Upton and McComas[29] demonstrated that the peripheral nerve and its cervical roots may manifest irritation at simultaneous sites. A further study, which investigated adverse tension in the neural system in 20 subjects suffering from unilateral symptoms of tennis elbow, appeared to suggest that the adverse tension could be a factor.[103]

The relative mobility between the nerve root and its investing sheath, which occurs in the lumbar spine,[8] also has been demonstrated in the cervical spine.[42] This mobility is produced with certain movements of the arm and occurs maximally at C5 and C6, to a lesser degree at C7, and to an even lesser degree at C8 and T1.[16]

The ULTTs, or brachial plexus tension tests, involve an ordered sequence of movement of the shoulder girdle, arm, elbow, forearm, wrist, and hand. Because there are a number of tissues in the cervicobrachial region that could be stressed by these maneuvers, cervical side bending or cervical flexion,

FIGURE 11-12 ULTT 1 (median nerve).

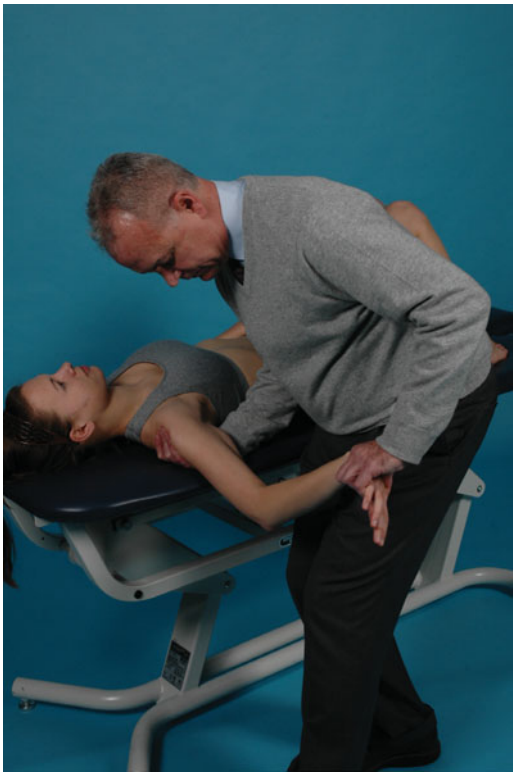

FIGURE 11-13 ULTT 2 (radial nerve).

which are thought to be more selective to the nervous system, are added.[105,106]

The principles behind the ULTT are the same as those described for the lower extremity tension tests. Therefore, only the procedures themselves are described here. During these procedures, care must be taken to maintain the cervical spine in neutral flexion–extension, side bending, and rotation.

ULTT 1 (Median Nerve Dominant)

The patient is positioned supine. The clinician depresses the shoulder girdle, abducts the humerus to approximately 110 degrees, supinates the forearm, and extends the elbow, wrist, and fingers (Fig. 11-12). The sensitizers for this test are cervical spine side flexions either toward or away from the involved side. The test is repeated on the contralateral extremity and the results are compared.

Several studies have shown that the longitudinal motion of the median nerve is affected by motion of the fingers and wrist, with digital flexion resulting in a proximal slide into the forearm, and wrist and finger extension both producing a distal slide of the nerve toward the hand.[10,12] Hyperextension of the wrist has been shown to cause the median nerve to slide 10–15 mm distally relative to a fixed bony landmark in the carpal tunnel whereas flexion of the wrist and fingers moves the nerve 4 mm proximally.[10]

ULTT 2 (Radial Nerve Dominant)

The patient is positioned supine. The clinician depresses, abducts, and internally rotates the shoulder, pronates the forearm, extends the elbow, and flexes the wrist and thumb (Fig. 11-13). The sensitizers for this test are cervical spine side flexions either toward or away from the involved side. The test is repeated on the contralateral extremity and the results are compared.

ULTT 3 (Ulnar Nerve Dominant)

The patient is positioned supine. The clinician extends the wrist, supinates the forearm, fully flexes the elbow, and depresses and abducts the shoulder. The sensitizers for this test are side flexion of the head and neck, both toward and away from the test side. The test is repeated on the contralateral extremity and the results are compared.

Evans[107] described a modification of the basic ULTT 3. The patient actively abducts the humerus with the elbow straight, stopping just short of the onset of symptoms. The patient then externally rotates the shoulder just short of symptoms and the clinician holds this position. Finally, the patient flexes the elbows so that the hand is placed behind the head. Reproduction of the symptoms with elbow flexion is considered a positive test.

Musculocutaneous Nerve

The patient is positioned supine with the head unsupported by a pillow. The clinician, facing the patient's feet, supports the patient's arm in about 80 degrees of elbow flexion. The shoulder is placed in full external rotation and approximately 10 degrees of abduction. Shoulder depression is then applied followed by glenohumeral extension (the "sensitizer"), elbow extension, and wrist ulnar deviation.

