-63 Progressive limb loading 6.

shoulders upward until the shoulder blades clear the table (Fig. 28-64). This position is held for approximately 5 seconds before the patient returns to the starting position.

Abdominal Sit-Back

The patient is positioned in the "up" position of the standard sit-up with the arms folded across the chest and the feet secured on the bed (Fig. 28-65). Keeping the arms folded across the chest, the patient performs the abdominal drawing-in maneuver and then slowly lowers the upper body to a predetermined height.

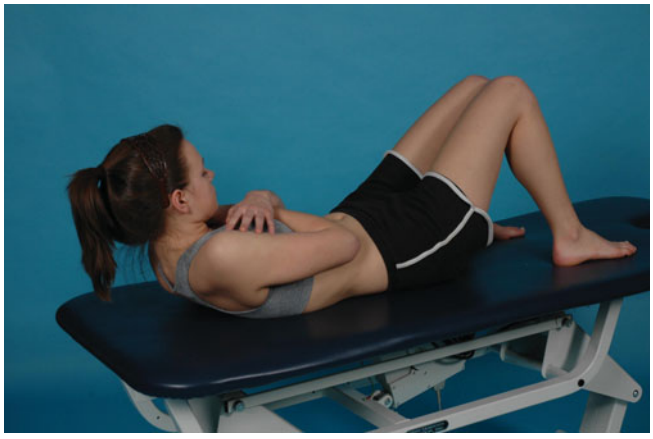

FIGURE 28-64 Abdominal crunch.

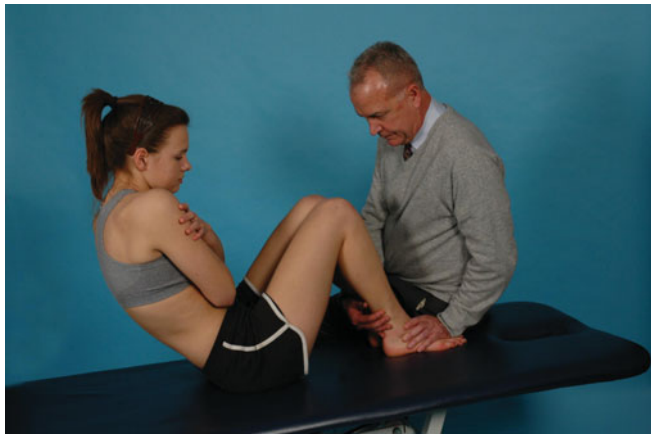

FIGURE 28-65 Abdominal sit-back.

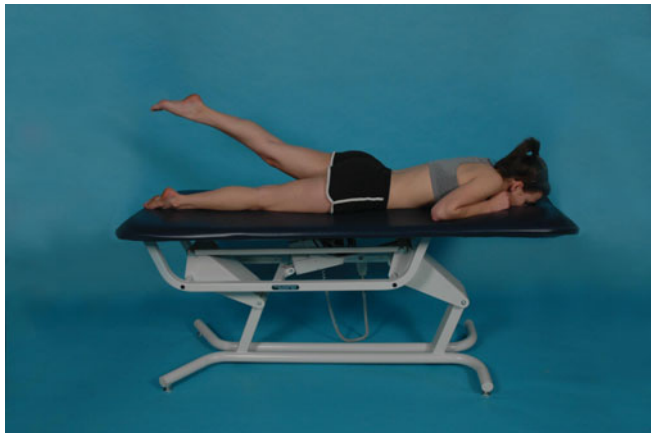

FIGURE 28-66 Prone progression.

Emphasis on the Trunk Extensors. The following exercises are performed with the patient lying in prone position[608]:

- extend one lower extremity (Fig. 28-66);
- extend both lower extremities (Fig. 28-67);
- lift the head, arms, and lower extremities (Fig. 28-68).

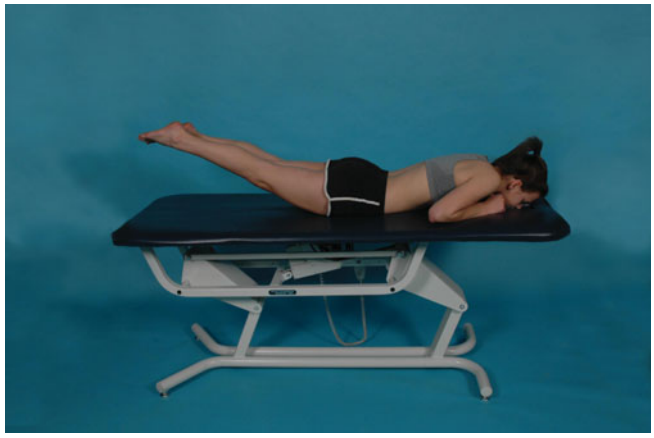

FIGURE 28-67 Prone progression 2.

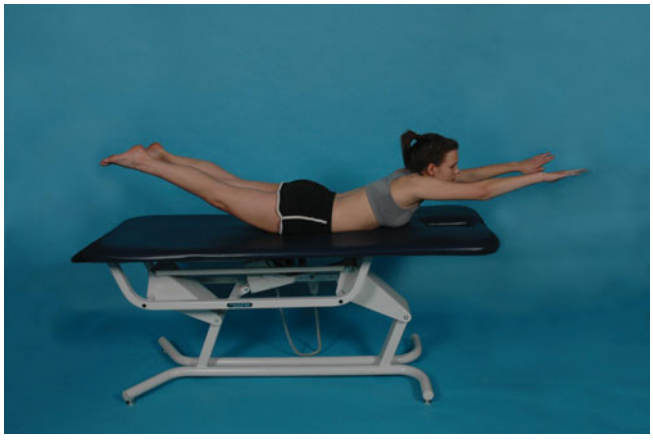

FIGURE 28-68 Prone progression 3.

For patients with limited lumbar extension, or those with increased symptoms with lumbar extension, a small pillow can be placed under the hips in prone for the starting position, and the patient can lift the upper and lower extremities to the neutral position of the lumbar spine.

At this stage, external resistance in the form of weights, elastic resistance, or pulleys can be added for strengthening.

These exercises are then performed in the quadriped position and include the following progression:

- flex one upper extremity (Fig. 28-69);
- extend one lower extremity by sliding it along the exercise mat (Fig. 28-70);
- flex one upper extremity and extend the contralateral lower extremity (Fig. 28-71).

Emphasis on the Lateral Stabilizers. These exercises are performed in the side-lying position and include the following progression

- side plank with hips on bed (Fig. 28-72);
- side plank (Fig. 28-73);
- side plank with arm extended (Fig. 28-74);
- side plank with hip abduction (Fig. 28-75);
- side plank with inward roll (Fig. 28-76).

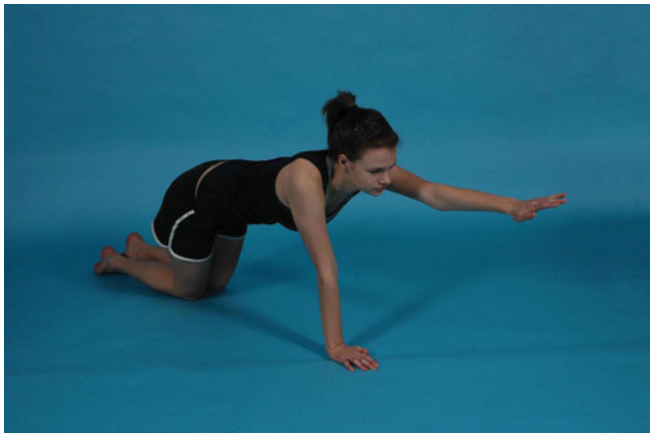

FIGURE 28-69 Quadriped progression 1.

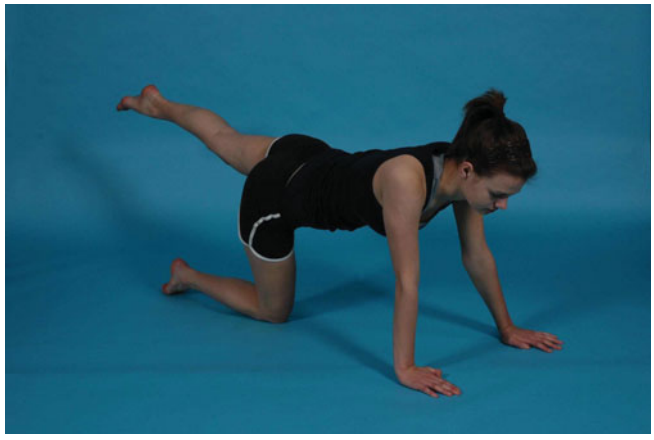

FIGURE 28-70 Quadriped progression 2.

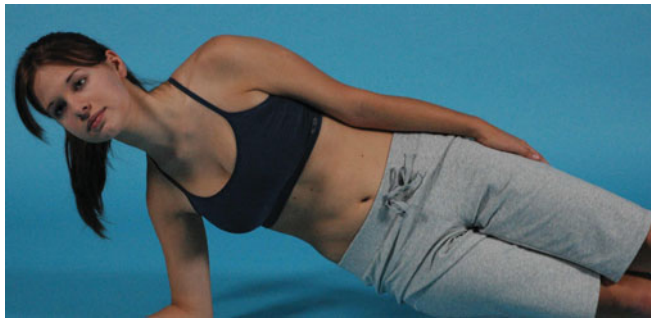

FIGURE 28-72 Side-lying progression 1.

FIGURE 28-73 Side-lying progression 2.

FIGURE 28-74 Side-lying progression 3.

FIGURE 28-75 Side-lying progression 4.

Emphasis on Function.

- ***Bridging.*** The patient is positioned supine, with the arms by the sides. The patient is asked to keep the knees bent and feet flat, and to lift the buttocks from the floor (Fig. 28-77). The exercise can be made more challenging by having the patient squeeze a ball with their thighs while performing the bridge (Fig. 28-78).
- Bridging with feet on a ball, knees bent (Fig. 28-79).
- Bridging with feet on a ball, knees straight (Fig. 28-80).

FIGURE 28-76 Side-lying progression 5.

FIGURE 28-77 Bridging progression 1.

FIGURE 28-78 Bridging progression 2.

- Bridging with shoulders on a Swiss ball (Fig. 28-81).
- ***Wall slides.*** With the back against a wall, the patient is asked to perform a squat and then return to standing, while maintaining the neutral zone throughout the exercise. Modifications to this exercise include
  - a medicine ball is placed between the patient's knees.
- ***Forward lunge.*** While maintaining the neutral zone throughout the exercise, the patient is asked to step forward

FIGURE 28-79 Bridging progression 3.

FIGURE 28-80 Bridging progression 4.

with one leg, and lower the opposite knee toward the ground. Hand weights, elastic resistance, or dumbbells (Fig. 28-82) can be used to make the exercise more challenging.

- ***Backward lunge.*** While maintaining the neutral zone throughout the exercise, the patient is asked to step backward with one leg, and lower the same knee to the ground, before returning to the starting position. Hand weights, elastic resistance, or dumbbells can be used to make the exercise more challenging.
- ***Chop and lift.*** The chop and lift motions are excellent at recruiting the lumbar stabilizers for mobility or stability. These motions can be performed in half kneeling (Fig. 28-83), tall kneeling (Fig. 28-84), or standing (Fig. 28-85). In contrast to the standing posture that offers a wide, adaptable BOS and can utilize all portions of the lower extremity kinetic chain, the kneeling position provides a narrow BOS, rendering distal portions of the kinetic chain unable to assist in corrected movements.[609] Tall kneeling creates a challenge to balance reactions in the anterior and posterior directions, whereas half kneeling creates a challenge to balance reactions laterally.[609]

Emphasis on Athletic Performance.

- ***Hip thrusts.*** The patient is positioned supine, with the hips and knees flexed to approximately 90 degrees and the arms by the sides (Fig. 28-86). From this position, the patient is asked to perform an abdominal hollowing and lift the pelvis off the bed, while maintaining the hip and knee positions. Once the patient is able to do this exercise independently,

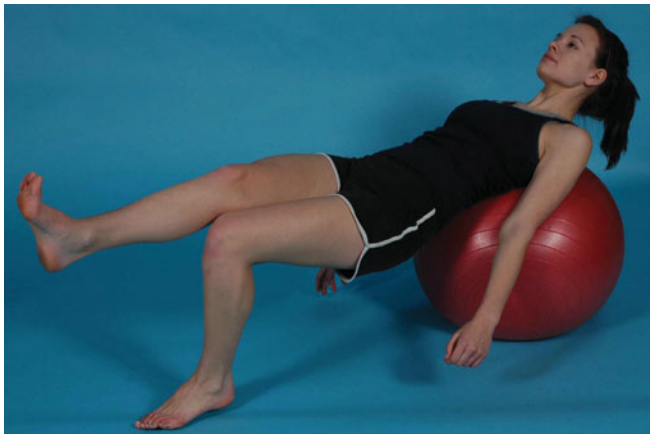

FIGURE 28-81 Bridging progression 5.

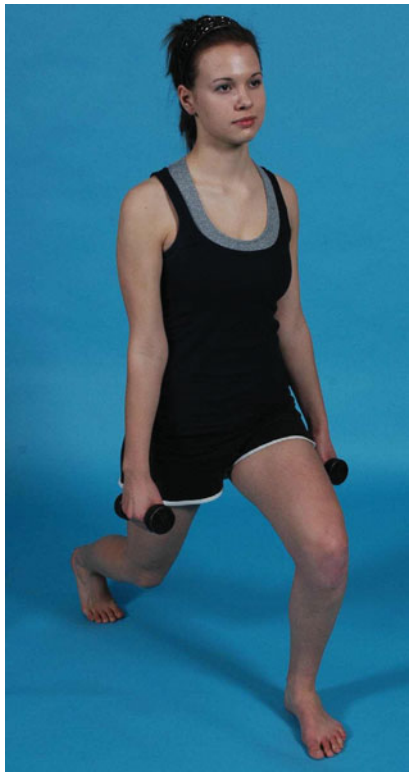

FIGURE 28-82 Forward lunge.

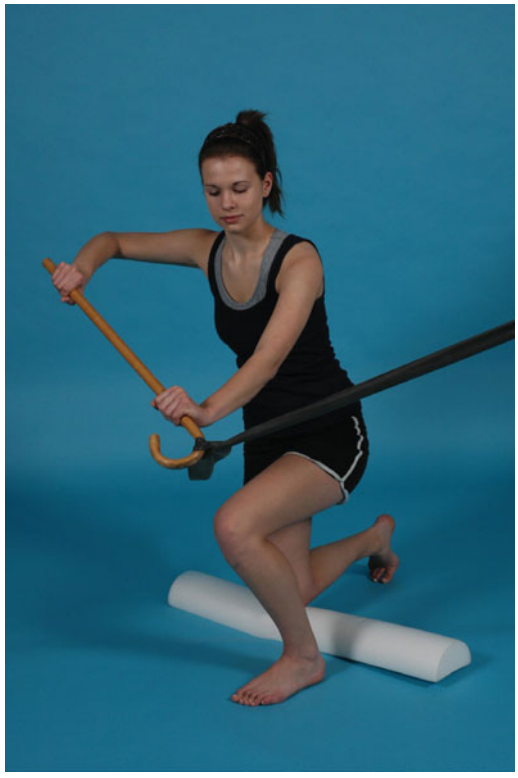

FIGURE 28-83 Chop and lift in half-kneeling.

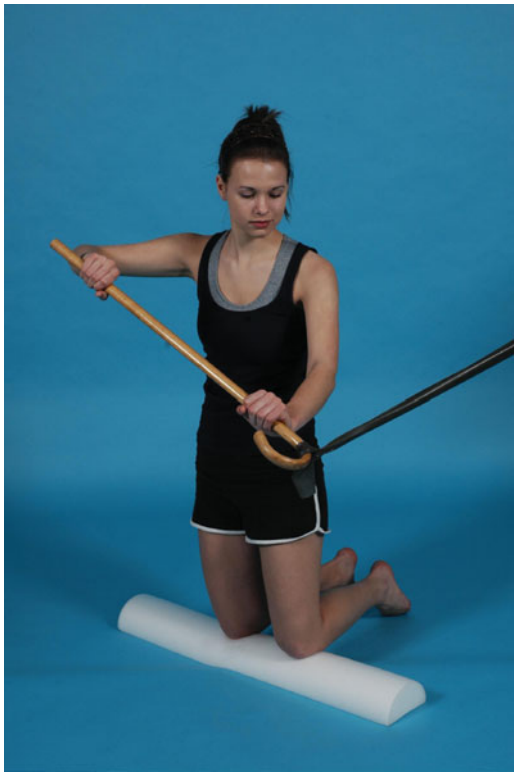

FIGURE 28-84 Chop and lift in tall-kneeling.

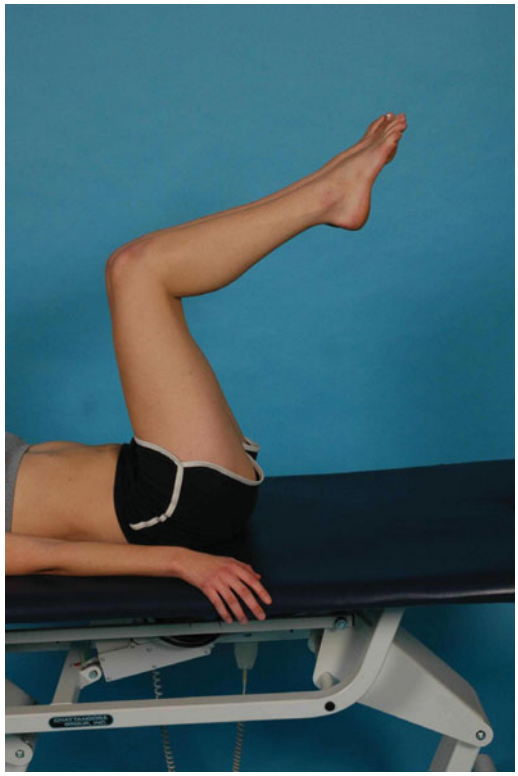

FIGURE 28-86 Hip thrusts.

the exercise can be performed with the hips flexed to 90 degrees and the knees extended (Fig. 28-87).

- ***Rotational partial sit-up.*** The patient is asked to lift the chin toward the chest. The patient is then asked to attempt to lift the right shoulder up from the table, while twisting the trunk to the left and touching the outside of the opposite knee (Fig. 28-88), before slowly lowering the shoulder to the table.
- ***Reverse curl-up.*** The patient lies in the supine position, with the legs bent at the knees and the feet flat on the floor. The arms are by the sides. The patient is asked to raise the feet off

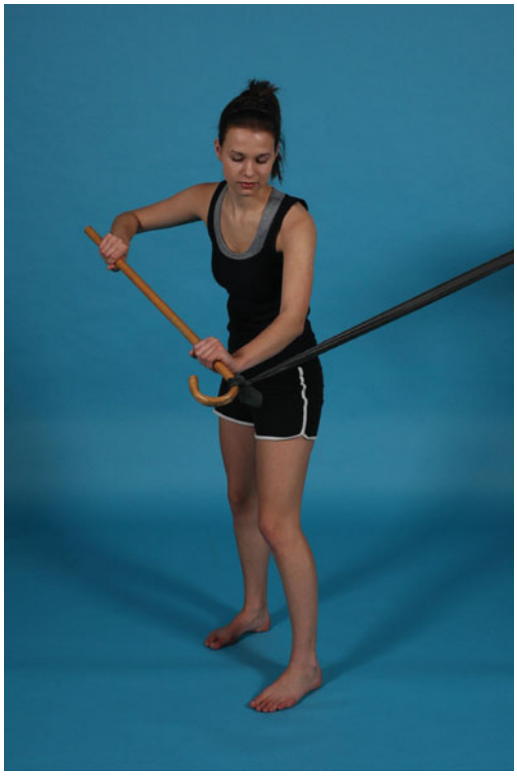

FIGURE 28-85 Chop and lift in standing.

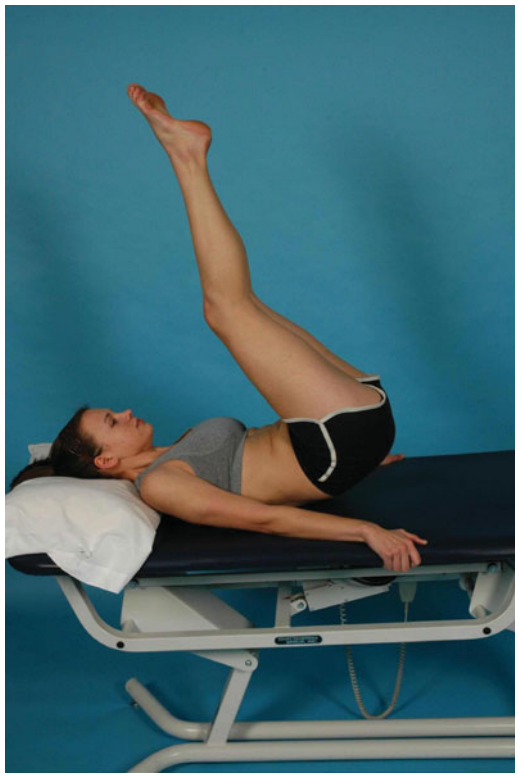

FIGURE 28-87 Hip thrust exercise with resistance.

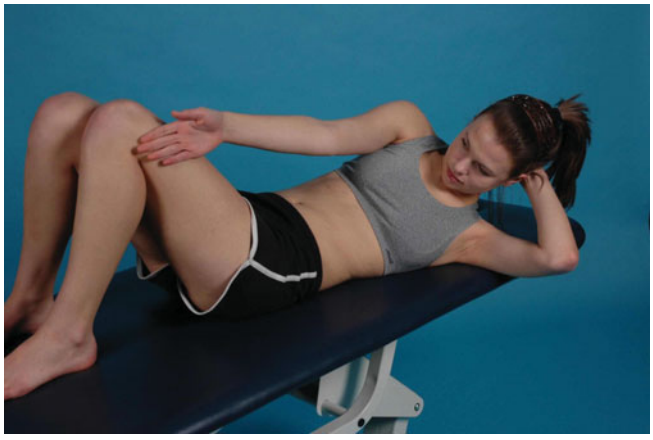

FIGURE 28-88 Rotational partial sit-up.

the bed until the thighs are vertical (Fig. 28-89). This is the start position. From this position, the patient is asked to raise the pelvis up and toward the shoulders, keeping the knees bent tightly, until the knees are as close to the chest as possible. The patient is allowed to push down on the bed with the hands. After holding this position for 2–3 seconds, the patient returns to the start position.

- ***Superman.*** The patient lies in the prone position, with the arms overhead and knees straight, the patient is asked to raise both arms and legs toward the ceiling, while keeping the head raised off the table (Fig. 28-90).
- ***Prone plank*** (Fig. 28-91). This exercise can be made more challenging by asking the patient to raise one upper extremity at a time, one lower extremity at a time, or opposite upper extremity and lower extremity simultaneously.
- ***Prone lying on a Swiss ball, hands touching floor (Fig. 28-92).*** This can be progressed to push-ups with the legs on a chair (Fig. 28-93), and to walking in circles around the Swiss ball using only the hands.
- ***Rhythmic stabilization.*** The patient is positioned in quadriped with one limb raised. The clinician applies perturbations to the patient, while the patient attempts to

FIGURE 28-89 Reverse curl up.

FIGURE 28-90 Superman position.

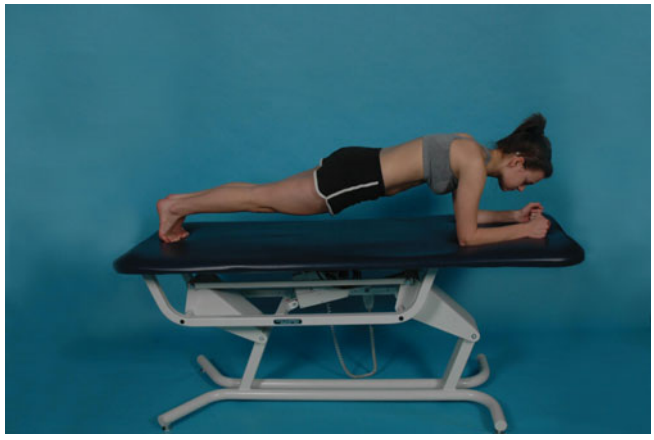

FIGURE 28-91 Prone plank.

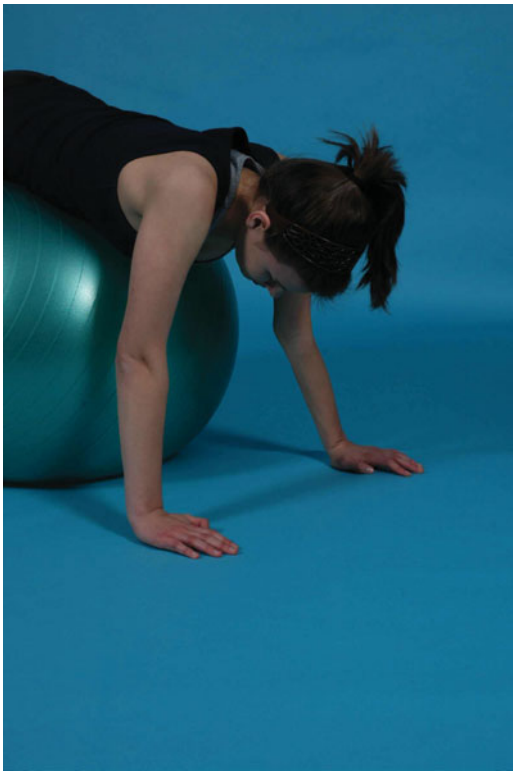

FIGURE 28-92 Prone lying on a Swiss ball, hands touching floor.

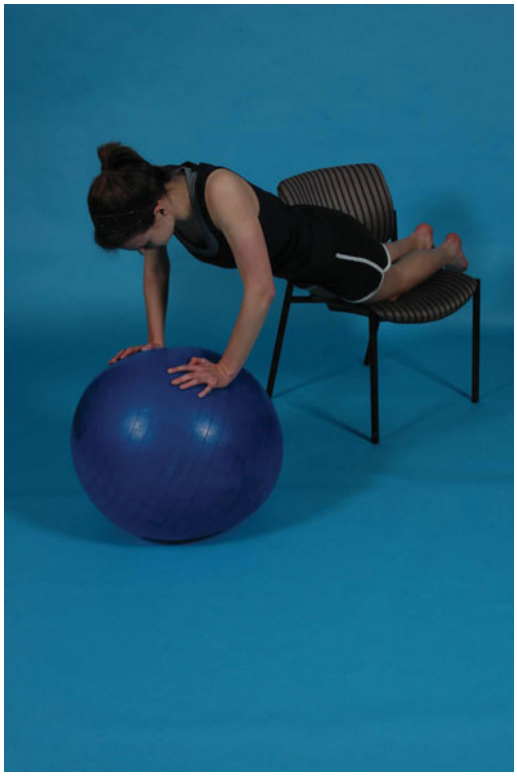

FIGURE 28-93 Push-ups with legs on a chair.

resist using a variety of points of contact, and positions (Fig. 28-94). This exercise can be progressed by raising both an upper extremity and the contralateral lower extremity.

Correction of Muscle Imbalances

In addition to addressing core stabilization, muscle imbalances must also be addressed in terms of flexibility as poor flexibility may cause excessive stresses to be borne by the lumbar motion segments. For example, adaptively shortened hip flexors and rectus femoris muscles can cause increased anterior shearing of the lumbar spine. Occasionally, stretching both the anterior and the posterior thigh muscles is beneficial. However, most of the time, only one should be stretched, and the decision is based on the diagnosis:

FIGURE 28-94 Rhythmic stabilization in quadriped.

- The patient with spinal stenosis or a painful extension hypomobility, and who responds well to lumbar flexion exercises, should be taught how to stretch the hip flexors and rectus femoris while protecting the lumbar spine from excessive lordosis.
- The patient with a painful flexion hypomobility or IVD herniation, and who responds well to lumbar extension exercises, should be taught how to stretch the hamstrings while protecting the lumbar spine from flexing.

THERAPEUTIC TECHNIQUES

Manual therapy is a common intervention used in the treatment of individuals with LBP.

Techniques to Increase Joint Mobility

Three types of techniques can be used to increase joint mobility. These include joint mobilizations, high-velocity thrust techniques, and muscle energy.

Joint Mobilizations and High-Velocity Thrust Techniques

The Guide to Physical Therapist Practice identifies mobilization/manipulation as an intervention appropriate for the care of patients spinal disorders.[610] Several randomized trials have found manipulation to be more effective than placebo[611,612] or other interventions.[613,614] However other studies have not shown any benefits for manipulation versus other interventions.[454,615,616] The literature tends to suggest that lumbar manipulation is most successful if performed in the subacute stage of a noncomplicated lumbar condition.[412,617] However, this description represents a very small percentage of patients with low-back dysfunction, and in most cases the patient is more likely to benefit from aerobic exercise, less invasive manual techniques, and dynamic stabilization training.[618]

Although a grade V technique shares similarities with a grade IV mobilization, in terms of amplitude and position in the joint's range, grade V differs in the velocity of delivery. Chapter 10 outlines the indications and contraindications for high-velocity thrust techniques. If a high-velocity thrust technique is to be used, the clinician should perform a premanipulative hold (see Chap. 10).

All of the examination techniques that are used to assess joint mobility can be employed as intervention techniques. However, the intent of the technique changes from one of assessing the end-feel to one in which the application of graded mobilizations, or muscle energy techniques, is applied at the appropriate joint range. The selection of a manual technique is dependent on a number of factors, including (1) the acuteness of the condition, (2) the goal of the intervention, and (3) whether the restriction is symmetric or asymmetric.

CASE STUDIES

1. A 58-year-old woman presented with a gradual onset of low-back and sacroiliac joint pain. Her chief complaint was a "stiff" back, especially in the morning. The patient had experienced mild discomfort over several years but had noticed a recent increase in its intensity over the past few months. The pain was reported as being worse with prolonged standing, lifting, bending, and walking and was relieved by sitting and lying down. The pain occasionally was felt in the right buttock, hip, and thigh. A recent radiograph revealed the presence of "arthritic changes" in the lumbar spine.

   The patient reported being in good general health. There were no reports of night pain, bowel and bladder changes, or pain with coughing or sneezing.

   1. List the differential diagnosis for complaints of pain in the low back and sacroiliac joint.
   2. What may be the significance of a history of morning stiffness?
   3. List the potential reasons for the patient's symptoms being worsened with prolonged standing, lifting, bending, and walking and improved with sitting or lying?
   4. From the history, what are the indications that this may be a musculoskeletal problem?
   5. Which tests could you use to rule in/out the potential reasons for the patient's complaints?
   6. Does this presentation/history warrant a Cyriax lower quarter scanning examination? Why or why not?

2. A 40-year-old man presented with a 3-month history of gradual onset of LBP, with no specific mechanism of injury. The pain was felt across the lower back at the level of the belt line. The patient reported no pain in the morning upon arising. The pain began soon after reporting to work as a cashier in a grocery store and worsened as the day wore on. The pain was also worsened with activities that involving prolonged walking or prone lying. The pain was relieved almost instantly by sitting or side lying, with the knees drawn to the chest. The patient had radiographs of the spine taken recently, which showed some evidence of arthritis but were otherwise unremarkable.

   The patient reported being in general good health. There were no reports of night pain, bowel and bladder changes, or pain with coughing or sneezing.

   1. List the differential diagnosis for complaints of a gradual onset of pain in the low back in this age group.
   2. What may be the significance of a history of no morning pain or stiffness?
   3. List the potential reasons for the patient's symptoms getting worse with prolonged standing, walking, and lying but better with sitting or the fetal position.
   4. From the history, what are the indications that LBP may be a musculoskeletal problem?
   5. What is your working hypothesis at this stage? Which tests could you use to confirm or refute your hypothesis?
   6. Does this presentation/history warrant a Cyriax lower quarter scanning examination? Why or why not?

3. A 20-year-old man complained of a sudden onset of unilateral LBP. The pain was so severe as to prevent the patient from standing upright. The patient described a mechanism of bending forward quickly to catch a ball near his left foot. He immediately experienced a sharp pain in his low back and was unable to straighten up because of the pain. The patient had no past history of back pain. No spinal radiographs had been taken.[619]

   1. List the differential diagnosis for complaints of a gradual onset of unilateral LBP.
   2. What may be the significance of the reported mechanism?
   3. List the potential reasons for the patient being initially unable to straighten up from the flexed position.
   4. From the history, what are the indications that this may be a musculoskeletal problem?
   5. Would the results from imaging studies be useful in this case? Why or why not?
   6. What is your working hypothesis at this stage? Which tests could you use to confirm or refute your hypothesis?
   7. Does this presentation/history warrant a Cyriax lower quarter scanning examination? Why or why not?

4. A 45-year-old woman was referred for LBP. She complained of pain across the center of her back at the waistline level. The pain, which had started gradually many years ago, had not spread from this small area, but it had increased in intensity. The increase in intensity resulted from a bending and lifting injury a few years previously, and, since that incident, the patient reported having difficulty straightening up from the bent-over position. Twisting maneuvers, whether in standing, sitting, or lying position, also produced the pain, but otherwise the woman was able to sit, stand, or walk for long periods without pain.

   1. List the differential diagnosis for complaints of a gradual onset of central LBP.

2. What may be the significance of the insidious onset?
3. List the potential reasons for the patient having difficulty straightening up from the flexed position.
4. From the history, what are the indications that this may be a mechanical problem?
5. Would the results from imaging studies be useful in this case? If so, which?
6. What is your working hypothesis at this stage? Which tests could you use to confirm or refute your hypothesis?
7. Does this presentation/history warrant a Cyriax lower quarter scanning examination? Why or why not?

5. A 65-year-old man presented with an insidious onset of right leg symptoms, which followed a period, or distance, of walking, or occurred after a period of standing, and which disappeared when he sat down. The patient also complained of pain at night, especially when he slept on his stomach. Further questioning revealed that the patient had a history of back pain related to an occupation involving heavy lifting but was otherwise in good health and had no reports of bowel or bladder impairment.

   1. Given the age of the patient and the history, do you have a working hypothesis?
   2. Why do you think the patient has pain with prone lying?
   3. Is the pain at night a cause for concern in this patient? Why?
   4. Does this presentation/history warrant a scanning examination? Why or why not?

6. A 21-year-old woman presented with LBP that had occurred while playing racket ball and had been accompanied by a sharp pain in the right buttock area. The patient was able to carry on playing, and the sharp pain subsided until the following morning, when attempted to weight bear through the right leg. The pain again subsided after a hot shower and her walk to work. That evening, the patient went jogging and was forced to stop after about a mile because of the return of the sharp pain in the buttock. A hot soak eased the pain but was replaced by a dull ache that lasted several days. The patient sought medical advice and was referred to physical therapy. When asked to indicate where her pain was, she pointed to a small area, medial to the right trochanter, over the piriformis muscle. Further questioning revealed that the patient had no previous history of back pain and was otherwise in good health, with no reports of bowel or bladder impairment.

   1. What structure(s) could be at fault with complaints of buttock pain?
   2. What does the history of the pain tell the clinician?
   3. What is your working hypothesis at this stage? List the various diagnoses that could present with buttock pain, and the tests you would use to rule out each one.
   4. Does this presentation/history warrant a scan? Why or why not?

REVIEW QUESTIONS*

1. Which of the spinal ligaments gives the best support against posterolateral IVD protrusions?
2. Which lumbar ligament, consisting of five bands, prevents anterior shearing of L5 on S1?
3. Which muscles make up the erector spinae?
4. Which motions does the multifidus muscle produce?
5. Approximately what is the normal amount of lumbar ROM with flexion and extension?

*Additional questions to test your understanding of this chapter can be found in the Online Learning Center for *Orthopaedic Assessment, Evaluation, and Intervention* at www.duttononline.net.

CHAPTER 29 The Sacroiliac Joint

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the bones, the ligaments, the muscles, and the blood and nerve supply that comprises the sacroiliac (SI) region.
2. Describe the biomechanics of the sacroiliac joint (SIJ), including coupled movements, normal and abnormal joint barriers, kinesiology, and reactions to various stresses.
3. Perform a detailed objective examination of the SIJ, including palpation of the articular and the soft tissue structures, specific passive mobility tests, passive articular mobility tests, and stability tests.
4. Evaluate the total examination data to establish the diagnosis.
5. Describe the intervention strategies based on clinical findings and established goals.
6. Design an intervention based on patient education, manual therapy, and therapeutic exercise.
7. Apply active and passive mobilization techniques, and combined movements to the SIJ, in any position using the correct grade, direction, and duration.
8. Describe the common pathologies and lesions of this region.
9. Evaluate intervention effectiveness in order to progress or modify an intervention.
10. Plan an effective home program and instruct the patient in this program.

OVERVIEW

The SIJ serves as the supporting base of the spine and as the point of intersection between the spinal and the lower extremity joints. The SIJ is the least understood and, therefore, one of the most controversial and interesting areas of the spine. Determining a diagnosis in this region is complicated by the biomechanics of the SIJ and its relationships with the surrounding joints including the hip, pubic symphysis, and lumbar spine.

Grieve[1] has proposed that the SIJ, together with the other areas of the spine that serve as transitional areas, is of prime importance in understanding vertebral joint problems. This level of importance is perhaps surprising, because isolated pelvic impairments are rare. However, findings for SIJ dysfunction appear to be common, and the literature is replete with intervention techniques aimed at correcting pelvic dysfunctions.[2–12] This may be explained by the fact that, in addition to producing pain on its own, the pelvic joints often can refer pain.[13]

The level of interest surrounding this joint dates back to the Middle Ages, a time when the burning of witches was commonplace.[14] It was noticed after these burnings that three of the bones were not destroyed: a large triangular bone and two very small bones. It can only be assumed that some degree of significance was given to the large triangular bone as it was deemed a sacred bone, and was thus called the sacrum. It is unclear what significance was given to the two smaller bones, the sesamoid bones of the great toe.