Axillary Nerve

The patient is positioned supine with the head unsupported by a pillow. The clinician places one hand on top of the patient's

shoulder and depresses the shoulder. The glenohumeral joint is then externally rotated and the patient side flexes the head away from the tested side. The shoulder is then abducted to approximately 40 degrees.

Suprascapular Nerve

The patient is positioned supine with the head unsupported by a pillow. The clinician places a hand on top of the patient's shoulder. The patient's arm is placed in internal rotation and shoulder girdle protraction. The arm is then moved into horizontal adduction followed by the patient side bending the head away from the test side. The clinician now depresses the shoulder.

NEURODYNAMIC MOBILITY INTERVENTIONS

Adverse neural tension is an abnormal response to mechanical stimuli of neural tissue. The genesis of this abnormal tissue response can be from a variety of factors to include injuries (compression, vibration, and postsurgical), intraneural, extraneural, and anatomic.[108] A factor that receives a significant amount of attention involves that of repetitive strain injuries specifically with the upper extremities.

The detrimental effects of immobilization on musculoskeletal structures are well documented as are the benefits of early mobilization protocols.[109–118] The rationale behind the use of neural mobilization techniques is to attempt to restore the dynamic balance between the relative movement of neural tissues and surrounding mechanical interfaces, thereby allowing reduced intrinsic pressures on the neural tissue and improving nerve conduction velocity.[13,43] By applying early mobilization to the neural system, it seems possible that similar benefits should occur. The hypothesized benefits from such techniques include facilitation of nerve gliding, reduction of nerve adherence, dispersion of noxious fluids, increased neural vascularity, and improvement of axoplasmic flow.[43,119,120] However, an important distinction needs to be made between techniques that lengthen or stretch the dura and techniques that stretch the anatomic structures that surround the involved neural tissue.

Elvey[18] recommends an initial intervention of passive, gentle, and controlled oscillatory movements to the anatomic structures that surround the neural tissue before progressing to the techniques that stretch both the surrounding tissues and the neural tissues together. Using this approach, the treatment barrier is represented by the onset of muscle activity.[102] For example, in the cervical spine, the sequence of neurodynamic mobilizations is initiated with shoulder depression with the neck in neutral and the arm by the side followed by shoulder depression with fixation of the cervical spine, then shoulder depression, cervical fixation, and arm traction with the arm by the side. Once this progression has been performed without any adverse effects, the more specific movements used to isolate the nerve are employed.

Evidence for the efficacy of this gradual approach has been demonstrated in subjects with low back pain and radiculopathy,[58,59,121] lateral epicondylalgia,[122] and chronic cervicobrachial pain.[18,123] Cleland and colleagues[124] performed a pilot clinical trial to determine if slump stretching resulted in improvements in pain, centralization of symptoms, and disability in 30 patients with nonradicular low back pain with suspected mild to moderate neural mechanosensitivity. Patients were randomized to receive lumbar spine mobilization and exercise ($n = 14$) or lumbar spine mobilization, exercise, and slump stretching ($n = 16$). All patients were treated in physical therapy twice weekly for 3 weeks for a total of six visits. Upon discharge, outcome measures were reassessed. Independent *t*-tests were used to assess differences between groups at baseline and discharge. No baseline differences existed between the groups ($P > 0.05$). At discharge, patients who received slump stretching demonstrated significantly greater improvements in disability (9.7 points on the Oswestry Disability Index, $P > 0.01$), pain (0.93 points on the numeric pain rating scale, $P > 0.001$), and centralization of symptoms ($P > 0.01$) than patients who did not. The authors suggested that slump stretching is beneficial for improving short-term disability, pain, and centralization of symptoms and also recommended that future studies should examine whether these benefits are maintained at a long-term follow-up.[124]

A recent systematic review of randomized controlled trials with an analysis of therapeutic efficacy of neural mobilizations found only limited evidence to support its use.[120] However, choosing the right technique for the right patient based on causal mechanism is fraught with difficulty when it comes to heterogenous groups.[125]

Stretching Program for the Sciatic Nerve

The home stretching exercise to improve tissue mobility and neural extensibility is performed in three phases or positions as follows:[117]

1. The patient is positioned supine with the hips and knees are flexed at a comfortable range. Using the uninvolved leg, the patient lifts the heel of the involved side up until he or she experiences a stretch (Fig. 11-14). This position is maintained for approximately 1 minute (can be performed up a wall to provide additional support).
2. From the position in step 1, the patient slides the heel further up. If this maneuver provokes any paresthesias, the patient allows the heel back down. Progress is measured by timing the period during which the patient is able to keep the knee straight.
3. The patient performs the same maneuver as in step 2 but with a pillow under the head. This stretch is performed 3–5 times a day for 3–5 minutes at a time.