Despite these illustrious beginnings for the sacrum, it was not until approximately 100 years ago that significant attention was applied to the study of pelvic anatomy and function, and its relationship to low back and pelvic pain. At the start of the 20th century, SIJ strain was thought to be the most common cause of sciatica.[15] Then, in 1934, Mixter and Barr[16] reported that sciatica could be caused by a prolapsed intervertebral disk, and the interest in the SIJ as a source of sciatica dwindled. Since then, there have been periods when the joint has been blamed for almost all low back and leg pain, and times when it has only been considered a problem during pregnancy. It is now generally accepted that approximately 13% (95% CI: 9–26%) of patients with persistent low back pain have the origin of pain confirmed as the SIJ.[17]

ANATOMY

Anatomically, the SIJ is a large diarthrodial joint that connects the spine with the pelvis (Fig. 29-1) and which serves as a central base through which forces are transmitted both

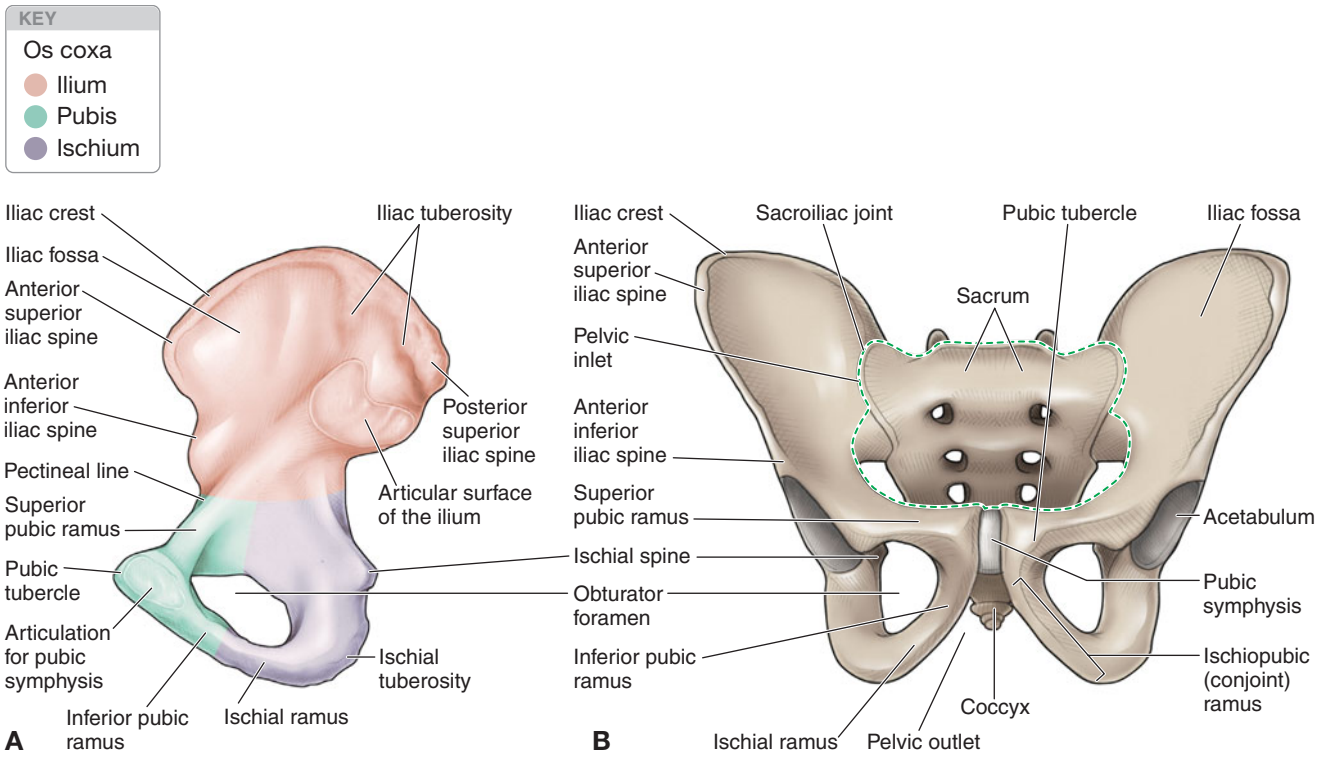

FIGURE 29-1 The pelvis. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy*. McGraw-Hill, 2011.)

directly and indirectly. Three bones comprise the SIJ: two innominates and the sacrum.

Innominates

The ilium, ischium, and pubic bone fuse at the acetabulum to form each innominate (Fig. 29-1). The ilium of each of the two innominates articulate with the sacrum, forming the SIJ, and the pubic bone of each of the innominates articulate with each other at the symphysis pubis.[18]

Sacrum

The sacrum (Fig. 29-1), a strong and triangular bone located between the two innominates, provides stability to this area and transmits the weight of the body from the mobile vertebral column to the pelvic region. The sacrum base is above and anterior, and its apex below and posterior (Fig. 29-1). Five centra fuse to form the central part of the sacrum, which contains remnants of the intervertebral disks enclosed by bone. The sacrum has four pairs of pelvic sacral foramina for transmission of the anterior (ventral) primary rami of the sacral nerves and four pairs of posterior (dorsal) sacral foramina for transmission of the posterior (dorsal) primary rami.

The transverse processes of the first sacral vertebra fuse with the costal elements to form the ala and the lateral crests (see Fig. 29-1). The ala of the sacrum forms the superolateral portions of the base. The superior articular processes of the sacrum (Fig. 29-1), which are concave and oriented posteromedially, extend upward from the base to articulate with the inferior articular processes of the fifth lumbar vertebra.

On the posterior (dorsal) surface of the sacrum is a midline ridge of bone called the median sacral crest, which represents the fusion of the sacral spinous processes of S1 to S4. Projecting posteriorly from this crest are four spinous tubercles. The fused laminae of S1 to S5, which are located lateral to the median sacral crest, form the intermediate sacral crest.

The sacral hiatus exhibits bilateral downward projections that are called the *sacral cornua*. These projections represent the inferior articular processes of the fifth sacral vertebra and are connected to the coccyx via the intercornual ligaments. On the inferolateral borders of the sacrum, approximately 2 cm to either side of the sacral hiatus, are the inferior lateral angles (ILAs). The triangular sacral canal houses the cauda equina. In addition to the more commonly considered bones and joints are those of the coccygeal spine.

Sacroiliac Joint

The articulating surfaces of this joint differ, with the iliac joint surfaces formed from fibrocartilage and the sacral surfaces formed from hyaline cartilage.[19] The hyaline cartilage is three to five times thicker than the fibrocartilage[20] and so between the sacral and iliac auricular surfaces, the SIJ is deemed a synovial articulation or diarthrosis.[21]

The inverted, L-shaped, auricular articular surface of the sacrum (Fig. 29-1) is surrounded entirely by the costal elements of the first three sacral segments. The short (superior) arm of this L-shape lies in a craniocaudal plane, within the first sacral segment, and corresponds to the depth of the sacrum (see Fig. 29-1). It is widest superiorly and anteriorly. The long (inferior) arm of the L-shape lies in an A-P plane, within the second and third sacral segments, and represents the length of the sacrum from top to bottom. It is widest inferiorly and posteriorly. There are large irregularities on each articular

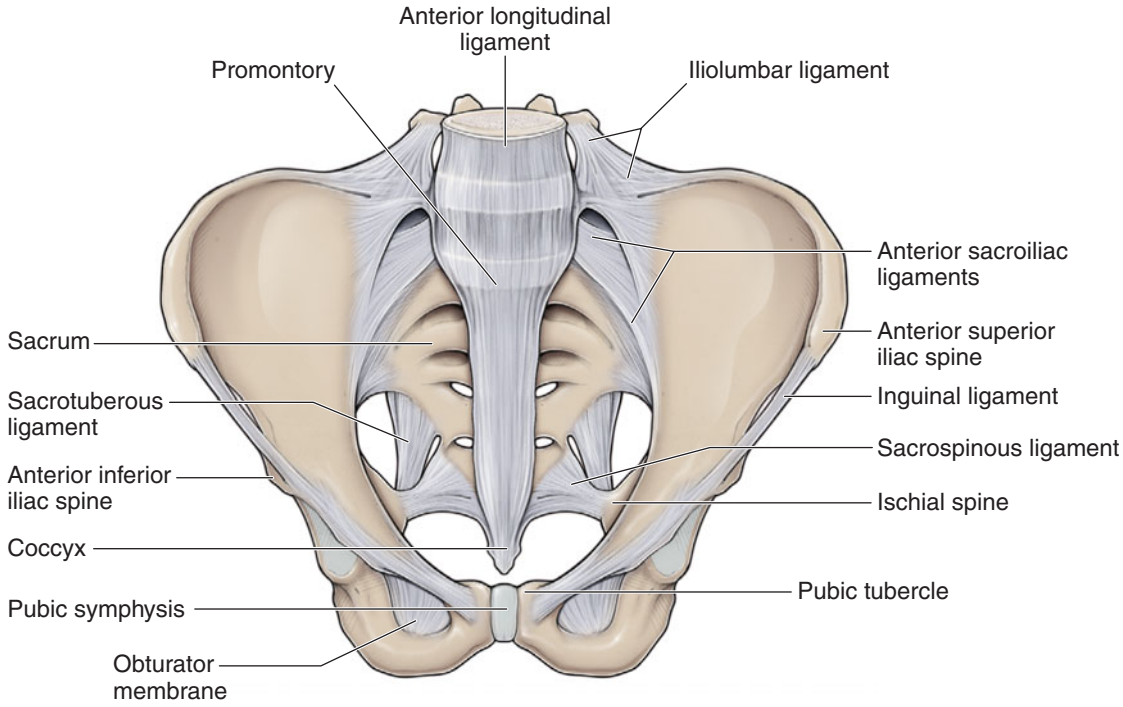

FIGURE 29-2 Anterior ligaments.

surface[22] that are roughly, though not exactly, reciprocal, with the sacral contours being generally deeper.[23,24] In addition to the larger irregularities, there are smaller horizontal crests and hollows that run anteroposteriorly. The sacral articular surface is wedge shaped in its upper portion, formed by the first sacral segment and half of the second. Below this, the joint surfaces run nearly vertically and then diverge somewhat, making a flare which tends to prevent the sacrum from sliding upward between ilia.[24]

Variations in the SIJ morphology are so common that they have been classified as type A, being less vertical than type B, and type C as an asymmetric mixture of types A and B.[5] Each of these variants can alter the function of the pelvis and its influence on the lumbar lordosis.[25]

CLINICAL PEARL

The configuration of the SIJs is extremely variable from person to person and between genders in terms of morphology and mobility.[24,26,27] However, it has been determined that these differences are not pathological, but normal adaptations.[26]

The articulating surfaces of the joint respond differently to the aging process, with early degenerative changes occurring on the iliac surface rather than on both surfaces of the joint simultaneously.[28] Other changes associated with aging include the development of intra-articular fibrous connections.[29] However, even with severe degenerative changes, the SIJ rarely fuses.[21]

The SIJ can be the site of manifestation for several disease processes, including SI tuberculosis, spondyloarthropathy (ankylosing spondylitis), and crystal and pyogenic arthropathies.

Joint Capsule

The SIJ capsule, consisting of two layers, is extensive and very strong. It attaches to both articular margins of the joint and is thickened inferiorly.

Ligaments

Like other synovial joints, the SIJ is reinforced by ligaments, but the ligaments of the SIJ are some of the strongest and toughest ligaments of the body.

Anterior Sacroiliac (Articular)

The anterior sacral ligament (Fig. 29-2) is an anteroinferior thickening of the fibrous capsule, which is relatively weak and thin compared with the rest of the SI ligaments. The ligament extends between the anterior and inferior borders of the iliac auricular surface and the anterior border of the sacral auricular surface.[21] The anterior sacral ligament is better developed near the arcuate line and the posterior inferior iliac spine (PIIS), where it connects the third sacral segment to the lateral side of the preauricular sulcus.

Because of its thinness, this ligament is often injured and can be a source of pain. It can be palpated at Baer's SI point*[30] and can be stressed using the anterior distraction and posterior compression pain provocation tests (see later).

Interosseous Sacroiliac (Articular)

This is a strong, short ligament located deep to the posterior (dorsal) SI ligament, and it forms the major connection between the sacrum and the innominate, filling the irregular

*Baer's SI point has been described as being on a line from the umbilicus to the anterior superior iliac spine, 5 cm from the umbilicus.

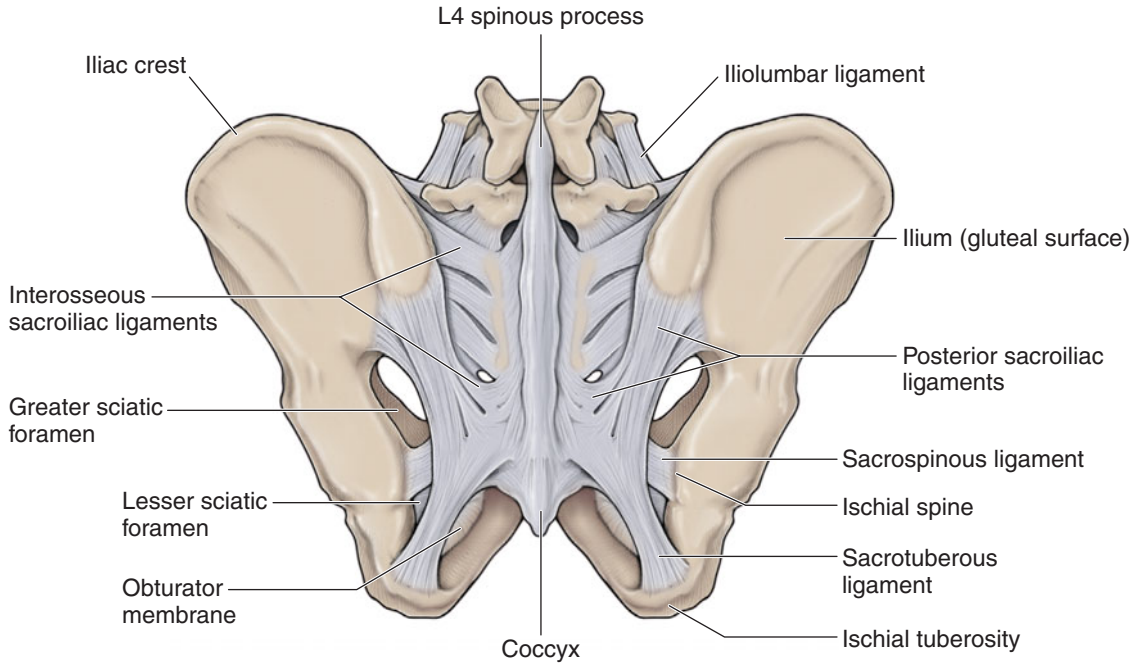

FIGURE 29-3 Posterior ligaments.

space posterosuperior to the joint between the lateral sacral crest and the iliac tuberosity (Fig. 29-3).[31] The deep portion sends fibers cranially and caudally from behind the auricular depressions. The superficial portion is a fibrous sheet connecting the superior (cranial) and posterior (dorsal) margins of the sacrum to the ilium, forming a layer that limits direct palpation of the SIJ. The interosseous SI ligament functions to resist anterior and inferior movement of the sacrum.

Posterior (Dorsal) Sacroiliac (Articular)

The posterior (dorsal) SI ligament or long ligament (see Fig. 29-3), which is easily palpable in the area directly caudal to the posterior superior iliac spine (PSIS), connects the PSIS (and a small part of the iliac crest) with the lateral crest of the third and fourth segments of the sacrum.[18] This is a very tough and strong ligament. The fibers from this ligament are multidirectional and blend laterally with the sacrotuberous ligament. It also has attachments medially to the erector spinae[32] and multifidus muscles[33] and the thoracodorsal fascia. Thus, contractions of the various muscles that attach to this ligament can result in the tightening of the ligament.

Directly caudal to the PSIS, the ligament is so solid and stout that one can easily think a bony structure is being palpated. What complicates matters is the fact that the area overlying the ligament is a frequent source of pain.[34]

The lateral expansion of the long ligament in the region directly caudal to the PSIS varies between 15 and 30 mm. The length, measured between the PSIS and the third and fourth sacral segments, varies between 42 and 75 mm. The lateral part of the posterior (dorsal) ligament is continuous with fibers passing between ischial tuberosity and iliac bone.

At the superior (cranial) aspect, the posterior (dorsal) ligament is attached to the PSIS and the adjacent part of the ilium, at the inferior (caudal) side to the lateral crest of the third and fourth, and occasionally to the fifth, sacral segments.[32]

Nutation (anterior motion) of the sacrum appears to slacken the posterior (dorsal) ligament, whereas counternutation (posterior motion) tautens the ligament.[32]

Sacrotuberous (Extra-articular)

This ligament (see Fig. 29-3) is composed of three large fibrous bands, broadly attached by its base to the PSIS, the lateral sacrum, and partly blended with the posterior (dorsal) SI ligament. Its oblique, lateral fibers descend and attach to the medial margin of the ischial tuberosity, spanning the piriformis muscle from which it receives some fibers. The medial fibers, running anteroinferior and laterally, have an attachment to the transverse tubercles of S3, S4, and S5, and the lateral margin of the coccyx. To the posterior surface of the sacrotuberous ligament are attached the lowest fibers of the gluteus maximus and the piriformis, the contraction of which produces increased tension in the ligament.[35] Superficial fibers on the inferior aspect of the ligament can continue into the tendon of the biceps femoris.

In addition to stabilizing against nutation of the sacrum, the sacrotuberous ligament also counteracts against the posterior (dorsal) and superior (cranial) migration of the sacral apex during weight bearing.[36,37]

Sacrospinous (Extra-articular)

Thinner than the sacrotuberous ligament, this triangular-shaped ligament extends from the ischial spine to the lateral margins of the sacrum and coccyx, and also laterally to the spine of the ischium (see Fig. 29-3). The ligament runs anterior (deep) to the sacrotuberous ligament to which it blends and then attaches to the capsule of the SIJ.[33]

The sacrotuberous and sacrospinous ligaments, which convert the greater and lesser sciatic notches into the greater and

lesser foramen respectively, oppose forward tilting of the sacrum on the innominates during weight bearing of the vertebral column.

Iliolumbar (Indirect)

The anatomy of the iliolumbar ligament (Fig. 29-2) is described in Chapter 28.

Pubic Symphysis

The pubic symphysis is classified as a symphysis because it has no synovial tissue or fluid, and it contains a fibrocartilaginous lamina or disk (Fig. 29-2). The bone surfaces of the joint are covered with hyaline cartilage, but are kept apart by the presence of the disk.

The following are the supporting ligaments of this joint[23]:

- Superior pubic ligament, a thick fibrous band.
- Inferior arcuate pubic ligament, which attaches to the inferior pubic rami bilaterally and blends with the articular disk.
- Posterior pubic ligament, a membranous structure that blends with the adjacent periosteum.
- Anterior ligament, a very thick band that contains both transverse and oblique fibers.

The pubic symphysis is a common source of groin pain, particularly in athletes (see section "Groin Pain").

Muscles

Lee[12] lists 35 muscles that attach directly to the sacrum or innominate, or both (Table 29-1). A muscle attaching to a bone has the potential for moving that bone, although the degree of potential varies. Rather than producing movement at the SIJ, the muscles around the pelvis are more likely involved directly or indirectly in helping to provide stability to the joint.

TABLE 29-1 Muscles That Attach to the Sacrum, Ilium, or Both

Latissimus dorsi
Erector spinae
Semimembranosus
Semitendinosus
Biceps femoris
Sartorius
Inferior gamellus
Multifidus

Superior gemellus
Gracilis
Iliacus
Adductor magnus
Rectus femoris
Quadratus lumborum
Pectineus
Psoas minor
Adductor brevis
Adductor longus
Levator ani
Sphincter urethrae
Superficial transverse perineal ischiocavernosus
Coccygeus

Piriformis

This muscle (see Chap. 19) arises from the anterior aspect of the S2, S3, and S4 segments of the sacrum; the capsule of the SIJ; and the sacrotuberous ligament. It exits from the pelvis via the greater sciatic foramen, before attaching to the upper border of the greater trochanter of the femur.

The piriformis primarily functions to produce external rotation and abduction of the femur, but is also thought to function as an internal rotator and abductor of the hip if the hip joint is flexed beyond 90 degrees. It also helps to stabilize the SIJ, although too much tension from it can restrict the motion of this joint.[38] The piriformis has been implicated as the source for a number of conditions in this area, including the following two:

- ***Entrapment neuropathies of the sciatic nerve (piriformis syndrome.[39–45]).*** Piriformis syndrome is described in Chapter 5.
- ***Trigger and tender points.***[46]

Transversus Abdominis

For a detailed description of the anatomy of the transversus abdominis (TrA), refer to Chapter 28. Although the TrA does not cross the SIJ directly, it can affect the stiffness of the pelvis through its direct anterior attachments to the ilium, as well as its attachments to the middle layer and the deep laminae of the posterior layer of the thoracodorsal fascia.[47,48]

Multifidus

The anatomy of the multifidus muscle is described in Chapter 28. Some of the deepest fibers of the multifidus attach to the capsules of the zygapophyseal joints[49] and are located close to the centers of rotation for spinal motion. They connect adjacent vertebrae at appropriate angles, and their geometry remains relatively constant through a range of postures, thereby enhancing spinal stability.[50]

Erector Spinae

For a detailed description of the anatomy of the erector spinae, refer to Chapter 28. Through its extending effect on the spine

and its substantial sacral attachments, the erector spinae might be thought to promote sacral nutation, although this has not been proven.

Gluteus Maximus

This is one of the strongest muscles in the body (see Chap. 19). It arises from the posterior gluteal line of the innominate, the posterior aspect of the lower lateral sacrum and coccyx, the aponeurosis of erector spinae muscle, the superficial laminae of the posterior thoracodorsal fascia, and the fascia covering the gluteus medius muscle, before attaching to the gluteal tuberosity. In the pelvis, the gluteus maximus blends with the ipsilateral multifidus, through the raphe of the thoracodorsal fascia,[33] and the contralateral latissimus dorsi, through the superficial laminae of the thoracodorsal fascia.[51] Some of its fibers attach to the sacrotuberous ligament. When these fibers contract, tension in the sacrotuberous ligament increases.[52]

Iliacus

This muscle arises from the iliac fossa (see Chap. 19), the iliac crest, the anterior SI ligament, the inferior fibers of the iliolumbar ligament,[53] and the lateral aspect of the sacrum. As it travels distally, its fibers merge with the lateral aspect of the psoas major tendon to form the iliopsoas, which continues onto the lesser trochanter of the femur, sending some fibers to the hip joint capsule as it passes.

Long Head of the Biceps Femoris

The long head of the biceps femoris originates from the ischial tuberosity and sacrotuberous ligament. In addition to functioning as a hip extensor and knee flexor, the long head of the biceps femoris, due to its connections to the sacrotuberous ligament, may also have a proprioceptive role during activities such as gait.

Pelvic Floor Musculature

The term "pelvic floor muscles" primarily refers to the levator ani, a muscle group composed of the pubococcygeus, puborectalis, and iliococcygeus. The levator ani muscles join the coccygeus muscles to complete the pelvic floor. The pelvic floor muscles work in a coordinated manner to increase intra-abdominal pressure, provide rectal support during defecation, inhibit bladder activity, help support the pelvic organs, and assist in lumbopelvic stability.[54]

Levator Ani. The levator ani (Fig. 29-4) originates anteriorly from the pelvic surface of the pubis, posteriorly from the inner surface of the ischial spine, and from the obturator fascia. It inserts into the front and sides of the coccyx, to the sides of the rectum, and into the perineal body. The levator ani forms the floor of the pelvic cavity, functions to constrict the lower end of the rectum and vagina, and can also be activated during forced expiration.

The muscle, which consists of anterior, intermediate, and posterior fibers, is innervated by the muscular branches of the pudendal plexus.

Anterior Fibers. The anterior fibers insert into the perineal body, comprise the levator prostatae or sphincter vaginae, and form a sling around the prostate or vagina.

Intermediate Fibers

- ***Puborectalis.*** The puborectalis (see Fig. 29-4) originates at the pubis and forms a sling around the junction of the rectum and the anal canal. The muscle pulls the anorectal junction anteriorly, assisting the external sphincter in anal closure.
- ***Pubococcygeus.*** The pubococcygeal muscle (see Fig. 29-4) arises from the pubis and its superior ramus, and passes posteriorly to insert into the anococcygeal body between the coccyx and the anal canal. The muscle functions to pull the coccyx forward. It also serves to elevate the pelvic organs and compress the rectum and vagina.

Posterior Fibers. The iliococcygeal muscle (see Fig. 29-4) arises from the arcus tendineus and ischial spine and inserts onto the last segment of the coccyx and the anococcygeal body. The muscle functions to pull the coccyx from side to side and to elevate the rectum.

- ***Levator Plate.*** The pubococcygeal muscle and the iliococcygeal muscle unite posterior to the anorectal junction to form the levator plate, which inserts into the coccyx.
- ***Coccygeus.*** This muscle (Fig. 29-4) arises from the pelvic surface of the ischial spine and sacrospinous ligament and inserts on the coccyx margin and side of the lowest segment of the sacrum. Supplied by the muscular branches of the pudendal plexus, the coccygeus functions to pull forward and support the coccyx. In addition, the coccygeus muscle provides support for the pelvic contents and the SIJ.

Neurology

It remains unclear precisely how the anterior and posterior aspects of the SIJ in humans are innervated, although the anterior portion of the joint likely receives innervation from the posterior rami of the L2 to S2 roots.[55] Contribution from these root levels is highly variable and may differ among the joints of given individuals.[56] Additional innervation to the anterior joint may arise directly from the obturator nerve, superior gluteal nerve, or lumbosacral trunk.[24,57] The posterior portion of the joint is likely innervated by the posterior rami of L4 to S3, with a particular contribution from S1 and S2.[58] An additional autonomic component of the joint's innervation further increases the complexity of its neural supply and likely adds to the variability of pain referral patterns from this area.[57,59]

BIOMECHANICS

Motions at the neighboring lumbar spine predominantly occur around the sagittal plane and comprise flexion and extension, whereas the motions occurring at the hip occur in three planes and include the one motion that the lumbar spine does not tolerate well, i.e., rotation. Thus, the pelvic area must function to transfer the loads generated by body weight and gravity during standing, walking, sitting, and other functional tasks.[60] To date, there is very little agreement, either among or even within disciplines, about how the structures of the pelvis

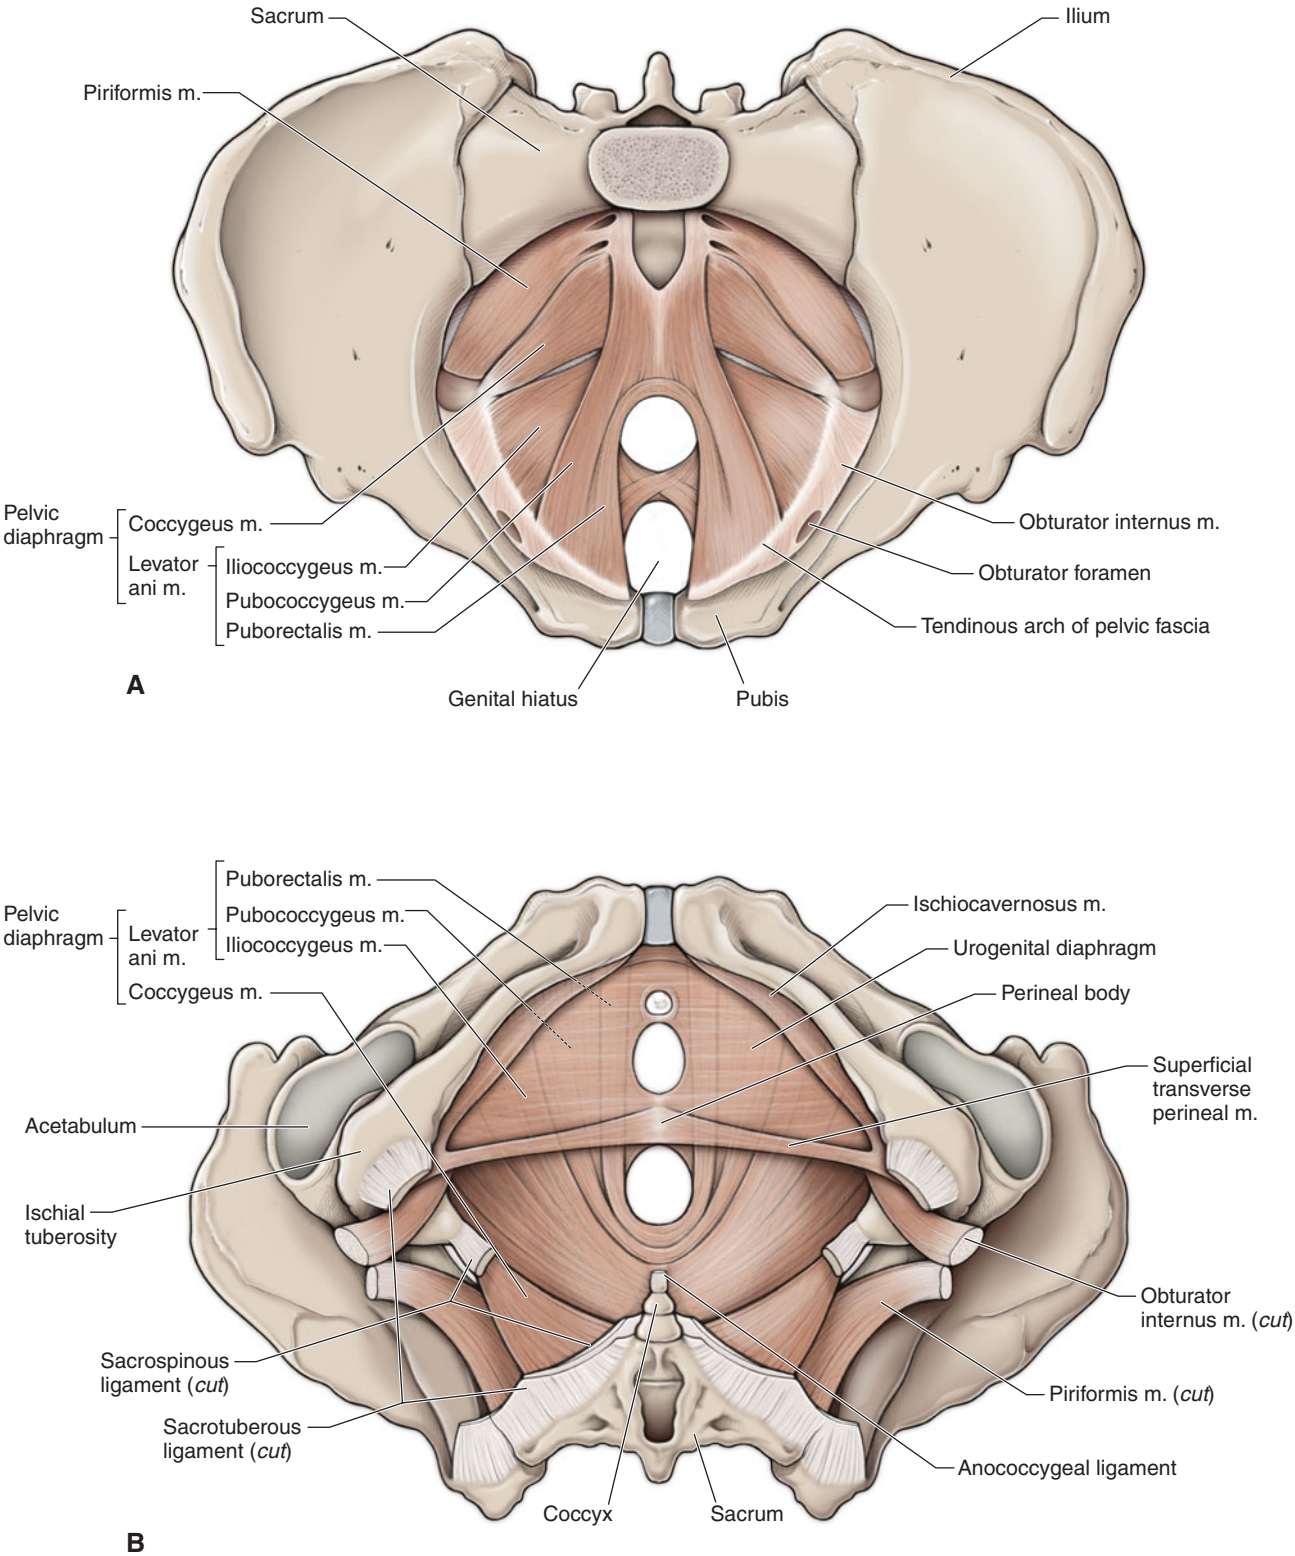

FIGURE 29-4 Pelvic floor muscles. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy*. McGraw-Hill, 2011.)

achieve this. For many decades, it was thought that the SIJ was immobile due to the close fitting nature of the articular surfaces. Research has now shown that mobility of the SIJ is not only possible[61–64] but also essential for shock absorption during weight-bearing activities.[65] However, the range of motion in the SIJ is small, less than 4 degrees of rotation and up to 1.6 mm of translation.[62,66] Of interest, is the fact that one study[67] found no difference in available range of motion between the symptomatic and asymptomatic sides.

It is likely that the movement of the pelvis is in the nature of deformations and slight gliding motions around a number of undefined axes, with the joints of the pelvic ring deforming in

response to body weight and ground reaction forces. The amplitude of this motion likely varies between individuals. Motion at the SIJ is facilitated by several features, including the following:

- The fibrocartilaginous surfaces of the innominate facets, which are deformable, especially during weight bearing, when the surfaces are forced together.
- The pubic symphysis—if the innominates are moving at the SIJ, then they must also be moving at their anterior junction, which would allow for an immediate, and almost perfect, reciprocal motion.

No manual diagnostic tests have shown reliability for determining how much an individual's SIJ is moving in either symptomatic or asymptomatic subjects. In contrast to Sturesson's study,[67] when Doppler imaging testing has been used to measure stiffness (or laxity) of the SIJ in subjects with and without pelvic pain, it has been shown that asymmetry of stiffness between sides correlated with the symptomatic individual.[68–70] These studies have shown that within the same subject, asymptomatic individuals have similar values for the left and right SIJs, whereas individuals with unilateral posterior pelvic girdle pain had different stiffness values for the left and right sides. Theoretically, when assessing SIJ mobility, a dysfunction at the SIJ can manifest as one of the two types of asymmetries:

- If one of the SIJs is hypermobile, the amplitude of motion is asymmetrically increased and the resistance to motion is decreased on the dysfunctional side.
- If one of the SIJs is hypomobile, the amplitude of motion is asymmetrically reduced and the resistance to motion is increased on the dysfunctional side.

Thus, the current trend is to focus more on the symmetry, or asymmetry, of the motions palpated or observed.

Anatomical research,[12,71,72] initiated to determine the source of low back pain, has demonstrated that alterations in the pattern of muscular contraction and the timing of specific muscle activation differ between healthy subjects and those demonstrating symptoms. Furthermore, studies[73] have shown that the strength and endurance of the trunk muscles is important in determining the muscle capacity of individuals. This research has led to theories about the force- and form-closure mechanisms of joints and how stability is necessary at joints for effective load transfer. Based on this knowledge, functional tests of load transfer through the pelvic girdle have been developed[74–76] together with a number of treatment protocols.[77–79] This approach has three physical components (form closure, force closure, and motor control), and one psychological component (emotions).

In upright positions, the SIJ is subjected to considerable shear force as the mass of the upper body must be transferred to the lower limbs via the ilia.[80,81] The body has two mechanisms to overcome this shear force: one dependent on the shape and structure of the joint surfaces of the SIJs (form closure), which is wedge shaped with a high coefficient of friction, and the other mechanism involving generation of compressive forces across the SIJ via muscle contraction (force closure).[81]

Form Closure. Form closure refers to a state of stability within the pelvic mechanism, with the degree of stability dependent on its anatomy, with no need for extra forces to maintain the stable state of the system.[72] The following anatomic structures are proposed to assist with form closure:

- The congruity of the articular surfaces and the friction coefficient of the articular cartilage. Both the coarseness of the cartilage and the complementary grooves and ridges increase the friction coefficient, and thus contribute to form closure by resisting against horizontal and vertical translations.[24] In infants, the joint surfaces are very planar, but between the ages of 11 and 15 years, the characteristic ridges and humps that make up the mature sacrum begin to form. By the third decade, the superficial layers of the fibrocartilage are fibrillated and crevice formation and erosion has begun. By the fourth and fifth decades, the articular surfaces increase irregularity and coarseness and the wedging is incomplete.[21]
- The integrity of the ligaments.
- The shape of the closely fitting joint surfaces.

According to current research, when the sacrum nutates, or flexes, relative to the innominate (Fig. 29-5), or when the innominate posteriorly rotates relative to the sacrum, the greatest number of ligaments, particularly the interosseous and posterior (dorsal) ligaments, are tightened at the SIJ.[72,82,83] These latter ligaments lie posterior to the joint and approximate the posterior iliac bones when placed under tension.[82] Thus, nutation of the sacrum can be described as the close packed position, or self-locking mechanism, for the SIJ and is, therefore, the most effective position for transferring high loads. This position somewhat conveniently produces a position of lumbar lordosis, which is advocated in many interventions for the lumbar spine.

Just as nutation of the sacrum enhances the self-locking mechanism, counternutation of the sacrum (Fig. 29-6), which occurs during activities such as the end range of forward bending, sacral sitting, long sitting, and hip hyperextension, reduces the self-locking mechanism.[82] This position results in a loss of the lumbar lordosis and an increase in intervertebral disk pressure (see Chap. 28).

Using forward bending at the waist as an example, a combination of anterior and outward rotation of both

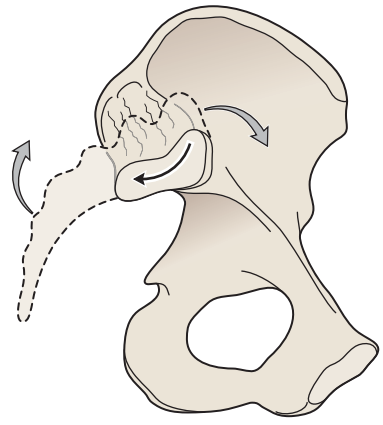

FIGURE 29-5 Sacral nutation.

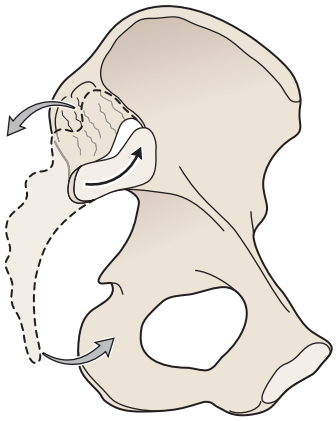

FIGURE 29-6 Sacral counternutation.

innominates results in the approximation and superior motion of both PSISs, while the sacrum nutates (Table 29-2). After approximately 60 degrees of forward bending, the innominates continue to rotate anteriorly, but the sacrum no longer nutates.[12] If the sacrum remains nutated throughout the forward bending, the SIJ remains compressed and stable. However, if the sacrum is forced to counternutate earlier in the range, as in individuals with tight hamstrings, less compression occurs, thereby increasing the reliance on dynamic stabilization provided by muscles and thus making the SIJ more vulnerable to injury.[12]

Force Closure. Force closure requires intrinsic and extrinsic forces to keep the SIJ stable.[72] These dynamic forces involve the neurological and myofascial systems and gravity. Together, these components produce a self-locking mechanism for the SIJ. Optimum force closure requires application of just the right amount of force at just the right time, which in turn requires a motor control system that can predict the timing of the load and prepare the system appropriately. The degree of force closure depends on the capability of an individual's form closure and the various loading conditions (e.g., speed, duration, magnitude, and predictability).[84]

In a kinetic analysis of the pelvic girdle, Vleeming and colleagues[51,82] identified a number of muscles that resist translational forces and which are specifically important to the force-closure mechanism: the erector spinae, gluteus maximus, latissimus dorsi, and biceps femoris (see Chap. 28). Two other muscle groups, an "inner muscle unit" and an "outer muscle unit" also play an important role.[12,73,79] The inner muscle unit consists of the following:

- ***Transversus abdominis (TrA).*** A study by Richardson and colleagues[85] found that contraction of the TrA significantly decreases the laxity of the SIJ , and that this decrease in laxity is larger than that caused by a bracing action using all the lateral abdominal muscles. Theoretically, contraction of the TrA produces a force that approximates the ilia anteriorly.[85]
- ***The muscles of the pelvic floor.*** Hemborg and colleagues[86] have demonstrated that the pelvic floor muscles coactivate with the TrA during lifting tasks.
- ***Multifidus.*** Studies[87–89] have reported that the deep fibers of the multifidus become inhibited and reduced in size in individuals with low back and pelvic girdle pain.

The outer muscle unit consists of four systems: the posterior oblique system (latissimus dorsi, gluteus maximus, and thoracolumbar fascia), the deep longitudinal system (erector spinae, deep lamina of the thoracolumbar fascia, sacrotuberous ligament, and biceps femoris), the anterior oblique system (external and internal oblique, contralateral adductors of the thigh, and the intervening anterior abdominal fascia), and the lateral system (gluteus medius–minimus and contralateral adductors of the thigh). The outer muscle unit is proposed to contribute to the force-closure mechanism in the following manner[12]:

- ***Posterior oblique system.*** The gluteus maximus (see Chap. 19), which blends with the thoracodorsal fascia, and the contralateral latissimus dorsi contribute to force closure of the SIJ posteriorly by approximating the posterior aspects of the innominates. This oblique system is a significant contributor to load transference through the pelvic girdle during the rotational activities of gait.
- ***Deep longitudinal system.*** This system serves to counteract any anterior shear or sacral nutation forces as well as to facilitate compression through the SIJs. As mentioned in the anatomy section, the long head of the biceps femoris muscle controls the degree of nutation via its connections to the sacrotuberous ligaments.[36]
- ***Anterior oblique system.*** The oblique abdominals, acting as phasic muscles, initiate movements[79] and are involved in all movements of the trunk and upper and lower extremities, except when the legs are crossed.[90]
- ***Lateral system.*** The lateral system functions to stabilize the pelvic girdle on the femoral head during gait through a coordinated action.

TABLE 29-2 Lumbar Motions and Sacroiliac Motions

Lumbar Motion	Innominate Motion	Sacrum Motion
Flexion	Anterior rotation	Nutation, then counternutation
Extension	Slight posterior rotation	Nutation
Rotation	*Ipsilateral:* Posterior rotation *Contralateral:* Anterior rotation	Nutates ipsilaterally
Side bending	*Ipsilateral:* Anterior rotation *Contralateral:* Posterior rotation	*Ipsilateral:* Side bends ipsilaterally *Contralateral:* Side bends contralaterally

CLINICAL PEARL

The stability of the SIJ is a factor of the length and strength of the muscle units, neuromuscular control, and the ability of the sacrum to nutate in all positions of threat. Weakness or insufficient recruitment and/or unbalanced muscle function within the lumbar/pelvic/hip region can reduce the force-closure mechanism, which can result in compensatory movement strategies.[91] These compensatory movement strategies and/or patterns of muscle imbalance may produce a sustained counternutation of the sacrum, thereby "unlocking" the mechanism and rendering the SIJ vulnerable to injury. This unlocked position of the pelvis may also increase shear forces at the lumbar spine and abnormal loading of the lumbar disks.

As alluded to earlier, the sacral positions that correspond to poor sacral biomechanics are very similar to those lumbar spine positions that are unfavorable for spinal stability. Conversely, the positions that enhance sacral stability also enhance lumbar spine stability. As a result, there has been much confusion amongst disciplines when determining whether the SIJ or lumbar spine is the cause of the patient's symptoms. For example, consider the prone on elbows position (see Chap. 28), which nutates the sacrum and increases the lordosis of the lumbar spine. If a patient with either a sacral dysfunction or an intervertebral disk herniation is asked to adopt this position, the symptoms would likely decrease.

EXAMINATION

Most investigators agree that no single test can be used to confirm the diagnosis of SIJ dysfunction because of the complexity of the anatomy and biomechanics and its proximity to other symptom-provoking structures.

Diagnostic physical examination tests that are commonly used to determine a diagnosis include[56]

- direct tenderness;
- soft tissue examination for zones of hyperirritability and tissue texture changes;
- evaluation of referral zones;
- associated fascial or musculotendinous restrictions;
- regional abnormal length–strength muscle relationships;
- postural analysis;
- true leg length and functional leg length determination;
- static and dynamic osseous landmark examinations;
- provocative testing, including traditional orthopaedic tests, motion demand tests, and ligament tension tests.

Although traditionally assumed to be reliable and diagnostically useful, none of these tests has ever been validated against an independent criterion standard.[56] As a consequence, controversy exists about which group of tests is the best.

Under the premise that a relationship exists between pelvic asymmetry and low back pain, orthopaedic, osteopathic, and physical therapy tests promote the use of pain provocation (symptom based) tests and static (positional) or dynamic (motion or functional) tests.[1,10,12,38,92–95]

The use of static tests has been questioned as,[96–100] although Cibulka and colleagues[101] found the results from these tests reliable, Levangie[100] found a weak association between standing PSIS asymmetry and low back pain, at least in selected groups. The problems with static testing are

- determining whether the asymmetry noted is normal or abnormal;
- determining which side is abnormal;
- determining whether the asymmetry is too asymmetric or not asymmetric enough. For example, if the right innominate is anteriorly rotated, compared with the left, is it rotated too much, too little, or just the right amount compared with its starting position? Because the starting position is not known, the degree of rotation cannot be assessed.

The dynamic tests do not fair much better. Dreyfuss and colleagues[56] reported 20% positive findings in one or more of the dynamic (motion or functional) tests in a group of asymptomatic people. An example of a dynamic test is the standing flexion test, which has been used frequently to analyze SIJ mobility and to determine the side of the impairment. The test is performed as follows: Each PSIS is palpated with the thumb placed under it caudally. The patient then bends forward at the waist. Provided there is no impairment in the SIJ or the lower lumbar spine, as the patient bends forward, both thumbs should move superiorly (cranially). If one SIJ joint is "blocked," it moves upward further in relation to the other side.[99] Thus far, reliability studies of the standing flexion test show that it lacks sufficient diagnostic power.[99,102,103] This shortfall may be because the compression of the joints caused by the sacral nutation in the early to midranges of forward flexion likely limits movement of the SIJ.[104]

Some studies have reported that pain provocation tests have a good interexaminer reliability,[99,105] but they have not been found reliable by others.[17,102] This is likely because the pain provocation tests have only been found reliable in identifying SIJ dysfunction in certain populations, such as patients with posterior pelvic pain during or following pregnancy.[106]

As several recent studies have found improved interrater reliability in the diagnosis of low back pain when using a combination of physical examination procedures as opposed to a single model approach,[17,56,99,107,108] it would be logical to assume that a similar approach would work with the SIJ.

Ideally, the diagnosis needs to be based on the results from a thorough biomechanical examination that includes an assessment of load transfer, and pain provocation. Patients with failed load transfer through the pelvic girdle often present with inappropriate force closure, in that certain muscles become overactive while others remain inactive, delayed, or asymmetrical in their recruitment.[109] When approaching SIJ dysfunction it is likely more important to determine why there are symptoms, rather than attempting to identify the specific symptom generating structures.

CLINICAL PEARL

The main objective of SIJ assessment is to determine whether the condition appears to primarily involve[84]

- too much compression occurring from stiff, fibrosed joints, or hypertonicity of the global muscles system.
- poor control of loose joints or underactivation of the deep (local) stabilizing muscles system.
- a combination of too much compression and too little control throughout the lumbopelvic–hip complex.

In most cases, an examination of the pelvic joints is of little use if the lumbar spine and the hip joints have not been previously cleared by examination or intervention, because both of these joints can refer pain to this area and may also profoundly affect the function of the SIJ. The algorithm depicted in Fig. 29-7 should serve as a guide.

History

A history of low back pain or leg pain, or both, warrants an examination of the lumbopelvic–hip complex. The most common presenting symptoms in patients with SIJ dysfunction are pain or tenderness over the region of the posterior superior iliac spine.[110–112]

Mechanical pain resulting from SIJ dysfunction may manifest as sacral pain but may also refer pain distally. For example, SIJ problems can refer pain to the iliac fossa, the buttock, the groin, the superior lateral and posterior thigh, and rarely below the knee.[113] In general, SIJ pain is characterized by unilateral pain below the level of L5, in the absence of midline pain, whereas irritation of a spinal nerve may cause radicular symptoms below the knee.[114] Pubic symphysis dysfunction typically results in localized pain, or groin pain, which is aggravated by activities involving the hip adductor or rectus abdominis muscles.[115] However, studies have shown that using evidence of pain referral patterns, or evidence of groin pain are neither sensitive nor specific for SIJ dysfunction.[116]

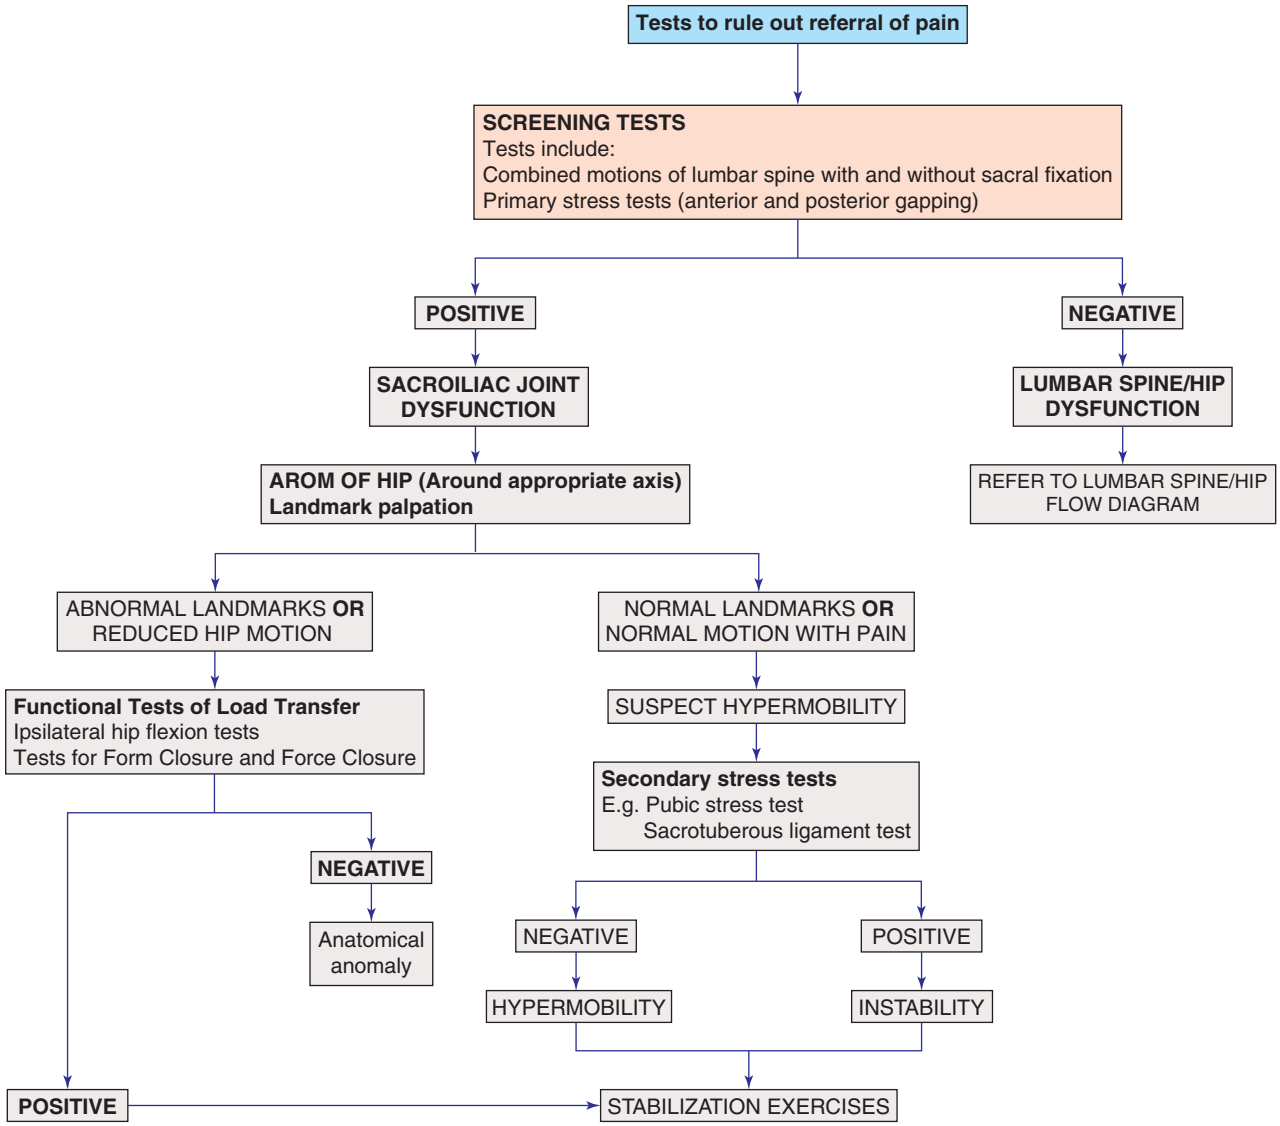

FIGURE 29-7 Decision-making algorithm for the SIJ.

Pain also may be referred to the sacrum from a distant structure, including the contralateral sacrospinalis muscle,[117] the ipsilateral interspinous ligaments of L3 to S2,[118] and the L4 to L5 facet joints.[119] In addition, it is well established that dysfunctional pelvic floor muscles can contribute to the symptoms of interstitial cystitis and the so-called urethral syndrome, which is urgency–frequency with or without chronic pelvic pain.[120–122]

The following findings are likely to be present with a SIJ dysfunction:[13,56,123,124]

- A history of sharp pain that occurred with a particular activity and that awakens the patient from sleep upon turning in bed.
- Pain with walking, ascending or descending stairs, or hopping or standing on the involved leg.
- Pain with forward bending of the trunk and pain with standing hip flexion.
- Pain with transitional movements such as rising to stand from a sitting position or getting in and out of the car.
- Pain with a straight leg raise at, or near, the end of range (occasionally early in the range when hyperacute).
- Pain and sometimes limitation on extension and ipsilateral side bending of the trunk.
- Pain that is worsened with long periods of sitting or standing if the lumbar lordosis is not maintained.

Systems Review

Given the number of visceral organs in the vicinity of the SIJ, the clinician must complete a thorough systems review to rule out a visceral source for the symptoms. A Cyriax scanning examination (see Chap. 4) should be performed on any patient who presents with an insidious onset of pelvic pain. The scanning examination, which includes the primary stress tests (anterior and posterior distraction), can be used to help detect sacroiliitis resulting from microtraumatic arthritis, macrotraumatic arthritis, or systemic arthritis (e.g., ankylosing spondylitis, Reiter's syndrome), or the more serious pathologies grouped under the sign of the buttock (see Chap. 19). Primary breast, lung, and prostate cancers are among the most common cancers to metastasize to the axial skeleton, including the pelvic ring.[125] A further source of sacral pain can be a stress fracture of the sacrum, which can be associated with a wide range of extrinsic and intrinsic risk factors (see "Intervention Strategies"), and an equally wide range of symptoms and signs.[126]

Tests and Measures

As previously mentioned, in order to rule in or rule out SIJ dysfunction, a thorough musculoskeletal examination of the low back, the pelvis, the hips, and the remainder of the lower extremities, including a full neurologic evaluation must be performed.

Observation

The observation should begin with an overall assessment of posture to check for the presence of asymmetry. The clinician should observe the degree of tilt at the pelvis. The question of cause and effect should be raised. An anterior pelvic tilt causes an increase in the lumbar lordosis and thoracic kyphosis. The anterior pelvic tilt results in a stretching of the abdominals and the sacrotuberous, SI, and sacrospinous ligaments, and an adaptive shortening of the hip flexors, the hamstrings, and the erector spinae. In contrast, a posterior pelvic tilt results in lengthening of the hip flexors, the hamstrings, and the erector spinae, and adaptive shortening of the abdominals and the gluteals.

A lateral pelvic tilt, in which one iliac crest is higher than the other, may be caused by scoliosis with ipsilateral lumbar convexity, a leg length discrepancy, or shortening of the contralateral quadratus lumborum. This position results in adaptive shortening of the ipsilateral hip abductors and contralateral hip adductors, and weakness of the contralateral hip abductors.

There appears to be a strong correlation between the position of the pelvis and the forward head.[127] If the pelvic landmarks are asymmetric and the patient has a forward head, the clinician should attempt to correct the forward head. If the attempted correction of the forward head worsens the pelvic asymmetry and increases the symptoms, the intervention should be aimed at correcting the asymmetry. If the attempted correction of the forward head improves the pelvic asymmetry and the symptoms, the subsequent intervention should be aimed at correcting the forward head.[128]

Hip Range of Motion

Range of motion of the hip, including internal and external rotation, is performed to help rule out pain referred from the hip joint. Although a unilateral limitation of hip motion, in which one of the motions is unequal between the left and right sides, has been observed in patients with disorders of the SIJ,[64,129–131] the evidence to demonstrate whether hip motion is limited in patients with signs of SIJ dysfunction is inconclusive. LaBan and colleagues[115] noted asymmetry in hip abduction and external rotation in patients with inflammation of the SIJs. Dunn and colleagues[132] reported limited hip mobility in patients with infection of the SIJ; however, no mention was made as to which movements were limited.

Others have described cases in which patients with low back pain had unilateral, limited internal hip rotation and excessive external hip rotation, and also exhibited signs of SIJ dysfunction. A recent study by Cibulka and colleagues[129] attempted to determine whether a characteristic pattern of hip range of motion existed in patients with low back pain, and whether those classified as having SIJ dysfunction have a different pattern of hip range of motion compared with those with unspecified low back pain. The study found that patients with low back pain, who had signs suggesting SIJ regional pain, had significantly more hip external than internal rotation range of motion on one side. The authors concluded that identifying unilateral hip range of motion asymmetry in patients with low back pain may help in diagnosing SIJ regional pain.[129]

Landmark Palpation

The palpation of landmarks can be used to locate areas of tenderness rather than for detecting pelvic asymmetry,

because as pelvic landmark asymmetry is probably the norm, "positive" findings are likely to be misleading.[100] The various landmarks of the pelvis are palpated with the patient positioned standing, sitting, and lying (see Figs. 29-8 and 29-9).

CLINICAL PEARL

An altered positional relationship within the pelvic girdle should only be considered positive if a mobility restriction of the SIJ or the pubic symphysis, or both, is also found.

The following landmarks and structures are palpated with the patient standing:

- ***Iliac crest.*** The iliac crests on both sides are located using the medial aspects of the index fingers. The crest heights should be level.
- ***Anterior superior iliac spine (ASIS).*** These structures are located anteriorly to the iliac crests. Tenderness of the ASIS may indicate a so-called hip pointer injury or injury to the inguinal ligament. An inferior ASIS relative to the other side may indicate a rotated innominate.[8] According to osteopathic doctrine, if the innominate is anteriorly rotated in the supine position, the leg will be longer on that side, but if posteriorly rotated, the leg will be shorter.[8] However, a study by Levangie[100] found that pelvic asymmetry was not positively associated with low back pain in any way that seemed clinically meaningful. It has been suggested to assess the ASIS in sitting versus standing, but there are no reliable studies to recommend this method.
- ***Posterior superior iliac spine (PSIS).*** These structures are located posteriorly to the iliac crests and approximately 2–3 cm beneath the dimples of the lumbar spine and level with the S2 spinous process. Slightly medially and distal to the PSIS are the SIJs. To assess the levels of the PSIS relative to the opposite side, the clinician hooks the thumbs under both PSIS. A superior PSIS relative to the other side may indicate a rotated innominate.[8] A study by Levangie[100] found that although pelvic asymmetry was not positively associated with low back pain in any way that seemed clinically meaningful, asymmetry of PSIS landmarks showed some evidence of a weak positive association with low back pain. This would indicate that the test does not qualify as a screening tool. PSIS asymmetry can also be assessed similarly in sitting, but the findings from Levangie[100] indicate that this test provides little value during the examination and does not qualify as a screening tool.
- ***Pubic symphysis and pubic tubercles.*** The pubic tubercles are lateral to the pubic symphysis.

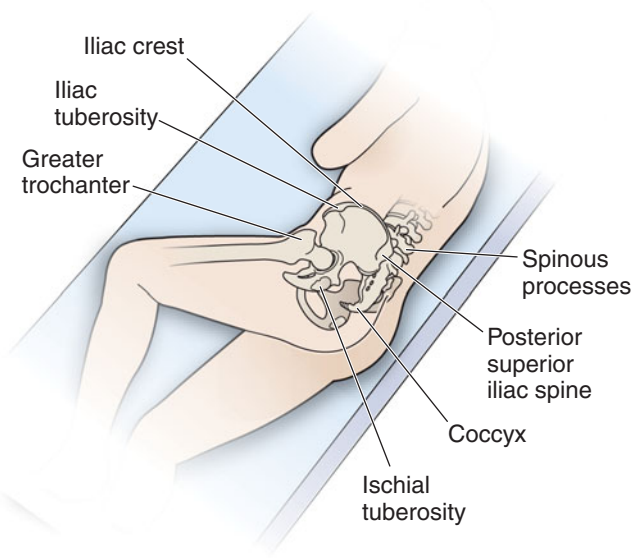

FIGURE 29-9 Bony landmarks.

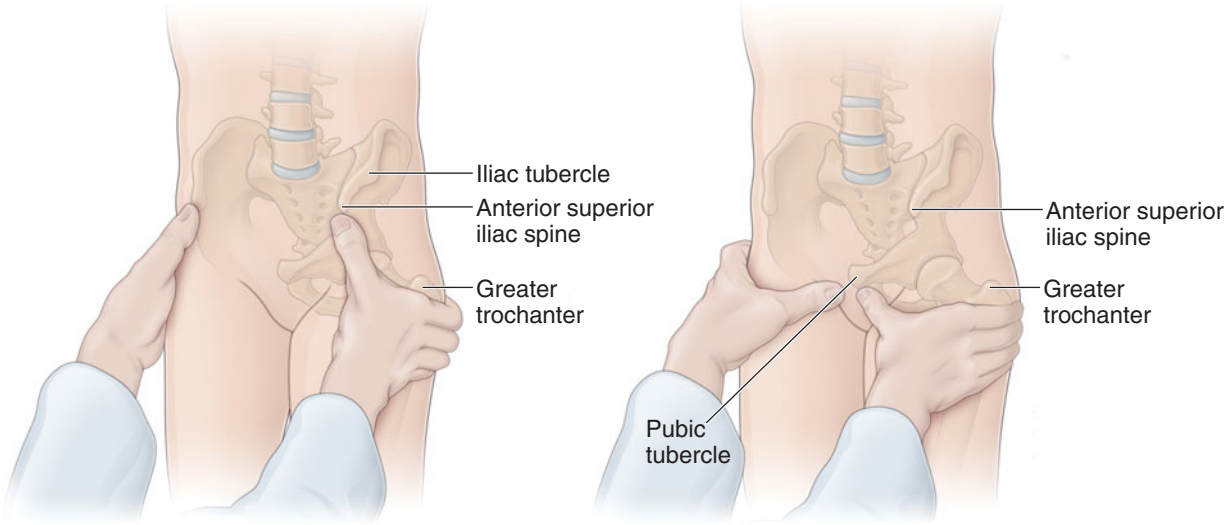

FIGURE 29-8 Palpation of the hip and pelvis.

- ***Posterior (dorsal) ligament.*** This strong ligament is situated in a deep depression between the sacrum and ilium.
- ***Ischial tuberosity and the sacrotuberous ligament (medial to the tuberosity).*** According to osteopathic doctrine, the sacrotuberous ligament is firm on the side of an anteriorly rotated innominate, and taut on the side of a posteriorly rotated innominate.[8] The patient is positioned prone, and the clinician stands at the patient's side. With the heel of the hands, the clinician locates the ischial tuberosities through the soft tissue at the gluteal folds. Then, with the thumbs, the clinician palpates the inferomedial aspect of the ischial tuberosities. From this point, the clinician slides the thumbs superolaterally and palpates the sacrotuberous ligament. The clinician then compares the relative tension between the left and right sides.
- ***Sacral sulcus (sacral base).*** The sacral sulcus (dimple) is located over the sacral base. From the PSIS, the clinician moves in a thumb width and then up a thumb width.
- ***Inferior lateral angle (ILA).*** These structures are level with the prominent part of the tailbone.
- ***L5 segment.*** The clinician palpates medially along the iliac crest. L5 is usually level with the point at which the palpating finger begins to descend on the crest. The L5–S1 zygapophyseal joints are located halfway between the L5 spinous process and the ipsilateral PSIS.
- ***Lumbosacral angle.*** An increased or decreased lumbosacral angle (the angle the sacrum makes with the lumbar spine) on one side may indicate a rotated innominate. Although very difficult to measure without radiographs, the normal lumbosacral angle is approximately 140 degrees from the vertical.
- ***S2 segment.*** S2 is normally level with the PSIS.

Functional Tests of Load Transfer Through the Pelvis

Forward Bending. This test *assesses* the ability of the pelvis to tolerate both vertical and horizontal shear forces, and its ability to control forward sagittal rotation during forward bending of the trunk. When the leg lengths are equal, the sacrum should nutate bilaterally relative to the innominates and remain nutated throughout the forward bending motion as the pelvic girdle flexes symmetrically at the hip joints.[104] The patient is positioned in standing and is asked to bend forward at the waist while the clinician observes the lumbo-pelvic hip rhythm (Fig. 29-10). A positive test for inadequate load transfer is if there is a lack of anterior pelvic tilt, excessive flexion of the thoracolumbar spine, and any twisting that occurs in the pelvic girdle.[84] Although asymmetry of motion of the innominate during forward bending is a positive finding, it is not indicative of any specific dysfunction of the SIJ.

Test for Form Closure. The patient is positioned in supine with the hips and the knees slightly flexed or supported over a bolster. Since muscle activation can compress the SIJ, the patient is instructed to completely relax during the test. The following description is for a test of the right side of the sacrum. With the right hand, the clinician grasps the anterior aspect of the patient's right innominate and ASIS (Fig. 29-11). The clinician then slides his or her left hand under the left side of the patient's lumbar spine and palpates the left sacral sulcus, just medial to the PSIS with the index and long finger to monitor translation between the sacrum and the innominate. From this position, the clinician stabilizes the left sacral base and sulcus with the left hand, and pushes the right innominate down toward the bed using the right hand, in a variety of directions to determine the plane of the SIJ. Slight motion should be felt before a ligamentous end-feel is reached. Once the plane of motion is determined, the stiffness for A-P translation of the SIJ is compared bilaterally. There should be no pain or asymmetry. A loss of motion or pain

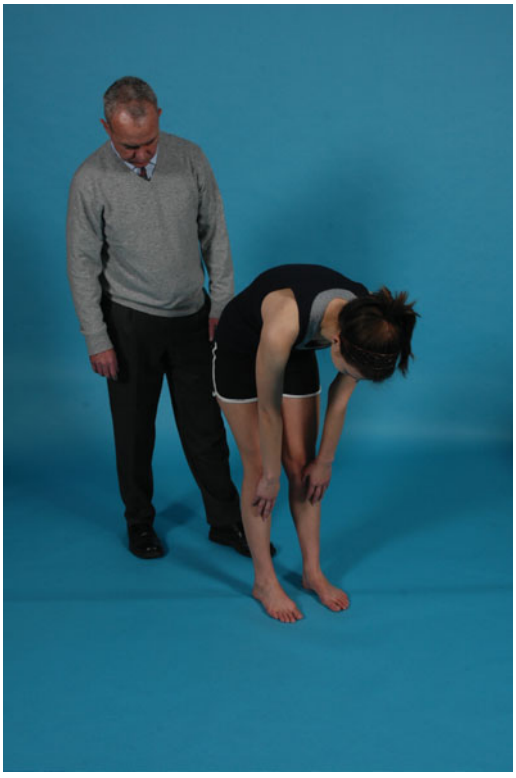

FIGURE 29-10 Forward bending test.

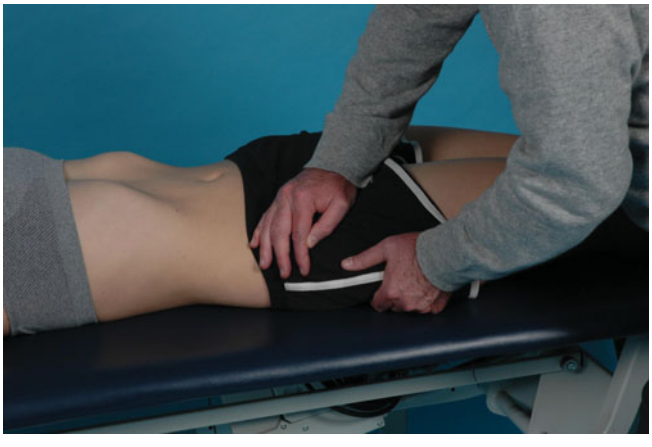

FIGURE 29-11 Grasping the right ASIS and right innominate.

FIGURE 29-12 Form-closure test—inferior–superior.

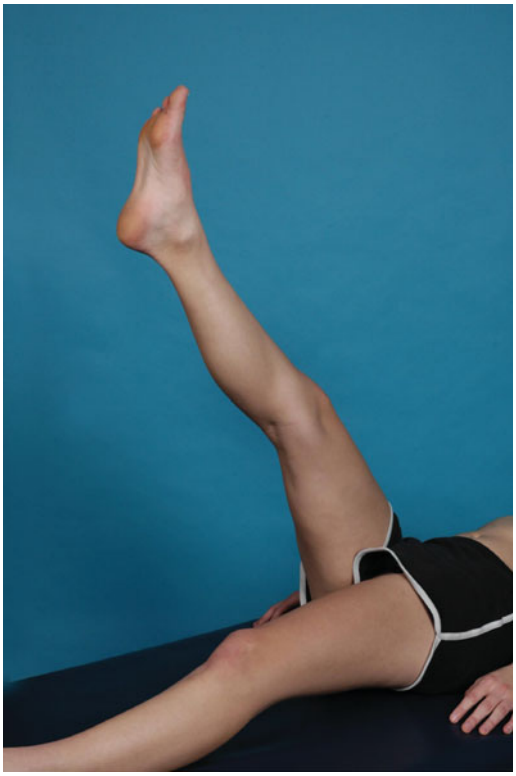

FIGURE 29-13 Asymmetrical Straight Leg Raise (ASLR).

reproduction compared with the contralateral side indicates dysfunction. To test the ability of the pelvic girdle to resist vertical translation, a superoinferior force is applied to the innominate through the distal end of the femur or through the ischial tuberosity (Fig. 29-12). Again, slight motion should be felt (although a little more than with the previous test) before a solid ligamentous end-feel is reached. The stiffness for superoinferior translation of the SIJ is compared bilaterally. There should be no pain or asymmetry. A loss of motion or pain reproduction compared with the contralateral side indicates dysfunction.

Tests for Force Closure and Motor Control. The active straight leg raise (ASLR) test and the reverse ASLR have been recommended as tests to help identify nonoptimal stabilization of the pelvic girdle and the ability to transfer loads between the lumbosacral spine and legs.

- ***The Active Straight Leg Raise (ASLR).*** The ASLR demonstrates the patient's ability to transfer load to the pelvis in the supine line position and has been validated for reliability, sensitivity, and specificity of pelvic girdle pain after pregnancy.[75,76,133] It can also be used to identify non-optimal stabilization strategies for load transfer through the pelvis.[84] The test is performed with the patient in supine with both legs straight. The patient is instructed to lift one leg off the table without bending the knee and the clinician observes the strategy used (Fig. 29-13). The leg should flex at the hip joint and the pelvis should not rotate, side bend, flex, or extend relative to the lumbar spine. The ribcage should not draw in excessively (over activation of the external oblique muscles), nor should the lower ribs flare out excessively (over activation of the internal oblique muscles), or the abdomen bulge (Valsalva). If the patient is unable to perform this maneuver correctly, or the maneuver causes pain, the test is repeated with the clinician applying a compression force through the pelvis (anterior then posterior) directed at the SIJs (form closure) (Fig. 29-14). If the patient is then able to perform the ASLR, the test is considered positive. If the application of

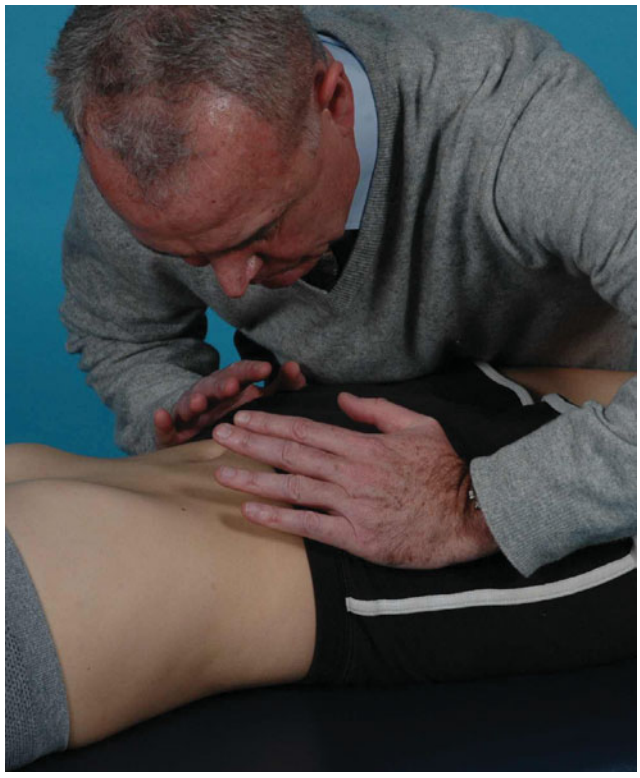

FIGURE 29-14 Asymmetrical Straight Leg Raise (ASLR)—2nd part.

anterior compression enabled the patient to perform the ASLR, an exercise program emphasizing the isolation, timing, and strength of the TrA is recommended. If the application of posterior compression enabled the patient to perform the ASLR, an exercise program emphasizing the isolation, timing, and strength of the multifidus is recommended. Slight modifications to the test can be used to help confirm the diagnosis.

- One knee is flexed, and the patient is asked to perform a straight leg raise with the other leg. Flexing the contralateral knee to the straight leg raise has the effect of relaxing the lumbar spine while maintaining the counternutation on the ipsilateral side. If this maneuver decreases the pain, a muscle imbalance could be present (quadratus lumborum, multifidus, etc.).
- The patient is asked to lift one shoulder off the bed against manual resistance from the clinician, while performing the straight leg raise on the contralateral side. This maneuver tests the ability of the anterior oblique system (force closure).

Assessment findings that indicate excessive compression include[84]

- reduced movement on active mobility tests;
- an ASLR test result that does not change all that worsens with compression;
- palpable hypertonicity in specific muscles and/or nonoptimum patterns of muscle recruitment during movement or in response to verbal cueing.

Assessment findings that indicate poor motion control include[84]

- an ASLR test result that improves with compression
- nonoptimum pattern of muscle recruitment in response to verbal cueing
- loss of joint position during functional load transfer tests.
- ***The reverse ASLR.*** This test is performed with the patient in prone with the patient performing active hip extension with the leg straight under three progressive conditions:
  - The patient performs hip extension with the leg straight (Fig. 29-15)

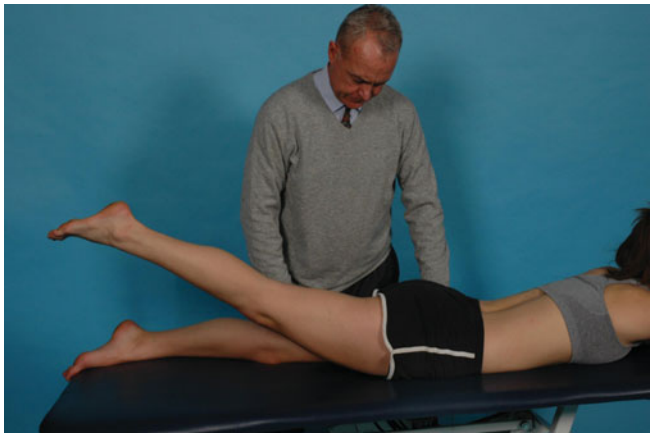

FIGURE 29-15 Reverse ASLR.