Stretches for the Upper Extremity Nerves

The recommended home stretching exercise to improve tissue mobility and neural extensibility of the peripheral nerves throughout the upper extremity is performed in four phases or positions as follows:[117]

1. The patient is seated with the cervical spine in neutral sidebending and the arm abducted to 90 degrees. The patient is asked to extend the fingers and to begin flexing

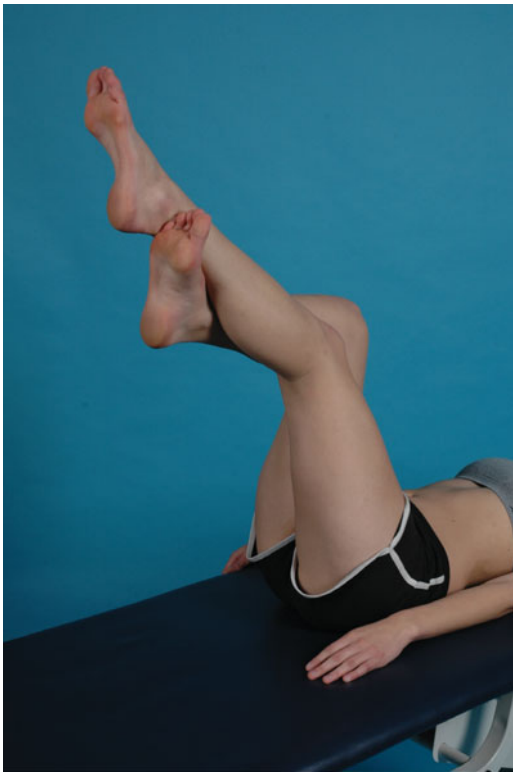

FIGURE 11-14 Sciatic nerve stretch.

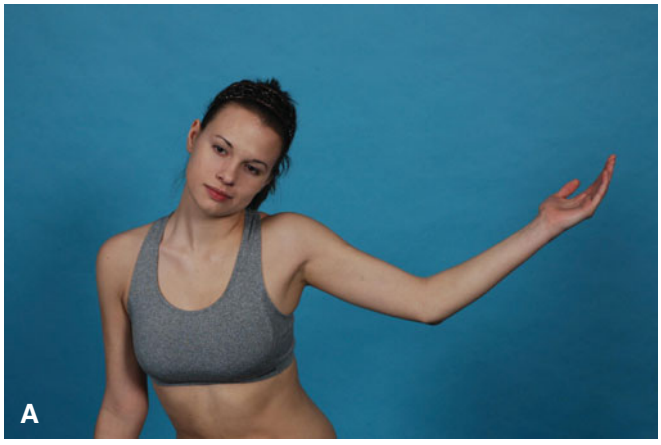
the elbow while sidebending toward the elevated arm (Fig. 11-15A).

2. Keeping the upper extremity in the same position, the patient is asked to side bend the head away from the elevated arm (Fig. 11-15B). When a gentle stretch is felt, the position is held for 10–15 seconds.
3. When the patient is able to maintain the previous stretch for 30–60 seconds, trunk rotation away from the involved side is added.
4. Once full trunk rotation is achieved, various positions of cervical side bending and elbow flexion/extension can be attempted (Fig. 11-15C). For example, elbow extension combined with contralateral cervical side bending. To increase tension, forearm supination or pronation can be superimposed on the elbow motions.

Each position is held for 7 seconds and is repeated five times per session.

A series of home stretching exercise to improve tissue mobility and neural extensibility of the median nerve in cases of carpal tunnel syndrome have been advocated. Theoretically, stretching exercises of the median nerve affect symptom resolution in a carpal tunnel syndrome by[126]

- stretching the adhesions
- broadening the longitudinal area of contact between the median nerve and the transverse carpal ligament
- reducing tenosynovial edema by a milking action



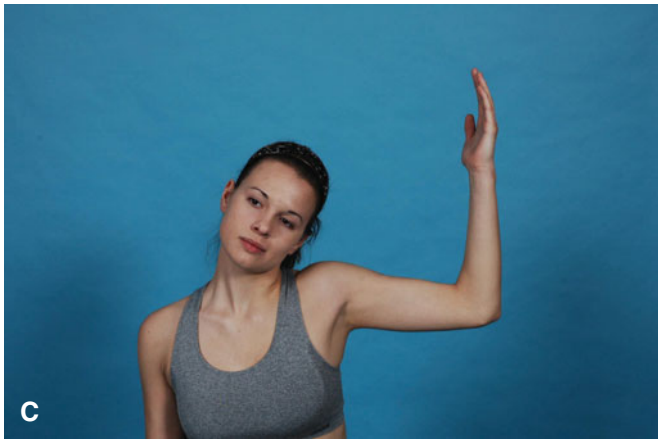


FIGURE 11-15 Upper extremity nerve stretches.

- improving venous return from the nerve bundles
- reducing pressure inside the carpal tunnel

Six positions are used for mobilization of the median nerve at the wrist:

1. The wrist in neutral, with the fingers and thumb in flexion
2. The wrist in neutral, with the fingers and thumb extended
3. The wrist and fingers extended, with the thumb in neutral
4. The wrist, fingers, and thumb extended
5. The wrist, fingers, and thumb extended, with the forearm supinated
6. The wrist, fingers, and thumb extended, with the forearm supinated and the other hand gently stretching the thumb

Each position is held for 7 seconds and is repeated five times per session.[126] All of the exercises performed in the clinic should be performed by the patient at home whenever possible.

REVIEW QUESTIONS*

1. List the number of mechanisms that are hypothesized to contribute to an injury of the peripheral nerve trunk.
2. Which term is used to describe a serial compromise of axonal transport along the same nerve fiber, causing a subclinical lesion at the distal site to become symptomatic?
3. In addition to complaints of pain, what other signs and symptoms are likely to be present with a diagnosis of neurodynamic tension?
4. The SLR test exerts a caudal traction on which of the lumbosacral nerve roots?
5. Within which range of the SLR are positive findings more significant for a decrease in neurodynamic mobility?

*Additional questions to test your understanding of this chapter can be found in the Online Learning Center for *Orthopaedic Assessment, Evaluation, and Intervention* at www.duttononline.net. Answers for the above questions appear at the back of this book.

Improving Muscle Performance

CHAPTER 12

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Outline the various roles of human skeletal muscle.
2. List the various roles of muscle in the human body.
3. Differentiate among muscle strength, endurance, and power.
4. Describe strategies to increase muscle strength.
5. List the different types of resistance that can be used to strengthen muscles.
6. List the different types of muscle contractions and the advantages and disadvantages of each.
7. Outline the various types of exercise progression and the components of each.
8. Describe strategies to increase muscle endurance.
9. Describe strategies to increase muscle power.
10. Explain the basic principles behind plyometrics.
11. Define delayed onset muscle soreness (DOMS) and explain why it occurs.
12. Define senescence sarcopenia.
13. List the changes that can occur with muscles during aging.
14. Describe the concept of specificity of training.

OVERVIEW

Movement of the body or any of its parts involves considerable activity from those muscles directly responsible. Muscle is the only biological tissue capable of actively generating tension. This characteristic enables human skeletal muscle to perform the important functions of maintaining upright body posture, moving body parts, and absorbing shock. For body motions to take place, the muscles producing movement must have a stable base from which to work from. Muscles serve a variety of roles depending on the required movement:

- ***Prime agonist.*** A muscle that is directly responsible for producing movement.
- ***Synergist (supporter).*** Performs a cooperative muscle function in relation to the agonist. Synergists can function as stabilizers or neutralizers.
  - ***Stabilizers (fixators).*** Muscles that contract statically to steady or support some part of the body against the pull of the contracting muscles, against the pull of gravity, or against the effect of momentum and recoil in certain vigorous movements.
  - ***Neutralizers.*** Muscles that act to prevent an undesired action of one of the movers.
- ***Antagonist.*** A muscle that has an effect opposite to that of the agonist.

Types of Muscle Contraction

The basic function of a muscle is to contract. The word *contraction*, used to describe the generation of tension within muscle fibers, conjures up an image of shortening of muscle fibers. However, a contraction can produce shortening or lengthening of the muscle, or no change in the muscle length. Thus, three types of contraction are commonly recognized (see Chap. 1): isometric, concentric, and eccentric.

- ***Isometric contraction.*** Isometric exercises provide a static contraction with a variable and accommodating resistance without producing any appreciable change in muscle length.[1]
- ***Concentric contraction.*** A concentric contraction (Fig. 12-1) produces a shortening of the muscle. This occurs when the tension generated by the agonist muscle is sufficient to overcome an external resistance and to move the body segment of one attachment toward the segment of its other attachment.[1]
- ***Eccentric contraction.*** An eccentric contraction (Fig. 12-2) occurs when a muscle slowly lengthens as it gives in to an external force that is greater than the contractile force it is exerting.[1] In reality, the muscle does not actually lengthen, it merely returns from its shortened position to its normal resting length. Eccentric muscle contractions, which are capable of generating greater forces than either isometric or concentric contractions,[2–4] are involved in activities that

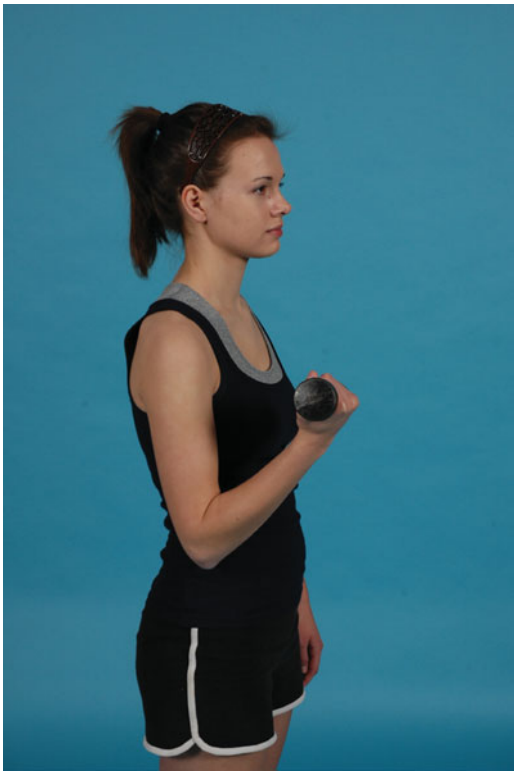

FIGURE 12-1 Concentric contraction.