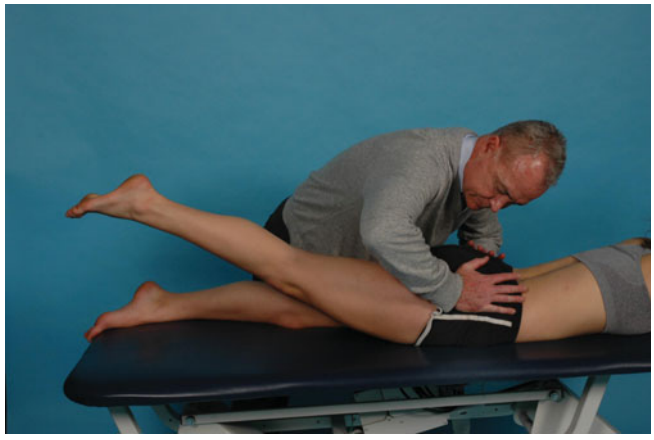

FIGURE 29-16 Reverse ASLR—2nd part.

  - The patient performs hip extension with the leg straight with the clinician applying manual compression to the innominate bones (form closure) (Fig. 29-16).
  - The patient performs hip extension with the leg straight with the clinician resisting extension of the contralateral medially rotated upper extremity (force closure).

No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

CLINICAL PEARL

Theoretically, with the ASLR and the reverse ASLR tests, if function improves when force-closure stabilization is used, exercise will likely benefit the patient. If during these tests, form closure seems to provide benefit, prescription of an SI belt is recommended.

Special Tests

Sacroiliac Joint Stress Tests. A positive stress test is one that reproduces unilateral or bilateral SI pain, either anteriorly or posteriorly.[134] A positive stress test indicates the presence of inflammation, but does not give any information as to the cause. If either test is positive in a patient who has recently fallen, there is a possibility that a fracture of the pelvis exists.[135] Some of the stress tests are considered to have fair reliability and moderate specificity.

Anterior Sacroiliac Joint Stress Test. The anterior stress test, also called the *gapping test,* is performed with the patient supine. The clinician stands to one side of the patient and, crossing the arms, places the palm of the hands on the patient's anterior superior iliac spines (Fig. 29-17). The crossing of the arms ensures that the applied force is in a lateral direction, thereby gapping the anterior aspect of the SIJ. The stress is maintained for 30 seconds once an end-feel is obtained. The procedure stresses the anterior (ventral) ligament and compresses the posterior aspect of the joint. A positive test is one in which the patient's groin or SIJ pain is reproduced anteriorly, posteriorly, unilaterally, or bilaterally.

The anterior gapping test and its posterior counterpart (see next section) are believed to be sensitive for severe arthritis or anterior (ventral) ligament tears of the SIJ,[134] although they have been shown to be poorly reproducible.[99]

FIGURE 29-17 Anterior Sacroiliac Joint Stress Test.

Posterior Sacroiliac Joint Stress Test. The posterior stress test, also called the *compression test,* is performed with the patient in the supine or sidelying position. The clinician, standing behind the patient, applies a medial force to both innominates, using both hands (Fig. 29-18). The stress is maintained for 30 seconds once an end-feel is obtained. The procedure creates a medial force that tends to gap the posterior aspect of the SIJ, while compressing its anterior aspect. The reproduction of pain over one or both of the SIJs is considered a positive test. The test also indirectly assesses the ability of the sacrum to counternutate.

The posterior (dorsal) SI ligament, which is accessible just below the posterior inferior iliac spine, should be palpated for tenderness.[32]

Thigh Thrust (Sacrotuberous stress test, 4 P test, POSH test, Oostagard test). This maneuver should only be performed on a normal hip joint. The patient is positioned in supine and the resting symptoms are assessed. The clinician stands on the painful side. The clinician flexes the hip on the painful side to 90 degrees and neutral adduction, and then places his or her hand under the sacrum to form a stable base for the sacrum. The clinician then applies a downward pressure through the femur to force a posterior translation of the innominate and the patient's symptoms are assessed (Fig. 29-19). A positive test is reproduction of the patient's symptoms (posterior to the hip or near the SIJ) on the side of the loaded femur. This is one of the few SI tests that exhibits a fair sensitivity. In a study by Broadhurst and Bond,[136] the test was found to have a sensitivity of 80% and a specificity of 100%.

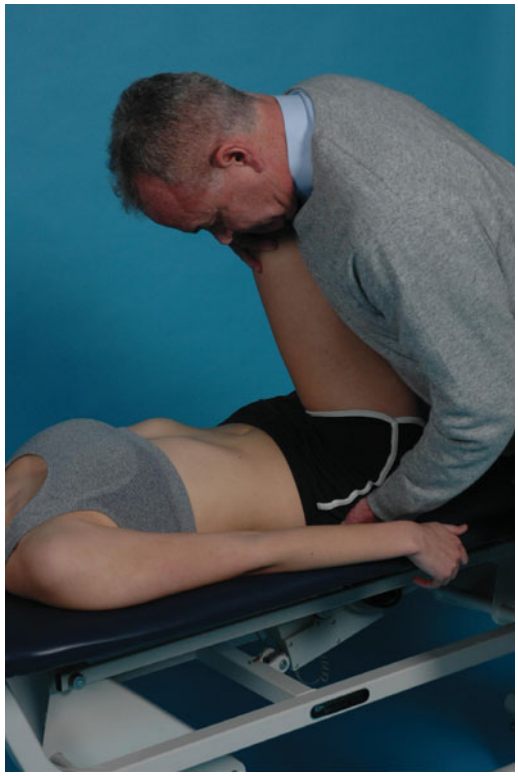

FIGURE 29-19 Thigh Thrust (Sacrotuberous stress test, 4 P test, POSH test, Oostagard test).

Mennell's Test. The patient is positioned in supine and the clinician positions the leg to be tested into 30 degrees of abduction and some flexion of the hip joint (Fig. 29-20) and asks the patient to hold his or her leg in this position. The clinician pushes the lower leg into, and then away from, the pelvis in a sagittal motion (extension then flexion). A positive test is reproduction of the patient's SIJ pain. Albert and colleagues[137] found this test to have a sensitivity of 54–70% and a specificity of 100%.

Resisted Hip Abduction. The patient is positioned in side lying and the clinician positions the uppermost leg into full

FIGURE 29-18 Posterior Sacroiliac Joint Stress Test.

FIGURE 29-20 Mennell's Test.

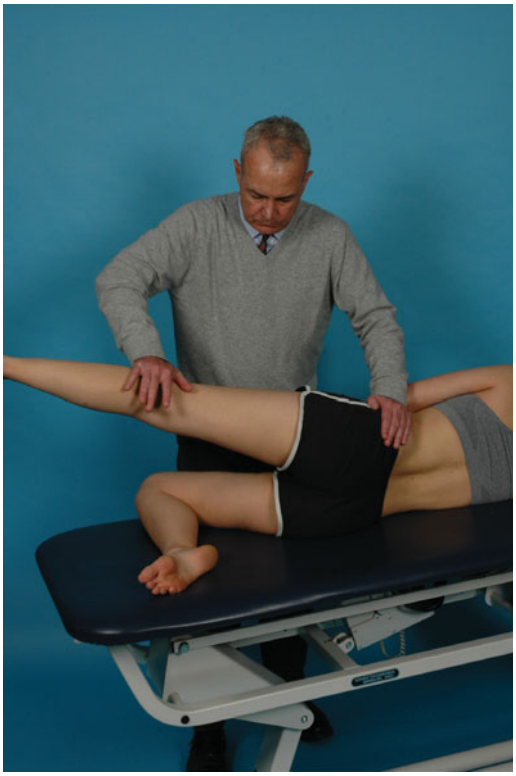

FIGURE 29-21 Resisted Hip Abduction.

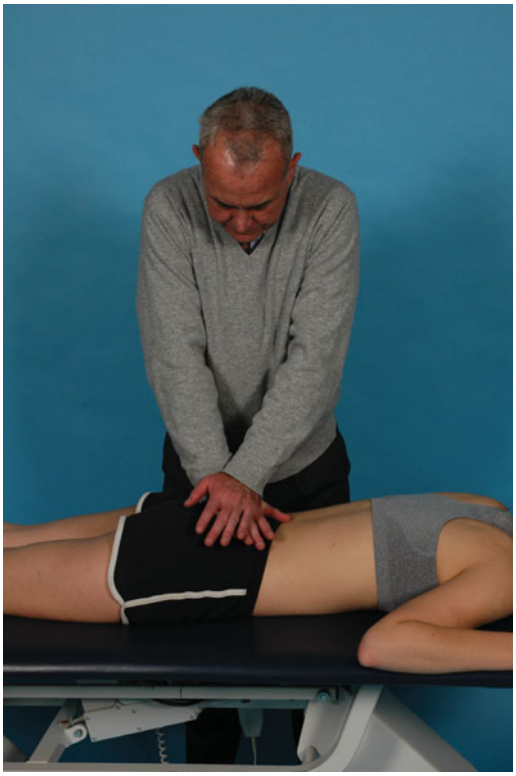

FIGURE 29-22 Sacral Thrust Test.

extension and 50 degrees of abduction and asks the patient to hold his or her leg in this position. The clinician then applies a force medially (into the hip adduction) while the patient resists the force isometrically (Fig. 29-21). A positive test is reproduction of SIJ pain in the superior aspect of the joint. Broadhurst and Bond,[136] found the test to have a sensitivity of 87% and a specificity of 90%.

Pubic Stress Tests.[138] The patient is positioned supine and the clinician stands at the patient's side. With the heel of one hand, the clinician palpates the superior aspect of the superior ramus of one pubic bone, and with the heel of the other hand, palpates the inferior aspect of the superior ramus of the opposite pubic bone. Fixing one pubic bone, the clinician applies a slow, steady, inferosuperior force to the other bone and, noting the quantity and end-feel of motion, as well as the reproduction of any symptoms, the clinician then switches hands and repeats the test so that both sides are stressed superiorly and inferiorly. Albert and colleagues[137] found this test to have a sensitivity of 81% and a specificity of 99% (LR+ 4.68; LR− 0.19). This test appears useful in the diagnosis of symphysiolysis.

CLINICAL PEARL

In some cases of trauma, or occasionally with child bearing, the pubis can become destabilized. This is a very severe and painful impairment, and one that is not easily missed. The pain is local to the pubic area, the patient is quite disabled with all movements, and weight-bearing postures are very painful. The impairment generally shows up on one-legged weight-bearing radiographs and often requires surgical intervention to stabilize the symphysis.

Sacral Thrust Test. The patient is positioned prone on a firm surface, and the clinician stands at the patient's side. With one hand, the clinician palpates the inferior aspect of the sacrum in the midline (second or third spinous process of the sacrum) and reinforces this hand with the other. The clinician then applies an anterior force at S3 (Fig. 29-22) vigorously and repeatedly (up to six thrusts), and the reproduction of symptoms is noted. The test is considered positive if pain is reproduced over the SIJs or the posterior (dorsal) SI ligament, or both.[139] In a study by Laslett and colleagues,[105] this test was found to have a sensitivity of 63% and a specificity of 75% (LR+ 2.5; LR− 0.49) suggesting that the test provides only marginal diagnostic value when used in isolation.

Fortin Finger Test. The patient completes a pain diagram and is then instructed to point to the region of pain using only one finger. The clinician reviews the area of pain and pain diagram for consistency and then asks the patient to repeat the procedure of pointing to his or her pain. A positive test for localization of SIJ pain has three criteria:

- The patient can localize the pain with one finger.
- The area pointed to is within 1 cm of, and immediately inferomedial to, the posterior superior iliac spine.
- The patient consistently points to the same area over at least two trials.

In a study by Fortin and Falco,[112] 16 subjects were chosen from 54 consecutive patients by using the Fortin finger test. All 16 patients subsequently had provocation-positive joint injections validating SIJ abnormalities (sensitivity of 100%). Another study by Dreyfuss and colleagues[56] found this test to have a sensitivity of 76% and a specificity of 47% (LR+ .09; LR− 1.3).

FABER or Patrick's Test. The FABER (flexion, abduction, external rotation) test is a screening test for hip (see Chap. 19), lumbar, or SIJ dysfunction, or an iliopsoas spasm.

The patient is positioned in supine and resting symptoms are assessed. The clinician places the foot of the test leg on top of the knee of the opposite leg (placing the sole of the test leg foot against the medial aspect of the opposite thigh may be more comfortable for the patient with knee pathology). The clinician then slowly lowers the test leg into abduction, in the direction toward the examining table. The clinician then provides a gentle downward pressure on both the knee of the painful side and the ASIS of the non-painful side. A positive test results in pain and/or loss of motion as compared with the uninvolved side. Having the patient demonstrate where the pain is with this test may assist with the interpretation of this test. For SI pain, the chief complaint is typically posterior. In the various studies that have assessed the sensitivity and specificity of this test, there are a wide range of values which is likely reflective of the variety of patients used in each study and the bias that results.

Seated Flexion Test (Piedallus Sign). The test is purported by osteopaths to help distinguish between a SI lesion and an iliosacral lesion when compared with the results of the standing flexion test.[5–7] The patient sits on a hard surface with the legs over the end of the table and feet supported.[8] In this position, innominate motion is severely abbreviated, because sitting places the innominates near the end of their extension range. The test is performed as follows. Each PSIS is palpated with the thumb placed under it inferiorly (caudally). The patient then bends forward at the waist (Fig. 29-23). Provided there is no impairment in the SIJ or the lower lumbar spine, as the patient bends forward, both thumbs should move superiorly (cranially). If the joint is blocked, it moves superiorly further in relation to the other side.[99] However, like other palpatory tests, this examination has been shown to lack reliability, have poor sensitivity, and have low specificity as a result a low false positive rate.[96,137,140] In contrast, Levangie[141] determined the sensitivity to be 9%, the specificity to be 93%, the positive predictive value to be 78%, and the negative predictive value to be 28%. Clearly there is need for further study. A similar test, referred to as the sitting bend over test or sitting forward flexion test, is performed in the same manner except the patient is seated on a soft surface. However, this test has demonstrated poor sensitivity, poor reliability, and, therefore, has very poor diagnostic value.[140,141]

Long Sit Test. According to osteopath doctrine, the long sit test is used to indicate the direction of the rotation that the innominate has adopted and is used in conjunction with the standing flexion test. After noting the side of the impairment obtained from the standing flexion test, the clinician observes whether the medial malleolus on that side moves distally or proximally during the long sit test. Rotation about a coronal axis, whose resultant movement leads to an increase in the length of a limb, is defined as extension. If it shortens the length of the limb, it is defined as flexion. Thus, if the apparent shorter leg becomes longer during the test, the innominate on that side is purportedly held in a posteriorly rotated malposition, whereas if the apparent longer leg becomes shorter during the test, the innominate on that side is allegedly held in an anteriorly rotated malposition.

The problems with this test involve the maneuver itself. To ask patients who are experiencing some degree of discomfort to raise themselves off the bed from a supine position into a long sit position without any twisting or use of the arms is unnecessarily painful. In addition, for the successful completion of the maneuver, the patient needs a minimum of 90 degrees of hip flexion and adequate hamstring length. Perhaps not surprisingly, the test has demonstrated poor reliability, questionable validity, and, therefore, may not yield useful results.[137,142]

Prone Knee Bending (Nachlas) Test. The patient is positioned in prone and the clinician, while stabilizing the pelvis, flexes the knee so that the heel is brought toward the buttocks (Fig. 29-24). If pain is felt in the front of the thigh before full range is reached, the problem is in the rectus femoris muscle; if

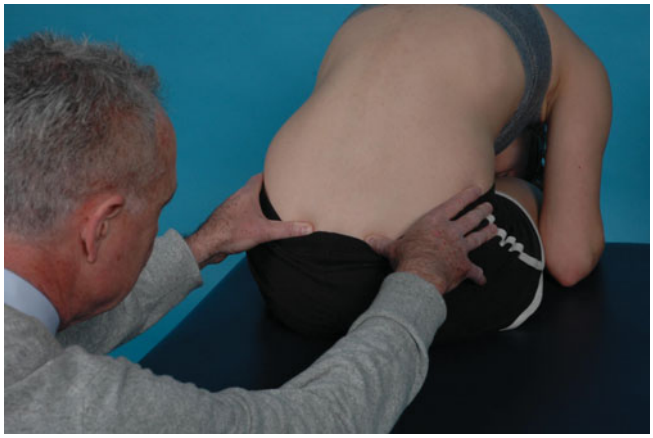

FIGURE 29-23 Seated Flexion Test (Piedallus Sign).

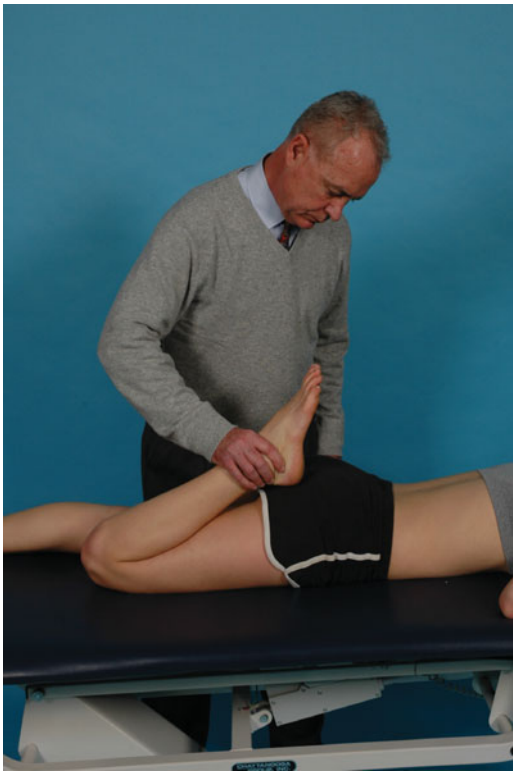

FIGURE 29-24 Prone knee bending (Nachlas) test.

the pain is in the lumbar spine, the problem is in the lumbar spine (usually the L3 nerve root). If the problem is a hypomobile SIJ, the ipsilateral pelvic rim (palpated at the ASIS) will be felt to rotate forward.[143] Leboeuf[144] found this test to have a specificity of 83% and a sensitivity of 44% (LR+ 2.59; LR− 0.67). Riddle and colleagues[142] found this test to have an interrater reliability of 0.26.

CLINICAL PEARL

Cibulka[145] and colleagues examined 219 patients with and without low back and SIJ-mediated pain to examine the sensitivity, the specificity, and the positive and negative predictive values of four commonly used SIJ tests: the standing flexion test, PSIS palpation while seated, the long sitting test, and the prone knee flexion test. SIJ dysfunction was considered positive if at least three of the four tests were positive. The combination of these tests yielded a sensitivity of 0.82, a specificity of 0.88, a positive predictive value of 0.86, and a negative addictive value of 0.84. However, because the individual test results were not documented, no conclusion can be made about isolated validity.

Leg Length Tests. These are usually performed as part of the bony landmark examination. Theoretically, posterior rotation of the innominate on the sacrum results in a decrease in leg length, as does an anterior rotation of the innominate on the contralateral side.[146] Although not exact measurements of leg length, these tests can highlight any significant asymmetries.

Prone Test. Chiropractors assess leg length with the patient prone. The comparative lengths of the legs are compared by observing the heels or the medial malleoli. If a discrepancy is noted, the knees are flexed to 90 degrees while maintaining neutral hip rotation, and the landmarks are reassessed to screen for a shortened tibia. The patient is then positioned supine, and the leg lengths are reassessed using the same landmarks. Finally, the leg lengths are assessed using the long sit test. Functional leg length inequality that is secondary to SI subluxation or dysfunction may reverse from the supine to sitting position, whereas anatomic leg length inequality or functional inequality secondary to dysfunction at other sites likely will not.[146]

Standing Leg Length Test. The iliac crest palpation and book correction (ICPBC) method for assessing leg length is used in many clinics. The patient stands with the feet shoulder-width apart. The clinician palpates the iliac crests and compares the relative heights for asymmetry. The asymmetry identified is corrected using a book opened to the required number of pages. The iliac crest heights are reassessed. If the iliac crests are level, the thickness of the book correction is measured. One study with 34 healthy subjects found the ICPBC technique for measuring leg length discrepancy to be highly reliable and moderately valid when there is no history of pelvic deformity and the iliac crests can be readily palpated.[147]

Functional Leg Length. The patient stands with the feet shoulder-width apart. The clinician palpates the iliac crests, the ASISs, and the PSISs and compares the relative heights for asymmetry. The patient is then positioned with the subtalar joints in neutral, the toes pointing forward, and the knees fully extended. The same landmarks are reassessed. If the second position corrects any asymmetry found in the first position, the test is positive for a functional leg length discrepancy and indicates that the leg is structurally normal but has abnormal joint mechanics.

Sign of the Buttock. The test for this syndrome is described here because its underlying pathologies occur in the lower quadrant The sign of the buttock is not a single sign, as the name would suggest, but rather a collection of signs indicating that a serious pathology is present posterior to the axis of flexion and extension in the hip (see Chap. 19). Among the causes of the syndrome are osteomyelitis, infectious sacroiliitis, fracture of the sacrum or pelvis, septic bursitis, ischiorectal abscess, gluteal hematoma, gluteal tumor, and rheumatic bursitis.

The patient lies supine, and the clinician performs a passive unilateral straight leg raise. If a unilateral restriction is noted, the clinician flexes the knee and notes whether the hip flexion increases. If the restriction was caused by the lumbar spine or hamstrings, the hip flexion should increase. The sign of the buttock test is positive if the hip flexion does not increase when the knee is flexed. If the sign of the buttock is encountered, the patient must be immediately returned to his or her physician for further investigation.[148]

Posterior Pelvic Pain Provocation Test. The posterior pelvic pain provocation test, as described by Ostgaard and colleagues,[149] is performed with the patient in supine. The clinician passively flexes the involved hip of the patient to 90 degrees and a posteriorly directed force is applied through the longitudinal axis of the femur (Fig. 29-25). The test is

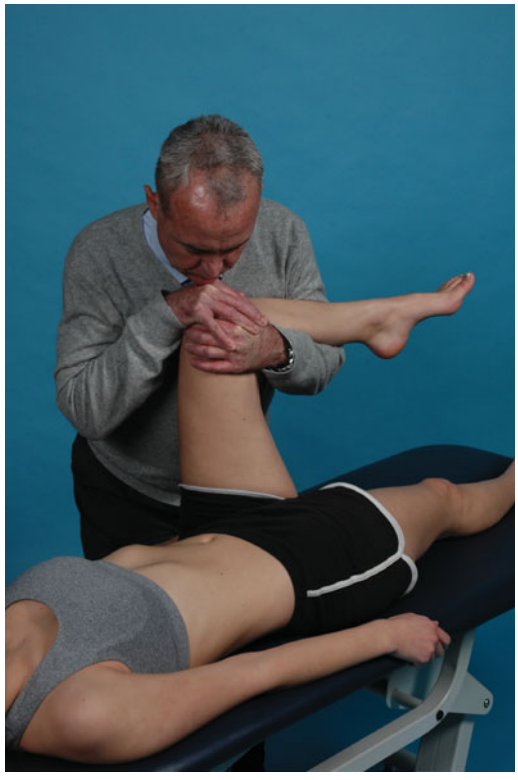

FIGURE 29-25 Posterior pelvic pain provocation test.

FIGURE 29-26 Gaenslen's test.

FIGURE 29-27 Yeoman's test.

considered positive for SIJ dysfunction if the patient reports a deep pain in the gluteal region during the test.

Gaenslen's Test. The patient is positioned supine at the edge of the side of the bed with the painful leg resting very near to the end of the bed, and resting symptoms are assessed. The leg furthest from the edge of the bed (non-tested leg) is flexed 90 degrees at the hip and held by the clinician using one hand. The clinician passively positions the upper leg (test leg) into hyperextension at the hip so that it hangs over the edge of the table (Fig. 29-26).[150] The clinician applies a further stretch to the test leg into hip extension and adduction up to six times while a flexion-based counter force is applied to the flexed leg. Pain with this maneuver is considered a positive test for an SIJ lesion, pubic symphysis instability, hip pathology, or an L4 nerve root lesion. The test also stresses the femoral nerve. This test demonstrates poor diagnostic value secondary to poor to fair specificity.[56] Overall, there is limited research pertaining to this test in order to make strong conclusions.

Yeoman's Test. This test[151] is performed with the patient positioned prone. The clinician stabilizes the patient's sacrum with the palm of one hand. With the other hand, the clinician grasps the patient's distal thigh and extends the patient's hip (Fig. 29-27). At the end of the available motion, the hip is hyperextended so that the innominate is forced into anterior rotation. A positive test produces pain over the SIJ. Other structures that are stressed with this maneuver include the lumbar spine, the hip joint, and the iliopsoas muscle.

INTERVENTION STRATEGIES

Thus far, the success of interventions at this joint has been mixed, due in part to the poor reliability with many of the examinations used. The success of any intervention depends on the quality and accuracy of the examination and the subsequent evaluation. It follows that if the examination gives an inaccurate diagnosis, the intervention may have a mixed result. It is reasonable to assume that the SIJ is a source of pain for one of the two reasons:[152]

1. There is some support for the notion of an inflammatory condition within the joint either causing or associated with the pain.[153–155] Inflammatory processes such as those found in ankylosing spondylitis are known to affect the SIJ.
2. The joint is unstable through ligamentous laxity or tearing of the joint capsule.[111,156,157]

Given that the chosen intervention for the SIJ, like the spine, depends largely on the philosophy or background that he clinician uses to establish the diagnosis. There appears to be three major schools of thought[152]:

1. Those who regard the SIJ as either irrelevant or rarely an issue in clinical practice.
2. Those who consider the clinical examination of the SIJ as either useless or of minimal utility.
3. Those who regard structural and biomechanical aspects of the SIJ as the key determinants in the problem of back pain.

Although the philosophies may differ, the principles behind the interventions for SIJ impairments should remain constant:

- A joint that has reduced motion (hypomobility) requires mobilizing techniques, muscle release techniques, and exercises that are designed to restore normal optimal alignment and controlled mobility.
- A joint that demonstrates excessive motion (hypermobility and/or instability) requires techniques and exercises that are designed to stabilize or balance forces around the hypermobile or unstable joint.[83] These include exercises to control joint motion and, on occasion, joint compression through the use of an external brace (SIJ belt).
- A joint that demonstrates signs and symptoms of excessive compression (due to intrinsic factors or extrinsic factors) requires techniques based on the cause of the compression. For example, joint compression caused by fibrosis benefits from the use of specific passive articular mobilization techniques whereas joint compression caused by over-activation of muscles benefits from techniques including muscle energy, trigger point therapy, and biofeedback.

The techniques and exercises used for the SIJ should always be based on the stage of healing and patient tolerance, and must take into account the influences that the lumbar spine and hip motions can have on this area.

FIGURE 29-28 An SIJ orthosis.

Acute Phase

In the acute phase of rehabilitation for the SIJ, the intervention goals are to

- decrease pain, inflammation, and muscle spasm;
- increase weight-bearing tolerance, where appropriate;
- promote healing of tissues through sufficient stabilization;
- increase pain-free range of SIJ motion and surrounding structures;
- regain soft tissue extensibility around the pelvic region;
- regain neuromuscular control;
- allow progression to the functional stage.

For the most part, exercises are avoided in the acute phase because they tend to increase the symptoms. Pain relief may be accomplished initially by the use of cryotherapy, and electrical stimulation (TENS), gentle muscle setting exercises. Thermal modalities, especially ultrasound with its ability to penetrate deeply may be used after 48–72 hours. Ultrasound is the most common clinically used deep heating modality to promote tissue healing.[158–160]

Clinicians often correct leg length discrepancies of greater than 0.5 inches, as such inequalities have been described as altering normal SIJ function.[161]

SIJ and pelvic stabilization orthoses have been employed in an attempt to limit SIJ motion and improve proprioception (Fig. 29-28).[161–164] These measures are particularly indicated when the joint has been demonstrated to be inflamed by the anterior or posterior stress tests. Not much force from these belts (20–50 N) is necessary to afford relief to the patient.[162] The position of the belt in terms of its height on the ilium should be experimented with to find the optimal position for pain relief. The recommended position is just above the greater trochanter (Fig. 29-28). A bicycle inner tube can be used as a substitute SI belt, as this is the right width and has the correct degree of elasticity. The following conditions appear to respond well to bracing:

1. Sacroiliitis.
2. SI hypermobility/instability: (pre- and postpartum and microtraumatic).
3. Pubic instability (may afford some relief).

Once the pain and inflammation is under control, the intervention can progress toward the restoration of full strength, range of motion, and normal posture. Range of motion exercises are initiated at the earliest opportunity. These are performed during the early stages in the pain-free ranges. Submaximal isometric exercises are then performed throughout the pain-free ranges. These exercises are progressed as the range of motion and strength increase.

Aggressive manual therapy has a very limited place in the intervention of the acutely inflamed joint. In almost every case, the presence of a positive stress test contraindicates the use of passive mobilization or manipulation for that joint. However, mobilization or manipulation of the contralateral joint may reduce the stress on the painful and inflamed articulation. Gentle manual techniques such as myofascial release, grade I–II joint mobilizations, massage, gentle stretching, and muscle energy techniques should be attempted and continued if effective.

Functional Phase

The duration of this phase can vary tremendously and depends upon several factors:

- The severity of the injury.
- The healing capacity of the patient.
- How the condition was managed during the acute phase.
- The level of patient involvement in their rehabilitation program.

The goals of this phase are

- to significantly reduce or to completely resolve the patient's pain;
- to restore full and pain-free SIJ range of motion;
- to integrate the lower kinetic chains into the rehabilitation;
- complete restoration of normal gait, where appropriate;
- the restoration of pelvic and lower quadrant strength and neuromuscular control.

Intervention strategies should emphasize pelvic stabilization,[124] the elimination of trunk/lumbar/hip and lower extremity muscle imbalances, and the correction of gait abnormalities.[165] The exercises used in the lumbopelvic stabilization exercise progression are described in detail in Chapter 28. During this stage, the patient learns to initiate and execute functional activities without pain and while dynamically stabilizing the SIJ in an automatic manner. Muscle imbalances around this joint complex are common. The same principles apply here as elsewhere: stretch those muscles that are tight or adaptively shortened and strengthen those muscles that are found to be weak. The muscles to be stretched around this joint complex are based on the clinical findings but usually include the erector spinae, the quadratus lumborum, the rectus femoris, the iliopsoas, the tensor fascia lata, the hip adductors, and the deep external rotators of the hip, especially the piriformis, and the gluteus maximus.[35,37] Postural correction and the correction of compensatory movements need to be addressed. Corrective exercises may be used to position the innominate bone in proper relation to the sacrum.

The focus of the therapeutic exercises for this region is to augment the force-closure mechanism and to reduce any stress that could prove detrimental to the SI complex. The exercises prescribed must challenge and enhance muscle performance while minimizing loading of the SIJ to reduce the risk of injury exacerbation. Inter-individual differences in injury status and/or training goals may allow for a continuum of required muscle stress and acceptable loading of the spine and SIJ.[166] Stabilization exercises and joint positioning can help the patient to (1) gain dynamic control of spine forces, (2) eliminate repetitive injury to the motion segments, (3) encourage healing of the injured segment, and (4) possibly alter the degenerative process.[167]

The strengthening component of the exercises is aimed at improving the function of the muscles of the inner and outer groups. The appropriate muscles must be isolated and then retrained to increase their strength and endurance, and to automatically recruit to support and protect the region.

A four-stage program has been designed to isolate and retrain the inner and outer muscle groups.[73,168]

Stage 1

- ***Levator ani.*** The patient is first taught the location of the levator ani in supine. To strengthen the muscle, the patient is asked to shorten the distance between the coccyx and the pubic symphysis and to hold the contraction for 10 seconds (Fig. 29-29). When the muscle contracts properly, the transverse abdominis muscle can be felt to contract at a point 2 cm medial and inferior to the ASIS, there is no contraction of the buttocks, and by carefully palpating the sacral apex, the sacrum is felt to counternutate slightly as the levator ani contracts. The exercise is repeated 10 times.

FIGURE 29-29 Levator ani contraction.

- ***Transversus abdominis/multifidus.*** The abdominal drawing-in maneuver is one exercise known to result in preferential activation of the internal oblique and TrA.[72,169–171] To test for isolation of the TrA, the patient is positioned prone, and a pressure biofeedback unit is placed underneath the abdomen[73,79] (Fig. 29-30). The cuff is

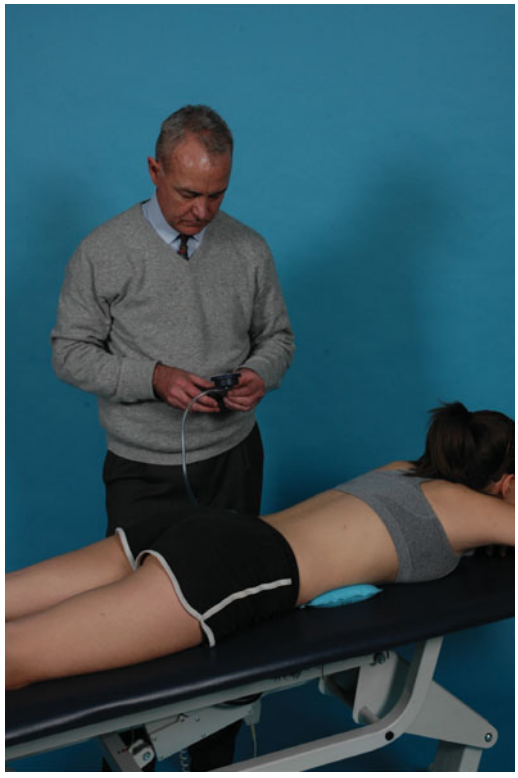

FIGURE 29-30 Transversus abdominis/multifidus.

FIGURE 29-31 Knee fall-out.

inflated to a base level of 70 mm Hg. The patient is asked to draw the navel up and in toward the chest (abdominal hollowing). When the muscle contracts properly, an increase in tension can be felt at a point 2 cm medial and inferior to the ASIS. If a bulging is felt at this point, the internal oblique is contracting. The multifidus is palpated simultaneously and should be felt to swell at a point just lateral to the spinous process.

Stage 2. The stabilization program is progressed to the next stage with the introduction of lower or upper extremity motion, which changes the focus of the program from the inner muscle group to the outer muscle group.

In the supine position with the hips and the knees flexed, the patient is asked to isolate the inner muscle group, while maintaining the lumbar spine in a neutral position. From this position, the patient is asked to slowly let the knee fall to one side (Fig. 29-31). Alternatively, the patient may extend the leg with the foot supported on the table.

The next step in the progression involves asking the patient to slowly extend this leg while maintaining the hip and the knee flexed (with the foot lifted) without touching the table (Fig. 29-32). This exercise initially is performed unilaterally and then is progressed to alternate leg extensions. The same exercises may be performed sitting on a gym ball or lying supine on a long roll. By making the base unstable, the exercise becomes more difficult without having to progress to the next stage.

Exercising on a gym ball requires core stability (inner muscle group control), coordination, and appropriate postural reflexes. While sitting on the ball, the patient is asked to contract the muscles of the inner muscle group. This contraction is maintained while the patient moves forward and backward, and up and down on the ball. The patient is instructed to incorporate the co-contraction of the inner muscle group into their activities of daily living.

FIGURE 29-32 Leg extension in supine.

If the individual muscles of the outer muscle group are weak or poorly recruited, the exercise program should include isolation and training at this time.

- ***Posterior oblique system.*** In the posterior oblique system, it is common to find the gluteus maximus both lengthened and weak.[12] Having the patient squeeze the buttocks together and sustain the contraction for 10 seconds isolates the gluteus maximus. A surface electromyography unit can provide a useful biofeedback system for this muscle. The exercise is progressed by having the patient lie prone over a gym ball and asking him or her initially to recruit the inner muscle group and then to extend the hip while the knee is flexed. Lifting the extended thigh increases the degree of difficulty. Leg extension machines can help to strengthen the gluteus maximus. Initially, the patient exercises in the supine position with one or both feet on the foot plate. Functional training is introduced by having the patient practice going from sitting to standing with a stabilized trunk, using primarily the gluteus maximus muscle.
- ***Lateral system.*** In the lateral system, the posterior fibers of the gluteus medius are often weak, which can have a marked effect on walking and load transference through the hip joint.[91] Isolation of the gluteus medius is taught in the side lying position with a pillow placed between the knees. The exercise is progressed by asking the patient to lift the knee off the pillow and then to extend the knee while maintaining the correct position of the trunk and the hip. Resistance can be added using elastic tubing or a cuff weight.
- ***Anterior oblique system.*** Isolation of the anterior oblique system involves training the specific contraction of the external and internal oblique abdominals. When the external obliques contract bilaterally, the infrasternal angle narrows, whereas when the internal obliques contract bilaterally, the infrasternal angle widens. The patient is taught to palpate the lateral costal margin and to specifically widen and narrow the infrasternal angle through specific contraction of the oblique abdominals.

The progression includes activation of the anterior and posterior oblique systems and differentiation of trunk from thigh motion. To begin, the patient is supine with the hips and the knees flexed, both feet on the bed. The patient is instructed to bridge and then to rotate the trunk and the pelvic girdle at the hip joints in the unsupported position, while maintaining the lumbar joints in a neutral position.

Stage 3. Stage 3 exercises involve controlled motion of the "unstable region."[73] Because this stage is much more advanced, it is used only when required by an individual's work or sport. The protocol includes concentric and eccentric work with variable resistance in all three planes.

Stage 4.[73] Stage 4 of the protocol involves stabilization during high-speed motions. Very few people require stage 4 stabilization, particularly in view of the fact that high-speed exercise tends to reduce the stabilizing capability of the trunk muscles.[79]

In addition to the exercise program, the patient should be educated on the trunk and the lower extremity positions to avoid (those that produce an excessive or sustained sacral counternutation or a decrease in lumbar lordosis) and those to adopt (the positions that enhance sacral nutation and enhance the lumbar lordosis). For example, the patient should be advised to maintain an anterior pelvic tilt during sitting, either actively or passively with the use of a lumbar roll.