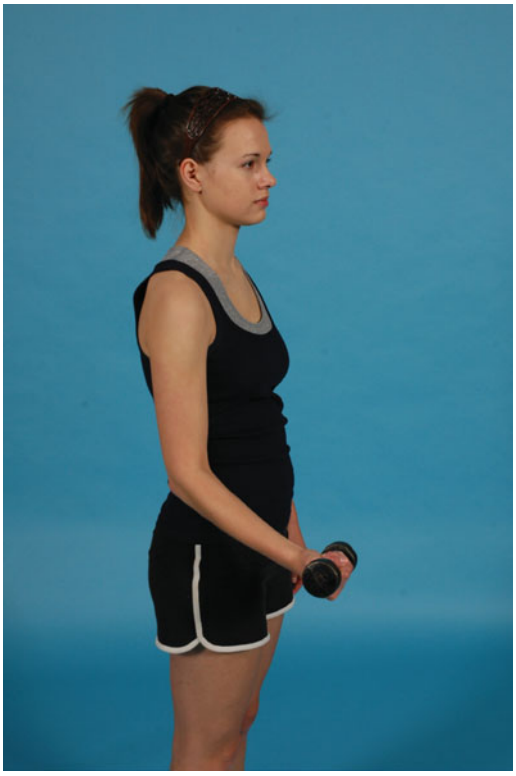

FIGURE 12-2 Eccentric contraction.

require a deceleration to occur. Such activities include slowing to a stop when running, lowering an object, or sitting down. Because the load exceeds the bond between the actin and myosin filaments during an eccentric contraction, some of the myosin filaments probably are torn from the binding sites on the actin filament while the remainder are completing the contraction cycle.[5] The resulting force is substantially larger for a torn cross-bridge than for one being created during a normal cycle of muscle contraction. Consequently, the combined increase in force per cross-bridge and the number of active cross-bridges results in a maximum lengthening muscle tension that is greater than the tension that could be created during a shortening muscle action.[5,6]

CLINICAL PEARL

An *isotonic* contraction is a contraction in which the tension within the muscle remains constant as the muscle shortens or lengthens.[1] This state is very difficult to produce and measure. Although the term *isotonic* is used in many texts to describe concentric and eccentric contractions alike, its use in this context is erroneous because in most exercise forms the muscle tension during exercise varies based upon the weight used, joint velocity, muscle length, and type of muscle contraction.[1]

Four other contractions are worth mentioning:

- ***Isokinetic contraction.*** An isokinetic contraction occurs when a muscle is maximally contracting at the same speed throughout the whole range of its related lever.[1] Isokinetic contractions require the use of special equipment that produces an accommodating resistance. Both high-speed/low-resistance and low-speed/high-resistance regimens result in excellent strength gains.[7–10] The major disadvantage of this type of exercise is its expense. In addition, there is the potential for impact loading and incorrect joint axis alignment.[11] Isokinetic exercises may also have questionable functional carryover.[12]
- ***Econcentric contraction.*** This type of contraction combines both a controlled concentric and a simultaneous eccentric contraction of the same muscle over two separate joints.[13] Examples of an econcentric contraction include the standing hamstring curl, in which the hamstrings work concentrically to flex the knee while the hip tends to flex eccentrically, lengthening the hamstrings. When rising from a squat, the hamstrings work concentrically as the hip extends and work eccentrically as the knee extends. Conversely, the rectus femoris work eccentrically as the hip extends and work concentrically as the knee extends.
- ***Isolytic contraction.*** An isolytic contraction is an osteopathic term used to describe a type of eccentric contraction that makes use of a greater force than the patient can overcome. The difference between an eccentric contraction and an isolytic contraction is that, in the former the contraction is voluntary, whereas in the latter it is involuntary. The isolytic contraction can be used in certain manual techniques to stretch fibrotic tissue (see Chap. 10).

Muscle Performance

The ability of a muscle to carry out its various roles is a measure of muscle performance. Muscle performance can be

measured using a number of parameters. These include strength, endurance, and power.