The techniques to increase joint mobility and the techniques to increase soft tissue extensibility are described under "Therapeutic Techniques".

As symptoms are controlled, therapy should be advanced to activity-specific stabilization exercises to facilitate return to function at the patient's occupation, sport, or avocational activities.

Integration of Practice Patterns 4D and 4E: Impaired Joint Mobility, Motor Function, Muscle Performance, Range of Motion Associated with Connective Tissue Dysfunction, and Localized Inflammation

Spondyloarthropathies

The spondyloarthropathies are a group of inflammatory arthritic conditions that share certain clinical and laboratory features (see Chap. 5).[172]

- An inflammatory arthritis, which manifests with pain associated with stiffness.
- The absence of a rheumatoid factor; hence the distinction of the group as "seronegative" spondyloarthropathies.
- The tendency for the arthritis to be asymmetric and involve the lower extremities.
- Often, inflammation at the insertion of tendons into bone (enthesitis), accompanied by certain extra-articular features, including skin and mucous membrane impairments, bowel complaints, eye involvement, and aortic root dilation.
- The familial aggregation, which occurs within each condition and among the entities within the group.
- An association with HLA-B27, documented in the diseases included in this group.

Ankylosing Spondylitis

Ankylosing spondylitis (Bekhterev's or Marie-Strümpell disease) is a chronic rheumatoid disorder that is usually progressive, resulting in a full ankylosing of the SIJs.[172] Men generally have the more severe form affecting the spine, whereas in women, the peripheral joints are more often affected.

The typical radiographic changes are seen primarily in the axial skeleton, especially in the SI, intervertebral, zygapophyseal, costovertebral, and costotransverse joints.[173] In addition, ankylosing spondylitis is one of the most common rheumatic disorders associated with radiologic abnormalities of the pubic symphysis, with pubic synchondrosis present in 20–25% of the patients.[174] In fact, changes of the symphysis can sometimes precede spine involvement.[174]

Tests to discriminate SIJ tenderness caused by ankylosing spondylitis from that caused by mechanical spine conditions have traditionally included passive hip extension, A-P pressure applied to the sacrum, and the primary stress tests. However, these tests have been found to be poorly reproducible and inaccurate in making any distinction.[99]

Although radiologic evidence of sacroiliitis is accepted as being obligatory for the diagnosis of ankylosing spondylitis, the clinical signs (see Chap. 5) may predate radiologic abnormalities by months or even years.[172]

Groin Pain

Chronic pain in the groin region (see Chap. 19) is a difficult clinical problem to evaluate, and in many cases, the cause of the pain is poorly understood. The differential diagnosis of groin pain and tenderness includes adductor muscle strain, prostatitis, orchitis, inguinal hernia, urolithiasis, ankylosing spondylitis, Reiter's syndrome, hyperparathyroidism, metastasis, osteitis pubis, stress fracture, rheumatoid arthritis, tendonitis, degenerative joint disease of the hip, bursitis, stress fracture, conjoint tendon strains, inguinal ligament enthesopathy, and entrapment of the lateral cutaneous nerve of the thigh.[175–177]

Other nerve entrapment syndromes have been described as a possible cause of adductor region pain, with the anterior division of the obturator nerve in the thigh,[178] the ilioinguinal nerve, and the genitofemoral nerve having all been inculpated.[179]

Osteitis Pubis

Many theories have been put forward concerning the etiology and progression of this disease, but the cause of osteitis pubis remains unclear.

Osteitis pubis is seen in athletes who participate in activities that create continual shearing forces at the pubic symphysis, as with unilateral leg support or acceleration–deceleration forces required during multidirectional activities. These include activities such as running, racewalking, gymnastics, soccer, basketball, rugby, and tennis. Pain with walking can be in one or several of many distributions: perineal, testicular, suprapubic, inguinal, and in the scrotum and perineum.[180] Overuse is the most likely etiology of the inflammation, and the process is usually self-limiting.[180]

Osteitis pubis has been likened to gracilis syndrome, an avulsion fatigue fracture involving the bony origin of the gracilis muscle at the pubic symphysis and occurring in relation to the directional pull of the gracilis.[181] However,

osteitis pubis does not necessarily involve a fracture. The process could be the result of stress reaction, which might be associated with several biomechanical abnormalities.

Osteitis pubis usually appears during the third and fourth decades of life, occurring more commonly in men.[182] The pain or discomfort can be located in the pubic area, one or both groins, and the lower rectus abdominis muscle. Symptoms of osteitis pubis have been described as "groin burning," with discomfort while climbing stairs, coughing, or sneezing.

During the physical examination, pain can be elicited by having the patient squeeze a fist between the knees with resisted long and flexed adductor contraction. Range of motion in one or both hips may be decreased. An adductor muscle spasm might occur with limited abduction and a positive FABER test.[183,184] A soft tissue mass with calcification, and an audible or palpable click over the symphysis might be detected during daily activities.[180]

Correct examination of this region involves examining the position of the pelvic girdle. The normal position for the pelvic bowl is 45 degrees in the sagittal plane and 45 degrees in the coronal plane. Pubic motion is assessed by locating the pubic crest and then gently testing the mobility of each available direction.

Dysfunction of this articulation may be primary or secondary and, when present, is always treated first, because a loss of function or integrity of this joint disrupts the mechanics of the entire pelvic complex. The impairment pattern is determined by palpating the position of the pubic tubercles and correlating the findings with the side of the positive kinetic test, with the restricted side indicating the side of the impairment.

An altered positional relationship within the pelvic girdle is significant only if a mobility restriction of the SIJ or pubic symphysis, or both, is found. The inguinal ligament is usually very tender to palpation on the side of the impairment. It is common to find the pubic symphysis held in one of the four following positions:

1. Anteroinferior
2. Posterosuperior
3. Anterosuperior
4. Posteroinferior

These articular dysfunctions are treated using manual techniques (see "Therapeutic Techniques").

Intervention for the inflammatory type of osteitis pubis is conservative and most athletes return to their respective sports within a few days to weeks.[185] The intervention includes plenty of rest from weight-bearing activities, a course of nonsteroidal anti-inflammatory medicine, and physical therapy to gently mobilize, stretch, and strengthen the muscles about the groin.[186] Patients should be able to swim for exercise.

An intervention protocol for osteitis pubis is outlined in Box 29-1.

Box 29-1 Intervention Protocol for Osteitis Pubis

Phase I

1. Static adduction against a soccer ball placed between feet when lying supine. Each adduction is held for 30 seconds and is repeated 10 times.
2. Abdominal sit-ups performed both in straight direction and in oblique direction. Patient performs five sets to fatigue.
3. Combined abdominal sit-up and hip flexion (crunch). Patient starts from supine position and with a soccer/basketball placed between knees. Patient performs five sets to fatigue.
4. Balance training on wobble board for 5 minutes.
5. One-foot exercises on sliding board, with parallel feet as well as with a 90-degree angle between feet.

Five sets of 1-minute continuous work are performed with each leg, and in both positions.

Phase II (from third week)

1. Leg abduction and adduction exercises in side lying position on side. Patient performs five series of 10 repetitions of each exercise.
2. Low-back extension exercises while in prone position over end of treatment table. Patient performs five series of 10 repetitions.
3. One-leg weight-pulling abduction–adduction, standing. Patient performs five series of 10 repetitions for each leg.
4. Abdominal sit-ups both in straightforward direction and in oblique direction. Patient performs five sets to fatigue.
5. One-leg coordination exercise flexing and extending knee and swinging arms in same rhythm (cross-country skiing on one leg). Patient performs five sets of 10 repetitions for each leg.
6. Skating movements on sliding board. This is performed five times for 1-minute continuous work.

Symphysis Pubic Dysfunction

Symphysis pubic dysfunction (SPD) describes the situation where the ligaments between the pubic symphysis become stretched and allow the bones to move with respect to each other (see Chap. 30). In severe cases, rupture of the symphysis may occur. This more severe form is called diastasis symphysis pubis (DSP). SPD commonly occurs during pregnancy, and should always be considered when examining patients in the postpartum period who are experiencing suprapubic, SI, or thigh pain. The associated ligamentous laxity during pregnancy is in response to the hormones progesterone and relaxin. Causes unrelated to pregnancy include the possibility of a structural misalignment of the pelvis. This pelvic misalignment results in increased pressure on the pubic symphysis cartilage, with subsequent pain.

The symptoms of SPD and DSP vary from person to person (see Chap. 30). Radiological evaluation may occasionally be useful in confirming the diagnosis.[187] Therefore, the intervention is based on the severity of symptoms rather than the degree of separation as measured by imaging studies.[187] Palpation reveals anterior pubic symphyseal tenderness. Occasional clicking can be felt or heard. The findings on the physical examination include positive SIJ stress tests (compression, distraction, and FABER tests). The range of hip movements

will be limited by pain, and there is an inability to stand on one leg. Characteristic pain can often be evoked by bilateral pressure on the trochanters or by hip flexion with the legs in extension. However, such maneuvers may result in severe pain or muscle spasm and are not necessary for diagnosis.

In cases of DSP, there is likely an associated anteroposterior (A-P) compression (common) or a vertical shear (rare) fracture. Three types of DSP are described, indicating the severity of the injury[188]:

- Type 1 involves minor anterior damage, mild (less than 2.5 cm) pubic symphysis diastasis, and/or (vertical) pubic rami fractures.
- Type II has wide diastasis of the symphysis pubis, disruption of the anterior SI ligament complex, and (hinging) of the iliac bone on the sacrum at the intact posterior SIJ.
- Type III designates total disruption of the SIJ, a diastasis of greater than 2.5 cm has been shown to indicate disruption of the anterior SIJ at least, but it is frequently associated with total SIJ disruption.

Although the symptoms can be dramatically severe in presentation for SPD and DSP, a conservative management approach is often effective (see Chap. 30).[187]

Resolution of symptoms in approximately 6–8 weeks with no lasting sequela is the most common outcome in SDP and DSP.[187] Occasionally, patients report residual pain requiring several months of physical therapy but long-term impairment is unusual. Surgical intervention is rarely required but may be used in cases of inadequate reduction, recurrent diastasis, or persistent symptoms.

Peripartum Posterior Pelvic Pain

More than 50% of women experience peripartum posterior pelvic pain (PPPP) or low back pain (LBP) during pregnancy with one-third of these women experiencing severe pain (see Chap. 30).[189–191,192]

Hall and colleagues,[189] in a two-case report provided preliminary evidence suggesting that a combination of manual therapy (muscle energy techniques directed at identified pelvic and sacral positional faults) and therapeutic exercise (neuromuscular reeducation of the transverse abdominis and multifidus with isometric hip adduction and abduction in a semireclined position, and standing exercises to strengthen the posterior oblique system [gluteus maximus and contralateral latissimus dorsi]) may be an effective intervention for peripartum patients reporting posterior pelvic pain.[189]

Coccydynia

Coccygeal pain is relatively common. The coccyx can move anteriorly or posteriorly. There are a number of ligaments around this area which can be injured:

- ***Anterior (ventral).***
  - Lateral sacrococcygeal.
  - Anterior (ventral) ligament of the coccyx (caudal extension of the anterior longitudinal ligament).
- ***Posterior (dorsal).***
  - Superficial posterior (dorsal) sacrococcygeal (caudal extension of the ligamentum flavum).
  - Deep posterior (dorsal) sacrococcygeal (caudal extension of the posterior longitudinal ligament).
  - Intercornual ligament.

The dominant muscle in this area is the levator ani, which has connections with the

- iliococcygeal ligament;
- pubococcygeal ligament.

Coccydynia tends to occur when the coccyx becomes stuck into flexion with an accompanying deviation. The causes can be muscle scarring or trauma.

Correction of this impairment involves grasping the coccyx after inserting the index finger in the anal canal. The coccyx is distracted and pulled posteriorly, while pulling laterally on the medial surface of the ischial tuberosity.

Practice Pattern 4G: Impaired Joint Mobility, Motor Function, Muscle Performance, Range of Motion Associated with Fracture

Sacral Stress Fracture

Repetitive loading on the body can lead to the development of stress fractures. Stress fractures have been described as a cause of back pain, especially fractures of the pelvis and pars interarticularis of the sacrum.[193] Back and buttock pain caused by sacral stress fractures are less common but may occur in athletes and in the elderly.[194] Fractures in the latter group have been reported both with and without trauma.

The cause of sacral stress fractures is controversial. These fractures are believed to result from stress concentrations of vertical body forces, which are dissipated from the spine to the sacrum and the sacral alae and then onto the iliac wings.[195] In addition to abnormal stresses on normal bone, normal stress on abnormal bone can produce these fractures, especially in the elderly. Patients who sustain such insufficiency fractures may have predisposing factors, including idiopathic osteoporosis, irradiation-induced osteoporosis, steroid-induced osteoporosis, or osteoporosis associated with malignancy.[193] Another cause cited for sacral fractures is progressive *insufficiency* of the supporting muscles.[196] These fatigue fractures may result from the transfer of loading forces directly to the bone, without absorption of some energy by the muscles. Other reported causes of sacral stress fractures are differences in physical demands, environmental and genetic influences, training methods, footwear, and intensity of training.[196] Atwell and Jackson[197] suggested that leg length inequality may increase the stress on one side of the sacrum, but this has not been proven by biomechanical analysis.[193]

Patients with sacral stress fractures typically present with low back pain and sacral pain that may radiate into the buttocks. However, pain may be referred to the groin and, occasionally, down the leg.[197] In the case of an athlete, the history may reveal a recent history of stress fracture in the same area, or a rapid increase in training intensity prior to the onset of symptoms.[126] Insufficiency fractures of the sacrum in nonathletes have been reported to mimic disk disease, spinal stenosis, and tumors.[198] Irritation of the cauda equina or the sacral nerve roots may explain the wide variety of symptoms seen in patients with sacral stress fractures.[193,199]

Physical examination may not provide reliable signs initially, because many of these patients have diffuse low back, sacral, and buttock pain. However, most patients will have localized tenderness over the sacrum and SIJ.[193–195,197–199] Tenderness in the upper gluteal areas tends to be coexistent with sacral stress fractures, and tenderness in this region may contribute to the impression that the origin of the pain is centered in the more proximal lumbar spine.[193] Most patients are neurologically intact, with no signs of nerve root irritation. The Patrick's, or the FABER (flexion, abduction, external rotation) test may or may not be positive, so it cannot be depended on in making a diagnosis.[193]

The most sensitive method of evaluating the sacrum for occult stress fractures and other bone lesions is a bone scan using three-phase scintigraphy.[200] This bone imaging technique can help detect stress fractures as early as several days after the fracture occurs. In contrast, plain radiographs of the lumbosacral spine and the pelvis, although useful to rule out other causes of back pain, are not helpful in diagnosing sacral stress fractures.[194]

Patients with sacral stress fractures recover quickly with rest. Most patients are able to return to their normal activity levels in 4–6 weeks with no long-term sequelae.[193] Anti-inflammatory agents and analgesics may be used as adjunctive treatment for patient comfort. Cycling or running in a pool may be used until weight-bearing activities are tolerated.

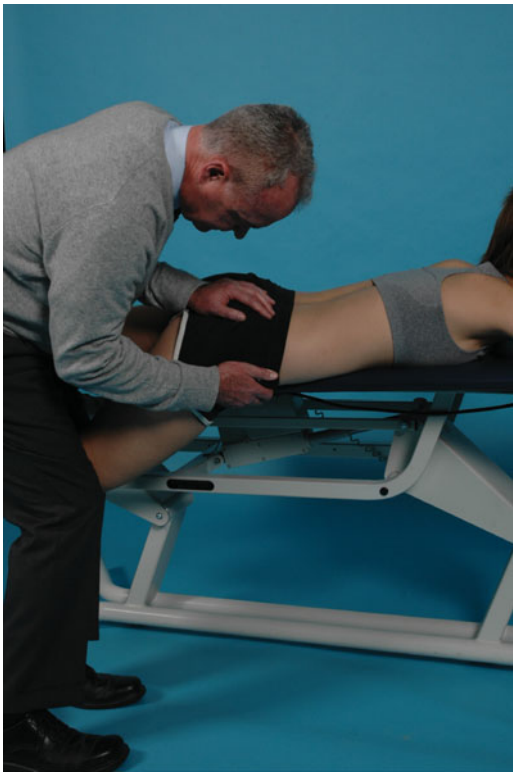

FIGURE 29-33 Method to restore posterior rotation of the right innominate.

THERAPEUTIC TECHNIQUES

Normally, pelvic impairments are presented as isolated entities when, in fact, clinically, they tend to occur in combination. It is essential that the impairments, functional limitations, and disability found during the examination guide the intervention.

To Restore Posterior Rotation of the Right Innominate

The patient is in the prone lying position, with the right hip and the leg over the edge of the table. The clinician stands at the patient's right side. The patient's right foot is placed between the clinician's legs and held there. While monitoring the sacral sulcus with the index finger of the left hand, the clinician moves the patient's right leg to the barrier (Fig. 29-33). The patient is asked to gently push the right foot toward the foot of the table. This movement is resisted by the clinician's legs, and after 3–5 seconds, the patient is told to relax. Once again, when full relaxation has occurred, the slack is taken up, and the patient's right leg is moved in the direction of hip flexion until the monitoring finger indicates the new barrier has been reached. This mobilization is repeated three times and followed by a reexamination.

To Restore Anterior Rotation of the Left Innominate

The patient is in the prone lying position, with the clinician standing on the patient's side. With the left hand, the clinician supports the anterior aspect of the patient's left thigh, at a point just above the knee. The clinician places the heel of his or her right hand over the patient's left posterior inferior iliac spine. Extending the left hip until motion at the lumbosacral junction is perceived (Fig. 29-34), the clinician localizes the motion barrier. The patient is instructed to flex the left hip against the clinician's resistance. This isometric contraction is held up to 5 seconds, following which the patient is instructed to completely relax. The new barrier to anterior rotation is achieved by further extension of the hip. The mobilization is repeated three times and followed by a reexamination of function.

FIGURE 29-34 Method to restore anterior rotation of the left innominate.

CASE STUDY

LEFT-SIDED LOW BACK AND BUTTOCK PAIN

HISTORY

A 47-year-old man presented at the clinic, with left-sided low back and buttock pain that had developed while he was at work 2 weeks previously. When describing the mechanism of injury, the patient reported feeling something "pop" in his low back during a lifting maneuver that involved bending forward and twisting to the right. The pain was now localized to an area slightly inferior to the left posterosuperior iliac spine, which he reported as being very tender to the touch. The pain was aggravated with forward bending and turning at the waist to the left in the sitting position. The patient reported sleeping well, if he remained prone, and there were no complaints of paresthesias or anesthesias. The patient denied any neurologic symptoms related to cauda equina or spinal cord involvement. He was in otherwise good health.

Questions

1. Given a distinct mechanism of injury, what type of structure(s) could be at fault with complaints of left-sided low back and buttock pain?
2. What does the region of *localized* tenderness tell the clinician?
3. Why do you think the patient is sleeping well in the prone position?
4. What is your working hypothesis at this stage? List the various diagnoses that could manifest with low back and buttock pain, and the tests you would use to rule out each one.
5. Does this presentation/history warrant a scan? Why or why not?

CASE STUDY

PUBIC PAIN

HISTORY

A 44-year-old man came to the clinic complaining of worsening abdominal and midline pelvic pain. The pain had developed gradually, and there was no report of recent direct trauma or acute injury. The pain was aggravated with forced flexion at the waist and the Valsalva maneuver, but the patient reported no pain at rest. The pain, described as a sharp, "stabbing" sensation, remained fairly localized to his upper pelvis and lower abdominal area.

The patient had no history of abdominal or genitourinary diseases or surgeries, and he had not experienced similar symptoms in the past. A review of systems was unremarkable. He denied dysuria, hematuria, diarrhea, constipation, fever, chills, or weight change.[185]

The patient frequently participated in physical activity and played soccer, averaging four games per week, an increase from his usual level of commitment. An inguinal hernia had been ruled out by his physician.

Questions

1. What structure(s) could be at fault when abdominal and midline pelvic pain is the major complaint?
2. What is the significance of the Valsalva maneuver?
3. Why are the questions with regard to dysuria, hematuria, diarrhea, constipation, fever, chills, or weight change pertinent?
4. What does no pain at rest suggest?
5. What is your working hypothesis at this stage? List the various diagnoses that could manifest with this pain and the tests you would use to rule out each one.
6. Does this presentation/history warrant a scan? Why or why not?

REVIEW QUESTIONS*

1. Which SIJ ligament forms the major connection between the sacrum and the innominate, filling the irregular space posterosuperior to the joint between the lateral sacral crest and the iliac tuberosity?
2. Which sacral motion places tension on the posterior (dorsal) SI ligament of the SIJ?
3. What are the muscle actions of the piriformis muscle?
4. Which muscle group comprises the pelvic floor muscle group?
5. During right side bending, which sacral and right innominate motions are purported to occur?

*Additional questions to test your understanding of this chapter can be found in the Online Learning Center for *Orthopaedic Assessment, Evaluation, and Intervention* at www.duttononline.net.

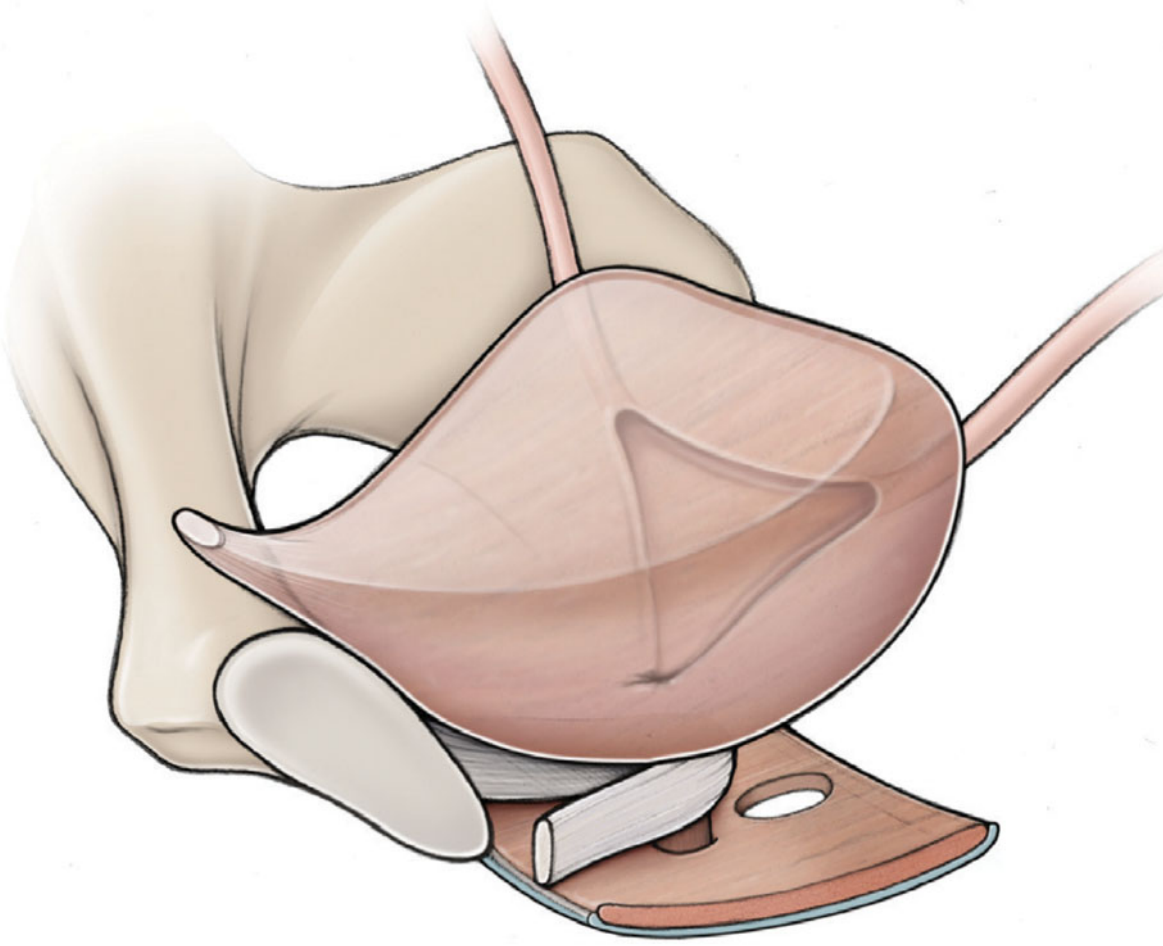
SECTION VI

SPECIAL CONSIDERATIONS



This page intentionally left blank

CHAPTER 30 Special Populations

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Discuss the physical therapy role with a variety of orthopaedic subtypes and the challenges each presents.
2. Describe the various pathologies for these populations in terms of the presentation and the role that physical therapy plays.
3. Outline the differences between a congenital condition and an acquired condition.
4. Describe the normal aging process as it relates to orthopaedics.
5. Outline the various theories of aging.
6. Describe the common pathological conditions and functional limitations associated with the geriatric population.
7. Describe some of the conditions that can affect women's health.
8. Describe the physiologic changes that occur during pregnancy within the various bodily systems.
9. Describe the physical therapy interventions for pregnancy-related dysfunctions.
10. Describe the complications related to breast-cancer-related lymphedema.

OVERVIEW

There are a number of population subtypes that require special consideration in terms of the orthopaedic examination and intervention. These include pediatrics and geriatrics, and the whole spectrum of women's health. Each of these populations is described in this chapter.

PEDIATRICS

The term pediatric refers to the 0- to 21-year age range during which an individual undergoes many changes while aging, evolving, and maturing. During the preschool years, physical growth, neurologic growth, and maturation are quite rapid and apparent, with new skills being acquired at a quick pace.[1] This process continues throughout the middle years (ages 6–11) at a somewhat slower pace. As a child enters puberty, rapid development of physical and sexual characteristics become more apparent and is accompanied by important psychosocial development. It is important to remember that chronologic age does not necessarily correlate well with many physiologic and somatic changes.

CLINICAL PEARL

A typical adult has a smaller surface area-to-mass ratio and a lower metabolic rate than a child. These discrepancies result in a greater transfer of heat and a greater challenge to the thermoregulatory system, respectively, in the pediatric population.

The major characteristics of somatic and skeletal growth and maturation during adolescence are outlined in Table 30-1. In addition, the following differences exist between the adult and the pediatric patient:[2]

- ***Cardiovascular system.*** The pediatric heart is smaller than that of the mature adult, resulting in a smaller capacity as a reservoir for blood, and thus a lower stroke volume at all levels of exercise, which is compensated for with an increased heart rate. As with the adult patient, systolic blood pressure rises during exercise in the pediatric patient, but the elevation is less. Finally, the thoracic cavity is obviously smaller in the younger child than that of the mature adult, resulting in the pediatric patient demonstrating a smaller vital capacity than the adult and an elevated resting respiration rate.[3] The red blood cell count for young boys and girls are similar with comparable abilities to carry oxygen to exercising organs. After menarche, however, females demonstrate lower blood volume and fewer red blood cells with a resultant decreased oxygen carrying capacity and a lower mean blood pressure.[4] These differences result in the following responses to exercise in the pediatric patient:
  - Until 12 years, absolute maximal oxygen uptake (VO_{2max}) values increase at the same rate in both

TABLE 30-1 Somatic and Skeletal Growth and Maturation During Adolescence

Characteristic	Description
Weight	In males, the average weight gain during its peak is approximately 9 kg per year with a range of 6–12.5 kg per year. The peaks of growth spurts in height, weight, and muscle occur at the same time In females the average weight gain during its peak is approximately 8 kg per year with a range of 5.5–10.5 kg per year. The peaks of growth spurts in height, weight, and muscle occur in sequence in that order
Height	In general, linear growth first occurs in the lower extremities, followed by the torso and then the upper extremities Males typically reach their peak height velocity (PHV) by 14 years. The growth of the shoulders in males is the most noticeable change Females typically reach their PHV by 12 years. The growth of the hip and pelvis in females are the most notable changes
Body composition	In general, both males and females tend to increase both fat mass as well as fat-free mass from the early to middle adolescent years. However, while males may show a transient decrease in fat accumulation in the extremities during PHV, females continue to gain fat through late adolescence. The pattern of growth of fat-free mass is similar to that noted for growth in height and weight
Flexibility	As skeletal growth precedes that of musculotendinous growth during the early to middle adolescence, there is a relative decrease in musculotendinous flexibility in some adolescents, especially males. Decreased flexibility is particularly noticeable in the hamstrings and ankle dorsiflexors
Muscle growth and strength	Although muscle growth and strength is seen in both males and females, it is relatively more pronounced in males compared with females due to androgens.
Bone mass	The female skeleton generally grows and fully matures (i.e., growth plate fusion) before the male skeleton. The largest percentage of lifetime acquisition of bone mineral density occurs during the second decade of life. Peak bone mass during adolescence is determined by genetic influences, exercise, calcium intake, and hormonal status

Data from Greydanus DE, Pratt HD: Adolescent growth and development, and sport participation. In: Patel DR, Greydanus DE, Baker RJ, eds. *Pediatric Practice: Sports Medicine.* New York: McGraw-Hill, 2009:15–25.

genders, although boys have higher values as early as 5 years. VO_{2max} increases concomitantly with growth until 18 years in boys and 14 years in girls.

- The pattern of relative magnitudes of cardiovascular and ventilatory responses to progressive and sustained dynamic exercise appears to be qualitatively similar between adults and children.
- Children rely more on oxidative rather than anaerobic metabolism compared to adults.
- Children demonstrate greater energy expenditure during weight-bearing activities such as running and walking compared to adults.

▸ ***Musculoskeletal system.*** Young children possess muscle fiber numbers, types, and distribution similar to that of adults. There is an increase in muscle hypertrophy during adolescence as a result of increased androgens. In addition, agility, motor coordination, power, and speed also show improvement during adolescence. There are a number of structural differences between the adult and pediatric patient:

- In the adolescent, growth cartilage is present at the epiphyseal plate, the joint surface (articular cartilage), and the apophysis. The epiphyseal plate or growth plate is divided into zones differentiated from one another via structure and function (see Chap. 1). Growing bone is the weak musculoskeletal link in the young athlete. Similar physical demands that can result in muscle strain or ligament sprain in the skeletally mature patient may result in an epiphyseal plate injury in a young patient. Two factors that impact epiphyseal plate injury are (1) the ability of the growth plate to resist failure and (2) the forces applied to bone or the stresses induced in the growth plate. The majority of epiphyseal fractures are due to high-velocity injuries.
- A certain amount of load is necessary for normal bone growth and remodeling. In most long bones, epiphysis is at least partially ossified at an early age. However in certain areas of the body (e.g., ischial tuberosity, iliac crest, base of the fifth metatarsal), the epiphysis may not become ossified until the near end of the final growth spurt. Most of the bone mineral density is acquired during the adolescent years and bone mass may fail to accrue optimally because of dieting and weight loss. Because the strength development of bones lags behind that of ligaments and tendons, there is an increased risk of tendon or bone avulsion at the apophyseal insertion compared to a ligament injury.

CLINICAL PEARL

Orthopaedic injuries commonly seen in the pediatric population include Osgood–Schlatter (OS) disease, spondylolysis, stress fractures, Little League elbow, and growth plate disorders.

Examination of the Pediatric Patient

In addition to the areas typically covered in the orthopaedic examination outlined in Chapter 4, a number of additional factors must be considered in the pediatric population. For example, when taking the history of a pediatric patient, the clinician should pay particular attention to the following:[2]

- ***Current life circumstances.*** The pediatric patient's current health, attitudes and values of the child's immediate family, and acculturation of the patient.
- ***Gender.*** Females and males develop differently, particularly during adolescence (Table 30-2).
- ***Health history.*** Health and nutrition history, repeated hospitalizations, and so on.
- ***Developmental history.*** The pediatric patient's past rate of achievement of developmental milestones, events that might have had profound effects on the patient either physically or psychologically.
- ***Extrapersonal interactions.*** The reaction of the pediatric patient to the treating clinician and the conditions under which the pediatric patient is observed.
- Age-related changes in muscle and muscle performance.
- ***The developing skeletal system.*** Examination of the pediatric patient requires an understanding of, and an awareness of, the timing of growth center appearance and epiphyseal closure. For example, the sequence and average timing of growth center appearance at the elbow are as follows[5]:
  - ***Capitellum.*** Female, 4 months; male, 5 months.
  - ***Medial epicondyle.*** Female, 5 years; male, 7 years.
  - ***Trochlea.*** Female, 8 years; male, 9 years.
  - ***Lateral epicondyle.*** Female, 11 years; male, 12 years.

Epiphyseal closure at the elbow occurs sequentially, first in the distal humerus, with the capitellum, lateral epicondyle, and trochlea fusing together at puberty (female, 14 years and male, 17 years), then fusing with the shaft.[5] The medial epicondyle fuses later (female, 15 years and male, 18 years). The radial head and olecranon close at 14 years in females and 15 years in males.[5]

Growing musculoskeletal tissue is innately predisposed to specific injuries that vary greatly from injuries sustained by their skeletally mature counterparts. Most of this growth occurs in two phases from birth to adulthood. There is a rapid gain in growth in infancy and early childhood that slows down during middle childhood. The second rapid increase in growth occurs during adolescence. An injury that occurs during one of these phases, which is significant enough to interrupt the growth process, can present serious challenges.

TABLE 30-2 Differences in Adolescent Females Compared to Males

Anatomic	Physiologic
Reduced muscle fiber size	Increased percentage of body fat (10–15 pounds more)
Wide hips with narrower shoulders	Women have 40– 45 less pounds of fat-free weight (bone, muscle, organs)
Shorter height (3–4 in. on average)	Basal metabolic rate is relatively lower
Relatively smaller total articular surface area	Reduced testosterone levels
Relatively more fat around the thighs and hips	Skeletal maturation occurs earlier
Heart size and volume are smaller	Aerobic capacity is lower
Lung volume is smaller	Vital capacity is less

CLINICAL PEARL

The main goals of a physical therapy intervention in pediatric rehabilitation are to reduce barriers limiting the performance of daily routines and to facilitate the successful integration of the child into the home, play, and school environments. Therapeutic exercise that is prescribed for the pediatric patient must be creative, and attempts must be made to try to make exercise fun in order to increase compliance. In addition, special consideration must be given when prescribing exercise due to the number of growth changes that are occurring:[6]

- ***≤7 years.*** Introduction to basic exercises, teaching correct technique using low-volume and little or no weight. For example, 1–3 sets of 6–15 repetitions.[7]
- ***8–10 years.*** Gradual increase of the number of exercises and progressive loading using simple exercises. Loads should be increased in 1- to 3-pound increments after the child can perform 15 repetitions with proper form.[7] Resistance equipment that can be adapted to the size of child should only be used.
- ***11–13 years.*** Teach all basic exercise techniques and continue progressive loading. More advanced techniques/exercises can be introduced with little or no resistance.
- ***14–15 years.*** More advanced youth programs and resistance exercise with sport-specific components.
- ***≥16 years.*** Entry-level adult programs

ACQUIRED ORTHOPAEDIC CONDITIONS

Skeletal Fracture

The mechanical properties and healing qualities of skeletal bone are described in Chapters 1 and 2, respectively. In the pediatric population, the metaphysic–physis junction is an anatomic point of weakness. Fractures of bone in pediatric patients may be due to direct trauma, such as a blow, or indirect trauma, such as a fall on the outstretched hand (FOOSH injury), or a twisting injury. Three types of fractures occur more commonly in the pediatric population:

- ***Greenstick.*** A type of simple fracture in which only one side of the bone is fractured while the opposite side is bent.

Because the bones in a pediatric patient have not fully developed, they are less rigid and brittle. This type of fracture tends to heal faster than other types.

- ***Avulsion.*** Avulsion occurs when a piece of bone attached to a tendon or ligament is torn away. In the younger population, ligaments and tendons are stronger than bone. When changes in muscle length do not match the changes in long-bone growth, tensile loads placed within the muscle predispose the pediatric patient to injury. Lower extremity avulsion fractures outnumber avulsion fractures of the upper extremity. Common sites of avulsion fracture in the lower extremity include the anterior superior iliac spine (ASIS), anterior inferior iliac spine (AIIS), ischial tuberosity, and the base of the fifth metatarsal. Common sites of avulsion fracture in the upper extremity include the medial humeral epicondyle and the proximal humerus. If a medial epicondyle avulsion fracture is suspected, it is important to assess the ulnar nerve, and for the presence of point tenderness of the medial epicondyle, swelling, ecchymosis, and valgus instability.
- ***Growth plate (physeal).*** This type of fracture may be defined as a disruption in the cartilaginous physis of long bones that may or may not involve epiphyseal or metaphyseal bone. Injuries to the physes are more likely to occur in the pediatric population, in part due to the greater structural strength and integrity of the ligaments and joint capsules than of the growth plates and the fact that the physes of an adult have ossified. Growth plate fractures can have severe consequences because of the potential for growth plate closure, which inhibits future growth resulting in limb length discrepancies. Conversely, an injury near, but not at, the physis can stimulate increased bone growth.

The Salter and Harris classification is the preferred and accepted standard in North America for classifying physeal fracture patterns:[3]

- ***Type I.*** This occurs due to shearing forces in which there is complete separation of the epiphysis without fracture of the bone. These fractures are most commonly seen in the very young patient when the epiphyseal plate is relatively thick.
- ***Type II.*** This is the most common type of growth plate fracture resulting from shearing and bending forces. The line of separation traverses a variable distance along the epiphyseal plate and then makes its way through a segment of the bony metaphysis that results in a triangular-shaped metaphyseal fragment.
- ***Type III.*** This typically results from shearing forces and results in intra-articular fractures from the joint surface to the deep zone of the growth plate and then along the growth plate to its periphery. These fractures are typically limited to the proximal tibial/distal femoral epiphysis and can result from valgus loading of the knee, which is frequently encountered in contact and collision sports.
- ***Type IV.*** These are intra-articular fractures that result from shearing forces. These fractures extend from the joint surface to the epiphysis across the entire thickness of the growth plate and then through a segment of the bony metaphysis.
- ***Type V.*** These types of fractures, which are due to a crushing mechanism, are relatively uncommon.

CLINICAL PEARL

The most common of the Salter Harris fractures is type II, followed by types I, III, IV, and V.

Clinical Findings

The most common clinical presentation with a pediatric fracture is pain, weakness, and functional loss of the involved area. The most common areas for epiphyseal fracture include the distal radius and the medial epicondyle, the proximal humerus, and the proximal tibia/distal femoral.

Intervention

In most cases, the medical management of a fracture involves immobilization through casting, splints, or surgical fixation to allow full healing to occur. Pediatric fractures tend to heal faster than an equivalent one in an adult. This can be advantageous: Children typically require shorter immobilization times. A disadvantage, however, is that any malpositioned fragments become immovable or fixed much earlier than in adults (3– 5 days in a young child, 5– 7 days in an older child, as opposed to 8–10 days in an adult). However, the normal process of bone remodeling in a child may correct malalignment, making near-anatomic reductions less important in children than in adults. Remodeling can be expected if the patient has two or more years of bone growth remaining. Rotational deformity remodels poorly, if at all, and is therefore corrected by surgical reduction. A further complication is that pediatric fractures may stimulate longitudinal growth of the bone, making the bone longer than it would have been had it not been injured. This is particularly true for fractures of the femoral or tibial shaft.

Children tolerate prolonged immobilization much better than adults, and disabling stiffness or loss of range of motion (ROM) is distinctly unusual after pediatric fractures. Physical therapy, if needed, typically begins after the immobilization period, and depending on the type and location of the fracture, it can involve any or all of the following:

- Pain management techniques including the use of noncontraindicated electrotherapeutic modalities (see Chap. 8) and manual techniques, including joint mobilizations.
- ROM exercises, following the hierarchy of progression outlined in Chapter 13.
- Strengthening exercises, beginning with isometrics and progressing using the hierarchy of progression outlined in Chapter 12.
- Gait and/or crutch training with an appropriate assistive device and following the prescribed prescription for weight bearing (see Chap. 6).
- Proprioception exercises for balance and coordination (see Chap. 14).
- Functional training including adaptive, supportive, or protective devices and activities of daily living (ADLs) and self-care.

- Patient and family education to decrease the risk of re-injury and to promote healing.

Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis (JRA) is a group of diseases that are manifested by chronic joint inflammation[8,9]. The exact etiology of JRA is unclear, but the prevailing theory is that it is an autoimmune inflammatory disorder, activated by an external trigger, in a genetically predisposed host. JRA is defined as persistent arthritis, lasting at least 6 weeks, in one or more joints in a child younger than 16 years of age, when all other causes of arthritis have been excluded. The clinical findings and manifestations of JRA are outlined in Chapter 5.

A detailed physical examination by a physician is a critical tool in diagnosing JRA to help rule out other causes. Medical care of children with JRA must be provided in the context of a team-based approach, considering all aspects of their illness (e.g., physical functioning in school and psychological adjustment to disease).

Intervention

Physical therapists are essential members of the rheumatology team that includes the rheumatologist, nurse, occupational therapist, ophthalmologist, orthopedist, and pediatrician.[10] Other specialists, including cardiologists, dermatologists, orthotists, psychologists, and social workers, provide occasional consultation as needed. The physical therapy examination is performed to determine the relationship between the impairments and observed or reported activity restrictions. The plan of care (POC) is designed to reduce current impairments, maintain or improve function, prevent or minimize secondary problems, and provide education and support to the child and family. Specific interventions can include any or all of the following:

- ROM and stretching exercises.
  - Acute stage: passive and active assisted to avoid joint compression.
  - Subacute/chronic stages: active exercises.
- Strengthening: avoid substitutions, minimize instability, atrophy, deformity, pain, and injury.
  - Acute and subacute stages: isometric exercises progressing cautiously to resistive.
  - Chronic stage: concentric exercises.
- Endurance exercises: encouraging exercise by using fun and recreational activities, swimming.
- Joint protection strategies and body mechanics education.
  - Mobility assistive devices.
  - Rest, as needed—balance rest with activity by using splinting (articular resting).
  - Posture and positioning to maintain joint ROM.
  - Patients should spend 20 minutes/day in the prone position to stretch the hip and knee flexors
  - Avoidance of high-impact activities.
  - Assess leg length discrepancy in standing and avoid scoliosis.
- Therapeutic modalities for pain control.
- Instructions on the wearing of warm pajamas, sleeping bag, electric blanket.

Idiopathic Scoliosis

The overall contour of the normal vertebral column in the coronal plane is straight. In contrast, the contour of the sagittal plane changes with development (see Chap. 22) [11–24]. Scoliosis represents a progressive disturbance of the intercalated series of spinal segments that produces a three-dimensional deformity (lateral curvature and vertebral rotation) of the spine. Despite an extensive amount of research devoted to discovering the cause of idiopathic scoliosis, the mechanics and specific etiology are not clearly understood, hence the name. It is known, however, that there is a familial prevalence of idiopathic scoliosis.

Clinical Findings

Using the James classification system, scoliosis has three age distinctions. These distinctions, though seemingly arbitrary, have prognostic significance.

- ***Infantile idiopathic.*** Children diagnosed when they are younger than 3 years, usually manifesting shortly after birth. Although 80–90% of these curves spontaneously resolve, many of the remainder of cases will progress throughout childhood, resulting in severe deformity. In the most common curve pattern (right thoracic), the right shoulder is consistently rotated forward and the medial border of the right scapula protrudes posteriorly.
- ***Juvenile idiopathic.*** Children diagnosed when they are 3–9 years. This type is found more frequently in girls than boys, and individuals that develop this condition are generally at a high risk for progression to more severe curves.
- ***Adolescent idiopathic.*** Manifesting at or around the onset of puberty and accounting for approximately 80% of all cases of idiopathic scoliosis.

The following are the main factors that influence the probability of progression in the skeleton of the immature patient:

- The younger the patient at diagnosis, the greater the risk of progression.
- Double-curve patterns have a greater risk for progression than single-curve patterns.
- Curves with greater magnitude are at a greater risk to progress.
- Risk of progression in females is approximately 10 times than that of males with curves of comparable magnitude.
- Greater risk of progression is present when curves develop before menarche.

Scoliosis is generally described by the location of the curve or curves. One should also describe whether the convexity of the curve points to the right or left. If there is a double curve, each curve must be described and measured. As the disease progresses, the spinous processes of the vertebrae in the area of the major curve rotate toward the concavity of

the curve. On the concave side of the curve, the ribs are close together. On the convex side, they are widely separated. As the vertebral bodies rotate, the spinous processes deviate more and more to the concave side and the ribs follow the rotation of the vertebrae. The ribs on the convex side are rotated more posteriorly, causing the characteristic rib hump seen in thoracic scoliosis. The ribs on the concave side are rotated more anteriorly. Because the onset and progression of scoliosis (until skeletal maturity) are generally asymptomatic, it can develop undetected without close examination.

The significant incidence of scoliosis in the adolescent population has prompted the creation of school screening programs in all 50 states. Visual observation is used during the Adam's forward bending test, which involves asking the patient to bend forward at the waist as though touching his or her toes while the clinician, who is standing behind the patient, looks along the line at the back and determines whether one side is higher than the other. If scoliosis is suspected, the magnitude of a rib hump is quantified by placing a scoliometer (an inclinometer) over the spinous process at the apex of the curve during the Adam's forward bending test to measure the angle of trunk rotation as the patient bends forward. During the physical examination by the patient's physician, a determination is made as to whether the deformity is structural (cannot be corrected with active or passive movement and there is rotation toward the convexity of the curve) or nonstructural (fully corrects clinically and radiographically with trunk side bending toward the apex of the curve and lacks vertebral rotation). Nonstructural scoliotic curves can result from length–length discrepancies, muscle disuse/overuse, habitual postures, and muscle guarding.

Height measurements are taken in sitting and in standing. Changes in sitting height can be less than changes in standing height and give a better estimate of truncal growth rate. Trunk compensation is typically assessed using a plumb-line, and a radiographic leg length measurement is also obtained.

CLINICAL PEARL

- Radiographs are usually only considered when a patient has a curve that might require treatment or could progress to a stage requiring treatment. The radiographs determine the location, type, and magnitude of the curve (using the Cobb method), as well as skeletal age. Alternatively, a noninvasive technique called Moiré topography can be used, in which light is projected through grids onto the back of the patient to assess structural asymmetry.

Skeletal maturity is determined using the Risser sign, which is a measurement of the progressive ossification from anterolaterally to posteromedially in the iliac apophysis. Once a child reaches a Grade 5 on the Risser scale, his or her scoliotic curve will stabilize. A child with idiopathic scoliosis usually progresses from a Risser grade 1 to a grade 5 over a 2-year period.

CLINICAL PEARL

If scoliosis is neglected, the curves may progress and create significant physical deformity. Severe curves can result in cardiopulmonary problems necessitating pulmonary function tests due to the resultant rib cage restrictions and decreased chest wall expansion.

Most curves can be treated nonoperatively through observation with periodic radiographs to check for the presence of curve progression. However, approximately 60% of curvatures in rapidly growing prepubertal children typically progress, and may require bracing (Boston, or custom thoracolumbosacral orthosis) or surgery.

CLINICAL PEARL

A child with idiopathic scoliosis who is skeletally immature (with a Risser sign of 0, 1, or 2) and has a curve from 25 to 45 degrees is typically prescribed an orthosis. Theoretically, curve progression is prevented by muscle contractions responding to the presence of the orthosis. Exercises to be performed while wearing the orthosis, (e.g., pelvic tilts, thoracic flexion, and lateral shifts), are often taught to patients to improve the active forces, although there is little evidence to support this.

Intervention

Physical therapy intervention for scoliosis is based on the skeletal maturity of the child, the growth potential of the child, and the magnitude of the curve. The primary benefits of exercise in a nonsurgical patient with scoliosis are as follows:[25]

- Help with correct postural alignment and any asymmetrical postural habits to prevent further development following the bracing program.
- Maintain proper respiration and chest mobility.
- Improve overall spinal mobility and to help reduce back pain.
- Help the patient resume prebracing functional skills.
- Maintain muscle strength, particularly in the abdominals.
- Maintain or improve correct length and strength relationships of the spinal and extremity musculature. The general rule is to strengthen the muscles on the convex side and to stretch the muscles on the concave side. Asymmetric exercise is used to promote symmetry. For example, in a patient with a right thoracic, left lumbar curve, typical findings may include weakness of the right iliopsoas and right external oblique. Exercises that could be prescribed for this patient would include resisted right hip flexion at the end range with the patient sitting to address the weakness of the right iliopsoas. Weakness of the right external oblique can be addressed using a left upper extremity diagonal reaching movement pattern emphasizing right thoracic side bending (Fig. 30-1). Other functional exercises for scoliosis include the following:

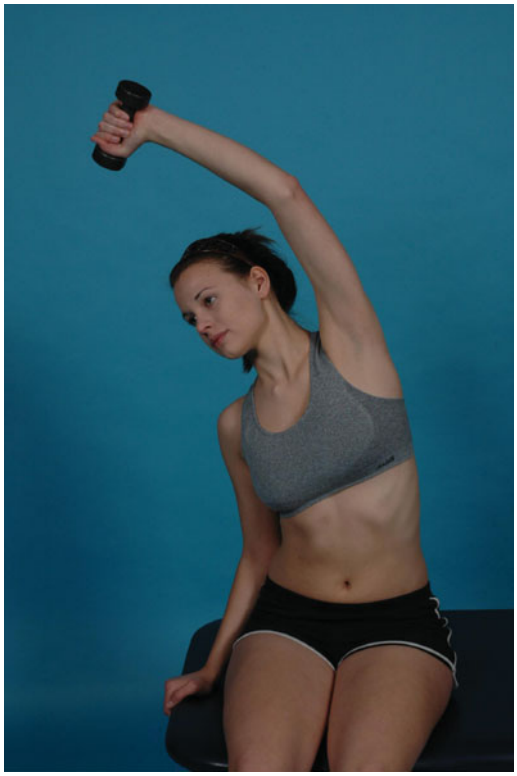


FIGURE 30-1 Left upper extremity diagonal reaching movement pattern emphasizing right thoracic sidebending.

- The patient is positioned in prone and is asked to place both hands above his or her head while deviating the thorax away from the concave side of the curve (Fig. 30-2).
- The patient is positioned in supine and is asked to reach overhead and extend the arm on the concave side (Fig. 30-3).
- The patient is positioned in heel-sitting and is asked to place both hands forward and flat while emphasizing trunk axial elongation (Fig. 30-4). The patient is then asked to stretch both arms laterally away from the concave side of the curve.
- The patient is positioned in side lying (convex side down) over the end of the table with a hand to provide balance (Fig. 30-5). A pillow can be placed directly under the apex of the thoracic convex curve. Once in this position, the patient is asked to reach overhead and then down toward the floor using the arm that is closest to the ceiling to enhance the stretch.
- Swiss ball exercises can also be used, focusing on gaining increased thoracic side bending, while stretching the convex side (Fig. 30-6).

FIGURE 30-2 Prone sidebending with arms overhead.

FIGURE 30-3 Prone sidebending by reaching overhead with one hand.

- Any of the strengthening exercises described in the intervention strategy section of Chapter 27 can be used to increase strength in the extensor muscle groups. Side-lying techniques (lying on the concave side) can be incorporated to strengthen the lateral muscle groups. The side-lying sit-up exercise is particularly effective (Fig. 30-7).

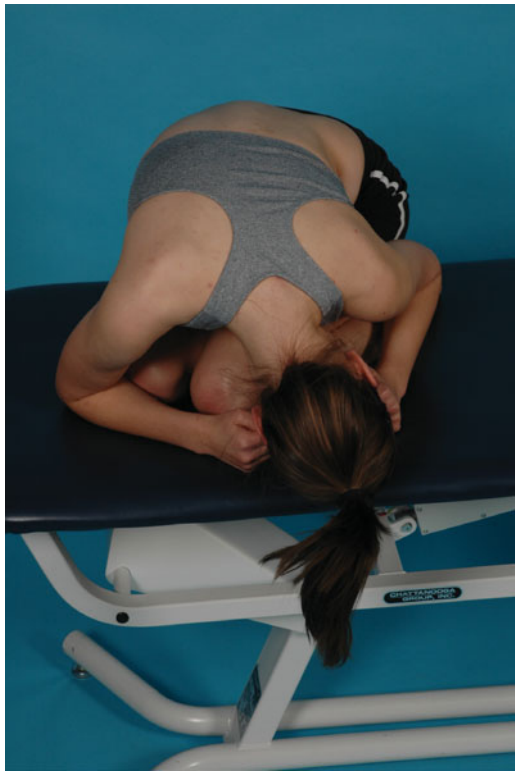

FIGURE 30-4 Prone heel sitting with forward flexion and sidebending.

FIGURE 30-6 Swiss ball sidebending to accentuate thoracic curve.

FIGURE 30-7 Side lying sit-up exercise.

If surgery is considered, the primary goal of scoliosis surgery is to achieve a solid bony fusion. Even in the setting of adequate correction and solid fusion, up to 38% of patients still have occasional back pain. The postsurgical management includes the previously mentioned strategies and the following:[26]

- Breathing exercises to promote rib cage expansion, pulmonary hygiene, and effective coughing.
- Patient and family education.

Legg–Calve–Perthes Disease

Legg–Calvé–Perthes disease, a disorder of the hip in young children, was described around the turn of the century, independently by Legg, Calvé, Perthes, and Waldenström.[27] The incidence of Perthes disease varies considerably from place to place. Low rates of around 5 or 6 per 100,000 have been reported from British Columbia, Massachusetts, and rural Wessex, England, whereas rates of between 11 and 15.6 per 100,000 have been found in Liverpool, England.

There is considerable epidemiologic, histologic, and radiographic evidence to support the theory that Legg–Calvé–Perthes disease is probably a localized manifestation of a generalized disorder of epiphyseal cartilage manifested in the proximal femur because of its unusual and precarious blood supply.[28,29]

The definitive cause of Legg–Calvé–Perthes disease remains unknown. Many etiologic theories have been proposed. Most current etiologic theories involve vascular embarrassment, with repeated episodes of infarction and ensuing abnormalities.[30]

Clinical Findings

The onset is usually insidious, and the course is prolonged over a period of several years. The initial sign is a limp. The child may be small for his/her age. There may also be a slight dragging of the leg and slight atrophy of the thigh muscles. A positive Trendelenburg sign is often seen. There may be some out-toeing of the involved extremity. The patient complains of a vague ache in the groin that radiates to the medial thigh and inner aspect of the knee. Muscle spasm is another common complaint in the early stages of the disease. On examination, there is usually decreased abduction and internal rotation. The ROM examination may show contracture in hip flexion and adduction.

Intervention

The intervention for Legg–Calvé–Perthes disease remains controversial.[31] The goal of treatment is to relieve pain and to maintain the spherical shape of the femoral head and to prevent extrusion of the enlarged femoral head from the joint. Children who are less than 6 years of age (possibly 5 years in girls) and those with minimal capital femoral epiphysis involvement and normal ROM are often followed with intermittent physical examinations and radiographs approximately every 2 months. In the more severe cases, there is lack of agreement regarding whether operative or nonoperative intervention is beneficial.[27] In reviewing long-term studies, it is apparent that the results improve with time.[32,33] Most patients (70–90%) are active and pain-free regardless of intervention.

The prognosis is much improved if there is no collapse of the femoral head. An important aspect in the intervention is the containment of the femoral head in the acetabulum. This is ensured by maintaining the hip in abduction and mild internal rotation for an extended period, using the Atlanta Scottish-Rite Hospital Orthosis. Although this brace does not use internal rotation-like casts as some other orthosis do, it does maintain the hip in abduction and permits approximately 90 degrees of hip flexion. This allows the patient to run and ride a bicycle while wearing the brace.[34] It is worth noting that forced abduction treatment can lead to damage of the lateral physis.[35,36] The advantages of operative intervention for containment of the femoral head are short time of restriction of movement, a more permanent containment, and perhaps enhanced remodeling of the femoral head.

Physical therapy may be provided at home, school, or in the clinic. Treatment methods include

- observation only;
- ROM exercises in all planes of hip motion (especially internal rotation and abduction);
- bracing;
- casting.

Specific procedural interventions can be used to relieve the forces incurred during weight bearing (crutch training, aquatic therapy). Gait training may be initiated with an orthosis or with bracing. The specific gait pattern and assistive devices depend on the type of orthosis. Patient and family education is necessary to teach hip protection strategies, thereby minimizing degenerative changes as the child ages.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) is the most common disorder of the hip in adolescents. The average age for girls in whom slipped capital femoral epiphyses develop is 12.1 $\pm$ 1 years and for boys 14.4 $\pm$ 1.3 years (Table 30-3).[37] The term SCFE is actually a misnomer—it is characterized by a sudden or gradual anterior displacement of the femoral neck from the capital femoral epiphysis, while the head remains in the acetabulum.[27] The effects of coxa vara and valga demonstrate the principles underlying the mechanism of this condition. While the adult femur has a collum angle of approximately 125 degrees, the developing femur demonstrates considerably more coxa valga initially.[38] Failure of the epiphyseal plate occurs as a result of shear forces, which are forces applied parallel to the surface of the growth plate.[39,40] The natural history of SCFE is that the capital femoral epiphysis eventually will fuse with the femoral neck at the end of adolescence. Two devastating complications that can affect the result adversely are avascular necrosis (osteonecrosis) and chondrolysis. These complications are uncommon sequelae in the untreated slip but are serious complications in the operative and nonoperative management of SCFE.[41]

Clinical Findings

The initiating traumatic episode may be as minimal as turning over in bed. Patients with chronic SCFE generally have a history of groin or medial thigh pain for months to years.[27] Approximately 45% will have knee or lower thigh pain as their initial symptom.[42] If the patient can walk, it is with difficulty and with a limp, often with external rotation of the involved foot. The pain is reported as dull or aching, and there can also be a mild weakness of the leg. The hip will often show decreased ROM, particularly of internal rotation, abduction, and flexion. On passive flexion of the hip, the patient will frequently externally rotate the leg. On the basis of the patient's history, physical examination, and radiographs, SCFE can be classified as a stable or unstable hip.[41,43] In the stable hip, weight bearing is possible with or without crutches. In the unstable hip, the patient presents more with fracture-like symptoms, with pain so severe that weight bearing is impossible.[1]

Intervention

The goals of intervention are relief of symptoms, containment of the femoral head, and restoration of ROM.[44] The current method of choice is in situ surgical fixation. The goal of containment is to maintain the sphericity of the femoral head. Other treatments are epiphysiodesis, osteotomy, salvage procedure, or spica cast. Complications from surgery include chondrolysis and/or necrosis of the femoral head, which increases the likelihood of significant joint degeneration in later years. Conservative intervention includes the use of traction for the relief of symptoms, at home or in the hospital, for periods ranging from 1 or 2 days to several weeks. Gait training postsurgery is initiated as soon as lower extremity strength and ROM are adequate for ambulation skills. The weight-bearing status can vary but is usually nonweight bearing or touch down weight bearing. Full weight-bearing is permitted when the growth plate has fused (within approximately 3–4 months).[44]

ROM exercises for the hip should be performed in all planes, but with particular emphasis on hip flexion, internal rotation, and abduction. Strengthening of the affected extremity is introduced when sufficient healing has occurred.

Scheuermann Disease

Scheuermann disease occurs in approximately 10% of the population, typically in pubescent athletes, and in males and females equally.[45] The disease, considered to be a form of juvenile osteochondrosis of the spine, involves a defect to the ring apophysis where the vertebrae grow unevenly with respect to the sagittal plane resulting in an anterior angle that is often greater than the posterior angle.[46] These structural changes can cause the vertebral end plate to crack, thus making it possible for disk material to bulge into the vertebral body (Schmorl node). The seventh and tenth thoracic vertebrae are most commonly affected.

Clinical Findings

The initial onset is typically asymptomatic but then progresses to lower and mid-level back pain, which can be severe and disabling. As the condition progresses, the patient may complain of an aching sensation in the upper spine. The patient may report pain at the apex of the curve, which can be aggravated by physical activity and by long periods of standing or sitting. In addition there may be observational evidence of

TABLE 30-3 Differentiation of Pediatric Hip Pathologies

	Congenital Hip Dislocation	Septic Arthritis	Legg–Calvé–Perthes Disease	Transient Synovitis	Slipped Femoral Capital Epiphysis
Age	Birth	Less than 2 years; rare in adults	2–13 years	2–12 years	Males: 10–17 years; females: 8–15 years
Incidence	Female > male; left > right; blacks < whites		Male > female; rare in blacks; 15% bilateral	Male > female; unilateral	Male > female; blacks > whites
Observation	Short limb, associated with torticollis	Irritable child, motionless hip, prominent greater trochanter, and mild illness	Short limb, high greater trochanter, quad atrophy, and adductor spasm	Decreased flexion, abduction, and external rotation; thigh atrophy; and muscle spasm	Short limb, obese, quadriceps atrophy, and adductor spasm
Position	Flexed and abducted	Flexed, abducted, and externally rotated			Flexed, abducted, and externally rotated
Pain		Mild pain with palpation and passive motion; often referred to knee	Gradual onset; aching in hip, thigh, and knee	Acute: severe pain in knee; moderate: pain in thigh and knee; tenderness over hip	Vague pain in knee, suprapatellar area, thigh, and hip; pain in extreme motion
History	May be breech birth	Steroid therapy; fever	20–25% familial, low birth weight, and growth delay	Low-grade fever	May be trauma
Range of motion	Limited abduction	Decreased (capsular pattern)	Limited abduction and extension	Decreased flexion, limited extension, and internal rotation	Limited internal rotation, abduction, and flexion, and increased external adductor spasm
Special tests	Galeazzi sign, Ortolani sign, and Barlow sign	Joint aspiration			
Gait		Refuses to walk	Antalgic gait after activity	Refuses to walk; antalgic limp	Acute: antalgic; chronic: Trendelenburg external rotation
Radiologic findings	Upward and lateral displacement and delayed development of acetabulum	CT scan: localized abscess; increased separation of ossification center	In stages: increased density, fragmentation, and flattening of epiphysis	Normal at first; widened medial joint space	Displacement of upper femoral epiphysis, especially in frog position

Data from Richardson JK, Iglarsh ZA: *The Hip, Clinical Orthopaedic Physical Therapy.* Philadelphia, PA: WB Saunders, 1994:367–368.

an increased thoracic kyphosis and pain with thoracic extension and rotation, usually detected during a school physical or noted by the parents. Many patients often develop an excessive lordotic curve in the lumbar spine to compensate for the kyphotic curve above.

Intervention

The intervention depends on the severity but typically involves postural education, a modification of the aggravating activity, exercise, or bracing. The Schroth Method, which originated in Germany as a treatment for scoliosis, is an exercise system which uses isometric and other exercises to strengthen or lengthen asymmetrical muscles in the spine with the goal to halt or reverse progression of abnormal spinal deviations. The exercise program includes the stretching of the pectoralis major and minor muscles, and muscle strengthening exercises for the thoracic spine extensors (seated rotation and extension in lying exercises), and the scapular adductors.[47]

Spondylosis

Spondylolysis refers to a defect in the pars interarticularis, a stress fracture caused by repetitive extension and torsion of the spine. Spondylolysis is common in patients involved with sports where repetitive extension and rotation of the lumbar spine occur frequently.[48] Bilateral spondylolysis at the same vertebral level can result in spondylolisthesis (see Chap. 28).

Clinical Findings

The patient typically presents with insidious onset of extension-related low back pain (LBP). Frequently, there is an associated reduction in hamstring flexibility. Occasionally, radiating pain, numbness, or weakness may be present. Physical examination may reveal hyperlordosis, ipsilateral paraspinal muscle spasm, and adaptive shortening of the hamstrings.[49] The ROM examination reveals pain with spinal extension. The single-legged hyperextension test may localize the spondylolysis when standing on the ipsilateral leg (Fig. 30-8), although one study found this to be an insensitive test.[50] Radiographically, the anteroposterior view may identify anatomic variants or developmental effects, whereas the lateral view may demonstrate spondylolisthesis or a lytic lesion, and oblique views may demonstrate a stress reaction of the pars interarticularis, the pathognomic *neck of the Scottie dog* lesion.[49]

Intervention

The conservative intervention includes activity modification with avoidance of any activities that cause pain. The exercise program focuses on strengthening of the abdominal muscles, and hip flexor and hamstring stretches, while avoiding lumbar extension. Once the athlete becomes pain-free, activity can be gradually increased. Bracing is somewhat controversial. Indeed, one study illustrated that the best results were obtained with a period of rest from sport for 3 months, regardless of whether bracing was used.[51]

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is a rare cause of anterior knee or elbow pain in the young athlete. OCD is a joint disorder in which fissures form in the articular cartilage and the underlying subchondral bone due to vascular deprivation (osteonecrosis). The result is fragmentation (dissection) of both cartilage and bone, and the free movement of these osteochondral fragments within the joint space, causing pain and further damage. If OCD occurs in the knee, it involves the weight-bearing portions of the medial and lateral femoral condyles.

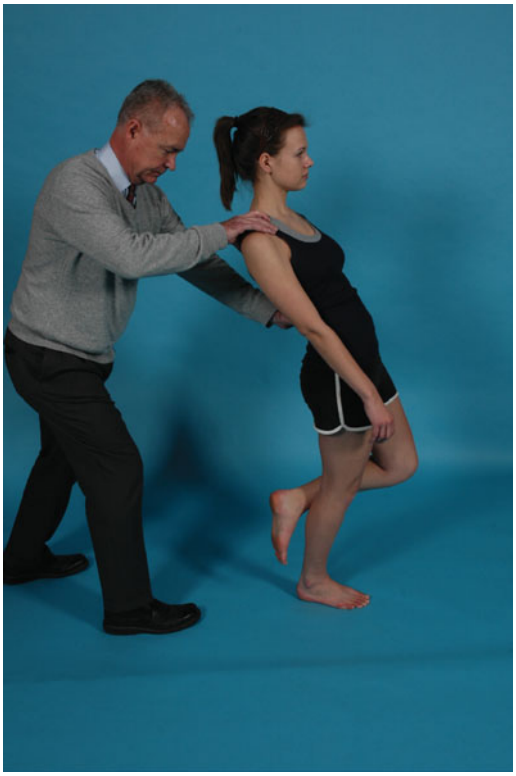

FIGURE 30-8 Single-legged hyperextension test.

Clinical Findings

Occasionally, pain may not be the most prominent symptom, but a catching sensation with joint motion may be the primary complaint if there is a loose body within the joint space. If the lesion is small, a painful arc is present during active and passive movement.

Intervention

When possible, nonoperative forms of management such as protected weight bearing (partial or nonweight bearing) and immobilization are used. However, nonsurgical treatment is rarely an option as the capacity for articular cartilage to heal is limited. As a result, even moderate cases require some form of surgery. Surgical treatment varies widely and includes arthroscopic drilling of intact lesions, securing of cartilage flap lesions with pins or screws, drilling and replacement of cartilage plugs, stem cell transplantation, and joint replacement.

Postoperative rehabilitation usually involves immobilization then physical therapy. During the immobilization period, isometric exercises are commonly used to restore muscle lost to atrophy without disturbing the cartilage of the affected joint. Once the immobilization period has ended, physical

therapy involves protection of the joint's cartilage surface and underlying subchondral bone with maintenance of muscle strength and ROM and low-impact activities, such as walking or swimming.

Osgood Schlatter Disease

The apophysis of growing bones differs from the epiphysis of skeletally immature bone in that the apophysis is an independent center of ossification that does not contribute to the longitudinal length of a long bone. The apophysis does, however, contribute to the structure and form of mature long bone by serving as a site of tendinous or ligamentous attachment. Development of the tibial apophysis begins as a cartilaginous outgrowth, with secondary ossification centers appearing with subsequent progression to an epiphyseal phase when the proximal tibial physis closes and the tibial apophysis fuses to the tibia.[3] OS disease is a benign traction apophysitis that occurs in the tibial tubercle. It is a self-limiting knee condition that is one of the most common causes of knee pain in active and nonactive adolescents.[52] The condition occurs in active boys and girls aged 11–18 coinciding with periods of growth spurts. OS occurs more frequently in boys than in girls, with reports of a male-to-female ratio ranging from 3:1 to as high as 7:1. During periods of rapid growth, stress from repetitive contractions of the quadriceps is transmitted through the patellar tendon onto a small portion of the partially developed tibial tuberosity. This may result in multiple subacute avulsion fractures and inflammation of the tendon, and subsequent secondary heterotopic bone formation occurring in the tendon near its insertion.

Clinical Findings

The diagnosis of OS disease is relatively straightforward. There may or may not be a history of injury. Symptoms are typically unilateral, although 20–30% of cases can be bilateral in nature.[3] In the acute phase the pain is severe and continuous in nature. The pain occurs during activities such as running, jumping, squatting, and especially during kneeling, acute knee impact, and ascending or descending stairs. There is often a visible lump over the site. The pain can be reproduced by extending the knee against resistance or stressing the quadriceps.

Intervention

The intervention for OS disease is usually symptomatic, including anti-inflammatory measures, rest from the offending activity, and judicious stretching of the quadriceps and hamstrings (adaptively shortened hamstrings require increased quadriceps force to overcome the tight posterior structures).[3] Bracing or enforced joint immobilization is rarely required, although the more persistent cases may require cast immobilization for 6–8 weeks. The progressive quadriceps stretching exercises begin with a bolster placed under the hips of the prone patient to place the muscle on slack at the hip joint. As tolerated, the bolster is removed to place the hip in extension for a complete stretch of the extensor mechanism as indicated. Rarely, individuals will require surgical excision of symptomatic ossicles or degenerated tendons if symptoms persistent into skeletal maturity.

Sever Disease (Calcaneal Apophysitis)

The calcaneal apophysis serves as the attachment for the Achilles tendon superiorly and for the plantar fascia and the short muscles of the sole of the foot inferiorly.[53] Sever disease is a traction apophysitis of the growth center of the calcaneus that occurs at the insertion of the Achilles tendon and which is a common cause of heel pain in the athletically active child, with 61% of cases occurring bilaterally.[54] Sever disease typically affects children 8–13 years, with the peak incidence occurring at 11 years in young females and in 12 years in young males.[55–57] Young gymnasts, soccer players, and dancers are particularly susceptible to this condition because of their repetitive jumping or landing from a height.[58]

Clinical Findings

Sever disease is characterized by pain, point tenderness, and local inflammation at the posterior calcaneus near the insertion of the Achilles tendon. Patients with adaptively shortened calf muscles, internal tibial torsion, forefoot varus, a dorsally mobile first ray, weak dorsiflexors, and genu varus may be more susceptible to Sever disease.[3]

Intervention

The intervention for Sever disease initially begins with a shortening of the gastrocnemius-soleus group using heel cups or heel wedges, and avoiding barefoot walking until becoming asymptomatic.[59] Stretching of the gastrocnemius-soleus, with the knee extended and the knee flexed, is only initiated after symptoms have subsided. When stretching in the weight-bearing position any rear foot to lower leg or forefoot to rear foot abnormality should be corrected before and during the exercise. Dorsiflexion strengthening exercises along with foot intrinsic strengthening may also help manage symptoms.[3]

Little Leaguer Elbow

Repetitive throwing results in muscular and bony hypertrophic changes about the elbow. Little Leaguer elbow is a common term, credited to Brogden and Cros,[60] for an avulsion lesion to the medial apophysis as a result of repetitive valgus stress. The term has since been used to describe a variety of pathoanatomic lesions in the immature athlete, all of which relate to the mechanics of throwing. Additional factors that influence its development include age, skeletal maturity, individual susceptibility, competitive level, and geographic location.[61]

The act of baseball pitching has been described in five stages[62–65]:

- ***Wind-up.*** This stage involves the initial preparation as the elbow is flexed and the forearm is slightly pronated, and is characterized by low load to the arm. Elbow flexion is maintained by an isometric contraction of the elbow flexors. During the stride of the wind-up phase, the biceps muscle contracts to isometrically and eccentrically control the elbow angle, while the wrist and finger extensors concentrically move the wrist from slight flexion to hyperextension.[66,67]
- ***Early cocking.*** This stage begins when the ball leaves the nondominant gloved hand and ends when the forward foot

comes into contact with the ground. The shoulder begins to abduct and externally rotate, and valgus stress to the elbow begins.

- ***Late cocking.*** This stage is characterized by further shoulder abduction and maximal external rotation. At the elbow, flexion of between 90 and 120 degrees and increasing forearm pronation to approximately 90 degrees occurs. Dynamic stability is provided by the flexor–pronator muscle mass, and the triceps contracts isometrically to limit elbow flexion.[67]
- ***Acceleration.*** This phase is characterized by the generation of a significant anteriorly directed force on the upper extremity by the shoulder musculature, resulting in internal rotation and adduction of the humerus, accompanied by rapid elbow extension. The period from the late cocking stage through the acceleration phase is the time when the elbow is subjected to maximum valgus stresses.[68]
- ***Follow-through.*** This phase is characterized by the dissipation of all excess kinetic energy as the elbow reaches full extension and ends when all motion is complete. McLeod further divides this phase into release and deceleration.[69]

The repetitive motions involved in the various phases of throwing place colossal strains on the elbow, particularly during the late cocking and acceleration phases. These strains can result in inflammation, scar formation, loose bodies, ligament sprains or ruptures, and the more serious conditions of osteochondritis or an avulsion fracture.[64,70] The onset of Little Leaguer elbow can be insidious or sudden, with the latter typically secondary to fracture at the site of the lesion.

Clinical Findings

The child typically presents with pain and local tenderness on the medial side of the elbow. Physical findings depend on the severity but commonly include persistent elbow discomfort or stiffness due to aggravation by the injury. A locking or "catching" sensation indicates a loose body. If the ulnar nerve is compromised, numbness in the ulnar distribution and a Tinel sign at the elbow may be present.

Intervention

Management is conservative, involving rest and elimination of the offending activity. Lesions involving less than 0.5–1 cm of apophyseal separation are initially treated with the rest. This is followed by a rehabilitation program similar to that described for medial epicondylitis except that resistance exercises are avoided until active range can be performed to full motion without pain (generally 2–3 weeks). Throwing is avoided for 6–12 weeks. If OCD is present, the joint needs protection for several months.[71] Any separation greater than 0.5–1 cm, sudden traumatic avulsions, or a failure to respond to conservative measures are indications for surgery. The patient cannot return to pitching until full and normal motion and strength has returned.

To prevent elbow disorders, young athletes should adhere to the rules of Little League, which limits the number of pitches per game, per week, and per season and the number of days of rest between pitching.[72] The pitch count is the most important of these statistics.

Proximal Humeral Epiphysitis

This condition, often referred to as Little Leaguer shoulder, is also known as osteochondritis, epiphysitis, and epiphysiolysis of the proximal humeral epiphysis.[73] The proximal humerus ossifies from four ossification centers: humeral head, greater tuberosity, lesser tuberosity, and humeral shaft.[74] The ossification center for the humeral head is usually radiographically evident within the first year of life, whereas the greater tuberosity appears at age 3 and the lesser tuberosity at age 5. The humeral head and tuberosity unite around age 6 to form a large proximal humeral epiphysis, which unites with the shaft around age 20.[73] Injury to the proximal humeral epiphysis usually occurs because of the two mechanisms in throwers: distraction and torsion.

Clinical Findings

Patients typically describe pain localized to the proximal humerus during both throwing and resisted shoulder strength testing. Palpation demonstrates local tenderness over the proximal humerus. The differential diagnosis of shoulder pain in adolescents throwers include glenohumeral instability, rotator cuff tendinopathy, impingement, and proximal humerus physeal fracture.[73] Radiographs characteristically show widening of the proximal humeral physis.