- ***Strength.*** Strength may be defined as the amount of force that may be exerted by an individual in a single maximum muscular contraction against a specific resistance, or the ability to produce torque at a joint. Dynamometry is the process of measuring forces that are doing work. Muscle strength can be measured as follows (see Chap. 4):
  - Manual muscle testing (MMT): MMT is an acceptable standardized process utilized to find gross strength deficits and to isolate muscle groups and actions.
  - Using a dynamometer: A dynamometer is a device that measures strength by using a load cell or spring-loaded gauge. These measurements are more objective than MMT. Examples of a dynamometer include the following:
    - Handheld: This is used to assess the grip strength of a patient, or to measure muscle group strength by having the patient exert maximal force against the dynamometer.
  - Isometric: This measures the static strength of the muscle group by stabilizing the extremity using stabilization straps or verbal instruction.
  - Isokinetic: This measures the strength of a muscle group during a movement with constant, predetermined speed.
- ***Endurance.*** Muscular endurance is the ability of a muscle, or group of muscles, to continue to perform without fatigue. The nature of muscular endurance encourages the body to work aerobically. This phenomenon, called *steady state*, occurs after some 5–6 minutes of exercise at a constant intensity level.[14] During steady state, the rate of mitochondrial adenosine triphosphate (ATP) production is closely matched to the rate of ATP hydrolysis and demonstrates the existence of efficient cellular mechanisms to control mitochondrial ATP synthesis in a wide dynamic range.[15] Endurance exercise training produces an increase in mitochondrial volume density in all three muscle fiber types[16] and thus muscle aerobic power. With a higher mitochondrial density in trained muscle, the rate of substrate flux per individual mitochondrion will be less at any given rate of ATP hydrolysis.[15] Therefore, the required activation of mitochondrial respiration by adenosine diphosphate (ADP) to achieve a given rate of ATP formation will be less, resulting in increased ADP sensitivity of muscle oxidative phosphorylation.[15]
- ***Power.*** Mechanical power is the product of force and velocity. *Muscular power*, the maximum amount of work an individual can perform in a given unit of time, is the product of muscular force and velocity of muscle shortening. Muscular power is an important contributor to activities requiring both strength and speed. Maximum power occurs at approximately one-third of maximum velocity.[17] Muscles with a predominance of fast-twitch fibers generate more power at a given load than those with a high composition of slow-twitch fibers.[18] The ratio for mean peak power production by type IIb, type IIa, and type I fibers in skeletal tissue (see Chap 1) is 10:5:1.[19]

These three components of muscle performance are important in functional activities as they can allow the patient to interact with their environment in a more efficient and pain-free way through increased movement control and capacity.

CLINICAL PEARL

The ultimate source of energy for muscular contraction is the ATP molecule. The catabolic breakdown of the chemical bonds of the ATP molecule provides the energy necessary to allow myosin cross-bridges to pull the actin filaments across the myosin filaments, which results in muscle contraction (see Chap. 1).

Exercise Prescriptions

Before initiating an exercise program, it is necessary to conduct a needs analysis to evaluate the physical requirements and physical attributes of the patient. Determining the selection of exercise is dependent upon the goals and objectives and the needs analysis. As with prescriptions for medications, a successful exercise prescription requires the correct balance between the dose (exercise variables) and the response (specific health or fitness adaptations).[20] The dosage of an exercise refers to each particular patient's exercise capability, and is determined by a number of variables (Table 12-1).[21] For these variables to be effective, the patient must be compliant and be able to train without exacerbating the condition.[22]

CLINICAL PEARL

The training volume describes the total amount of resistance lifted during a strength training session, and is therefore dependent upon the weight lifted, the repetitions (reps), and sets.

Training volume = number of sets × number of reps × weight lifted per rep

Depending on the specific program design, resistance training is known to enhance muscular strength, power, or endurance and can provide a potent stimulus to the neuromuscular system. Other variables such as speed, balance, coordination, jumping ability, flexibility, and other measures of motor performance have also been positively enhanced by resistance training.[23]

TABLE 12-1 Resistive Exercise Variables

Resistance (load or weight)
Duration
Training frequency (weekly, daily)
Point of application
Bouts (timed sessions of exercise)
Sets and repetitions
Training volume
Mode (type of contraction)
Rests

CLINICAL PEARL

- If pain is present before resistance or the end-feel, the patient's symptoms are considered irritable. The intervention in the presence of irritability should not be aggressive, particularly inclusive of exercise[24]
- If pain occurs after resistance, then the patient's symptoms are not considered irritable and exercise, particularly stretching, can be more aggressive.

It is worth remembering that when the individual trains for two different types of adaptations (e.g., aerobic fitness versus strength), the training stimuli can interfere with one another and result in less improvement in one or both of the effects. For example when strength loads are combined with aerobic training, the aerobic adaptation is not detrimentally affected, but there is a negative impact on strength development.[25,26]

CLINICAL PEARL

Contraindications to muscle performance training:

- ***Inflammation.*** Exercise can increase swelling and cause damage to muscles or joints.
- ***Pain.*** Severe joint or muscle pain during exercise, or for more than 24 hours after exercise, requires an elimination or reduction of the exercise.

Each exercise session should include a 5–15 minute warm-up and a 5–15 minute cool-down period.

- Warm-up
  - includes low-intensity cardiorespiratory activities.
  - prevents the heart and circulatory system from being suddenly overloaded.
- Cool-down
  - includes low-intensity cardiorespiratory activities and flexibility exercises.
  - helps prevent abrupt physiological alterations that can occur with sudden cessation of strenuous exercise.