Intervention

Treatment includes cessation of throwing until the patient has pain-free ROM of the shoulder and radiographs return to normal, which may take up to 1 year.[75]

Pulled Elbow

The term *pulled elbow* or "nurse maid's elbow," refers to a common minor soft-tissue injury of the radiohumeral joint in children of preschool age. The incidence of this condition is 3% in children under the age of 8,[76] and it comprises 5.6% of all upper extremity injuries involving children under the age of 10.[77,78] The left elbow is more commonly affected than the right,[79]and the disorder is more common in boys than in girls. The injury is caused by a sudden longitudinal traction force on the pronated wrist and extended elbow[80,81] resuling in the radial head slipping through the annular ligament, which causes the fibers of the annular ligament to become interposed between the radius and the capitellum of the humerus.[77,82]

These are the more common causes of pulled elbow[77]:

- The child is lifted by an adult from the ground by his hands.
- The child's forearm, wrist, or hand is being held firmly by a parent as the child attempts to walk away.
- A mother grabs the hand of a child to prevent a fall as the child wanders toward something potentially harmful.
- The young child is lifted by the hand from a lying or sitting position.

- The child is swung around by the hands several times during the course of play.

Clinical Findings

There is usually no obvious swelling or deformity, but the child presents with a painful and dangling arm, which hangs limply with the elbow extended and the forearm pronated.[77] The child is reluctant to use the arm and resists attempted supination of the forearm. The common sites of pain are (in order of occurrence) the forearm and wrist, the wrist alone, and the elbow alone.[82]

Intervention

The intervention of choice is manipulation.[77] Before attempting the manipulation, it is important to explain the procedure to the parents and to win the confidence of the child, by gently supporting the injured arm before manipulation. During the procedure, the clinician holds the child's wrist with one hand while the other hand supports the elbow and palpates the radial head. The child's attention is diverted and the forearm is forcibly supinated with one quick motion, together with the application of downward pressure on the radial head. A click in the region of the radial head (palpable and sometimes audible) is indicative of a successful reduction. Sometimes, the forearm has to be pronated after forcible supination to reduce the pulled elbow. The click results from release of the trapped annular ligament. Soon after the manipulation, the child typically begins to use the arm again, but sometimes there can be a delay of a day or two. In such cases, a sling can be used to both give comfort and protect the arm from a recurrence.

The parents should be advised to avoid a longitudinal traction strain on the child's arm by not pulling on the hands or wrists.[77]

Distal Radial Epiphysitis

Radial physes appear at 12–18 months and fuse by 15–18 years.[83] Distal radial apophyseal injuries are most common in male and female gymnasts but occasionally happen in other sports.

Clinical Findings

The patient typically describes a gradual onset of wrist pain made worse by weight-bearing activities while the wrist is in extension. Physical examination often reveals normal ROM but swelling of the distal radius. Tenderness is frequently found over the posterior (dorsal)-radial growth plate but may also be elicited on the anterior (volar)-radial physis as well. Radiographic findings depend on the stage of the disease. Although these injuries are usually confined to the distal forearm, the carpus can sometimes be involved.

Intervention

Time to healing is dependent on the stage of the disease in the radiographic findings. When radiographs are negative, 4 weeks of rest usually allow for healing and return to activities. In other cases, immobilization in a cast is the mainstay of treatment.

CONGENITAL ORTHOPAEDIC CONDITIONS

Arthrogryposis Multiplex Congenita

Arthrogryposis multiplex congenita (AMC) is a nonprogressive syndrome present at birth that is characterized by severe joint contractures, muscle weakness, and fibrosis.[84] There are many known subgroups of AMC, with differing signs and symptoms. Some of the more common signs and symptoms are associated with the shoulder (internal rotation), elbow (extension and pronation), wrist (flexed and ulnarly deviated), hand (fingers in fixed flexion and thumb-in-palm), hip (flexed, abducted, and externally rotated, often dislocated), knee (flexion), and foot (clubfoot). Although the specific cause of AMC is unknown, several mechanisms have been suggested including hyperthermia of the fetus, prenatal virus, fetal vascular compromise, septum of the uterus, decreased amniotic fluid, and muscle and connective tissue developmental abnormalities.[85]

Clinical Findings

No definitive laboratory studies or invasive procedures are available to detect AMC. The clinical findings associated with AMC vary tremendously among infants and include those already mentioned. The purpose of the initial examination is to establish a baseline from which to set realistic goals. Measurements of passive, active, and functional ROM are assessed as are gross motor function and developmental milestones.

Intervention

The intervention for AMC involves a multidisciplinary approach. The cornerstone of the intervention is family education, including instruction on low load, prolonged stretching (3–5 sets of stretches per day, with 3–5 repetitions in each set, and each repetition held for 20–30 seconds), positioning, strengthening activities through play, facilitation of developmental activities, and teaching of compensatory strategies.[86] Splints are adjusted for growth and improvement every 4–6 weeks. Reducing the disability associated with immobility is a major focus of treatment. Key functional motor skills such as rolling, hip hiking, and standing are addressed. Standing is initiated in standing frames with the lower extremities held in as optimally correct a position as possible with the help of splints and high-top shoes.[86] In the preschool patients, goals should be to emphasize ability versus disability, improve the child's function in basic ADLs, and enhance independent immobility and ambulation with minimal bracing and assistive devices.[86]

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is an inherited condition resulting from abnormality in the type I collagen (found in bones, organ capsules, fascia, cornea, sclera, tendons, meninges, and dermis), which causes the bones to be brittle. In the most severe forms, the infant is born with multiple fractures sustained in utero or during the birth process.

Clinical Findings

The diagnosis of OI is made primarily from clinical and radiographic findings, as no definitive laboratory test exists to identify OI. The clinical features of OI are extremely variable and depend on the type and severity of the disorder. Primary impairments include bone fragility, short stature, scoliosis, lax ligaments, weakened muscles, failure of postnatal growth, and multiple recurrent fractures sustained from minor or no trauma.[86] The clinician should be aware of the infant's medical history of past and present fractures and know the types of immobilizations employed before beginning the examination.[87–90] Pain is assessed using a tool such as the FLACC (face, legs, activity, cry, and consolability), which is an observational scale for assessing pain behaviors quantitatively with preverbal patients. Assessing active, but not passive, ROM is essential. Functional ROM may prove more useful because it will assist in visualizing the whole composite of motion needed in functional abilities. Assessing muscle strength is done through observation of the infant's movements and palpation of contracting muscles rather than by using formal manual muscle tests.

Intervention

Typical participation restrictions for an infant with OI depend on the severity of the case. Goals for infants with severe OI are to prevent deformities of the head, spine, and extremity; avert cardiopulmonary compromise by avoiding constant positioning in the supine position; and maximizing the child's ability to move actively.[86,90] Caregiver education on proper and safe handling, positioning, and facilitation of movement is provided. Bathing, dressing, and carrying the infant are critical times when the infant is at risk for fractures.

CLINICAL PEARL

When handling the infant, it is important that forces not be put across the long bones; instead the head and trunk should be supported with the arms and legs gently draped across the supporting arm. It is also important to change the carrying position of the infant periodically because he or she develops strength by accommodating to postural changes.

The caregiver and clinician must be aware of the signs of a fracture which include inflammation (warmth of the site, edema, and pain), bruising, irritability, and deformity. An aquatic exercise program is an excellent therapeutic program for the child with OI. The degree of ambulation attainable varies for preschool children with OI. Gait training, which progresses in the usual fashion (parallel bars and moving to various assistive devices), is commonly initiated when the child has achieved strength with a rating of at least 3/5 (Fair) and when ROM has reached a plateau. In moderate to severe OI, braces and splints are usually required to begin standing activities on solid surfaces. It must be remembered that when children use walkers or crutches a large percentage of the body weight is borne through the upper extremities, necessitating precautions against bowing deformities of the radius and ulna. A walker that supports the majority of body weight through the trunk and pelvis is often used to assist in weight bearing during initial overland ambulation. Customized mobility carts may be fabricated to encourage independent mobility when the child is immobilized, enabling the child to explore his or her environment, gain some independence, and maintain strength in the upper extremities. Children with severe types of OI often require wheelchairs for mobility. Because of the shortened extremities, these chairs are often specially ordered and may require adaptations.

For severe cases presenting with severe osteopenia and repeated fractures, cyclic administration of intravenous aminohydroxypropylidene (i.e., pamidronate) may reduce the incidence of fracture and increase bone mineral density. Surgical interventions include intramedullary rodding, surgery for basilar impression, and correction of scoliosis.

Developmental Dysplasia of the Hip

Up to 10% of infants in the United States are born with congenital dislocation of the hip.[91] The acronym CDH is confusing and has been used synonymously with congenital dislocation or congenital disease of the hip. A dislocated hip is a physical sign, not a diagnosis, and the term *congenital* means present at birth.[92]

Thus, the acronym DDH is replacing CDH. The word *developmental* invokes the dimension of time, acknowledging that the dysplasia or dislocation may occur before or after birth, while *dysplasia* means an abnormality of development and encompasses a wide spectrum of hip problems.[92]

DDH includes hips that are unstable, malformed, subluxated, or dislocated. Instability is the inability of the hip to resist an externally applied force without developing a subluxation or dislocation.[92] A subluxation is an incomplete dislocation with some residual contact between the femoral head and acetabulum, whereas a dislocation indicates complete displacement of the femoral head from the acetabulum.[92]

The etiology of DDH is felt to be multifactorial, including both mechanical and physiological factors. In utero, the hip is in a position of flexion and abduction that results in a tightened iliopsoas tendon and anterior–lateral orientation of the acetabulum.[93] The tight iliopsoas may push the femoral head out posteriorly with hip extension during kicking. The labrum (cartilaginous rim of the acetabulum) becomes everted and flattened.

The acetabulum and femoral head develop rapidly in the neonatal period. When the acetabulum and femoral head are in the correct position, each reinforces the development of the other by this physical contact; however, if the hip is not concentrically reduced, it will develop in a dysplastic manner.[94–96] If the hip reduces spontaneously within a few days, hip development usually proceeds normally. In contrast, if a subluxation or dislocation persists, the femoral head becomes flattened on the posteromedial surface, the acetabulum becomes shallow and dysplastic, and femoral anteversion gradually increases.[94–96]In addition, the muscles surrounding the hip may shorten and contract.

Prolonged dislocation makes it difficult to return the femoral head to the acetabulum and is associated with a higher incidence of OA and impaired hip function in adulthood.[91]

Clinical Findings

The value of the neonatal hip screening examination remains controversial.[92] At present, tests including the ones outlined below are currently used to examine the infant. The examination requires patience and skill, and the newborn must be relaxed on a firm surface.

The examiner attempts to reduce the dislocation or subluxation using the Ortolani and Barlow maneuvers.[92]

With the newborn supine, the clinician places the tips of the long and index fingers over the greater trochanter, with the thumb along the medial thigh. The infant's leg is positioned in neutral rotation with 90 degrees of hip flexion and is gently abducted while lifting the leg anteriorly.[92] With abduction one can feel a clunk, as the femoral head slides over the posterior rim of the acetabulum and into the socket. This is the clunk originally described by Ortolani,[97] and is called the sign of entry, as the hip relocates with this maneuver. Maintaining the same position, the leg is then gently adducted, while gentle pressure is directed posteriorly on the knee, and a palpable clunk is noted as the femoral head slides over the posterior rim of the acetabulum and out of the socket.[92] This clunk was originally described by Barlow,[98] and is called the sign of exit, as the hip dislocates with this maneuver. Both tests are designed to detect motion between the femoral head and the acetabulum.[92] The reproducibility of these tests is dependent on ligamentous or capsular laxity, which usually disappears by the age of 10–12 weeks.[92]

Clinical screening programs are important in reducing the incidence of surgery. Ultrasound is the diagnostic modality of choice.[99] Early intervention has been reported to lead to a successful outcome in 90 and 96% of children radiographically and functionally, respectively.[94–96] Later examinations include assessment of gluteal folds, knee height, and the degree of hip abduction.[100] In the 3- to 12-month-old infant, the best physical finding is a limitation of hip abduction. In the supine position, with the hip in 90 degrees of flexion and one hand stabilizing the pelvis, each hip should easily abduct to 75 degrees and adduct to 30 degrees past the midline.[92] In the older child, a limp, positive Trendelenburg, toe-walking, in-toeing, or out-toeing may be secondary to DDH.[92]

Intervention

The treatment of this condition depends on the age of the patient and the severity of the condition. The goal of intervention is to safely obtain and maintain a concentric reduction of the hip to provide an environment for normal bony development. The conservative approach is most effective for infants whose subluxation or dislocation have been discovered and treated early, within the first 6 months of life. The conservative approach involves maintaining the hip in flexion and abduction through diapering, and bracing/splintinguntil it is adequately remodeled.

- ***Diapering.*** The child is placed in 2 to 3 diapers, which is designed to hold the legs in abduction, and parents are instructed to position the infant in hip flexion as well.
- ***Pavlik harness.*** The preferred conservative intervention is an outpatient intervention regimen using the Pavlik harness, that provides effective reduction in 90% of the cases.[100] However, the harness is ineffective after 3 weeks making early detection critical. In infants older than 9 months who are beginning to walk independently, an abduction orthosis can be used as an alternative to the Pavlik harness.[31] The harness, which is initially worn 24 hours a day for 6–12 weeks, is used if symptoms persist after several weeks and is designed to restrict hip extension and adduction while allowing the hip to be maintained in flexion and abduction. [31] This "protective position" of flexion and abduction enhances normal acetabular development, and the kicking motion allowed in this position stretches the contracted hip adductors while promoting spontaneous reduction of the dislocated hip.[31] After the initial period, the harness is worn 12 hours per day for 3–6 additional months or until both clinical and radiographic signs are normal,[100]. If the Pavlik harness is used, it is important to teach the parents that the hips are placed in the correct position—too much flexion or abduction can cause excessive pressure through the femoral heads, resulting in possible avascular necrosis.

In more severe cases, skin traction, closed reduction, and spica-cast application may be needed. Open reduction and recasting are also options. In rare cases, total hip replacement is necessary in later life.

Equinovarus

Clubfoot, or talipes equinovarus, is a deformity consisting of hindfoot equinus (i.e., plantar flexion), hindfoot varus (i.e., the long axis of the talus lies lateral to the base of the first metatarsal bone), and forefoot varus (i.e., the forefoot is curved inward in relation to the heel, the heel is bent inward in relation to the leg, and the ankle is fixed in plantar flexion with the toes pointing down), which can be classified as follows:

- Inversion at the subtalar joint
- Adduction at the talonavicular joint
- Equinus at the talocrural (ankle) joint (plantarflexed position)
  - Fixed or rigid: this type of equinovarus can be either correctable without surgery (i.e., flexible) or require surgical release (i.e., resistant).

Clinical Findings

The clinical findings vary according to severity. Most cases are detected with fetal screening using an ultrasound scan.

Intervention

Treatment consists of manipulation (reducing the talonavicular joint by moving the navicular laterally and the head of the talus medially), taping, stretching, and serial casting, which is most effective if started immediately after birth. Other options include knee ankle foot orthoses (KAFO), Dennis-Brown bars with straight last boots, ankle foot orthoses, and/or custom foot orthoses. The role of the clinician involves monitoring, providing developmental intervention to promote typical functional skills and to assist in stretching and splinting.

Congenital Limb Deficiencies

Congenital limb deficiencies can be described as transverse and longitudinal.

- Transverse: These types resemble amputation to a residual limb in which the limb has developed normally to a particular level, but beyond which no skeletal elements are present. These deficiencies are described by naming the segment at which the limb terminates and the level within the segment beyond which no skeletal elements exist. For example, a child's lower extremity has a fully developed femur, but no tibia, fibula, tarsal, metatarsals, or phalanges.
- Longitudinal: These include all of the cases that are not transverse and involve a reduction or absence of an element or elements within the long axis of the limb. These deficiencies are named according to the bones affected (in a proximal-distal sequence) and whether the affected bone is totally or partially absent. For example, a child who is missing the radius and thumb in one upper extremity, with the ulna, carpals, and other digits present.

In the upper limb, congenital deficiencies most frequently involve the hand. According to the Association of Children's Prosthetic and Orthotic Clinic (ACPOC), 60 percent of congenital limb deficiencies either have no known cause or are genetic in origin. Although some congenital abnormalities may be due to poor blood supply to the fetus due to constricting amniotic bands, only 4 percent are due to taking some type of drug or toxin (i.e., maternal drug exposure like thalidomide).

Clinical Findings

The clinical presentation varies according to the type of children with limb deficiencies, the level of the deficiency, and the number of deficiencies or limbs involved.

Intervention

The intervention is directed toward helping the child develop appropriate functional and developmental skills while reducing any secondary impairments, such as soft-tissue contractures. Some children with congenital limb deficiencies may be candidates for an Ilizarov procedure, an orthopaedic surgical procedure that involves gradual lengthening of the limb over many months using implanted pins connected to a traction device.

GERIATRICS

The field of geriatrics continues to gain attention due to the rapid growth of this segment of the population and its predicted future socioeconomic impact. It is therefore inevitable that future rehabilitation professionals will see an increase in the number of elderly individuals seeking services for the management of both acute and chronic conditions that can negatively impact active life expectancy or the number of years that an individual may expect to be independent in ADLs.[101,102] Therefore, rehabilitation, with its potential to restore function, prolong independence, and improve quality of life, can be extremely important in this population.

The Aging Process

Aging is the accumulation of diverse adverse changes that increase the risk of death.[103] The rate of aging, that is, the rate at which aging changes occur, typically varies from individual to individual, resulting in differences in the impact of aging on function.[103] The aging process can be attributed to a combination of development, genetic defects, the environment, social and recreational habits, and disease, some or all of which are responsible for sequential alterations that accompany advancing age and the progressive probability of experiencing a chronic debilitating disease.[103] This increase in the incidence of chronic conditions with advancing age occurs largely because this period in life is often accompanied by a deterioration in health and a subsequent loss of independence. Complicating matters is the presence of comorbidities at this time of life, such as cardiovascular disorders, osteoporosis, arthritis, and diabetes, which increase the vulnerability of the geriatric patient.

Musculoskeletal impairments are some of the most prevalent and symptomatic health problems of middle and old age,[104] and result in a gradual loss of strength, motion, and increasing pain. These changes prevent elderly individuals from participating in regular physical activity, optimum mobility and, in some cases, reduce independence.[105] The history and physical examination of the geriatric patient must differentiate between the effects of aging, inactivity, and disease on the underlying impairments and functional limitations that result in movement dysfunction.[106] For example, mild impairments in the ROM may be due to increased stiffness associated with aging that occurs in the tendinous or ligamentous structures around a joint, or it could be due to acute immobilization, or chronic inactivity and reduced demands on a particular joint for full ROM.[107]

Theories of Aging

Normal aging produces age-related changes that are the result of the passage of time rather than the result of pathologic conditions. A wide array of theories exist as to why aging occurs, why species have the life spans they do, and what kinds of factors are likely to influence the aging process. For example, the aging process has been attributed to the following:

- ***Glycosylation.***[108–110] Glycosylation involves the abnormal process of the binding of glucose (simple sugar) to protein, a process that requires oxygen. Once this binding has occurred, the protein becomes impaired and is unable to perform as efficiently. Examples of known cross-linking disorders include senile cataract and the appearance of tough, leathery, and yellow skin.
- ***Neuroendocrine-immuno theory.***[111–114] The immune system is the most important line of defense against foreign substances that enter the body. With age the system's ability to produce necessary antibodies that fight disease declines, as does its ability to distinguish between antibodies and proteins. In a sense the immune system itself becomes self-destructive and reacts against itself.
- ***Damage by free-radical reactions.***[115] The term free radical describes any molecule that has a free electron. Theoretically, this free electron reacts with healthy

molecules in a destructive way by creating an extra negative charge. This unbalanced energy makes the free radical bind itself to another balanced molecule as it tries to steal electrons. In so doing, the balanced molecule becomes unbalanced and transforms into a free radical itself. It is known that diet, lifestyle, drugs (e.g., tobacco and alcohol), radiation, and so on are all accelerators of free radical production within the body. However, there is also natural production of free radicals within the body as a byproduct of energy production, particularly from the mitochondria.

- ***Planned obsolescence.***[103] This theory focuses on the genetic programming encoded within the DNA, the blueprint of individual life obtained from parents. Individuals are born with a unique code and a predetermined tendency to certain types of physical and mental functioning that regulate the rate at which we age (graying of hair, wrinkles, etc.). Many genes show changes in expression with age and these premature aging syndromes provide evidence of defective genetic programming: Hutchinson–Gilford syndrome and Werner syndrome
- ***Telomere shortening.*** This theory was born from the surge of technological breakthroughs in genetics and genetic engineering. Telomeres are DNA–protein complexes that cap the ends of chromosomes and promote genetic stability. Each time a cell divides, a portion of telomeric DNA dwindles away, and after many rounds of cell division, so much telomeric DNA has diminished that the aged cell stops dividing. Thus, telomeres play a critical role in determining the number of times a cell divides, its health, and its life span.
- ***Caloric restriction.*** Calorie restriction or energy restriction is a theory proposed after years of animal experiments and research on longevity that demonstrated how a high-nutrient low-calorie diet can dramatically retard the functional, if not the chronological, aging process.
- ***Evolutionary theory.*** As evolution acts primarily to maximize reproductive fitness in an individual, longevity is a trait to be selected only if it is beneficial for fitness. Over successive generations, late acting deleterious mutations will accumulate in the population and ultimately lead to pathology and senescence.

As previously mentioned, coexisting pathologic processes or comorbidities can exacerbate the effects of other conditions and result in greater functional limitations and disability. Throughout youth and early adulthood, the body has a number of physiologic reserves from which to draw upon when faced with physical challenges and injury, without a loss of functional abilities. However, older individuals have fewer of these system redundancies due to a gradual decline of health and increased incidence of injury and disease.[105] Without these physiologic reserves, an older individual is more susceptible to functional limitations and disability, resulting in frailty—the opposite end of the spectrum from successful aging.[105]

Pathological Conditions Associated with the Elderly

The geriatric patient who has been given a prescription for physical therapy may not have been physically active for some time, and his or her level of fitness may have declined considerably. Age-related changes of the heart and blood vessels, which can either be mitigated or exacerbated with activity level, typically result in reduced capacity for oxygen transport at rest and in response to situations imposing an increase in metabolic demand for oxygen.[105] In addition, maximal oxygen consumption decreases 5–15% per decade after the age of 25 years.[116] As a result, at submaximal exercise, cardiac output and stroke volume are lower in older adults at the same absolute work rates, while blood pressures tends to be higher.[116] It is very important that elderly patients have a physician's evaluation of their cardiovascular status before engaging in a rehabilitation program. In addition, the patient should be carefully monitored for their cardiovascular response and tolerance to exercise during their rehabilitation sessions. Heart rate, blood pressure, and rate of perceived exertion (RPE) should be assessed before, during, and after exercise, and the physician should be notified of any abnormal or unusual findings. In addition to the normal aging changes a number of complications can occur in the elderly:[107]

- Acute inactivity, such as that which occurs with hospitalization, can significantly reduce VO_{2max} and increase blood viscosity and venous status, which increases the risk of thromboembolic disease. Immobility is a common pathway by which a host of diseases and problems in the elderly produce further disability. Persons who are chronically ill, aged, or disabled are particularly susceptible to the adverse effects of prolonged bed rest, immobilization, and inactivity. Common causes for immobility in the elderly include arthritis, osteoporosis, fractures (especially hip and femur), podiatric problems, and neurologic disorders and diseases (see next)
- ***Neurologic disorders and diseases.*** A wide variety of neurologic disorders and diseases can affect the aging population, including cerebrovascular accident, Parkinson disease, cerebellar dysfunction, neuropathies, cognitive, psychological and sensory problems (depression, fear and anxiety), pain, and impaired vision. Age-related changes in the brain start at approximately age 60, although normal, nonprogressive, and negligible declines among the aged do not dramatically impact daily functioning until the early 80s. Many cognitive disorders require timely identification and intercession to offset permanent dysfunction.
- ***Dementia and Delirium.*** Primarily a disease of the elderly, dementia is a generic term used to describe a progressive, persistent loss of cognitive and intellectual functions. Dementia is associated with a history of chronic, steady decline in short- and long-term memory, depression, and with difficulties in social relationships, work, and activities of daily living. The typical end result of dementia is impairment of cognition including a decline in alertness, orientation, emotion, behavior, memory, perception, language, the application of knowledge (praxis), problem solving, and judgment. In contrast, delirium presents with an acute onset of impaired awareness, confusion, easy distraction, and disturbances of perception (e.g., misinterpretations, visual hallucinations).

- Cardiac diseases, such as coronary artery disease (CAD) and the sequelae of myocardial infarction (MI) and cardiomyopathy:
  - CAD is a complex disease of the cardiac arteries resulting in ischemia to the myocardium. The clinical symptoms of CAD include angina (an ache, pressure, pain, or other discomfort in the chest, arms, back, or neck), shortness of breath, a decrease in activity tolerance, or palpitations.
  - MI is a development of myocardial necrosis caused by an imbalance between the oxygen supply and demand of the myocardium, typically resulting from plaque rupture with thrombus formation in a coronary vessel, and subsequent acute reduction of blood supply to a portion of the myocardium. This patient population is a much greater risk of an adverse event during exercise, and therefore careful consideration, screening, and monitoring must occur to ensure safety with a rehabilitation program.
- ***Hypertension.*** Hypertension, which may be either essential or secondary, can have a number of negative impacts including the following:[117–126]
  - Left ventricular hypertrophy, left atrial enlargement, aortic root dilatation, arrhythmias, and ischemic heart disease.
  - Hemorrhagic and atheroembolic cerebrovascular accident (CVA) or encephalopathy.
  - Increased glomerular hydrostatic pressure secondary to efferent glomerular arteriolar constriction, which results in a reduction in renal blood flow in conjunction with elevated afferent glomerular arteriolar resistance.
- ***Musculoskeletal.*** The musculoskeletal changes associated with aging affect all of the soft tissues and bone. Many of these changes are associated with a decrease in physical activity. Muscle size can decrease an average of 30–40% over one's lifetime, affecting the lower extremities more than the upper extremities.[127] Type II muscle fibers, which are used primarily in activities requiring more power are not stimulated by normal ADLs disappear at a faster rate than Type I fibers. Indeed, Type II fibers decrease from an average of 60% of total muscle fiber type in sedentary young men to below 30% after the age of 80.[128] Therefore, the focus on this age group should be the prescription of exercises that develop power, not just strength. In addition, a loss of range in the lower extremities can have a negative impact on functional activities such as gait. Two musculoskeletal conditions that can severely impact function in the geriatric population are osteoporosis and osteoarthritis. Fractures, which can have a significant impact on morbidity, mortality, and functional dependence, commonly occur among the elderly. Such fractures include pathologic fractures, proximal femur fractures, proximal humerus fractures, distal radius fractures, compression fractures of the spine, and stress fractures. Fractures in the elderly have their own set of problems:
- The fractures heal more slowly.
- Secondary complications, including the following:
  - Pneumonia and/or decubiti (if the fracture results in a prolonged period of immobility or bedrest).
  - Detrimental changes in mental status secondary to adverse reactions to anesthesia or pain medications.
  - Decreased vision placing patients at increased risk of falls.
  - Poor balance exacerbated by limited weight-bearing status after a lower extremity fracture.
- ***Gait deviations.*** Individuals over 65 tend to walk with a slower self-selected gait speed, a shorter stride width, and an increase in double support time. Some of these changes are the inevitable effects of aging, while others are due to pathology or disuse. In addition, elderly patients tend to demonstrate increased gait variability. For example, elderly individuals tend to go through a decreased range of dorsiflexion during midstance.[129,130] However, significant changes in gait are not noted unless multiple joints are involved or there are impairments in other systems such as loss of strength or motor control.

Bloem and colleagues[131] in a study of individuals aged over 88 noted that 20% of the subjects exhibited unimpaired gait. Another study has demonstrated that those who exhibit senile gait disorders are more likely to go on to develop dementia and die earlier than age-matched individuals who walk normally.[132] This raises the enticing possibility that gait changes associated with aging may actually be an early manifestation of pathologies such as subtle white matter changes, vestibular dysfunction, musculoskeletal disorders, or visual changes.[132] What is known is that sensory system impairments have a tremendous impact on gait, and that training to improve proprioception can improve gait parameters and safety.[133]

- ***Impaired balance.*** Age-related balance dysfunctions can occur through a number of mechanisms including gradual degenerative changes in the vestibular apparatus of the inner ear, an inability to integrate sensory information, and muscle weakness. In addition, some diseases (benign paroxysmal positional vertigo), cerebrovascular disease, Ménière's disease, cerebellar dysfunction, vertebrobasilar artery insufficiency, and cardiac disease common in aging populations can lead to further deterioration in balance function. Balance disorders can also be associated with a number of other causes including
  - medications,
  - postural hypotension,
  - visual/auditory deficits.

It is important to remember that frailty is not a natural consequence of aging. Physical activity throughout the aging years can produce a number of physiologic benefits:

- Substantial improvements in cardiovascular functioning.
- A significant impact on the maintenance of independence in old age.
- The prevention and/or postponement of age-associated declines in flexibility, balance, and coordination.

In contrast, disuse exacerbates the aging process. Intervention strategies to prevent disability from immobility should include the following, while monitoring vital signs:

- Minimize duration of bed rest. Avoid strict bed rest unless absolutely necessary. The patient should be allowed to stand 30–60 seconds during transfers (bed to chair).
- Encourage sitting up at a table for meals, and getting dressed in street clothes each day.
- Encourage daily exercise as a basis of good care. Exercises should emphasize balance and proprioception, strength and endurance, coordination and equilibrium, aerobic capacity, and posture.
- Design possible ways to enhance mobility through the use of assistive devices (e.g., walking aids, wheelchairs) and making the home accessible. If the patient is bed-bound, proper body alignment should be maintained and the patient should change positions every few hours. Pressure padding and heel protectors may be used to provide comfort and prevent pressure sores.
- Encourage socialization with family, friends, or caregivers.
- Regular checks of skin integrity, protective and discriminatory sensations

Falls

Falls in the elderly are often associated with significant morbidity and can be markers of poor health and declining function.[134] Elderly patients with known risk factors for falling should be questioned about falls on a periodic basis. Recurrent falls, defined as more than two falls in a 6-month period, should be assessed for treatable causes. It is particularly important to assess housing arrangements, environmental hazards, alcohol use, and compliance with medications.

Several functional balance measures have exhibited a strong correlation with a history of falling. These simple tests, which can also be used to measure changes in mobility after interventions have been applied, are quantifiable and correlate well with the ability of older adults to ambulate safely in their environment.

- ***Timed single-leg stance (SLS).*** The patient stands unassisted on one leg (by flexing the opposite knee to allow the foot to clear the floor) for 30 seconds. The choice of which leg to stand on can be determined by the patient based on personal comfort. The clinician times the patient's one-leg balance using a watch. The ability to maintain SLS generally decreases with increasing age. One study[135] found that older adults in the community could maintain the SLS for 10 sec about 89% of the time and nursing home residents for 45% of the time.
- ***The timed "Up & Go" test.*** The timed "Up & Go" test measures, in seconds, the time taken by an individual to stand up from a standard arm chair (seat height of approximately 46 cm/18.4 in, arm height 65 cm/25.6 in), walk a distance of 3 m (10 feet), turn, walk back to the chair, and sit down again. The patient wears his/her regular footwear and uses his/her customary walking aid (none, cane, or walker). The subject walks through the test once before being timed in order to become familiar with the test. Either a wrist-watch with a second hand or a stop-watch can be used to time the performance.

Overall physical function should also be assessed. This is accomplished by evaluating the patient's ADLs and instrumental ADLs.

Physical Therapy Intervention

The intervention is directed at determining the underlying cause of the fall, the identification of risks, and in preventing recurrence through patient and family/caregiver education on safety issues (adequate lighting, contrasting colors, and reduction of clutter). Functional training should include sit to stand transfers, walking and turning, and stair negotiation. Therapeutic exercises should be designed to address any strength and flexibility deficits, and balance and/or gait deficits.

THE PHYSICALLY ACTIVE FEMALE

Both male and female children are basically equal in physical condition and have the same strength before puberty. After puberty (Table 30-2), females aged 11–12 years are 90% as strong as their male counterparts versus 85% as strong at ages 13–14, and 75% at ages 15–16 years.[136]

Although skeletal muscle physiology in men and women does not differ significantly—the actual number of muscle fibers is similar between genders—men do appear to demonstrate larger absolute strength gains due to a larger cross-sectional muscle fiber size. When comparing strength to lean body mass or cross-sectional area, women are about equal to men and are equally capable of developing strength relative to total muscle mass. However, differences in anatomy make the female more prone to certain injuries. For example, women demonstrate greater amounts of static external knee rotation, greater active internal hip rotation, and increased hip width when normalized to femoral length than men, resulting in a number of structural combinations:[137]

- Women have an increased hip adduction, femoral anteversion, and genu valgum resulting in a larger Q angle and rotational positioning of the lower extremity (see Chap. 20).
- Women have anatomical differences at the knee that predispose them to a higher incidence of anterior cruciate ligament (ACL) injury (see Chap. 20).

Despite these differences, both men and women should undergo similar strength training progressions.

Female-Related Conditions

Pregnancy

Pregnancy is a state of wellness that spans approximately 40 weeks from conception to delivery. A number of physiologic changes occur during pregnancy and the postpartum period within the various body systems that can present the clinician with some unique challenges. Given the number of physiologic changes during pregnancy and the postpartum period within the various body systems, the extent of the physical therapy intervention will depend on the findings of the examination.

Endocrine System. Changes that occur in the endocrine system include but are not limited to the following:

- Enlargement of the adrenal, thyroid, parathyroid, and pituitary glands.
- An increase in hormonal levels to support the pregnancy and the placenta and in preparation for labor. For example, a female hormone (relaxin) is released that assists in the softening of the pubic symphysis so that during delivery, the female pelvis can expand sufficiently to allow birth. Unfortunately, the hormone is not specific to this region and produces greater laxity in all joints.[138,139] This can result in an increased susceptibility to musculoskeletal injury.

Musculoskeletal System. The recommended weight gain during pregnancy is 25 to 27 pounds.[140] Pregnancy can produce a number of changes within the musculoskeletal system:

- The abdominal muscles are stretched and weakened.
- The development of relative ligamentous laxity, both capsular and extracapsular.
- The rib cage circumference increases resulting in a natural state of hyperventilation to meet the oxygen demands.
- Pelvic floor muscle weakness due to the increased weight and pressure directly over these muscles—the pelvic floor drops as much as 2.5 cm (1 inch) as a result of pregnancy.[141] Pelvic floor muscle weakness can result in stress incontinence (refer to "Urinary Incontinence").
- Postural compensations to maintain stability and balance. These changes are related to the weight of growing breasts, and the uterus and fetus, resulting in a shift in the woman's center of gravity in an anterior and superior direction. Specific postural changes include an increased lumbar lordosis, an increased thoracic kyphosis with scapular retraction, and an increased cervical lordosis and forward head. These changes in posture can become habitual postpartum.
- Changes in gait. In advanced pregnancy, the patient develops a wider base of support and increased external rotation at the hips and demonstrates increased difficulty with walking, stair climbing, and rapid changes in position. [142]

Common diagnoses associated with some of the above include

- ***Symphysis pubis dysfunction (SPD).***[143–146] This disorder can occur as a result of trauma during vaginal delivery. SPD should always be considered when treating patients in the postpartum period who are experiencing suprapubic, sacroiliac, or thigh pain. Subjectively the patient reports pain with any activity that involves lifting one leg at a time or parting the legs (e.g., lifting the leg to put on clothes, getting out of a car, turning over in bed, and walking up stairs). Objectively, the patient typically demonstrates an antalgic, waddling gait. Palpation reveals tenderness over the anterior pubic symphyseal area, and occasionally, clicking can be felt or heard. The ROM examination reveals limited hip movements due to pain, and there is an inability to perform unilateral standing. Radiological evaluation may occasionally be useful in confirming the diagnosis, although the amount of symphyseal separation does not always correlate with severity of symptoms or the degree of disability.[147]

Although the symptoms can be dramatically severe, a conservative management approach, including bed rest in the lateral decubitus position, pelvic support with a brace or girdle, ambulation with an assistive device and a graded exercise progression.[147] Patient education, which is extremely important in terms of providing advice on how to avoid stress to the area, should include the following suggestions:

- Use a pillow between the legs when sleeping, and keep the legs and hips parallel and as symmetrical as possible when moving or turning in bed and when standing and turning. Silk/satin sheets and night garments may make it easier to turn over in bed.
- Move slowly and without sudden movements.
- Sit down to get dressed, especially when putting on socks, shoes, or pants.
- If bending over to pick up objects is difficult, use specific devices such as reachers.

Swimming, with the exception the breaststroke, and deep-water aerobics using floatation devices may help relieve pressure on the joint.

The symptoms of SPD typically resolve in approximately 6–8 weeks with no lasting sequela, although in rare cases residual pain occurs, requiring several months of physical therapy.[147] In severe cases surgical intervention may be utilized in cases of inadequate reduction, recurrent diastasis, or persistent symptoms.

- ***Low back pain.***[142,148–155] LBP during the childbearing year is quite prevalent with the incidence ranging from 47 to 82%.[156,166,167] Back pain after delivery has been reported to occur 67%, while 37% experienced back pain 18 months postpartum.[151] Back pain tends to begin early in pregnancy, with 25% prevalence at 12 weeks.[149] The most common location of back pain in pregnant women is the sacroiliac region. The cause of back pain during the childbearing year is thought to be related to the mechanical and hormonal changes. Several studies indicate that women with severe LBP during pregnancy are at extremely high risk for developing new episodes of severe LBP during a subsequent pregnancy as well as later in life.[168–170] It is not clear whether the LBP is the result of the shift in the center of gravity, the associated postural changes, or changes to an intervertebral disk due to the release of relaxin. However, disk herniations are no more common during pregnancy than at other times. It is also important to consider systemic causes for LBP in this population. Kidney or urinary tract infections can both cause LBP.
- ***Peripartum posterior pelvic pain (PPPP).*** PPPP can be defined as unexplained and undiagnosed pain in the pelvic region (with or without radiation) that started during pregnancy or within 3 weeks after delivery. About 49% percent of pregnant women experiences some type of pelvic pain,[171] with 33% of these women experiencing severe pain.[152,157,158] The pain is typically experienced in the lumbar region and over the sacroiliac joints (with no findings suggesting nerve root involvement). Although the etiology of PPPP is unknown, it has been linked to the many physiological adaptations that occur in preparation for

childbirth. The previously mentioned change in the center of gravity leads to a change in the degree of lordosis of the spine, which in turn affects the paraspinal musculature. In addition, the hormonal changes that occur during pregnancy may cause an imbalance between the ligaments, muscles, and joints in the posterior aspect of the pelvis.[159] Although a systematic review[160] of the literature investigating the effectiveness of physical therapy interventions in the treatment of PPPP and LBP found scant evidence to support the use of exercise or mobilization in this patient population, exercise is thought to be beneficial in the post-partum period. In addition, the patient should be given posture/body mechanics advice using the suggestions listed for SPD.