The length of the warm-up and cool-down sessions may need to be longer for deconditioned or older individuals. The type of exercise prescribed determines the type of warm-up.[27] The possible benefits of a warm-up prior to physical activity are listed in Table 12-2. The most effective warm-up consists of both general (walking, biking, jogging, and gentle resistive exercises) and specific (movements that are appropriate for the particular activity to be undertaken) exercises.[27]

Once the warm-up is completed, it is recommended that a flexibility program be incorporated to increase joint movement and muscle extensibility (see Chap. 13).

The initial exercise is prescribed at a level that the patient can perform, before progressing in difficulty. The early goals of exercise are concerned with increasing circulation, preventing atrophy, increasing protein synthesis, and reducing the level of metabolites.[22]

TABLE 12-2 Possible Benefits of a Warm-Up Prior to Physical Activity

Increased blood flow to muscles.
Increased oxyhemoglobin breakdown, with increased oxygen delivery to muscles.
Increased circulation leading to decreased vascular resistance.
Increased release of oxygen from myoglobin.
Enhanced cellular metabolism.
Reduced muscle viscosity leading to smoother muscle contraction and increased mechanical efficiency.
Increased speed of nerve impulses.
Increased sensitivity of nerve receptors.
Decreased activity of alpha fibers and sensitivity of muscles to stretch.
Decreased number of injuries due to increased range of motion.
Decreased stiffness of connective tissue leading to decreased likelihood of tears.
Increased cardiovascular response to sudden strenuous exercise.
Increased relaxation and concentration.

CLINICAL PEARL

Resistance training, particularly when incorporated into a comprehensive fitness program, reduces the risk factors associated with coronary heart disease, non–insulin-dependent diabetes, and colon cancer; prevents osteoporosis; promotes weight loss and maintenance; improves dynamic stability and preserves functional capacity; and fosters psychological well-being.[23]

The following factors should be considered with exercise prescriptions.

Frequency. Training frequency refers to the number of times strength-training sessions are completed in a given period (e.g., the number of work-outs per week). Optimal training frequency depends on several factors such as experience, training volume and status, intensity (see later), exercise selection, level of conditioning, recovery ability, and the number of muscle groups trained per workout session. Strength is most effectively enhanced by a program featuring high resistance and few reps. More training sessions can be accomplished and provide adequate rest if a *split routine* is used. A split routine divides the training session into groupings, split between the upper body and lower body exercises. Another alternative is to perform a push and pull exercise program, in which the strength training is divided into exercises in which the individual pushes a weight (e.g., triceps extension, bench press), then pulls a weight (e.g., biceps curl, latissimus dorsi pull down).

Based on the studies of isokinetic and eccentric/concentric exercise,[28,29] muscle strength recovery follows a steady,

nonlinear, and predictable increase over time.[21] In the rehabilitation population, strengthening exercises are typically performed on a daily basis initially, with the weight and frequency governed by the individual's response to the exercise. As healing progresses, evidenced by a decrease in pain and swelling and an increase in range of motion, the exercises should be performed every other day. If the training loads are near the maximum capacity, more time for recovery will be required to minimize soreness and provide adequate rest.

Once sufficient strength is attained, even if the patient only performs the strength training at a minimum of once per week, the strength can be fairly well maintained over a 3-month period.[30]

Repetitions. Initial selection of a starting weight may require some trial and error to find the correct number of reps. For any given exercise, the amount of weight selected should be sufficient to allow 8–12 reps per exercise for three sets with a recovery period between sets of 60–90 seconds to elicit improvements in muscular strength and endurance as well as muscle hypertrophy.[31]

Duration. Duration refers to the length of the exercise session. Physical conditioning occurs over a period of 15–60 minutes depending on the level of intensity. Average conditioning time is 20–30 minutes for moderate intensity exercise. However, individuals who are severely compromised are more likely to benefit from a series of short exercise sessions (3–10 minutes) spaced throughout the day.

Rest periods. In most functional exercises, fatigue of the muscle being exercised is the goal. However, fatigue may also occur due to lack of coordination, insufficient balance, poor motivation, or the addition of compensatory movements. In addition, fatigue may also be associated with specific clinical diseases, e.g., multiple sclerosis, cardiac disease, peripheral vascular dysfunction, and pulmonary diseases. Because fatigue is detrimental to performance, rest is an important component of any exercise progression. The rest period must be sufficient to allow for muscular recuperation and development while alleviating the potential for overtraining.[32] In general, the heavier loads lifted, the longer the rest period between sets. The rest period between sets can be determined by the time the breathing rate, or pulse, of the patient returns to the steady state, or by using the following guidelines:

- muscular endurance: less than 30 seconds rest
- muscular hypertrophy: 60–90 seconds
- muscular strength: 2–5 minutes
- muscle power: 2–5 minutes

A 48-hour rest period between concurrent training sessions is generally recommended.[23]