Coccydynia.[161–165] Pain in and around the region of the coccyx, especially with sitting, is relatively common postpartum. Seating adaptations such as a donut cushion can be prescribed to lessen the weight on the coccyx and to support the lumbar lordosis. If symptoms persist for more than a few weeks, the displaced coccyx can often be corrected manually (see Chap. 29).

- ***Diastasis recti abdominis (DRA).*** A DRA is known as a split between the two rectus abdominis (RA) muscles to the extent that the linea alba may split under strain. The size of the DRA can vary from 2–3 to 12–20 cm in width and from 12–15 cm to the entire length of the recti muscles. It has not been determined whether the separation is a true tear or a relaxation of the tissue. A DRA is common in pre- and postpartum women. Predisposing factors for a DRA in women include obesity, a narrow pelvis, multipara, multiple births, excess uterine fluid, large babies, and weak abdominals prior to pregnancy. The separation may develop during the second and third trimesters of pregnancy, during second stage labor, and during the postpartum period. It is believed that a DRA may hinder the abdominal wall function related to posture, trunk stability and strength, respiration, visceral support, diminished pelvic floor facilitation, and delivery of the fetus. An umbilical hernia may result as well. The DRA is believed to contribute to chronic pelvic and LBP.

  Criteria have been established for determining a DRA. The patient is positioned in the hook lying position. The clinician palpates with fingers horizontally, at the umbilicus and 2 inches above and below the umbilicus, and the patient is asked to raise their head and shoulders while reaching toward their feet. Any separation will be palpable, and a wide ridge of bulging tissue may actually be visible. If a DRA of 1–2 fingers width (1–2 cm) is present, this is considered within normal limits.[174] Any separation greater than two-finger wide constitutes a DRA, and, therefore, restrictions on abdominal exercise prescription should apply. However, it is worth remembering that the interrater reliability for measuring a DRA by manually inserting the fingers into the gap has been considered poor.

  Electromyography studies of the rectus abdominis (RA) and external oblique have been done on primiparas women during the pre- and postpartum stages.[172] It was found that the abdominals generated the same muscle activity throughout the pregnancy; however, the ability to stabilize the pelvis against resistance decreased as the pregnancy progressed and continued to remain low postpartum.[172] It was observed that the RA length, angles of insertion, and DRA were significant between 18 and 30 weeks, with further structural changes between 26 and 38 weeks; therefore, the ability to produce torque may be reduced.[172] The decreased functional deficits were present up to 8 weeks postpartum, in conjunction with the incomplete resolution of the structural adaptations of RA. It is essential that these functional and structural deficits be addressed with pre- and postpartum women.[172]

  Ostgaard et al.[167] found that individualized exercise and education were significantly helpful in reducing back pain during the 8-week postpartum phase; however, no differences in back pain were found during pregnancy. Weekly physical exercise before pregnancy was found to reduce the risk for back pain during pregnancy. Diagnostic ultrasound has been used to determine exercise effectiveness on decreasing the amount of a DRA.[173] It was determined that when performing a curl-up, the RA contraction significantly reduced the DRA compared to other movements studied.[173] The additional movements tested were curl-up with rotation to left and right, posterior pelvic tilt, and abdominal hollowing.[173] There was no evaluation of a possible relationship between DRA and back pain.

  A RA that had exercised prior to the onset of pregnancy was not present in those women. Although it was not a controlled variable in this study, exercise prior to pregnancy may reduce the risk of a DRA.

  According to Noble,[166] exercises for the abdominals to prevent, decrease, and/or eliminate a DRA should be prescribed. Proper exercise intensity is essential, and intervention should occur as soon as possible. If exercise has not been started before or during pregnancy, basic abdominal isometrics with exhalation should begin within 24 hours of delivery.[174] On postpartum day 3, the abdominals should be evaluated for a DRA.[174] Curl-ups with the abdominal isometric and the crossover of the upper extremities for additional support can be done.[166] If the DRA is greater than three fingers width (3 cm), there are restrictions on curl-ups and leg lowering exercises.[174] Curl-ups of the head only, with the abdominal isometric and the crossover of the upper extremities, should be prescribed.[174] Advancement of the exercises should not occur until the DRA has decreased.[174] Many times women will actually increase the DRA during the postpartum phase with abdominal exercises that are too aggressive for the individual.[174] The patient should be instructed in self-monitoring of her DRA.[174] A diastasis correction exercise can be performed to maintain alignment and discourage further separation. The exercise is performed in the supine hook-lying position (if tolerated and not contraindicated). With the arms crisscrossed over the abdomen, the patient manually approximates the recti muscles toward midline, performs a posterior pelvic tilt, and slowly exhales while lifting her head so that the scapulae clear the surface.[166,175] In addition, the patient can perform any exercise that does not stress the sacroiliac joint or increase intra-abdominal pressure including leg sliding (see Chap. 28), abdominal isometrics with lower extremity movements, supine bridging (see Chap. 28), quadruped leg

raising (see Chap. 28), modified squats (see Chap. 28), and posterior pelvic tilts (see Chap. 28) while using hands to support the abdominal wall.[174] Maintaining the stability of the pelvis and decreasing the DRA are the goals for exercise progression.[174] Educating the patient about proper body mechanics and posture is necessary to prevent undue stress on the back and a DRA during the postpartum phase.[174]

Neurologic

Swelling and increased fluid volume can cause symptoms of thoracic outlet syndrome due to compression of the brachial plexus, carpal tunnel syndrome due to median nerve compression, or meralgia paresthetica, which is compression of the lateral (femoral) cutaneous nerve of the thigh.[176–178]

Pregnancy-related depression and postpartum depression has been documented to occur in 5–20% of all postpartum mothers[179–181] but can also occur in fathers.[182] These disorders can range from a mild "postpartum blues," which occurs from 1–5 days after birth and lasts for only a few days, to the more severe forms that include postpartum depression and postpartum psychosis, which require medical or social intervention.[183–185]

Gastrointestinal. Nausea and vomiting may occur in early pregnancy and are generally confined to the first 16 weeks of pregnancy but occasionally remain throughout the entire 10 lunar months (hyperemesis gravidarum).[183,186–189] The causes of hyperemesis gravidarum are largely unknown.

Cardiopulmonary System. The pregnancy-induced changes in the cardiovascular system develop primarily to meet the increased metabolic demands of the mother and fetus. These changes include the following:

- A predominance of costal versus abdominal breathing as the diaphragm elevates with a widening of the thoracic cage.
- Mild increases in oxygen consumption due to increased respiratory center sensitivity and drive.[190] Even with mild exercise there is a greater than normal increase in respiratory frequency and oxygen consumption to meet the greater oxygen demand.[190] However, pregnant women demonstrate decreased respiratory frequency and maximal oxygen consumption as exercise increases to moderate and maximal levels.[190]
- A compensated respiratory alkalosis.[191]
- A low expiratory reserve volume.[190,192]
- Increased blood volume: The blood volume increases progressively from 6–8 weeks of gestation (pregnancy) and reaches a maximum at approximately 32–34 weeks with little change thereafter.[193] The increased blood volume serves two purposes:[194,195]
  - To facilitates maternal and fetal exchanges of respiratory gases, nutrients, and metabolites.
  - To reduce the impact of maternal blood loss at delivery.
- Increased plasma volume is relatively greater than that of red cell mass resulting in hemodilution and a decrease in hemoglobin.[194,196,197]
- ***Increased cardiac output.*** This increases to a similar degree as the blood volume.[194,195]

CLINICAL PEARL

Hypertensive disorders complicating pregnancy are the most common medical risk factor responsible for maternal morbidity and death related to pregnancy.[183]

Changes in blood pressure during pregnancy include the following:

- Systemic arterial pressure should not increase during normal gestation.
- Pulmonary arterial pressure also maintains a constant level.
- Vascular tone is more dependent upon sympathetic control than in the nonpregnant state, so that hypotension develops more readily and more markedly.
- Central venous and brachial venous pressures remain unchanged during pregnancy, but femoral venous pressure is progressively increased due to mechanical factors.

During pregnancy, a condition called supine hypotension (also known as inferior vena cava syndrome), manifested by a decrease in blood pressure (BP), may develop in the supine position, especially after the first trimester. The drop in BP is thought to be caused by the occlusion of the aorta and inferior vena cava by the increased weight and size of the uterus as spontaneous recovery usually occurs upon change of maternal position. However, although a change in position is necessary, patients should not be allowed to stand up quickly to avoid another condition related to a decrease in blood pressure; orthostatic hypotension. Signs and symptoms of this condition run the gamut from headache, bradycardia, dizziness, and shortness of breath to numbness in extremities, nausea and vomiting, and syncope (fainting). Ideally, the time spent in supine should be limited to approximately 5 minutes. Alternative positions include side lying (best position for minimizing compression), supine reclined, or supine with a small wedge under the right hip.

Metabolic System. The metabolic rate increases during both exercise and pregnancy, resulting in greater heat production. Fetoplacental metabolism generates additional heat, which maintains fetal temperature at 0.5–1°C (0.9–1.8°F) above maternal levels.[198–200] Because of the increased demand for tissue growth, insulin is elevated from plasma expansion and blood glucose is reduced for a given insulin load. Fats and minerals are stored for maternal use.

Gestational diabetes is defined as carbohydrate intolerance of variable severity, with onset or first recognition during pregnancy. After the birth, blood sugars usually return to normal levels; however, frank diabetes often develops later in life. Typical causes include

- genetic predisposition;
- high-risk populations include people of Aboriginal, Hispanic, Asian or African descent;
- family history of diabetes, gestational diabetes, or glucose intolerance;
- increased tissue resistance to insulin during pregnancy, due to increased levels of estrogen and progesterone.

TABLE 30-4	Exercise Precautions During Pregnancy
Exercise Intensity	Exercise programs for high-risk pregnancies should be individually established based on diagnosis, limitations, physical therapy examination and evaluation, and in consultation with the physician. Exercise acts in concert with pregnancy to increase heart rate, stroke volume, and cardiac output. However, during exercise, blood is diverted from abdominal viscera, including the uterus, to supply exercising muscle. The decrease in splanchnic blood flow can reach 50% and raises theoretic concerns about fetal hypoxemia. Women should avoid becoming overtired. Exercise activity should be performed at a moderate rate during a low-risk pregnancy. Guidelines for a low-risk pregnancy permit women to remain at 50–60% (12–14 on the Borg scale of perceived exertion) of their maximal heart rate (monitored intermittently) for approximately 15–30 minutes per session.
Exercise Type	Recommended activities include stationary cycling, swimming, or water aerobics. Weight-bearing exercises and high impact exercises should be prescribed judiciously as increases in joint laxity may lead to a higher risk of strains or sprains.
Exercise Position	Patients should not exercise in the supine position for more than 5 minutes after the first trimester (see "Supine Hypotension"). To prevent inferior vena cava compression when the patient is lying supine, a folded towel can be placed under the right side of the pelvis so that the patient is tipped slightly to the left. If the supine position is contraindicated, exercises can be performed in side lying, the quadruped position or sitting. Positions that involve abdominal compression (flat prone lying) should be avoided in mid to late pregnancy. Modifications to exercise for the abdominal muscles must be made for a woman with diastasis recti, as the presence of this condition potentially reduces the ability of the abdominal wall muscles to contribute to their role in trunk and pelvic girdle alignment, motion, and stability. Traditional abdominal exercises, such as full sit-ups or bilateral straight leg raises, are not recommended as they may encourage further separation. However, these exercises can be resumed when the separation is less than 2 cm.
Exercise Environment	Adequate hydration and appropriate ventilation are important in preventing the possible teratogenic effects of overheating. Theoretically, when exercise and pregnancy are combined, a rise in maternal core temperature could decrease fetal heat dissipation to the mother. Some data suggest a teratogenic potential when maternal temperatures rise above 39.2°C (102.6°F), especially in the first trimester.

Current risk factors include

- maternal obesity (>20% above ideal weight),
- excessive weight gain during pregnancy,
- low level of high-density lipoprotein cholesterol (<0.9 mmol/L) or elevated fasting level of triglycerides (>2.8 mmol/L),
- hypertension or preeclampsia (risk for gestational diabetes is increased to 10% to 15% when hypertension is diagnosed),
- maternal age >25 years.

Most individuals with gestational diabetes are asymptomatic. However, subjectively the patient may complain of

- polydipsia,
- polyuria,
- polyphagia,
- weight loss.

Renal and Urologic Systems. Anatomic and hormonal changes during pregnancy place the pregnant woman at risk for both lower and upper urinary tract infections and for urinary incontinence.[183] As the fetus grows, stress on the mother's bladder can increases. This can result in urinary incontinence (refer to "Urinary Incontinence").

Exercise Prescription. The goals of therapeutic exercise during pregnancy are to improve muscle balance and posture, help provide support of the growing uterus, stabilization of the trunk and pelvis, and maintenance of function for more rapid recovery after delivery.[175] Contraindications to exercise include the following:[201]

- An incompetent cervix (early dilation of the cervix before pregnancy is full-term)
- Vaginal bleeding (especially second or third trimester)
- Placenta previa (the placenta is located on the uterus in a position where it may detach before the baby is delivered)
- Multiple gestation with risk of premature labor
- Pregnancy-induced hypertension
- Premature labor (labor beginning before the 37th week of pregnancy)
- Maternal heart disease
- Maternal type I diabetes
- Intrauterine growth retardation

Even without these conditions, the patient requires permission from her physician before beginning an exercise program. Some precautions should be observed during exercise (Table 30-4)[202–209] Warning signs associated with exercise during pregnancy include pain, vaginal bleeding, tachycardia, dyspnea, uterine contractions, and chest pain.[210]

Exercise programs for high-risk pregnancies should be individually established based on diagnosis, limitations, physical therapy examination and evaluation, and in consultation with the physician. Exercises for the pelvic floor are described in "Urinary Continence."

TABLE 30-5 Types of Urinary Incontinence	
Type of Urinary Incontinence	**Description**
Functional	Includes people who have normal urine control but are unwilling (impaired cognition) or who have difficulty reaching a toilet in time because of muscle or joint dysfunction or environmental barriers
Stress	Describes the loss of urine during activities that increase intra-abdominal pressure such as coughing, lifting, or laughing. Stress incontinence is also particularly noted in high-impact sports that involve running and jumping, gymnastics, and basketball
Overflow	The constant leaking of urine from a bladder that is full but unable to empty due to ▶ anatomic obstruction, for example, prostate enlargement ▶ neurogenic bladder, for example, spinal cord injury
Urge	The sudden unexpected urge to urinate and the uncontrolled loss of urine; often related to reduced bladder capacity, detrusor instability, or hypersensitive bladder

Adjunctive Interventions. Modalities that increase body heat (hot packs, ultrasound, shortwave or microwave diathermy) should be used with caution, especially over the abdomen or uterus. Except for the use of transcutaneous electrical stimulation during labor and delivery, electrical stimulation is contraindicated during pregnancy.

Urinary Incontinence

Urinary incontinence includes the various types of incontinence: stress incontinence (a loss of bladder control associated with increased abdominal pressure that occurs during coughing or exercise), urge incontinence (a sudden urge to urinate), or mixed incontinence (a combination of stress and urge incontinence).[211] One of the contributing factors to urinary incontinence can be a weakness of the pelvic floor musculature. The various types of urinary incontinence are described in Table 30-5. Stress incontinence has prevalence rates that range from 10 to 55% in 15- to 64-year-old females.[212] Although often associated with aging, incontinence due to PFM weakness is not an automatic response to aging and many patients have achieved significant improvement through behavior modification, muscle reeducation, and PFM (see Chap. 29) strengthening.[213,214] Behavior modification techniques include timed voiding schedules, proper toileting techniques, dietary modification, and patient education. Muscle reeducation is primarily used for those patients who do not demonstrate improvement with the PFM strengthening program after approximately 4 weeks. Muscle reeducation can be achieved in a number of ways:

- ***Biofeedback.*** A study by Cardozo et al.[215] reported improvements in 81% of patients with urge incontinence who were treated with biofeedback.
- ***Acupuncture.*** A study by Philp et al.[216] reported improvements in 77% of patients with urge incontinence who were treated with acupuncture.
- ***Electrical stimulation.*** Various forms of electrical stimulation have been used in the treatment of female urinary incontinence. Electrical stimulation is an option for patients who demonstrate difficulty with identifying the PFMs or with producing a contraction of these muscles. Transvaginal stimulation with a removable electrode has been in clinical use in Europe and North America for three decades. The typical neuromuscular stimulation system is a portable electrical pulse generator powered by a 9-V alkaline battery. A fully insertable vaginal electrode, which is composed of silicone rubber, is commonly used. Two randomized studies have reported the usefulness of transvaginal electrical stimulation.[217,218] In the study by Sand et al.,[217] comparisons of changes from baseline between active-device and control patients showed that active-device patients had significantly greater improvement in weekly ($p = .009$) and daily ($p = .04$) leakage episodes, pad testing ($p = .005$), and vaginal muscle strength ($p = .02$) when compared with control subjects. Significantly greater improvement was also found for both visual analog scores of urinary incontinence ($p = .007$) and stress incontinence ($p = .02$), as well as for subjective reporting of frequency of urine loss ($p = .002$), and urine loss with sneezing, coughing, or laughing ($p = .02$), when compared with controls. In the Smith et al.[218] study, of the patients using electrical stimulation in the stress urinary incontinence group, 66% improved and 72% of the patients with detrusor instability treated with electrical stimulation improved. These rates were not considered statistically significant when compared to traditional therapy, but the authors concluded that electrical stimulation was as safe and at least as effective as properly performed Kegel and drug therapy in the treatment of stress urinary incontinence and detrusor instability. A typical protocol is outlined below:[219]
  - For patients with urge incontinence: 12.5 Hz for 15 minutes twice a day.
  - For patients with stress incontinence: 50 Hz for 15 minutes twice a day.
  - For patients with mixed incontinence: 12.5 Hz for 15 minutes a day and 50 Hz for 15 minutes a day.

In 1948, Kegel first advocated PFM exercise to enhance urethral resistance and promote urinary control.[220] The application of Kegel exercises has been broadened to various applications, but the concentration continues to be considered a useful adjunct in the management of functional urinary incontinence.[211] Many studies have shown that the success of PFM exercise for female stress urinary incontinence depends on the degree and duration of treatment and close supervision by a PT.[221] The patients are initially educated in PFM awareness. Several teaching methods can be used, including verbal cues, visualization with an anatomical model, palpation,

objective PFM contraction at the anus, or biofeedback with electromyography recordings via a rectal probe.[222] The method chosen depends on the patient's baseline awareness, coordination, and comfort level. The palpation method is performed as follows:

The patient is asked to sit forward on a chair with their legs apart, their spine extended, and their feet flat on the floor. The clinician and patient each place a hand anterior to the ASIS and along the inguinal region to feel the contraction of the transverse abdominis and the internal obliques. The fingers are also spread superiorly to feel the weight of the belly and the RA. The patient is asked to "move the urethra and vagina gently upward" and to maintain the contraction for endurance.

Bracing. The patient is asked to sit forward on a chair with their legs apart, their spine extended, and their feet flat on the floor. The patient is asked to "push their abdomen out" without using an inspiratory effort and to isometrically contract the upper and lower RA in its outer range. The patient is taught to initiate, and hold, this action during a defecatory urge.

Abdominal Drawing-In. The patient is positioned in supine with the spine in neutral and the abdominal wall relaxed. The patient is asked to draw the lower part of the abdomen up and in toward the spine without moving the trunk or pelvis, or using an inspiratory effort, thereby contracting the transverse abdominis and the internal obliques. This exercise is taught in a variety of patient positions, with the appropriate muscles being palpated by the patient and clinician and the use of normal breathing.

Other exercises are added as tolerated. For the following four exercises the patient is positioned in the supine, hook-lying position[221]:

- ***Exercise 1.*** The patient performs a PFM contraction with a posterior pelvic tilt.
- ***Exercise 2.*** The patient performs a PFM contraction with a bridging motion.
- ***Exercise 3.*** The patient performs a PFM contraction with hip adduction against a pillow between the knees.
- ***Exercise 4.*** The patient performs a PFM contraction with hip external rotation against an elastic exercise band.

Swiss ball exercises may then be added.[221,223] The patient is positioned sitting on a Swiss ball:

- ***Exercise 1.*** The patient performs a PFM contraction with a posterior pelvic tilt in the sagittal plane while rolling on the ball.
- ***Exercise 2.*** The patient performs a PFM contraction with a posterior pelvic tilt in the oblique plane while rolling on the ball.
- ***Exercise 3.*** The patient bounces vertically on the ball, while performing a PFM contraction during each ascending movement.
- ***Exercise 4.*** The patient performs a PFM contraction while rolling on the ball from sitting to standing for functional training with transfers.

Medical management of urinary incontinence is aimed at prevention and may include the following:

- Nutritional counseling to help prevent constipation and to encourage adequate hydration.
- Medications to relieve urge incontinence: estrogen replacement therapy, anticholinergics, alpha-adrenergic blockers to increase bladder outlet/sphincteric tone, antispasmodics, and combination therapy with tricyclic antidepressant agents and antidiuretic hormone.[224–228]
- Surgical intervention can include catheterization, and surgically implanted artificial sphincters and bladder generators (sends impulses to the nerves to control the bladder function).

Menstruation

Normal menstrual cycles are defined by three phases, all of which are governed by alterations in blood levels of estrogen and progesterone:

- ***Follicular.*** Ovarian-produced estrogen increases resulting in endometrial growth, characterized by a compact, proliferative stroma, and increases in endometrial glands in number and length.
- ***Ovulatory.*** Ovulation produces the corpus luteum that leads to the production of estrogen and progesterone with progesterone-stimulated production of a secretory endometrium.
- ***Luteal.*** The endometrium acquires an edematous stroma with glands that are tortuous and dilated. In the absence of pregnancy, the corpus luteum becomes atretic with a resultant sudden drop in hormonal levels of estrogen and progesterone and then menstruation.

Menarche, or the onset of menstrual periods, normally develops between ages 9 and 16 years in the United States with 12.4 years as the mean age for menarche.[229] The development of menarche is under many influences, including nutritional status, intensity exercise patterns, weight, race, genetic factors, and others.

Abnormal menstrual cycles include the following:

- Amenorrhea: absence of menses.
- Oligomenorrhea: infrequent, irregular bleeding at >45 day intervals.
- Menorrhagia/hypermenorrhea: prolonged or excessive uterine bleeding occurring at regular intervals.
- Metrorrhagia: uterine bleeding occurring at irregular but frequent intervals, the amount being variable.
- Menometrorrhagia: prolonged uterine bleeding occurring at irregular intervals.

The effect of exercise on the severity of menarche is inconclusive. However, the side effects of menarche including menstrual pain, edema, bloating, and other symptoms may have a negative impact.

Breast-Cancer-Related Lymphedema

The lymphatic system is comprised of strategically placed lymph nodes connected by a network of lymphatic vessels, which act as the circulatory system for the immune system.

TABLE 30-6	Impairments and Complications Associated with the Treatment of Breast Cancer
Incisional pain	
Posterior cervical and shoulder girdle pain	
Vascular and pulmonary complications including pneumonia and deep venous thrombosis (DVT)	
Chest wall adhesions	
Weakness of the involved upper extremity	
Postural malalignment	
Fatigue and decreased endurance	

Data from Kisner C, Colby LA: Management of vascular disorders of the extremities. In: Kisner C, Colby LA, eds. *Therapeutic Exercise. Foundations and Techniques*, 5th ed. Philadelphia, PA: FA Davis, 2002:825–849.

Larger lymph collectors, known as trunks or ducts, handle these larger volumes of lymph fluid. The majority of the lymph produced by the body in a 24-hour period (2–4 L) returns to the heart. As lymph fluid moves more centrally, the diameter of lymph vessels increases. The major lymph nodes are the submaxillary, cervical, maxillary, mesenteric, iliac, inguinal, popliteal, and cubital nodes. Lymphedema results from a mechanical insufficiency that arises in an area, when lymph collectors sustain functional and structural damage. Breast-cancer-related dysfunction of the lymphatic system and subsequent lymphedema of the upper extremity can occur as a complication of the treatment for breast cancer. Current treatment for breast cancer usually involves removing a portion or all of the breast accompanied by excision or radiation of the adjacent axillary lymph nodes, the principal site of regional metastasis.[230] In addition to upper extremity lymphedema, other complications include loss of shoulder mobility and limited function of the arm and hand.[231]

The other impairments and complications that may occur in association with the treatment of breast cancer are listed in Table 30-6[230] The most common method to diagnose and measure upper extremity (UE) lymphedema is circumferential measurements using specific anatomical landmarks to estimate volume differences between the affected and unaffected extremities. A more accurate measure of volume difference is the water displacement technique using a volumeter.

The intervention for breast-cancer-related lymphatic dysfunction includes the following:[230]

- Strengthening exercises. Exercise encourages muscle contractions to provide the primary pumping mechanism for lymphatic and venous drainage. Progressive resistance training (using light weights initially and progressing as tolerated) for the major muscle groups of the upper trunk and upper extremity are emphasized (e.g., seated row, bench press, latissimus dorsi muscle pull-down, triceps muscle extension, and biceps curl).[232]
- Aerobic exercises. After 2 weeks, an arm ergometer can be introduced as an upper-body aerobic exercise. Moderate-intensity aerobic conditioning exercises are added as tolerated.
- ROM exercises. Individualized shoulder (Chap. 16) and cervical (Chap. 25) ROM exercises to address any muscle imbalances.
- Massage and wrapping. Various types of specialized wrapping, taping, and lymphedema massage are advocated, followed by pressure garment wear.

Although traditionally popular, pneumatic compression devices are not currently prescribed for lymphedema because the natural drainage system has been damaged, and these devices can potentially cause more stress to an already-damaged system.

Solutions for Review Questions

CHAPTER 2

1. Primary injuries can be self-inflicted, caused by another individual or entity, or caused by the environment. Secondary injuries are essentially the inflammatory response that occurs with the primary injury.
2. Microtraumatic injuries occur as a result of a cumulative repetitive overload, incorrect mechanics, and/or frictional resistance. Macrotraumatic injuries occur with a sudden overloading of the musculoskeletal tissues.
3. (1) Coagulation and inflammation stage. (2) Migratory and proliferative stage. (3) Remodeling stage.
4. Neutrophils are white blood cells of the polymorphonuclear (PMN) leukocyte subgroup that appear during the inflammation stage. Neutrophils are filled with granules of toxic chemicals (phagocytes) that enable them to bind to microorganisms, internalize them, and kill them.
5. Monocytes are white blood cells of the mononuclear leukocyte subgroup. The monocytes migrate into tissues and develop into macrophages, and provide immunological defenses against many infectious organisms.

CHAPTER 3

1. E
2. A
3. A
4. A
5. C

CHAPTER 4

1. Empathy is the ability to see another person's viewpoint so that a deep and true understanding of what the person is experiencing can be made.
2. An *examination* refers to the gathering of data and information concerning a topic. An *evaluation* refers to the making of a value judgment based on the collected data and information.
3. The history, systems review, and tests and measures.
4. Neutral questions are structured in such a way so as to avoid leading the patient into giving a particular response.
5. To identify possible health problems that require consultation with, or referral to, another health-care provider.

CHAPTER 5

1. Viscerogenic, vasculogenic, neurogenic, psychogenic, and spondylogenic.
2. The intentional production of false symptoms or the exaggeration of symptoms that truly exist.
3. False.
4. L4–L5.
5. Migraine.

CHAPTER 6

1. The swing period begins as the foot is lifted from the ground and ends with initial contact with the ipsilateral foot.
2. The four intervals of the swing period include *preswing, initial swing, midswing, and terminal swing.*
3. Normal cadence is considered to be between 90 and 120 steps per minute.
4. False.
5. Stability of the weight-bearing foot throughout the stance period, foot clearance of the non-weight-bearing foot in swing, appropriate prepositioning of the foot for initial contact, and adequate step length.
6. The lower crossed syndrome has the following characteristics: the erector spinae and iliopsoas are adaptively shortened (tight), the abdominals and gluteus maximus are weak, there is an anterior pelvic tilt, an increased lumbar lordosis, and a slight flexion of the hip. The hamstrings are frequently shortened in this syndrome.
7. Any five of the following: age, strength and flexibility imbalances, psychological aspects, evolutionary and

hereditary influences, structural deformities, disease, pregnancy, habit, or pain.

8. *Postural muscles*—Relatively strong muscles that are likely to be poorly recruited, lax in appearance, show an inability to perform inner range contractions over time, or provide a stable base for other muscles to work from.

   Phasic muscles—These muscles tend to become relatively weak compared to the postural muscles and are more prone to atrophy and adaptive shortening and show preferential recruitment in synergistic activities. In addition, these muscles will tend to dominate movements and may alter posture by restricting movement.

CHAPTER 7

1. Plain radiographs.
2. The following structures are listed in order of descending density: metal, bone, soft tissue, water or body fluid, fat, and air.
3. Plain-film, or conventional, radiographs.
4. Ligamentous injuries, joint instabilities.
5. Magnetic resonance imaging (MRI).
6. Arthrography.
7. Angiography.
8. Spatial resolution and contrast resolution.

CHAPTER 8

1. Coordination, communication, and documentation; patient/client-related instruction; and direct interventions.
2. PRICEMEM (**P**rotection, **R**est, **I**ce, **C**ompression, **E**levation, **M**anual therapy, **E**arly motion, and **M**edications).
3. Stimulation of the large fiber joint afferents of the joint capsule, soft tissue, and joint cartilage, which aids in pain reduction; stimulation of endorphins, which aids in pain reduction; a decrease of intra-articular pressure, which aids in pain reduction; the mechanical effect which increases joint mobility; the remodeling of local connective tissue; the increase of the gliding of tendons within their sheaths; and an increase in joint lubrication.
4. The inflammatory stage of healing.
5. The clinical aims during the inflammatory phase are to avoid painful positions, improve range of motion, reduce muscle atrophy through gentle isometric muscle setting, and to maintain aerobic fitness.

CHAPTER 9

1. Pharmacokinetics is the study of the physicochemical factors involved as the body absorbs, distributes, metabolizes, and eliminates a drug. Pharmacodynamics refers to the effect the drug has on the body.
2. The part of the autonomic system (sympathetic or parasympathetic) that is in control at rest is said to exert predominant tone.
3. Water-soluble vitamins include the B complex, vitamin C, biotin, choline, and folacin (folic acid).
4. Liver and kidneys.
5. Exercise increases muscular blood flow and temperature and thus can enhance absorption through molecular diffusion across biological membranes. Exercise may also sequester some drugs and reduce the availability of the drug for elimination. Thermal agents that increase regional blood flow can potentially increase delivery of a drug to a specific tissue site. Theoretically, cold can restrict drug delivery by causing vasoconstriction at the cryotherapy site.

CHAPTER 10

1. When there is mild pain; a nonirritable condition demonstrated by pain that is provoked by motion but which disappears very quickly; intermittent musculoskeletal pain; the pain reported by the patient is either relieved by rest or by particular motions or positions; and the pain is altered by postural changes or movement.
2. Any five from the following: bacterial infection, malignancy, systemic localized infection, sutures, recent fracture, cellulitis, febrile state, hematoma, an acute circulatory condition, an open wound, osteomyelitis, advanced diabetes, hypersensitivity of the skin, and constant severe pain.
3. Traumatic hyperemia, pain relief, and decreasing scar tissue.
4. Strain–counterstrain, or functional techniques.
5. Joint mobilizations.

CHAPTER 11

1. Posture, direct trauma, extremes of motion, electrical injury, and compression.
2. Double-crush syndrome.
3. Visible atrophy, pain with palpation, diminished active and passive range of motion in the same direction, and weakness in the muscle distribution of a peripheral nerve.
4. L4–S2.
5. 30–70 degrees.

CHAPTER 12

1. Extensibility, elasticity, irritability, and the ability to develop tension.
2. The erector spinae, the biceps brachii, the long head of the triceps brachii, the hamstrings, and the rectus femoris.
3. Isometric, concentric, and eccentric.

4. An isotonic contraction is a contraction in which the tension within the muscle remains constant as the muscle shortens or lengthens.
5. True.

CHAPTER 16

1. External rotation > abduction > internal rotation in a 3:2:1 ratio.
2. D
3. Subscapularis, teres major, pectoralis major, and latissimus dorsi.
4. Infraspinatus, teres minor, and posterior deltoid.
5. Supraspinatus, infraspinatus, teres minor, and pectoralis major.

CHAPTER 17

1. False. It is the anterior band of the ulnar collateral ligament.
2. Full elbow extension and maximum forearm supination.
3. Pronator quadratus, pronator teres, flexor carpi radialis.
4. Posteriorly (especially posterior–lateral).
5. A

CHAPTER 18

1. The scaphoid and the lunate.
2. Hamate, capitate, trapezoid, trapezium.
3. Ulnar nerve and artery.
4. D
5. B

CHAPTER 19

1. Extension, internal rotation, and abduction–adduction.
2. Laterally, inferiorly, and anteriorly.
3. Ligamentum teres.
4. External rotation, abduction, and extension.
5. Gluteus medius.

CHAPTER 20

1. Lateral collateral ligament.
2. Improve the weight-bearing capacity of the knee, decrease friction, and act to restrict anterior tibial translation.
3. Femoral.
4. Genu valgum.
5. Inferior facet.

CHAPTER 21

1. Anterior tibiofibular, posterior tibiofibular, and interosseous.
2. Tibial.
3. A combination of ligaments, tendons, and muscle.
4. Calcaneal inversion, talar abduction, and talar dorsiflexion external rotation of the tibia.
5. The interdigital nerve.

CHAPTER 23

1. Occipito–atlantal (O-A) joint: Occipital condyles are biconvex and articulate with the superior facets of the atlas which are biconcave. The atlanto–axial (A-A) joint has two lateral and two median articulations. The lateral articulations are biconvex, with lax capsular ligaments allowing for good mobility. The median articulations are formed between the posterior surface of the dens and the anterior aspect of the transverse ligament.
2. Dens, alar ligament, transverse ligament, and tectorial membrane.
3. Rectus capitis lateralis.
4. Tectorial membrane.
5. Obliquus capitis superior.

CHAPTER 24

1. The usual site of origin is from the proximal part of the subclavian artery.
2. Four percent of the left arteries arise from the aorta. In this variation, the artery runs vertically and slightly medial and posterior to reach the transverse foramen of the lower cervical spine, although its exact direction is dependent on its exact point of origin (any anomalies result in tortuosity). The typical point of entry is at the C6 transverse foramen, but 10% of the population has entry points from C5 to C7. Also, the postsubclavian artery could have a kink in it.
3. Divided into four parts: (1) Within the transverse foramen of C2. The C2 vertebral foramen has two curves: the inferior curve is almost vertical, whereas the superior curve is more horizontal and orientated laterally. (2) Between C2 and C1. The second part runs vertically upward in the transverse foramen of C2 and is covered by the levator scapulae and the inferior capitis muscles. (3) In the transverse foramen of C1. In the third part, the suboccipital portion of the vertebral artery bends backward and medially in the transverse foramen of C1. (4) Between the posterior arch of the atlas and its entry into the foramen magnum. On exiting the transverse foramen of C1, the artery travels behind the mass of the superior articular process of the atlas to cross the posterior arch of the atlas in a groove in which it is held by a restraining ligament. From the medial end of this groove, the artery runs forward, inward, and upward to pierce the posterior atlanto-occipital membrane with the nerve of C1 which separates it

from the posterior arch of the atlas. It penetrates the dural matter on the lateral aspect of the foramen magnum, about 1.5 cm lateral to the midline of the neck. The artery is vulnerable to direct blunt trauma in this portion.

4. (1) Pontine branches—pons. (2) Anterior inferior cerebellar artery—pons and cerebellum. (3) Superior cerebellar artery—pons midbrain and cerebellum. (4) Internal auditory (labyrinthine)—membranous labyrinth and eighth cranial nerve (vestibulocochlear). (5) Superior cerebral—thalamus (central), temporal lobe (temporal branch of the cortical), and the occipital lobe (calcarine branch of the cortical).
5. Olfactory (CN1).

CHAPTER 25

1. D
2. C
3. D
4. Uncinate process.
5. Lowest (C8–T1).

CHAPTER 26

1. The temporomandibular joint (TMJ), the masticatory systems, and the related organs and tissues such as the salivary glands. It also includes the muscles of facial expression.
2. The lateral pterygoid muscle.
3. Masseter, temporalis, and medial pterygoid.
4. E
5. The position when the tongue is against the palate of the mouth and the teeth are not in contact.

CHAPTER 27

1. Coronally (to facilitate rotation).
2. Ribs 1, 10, 11, and 12 are atypical because they only articulate with their own vertebra and do not possess inferior demifacets.
3. Costovertebral.
4. Ribs.
5. T1–T6 = pump handle; T7–T12 = bucket handle.

CHAPTER 28

1. Posterior longitudinal ligament.
2. Iliolumbar ligament.
3. E
4. Lumbar extension, ipsilateral side bending, and contralateral rotation of the lumbar spine.
5. Approximately 60 degrees of flexion and 25 degrees of extension.

CHAPTER 29

1. The interosseous ligament.
2. Counternutation (posterior motion).
3. The piriformis primarily functions to produce external rotation and abduction of the femur, but is also thought to function as an internal rotator and abductor of the hip if the hip joint is flexed beyond 90 degrees.
4. The levator ani, a muscle group composed of the pubococcygeus, puborectalis, and iliococcygeus.
5. The right innominate rotates anteriorly, and the sacrum right side flexes and left rotates.