CLINICAL PEARL

In the rehabilitation population, fatigue should be achieved without exceeding the patient's tolerance and while protecting the injury site. It is now clear that the development of fatigue probably involves several factors that influence force production in a manner dependent on muscle fiber type and activation pattern, and that one of these factors may be the regulation of Ca^{2+} by the sarcoplasmic reticulum.[33] Characteristics of muscle fatigue include reduction in muscle force production capability and shortening velocity, a reduction in the release and uptake of intracellular calcium by the sarcoplasmic reticulum, as well as prolonged relaxation of motor units between recruitment.[33,34]

One of the biggest challenges for a clinician is to find a balance between achieving a maximum training effect while alleviating fatigue. Fortunately, fatigue has a much faster decay time than the training effect. Thus, to remove the fatigue, the volume of training should be reduced while maintaining the training effect by holding the intensity of the training load constant.[35]

Intensity. Intensity refers to the power output (rate of performing work) or how much effort is required to perform the exercise. In clinical terms, intensity refers to the weight or resistance lifted by the patient. It is now recognized that an individual's perception of effort (rated perceived exertion or RPE) is closely related to the level of physiological effort.[36,37] The Borg Scale is commonly used to help determine a patient's RPE, as an individual's perception of effort is closely related to the level of physiological effort—a high correlation exists between a person's RPE multiplied by 10, and their actual heart rate.[36,37] For example, if a person's RPE is 15, then $15 \times 10 = 150$; so the heart rate should be approximately 150 beats per minute. A cardiorespiratory training effect can be achieved at a rating of "somewhat hard" or "hard" (13–16). Note that this calculation is only an approximation of heart rate, and the actual heart rate can vary quite a bit depending on age and physical condition. The original scale introduced by Borg[37] rated exertion on a scale of 6–20, but a more recent one designed by Borg included a category (C) ratio (R) scale, the Borg CR10 Scale® (Table 12-3).

TABLE 12-3 Rating of Perceived Exertion[a]

Traditional Scale	Verbal rating	Revised 10-Grade Scale	Verbal Rating
6		0	Nothing at all
7	Very, very light	0.5	Very, very weak
8		1.0	Very weak
9	Very light	2.0	Weak (light)
10		3.0	Moderate
11	Fairly light	4.0	Somewhat strong
12		5.0	Strong (heavy)
13	Somewhat hard	6.0	
14		7.0	Very strong
15	Hard	8.0	
16		9.0	
17	Very hard	10.0	Very, very strong (almost maximum) maximal
18			
19	Very, very hard		

[a]Data from Borg GAV: Psychophysical basis of perceived exertion. *Med Sci Sports Exerc* 14:377–381, 1992.

Patient responses that can modify the intensity include increases in pain level, muscle fatigue, time taken to recover from fatigue, cardiovascular response, compensatory movements, level of motivation, and degree of comprehension.

Speed of Exercise. The speed of the exercise should depend on the imposed demands of an individual. In some cases, increasing the speed of an exercise following the initial phase of learning a particular exercise and developing proficiency in the performance of the exercise is beneficial.[38] In addition, higher velocity training appears to improve peak power measures.[23]

Variation. Variation in training is a fundamental principle that supports the need for alterations in one or more program variables over time to allow for the training stimulus to remain optimal (Table 12-4).[23] The concept of variation has been rooted in program design universally for many years. The most commonly examined resistance training theory is periodization. Periodization is the systematic process of planned variations in a resistance-training program over a specified training cycle to prevent overtraining and to perform at peak or optimum levels at the right time.[39] Two models of periodization are classic (linear) and undulating (nonlinear)[23]:

- ***Classic.*** This model is characterized by high initial training volume and low intensity. As training progresses, volume decreases and intensity increases in order to maximize strength, power, or both.
- ***Undulating.*** The nonlinear program enables variation in intensity and volume within each 7- to 10-day cycle by rotating different protocols over the course of the training program. Nonlinear methods attempt to train the various components of the neuromuscular system within the same 7- to 10-day cycle. During a single workout, only one characteristic is trained in a given day (e.g., strength, power, or muscular endurance).

It has been shown that systematically varying volume and intensity is most effective for long-term progression.[23,39] Periodization consists of several phases including the macrocycle, mesocycle, and microcycle. The macrocycle for an athlete can, for example, last for 1 year ending with the end of a competitive season. The macrocycle is divided into several mesocycles. A mesocycle defines distinct variations in the resistance and exercise program. For example, a mesocycle for an athlete can be divided into three distinct phases[27]:

- ***Conditioning.*** This phase emphasizes developing aerobic and anaerobic fitness, strength, and power.
- ***Precompetition.*** This phase emphasizes correct technique.
- ***Competition.*** During this phase, the emphasis is on competitive performance while maintaining basic conditioning.

The final breakdown of periodization is the microcycle, which involves changes in training parameters such as intensity, work–rest ratios, sets, reps, exercise order, and specific exercises, and generally lasts for 1–2 weeks. A common format is a 4-week mesocycle that consists of three microcycles of 1 week each, in which the loads are progressively increased, followed by a 1-week microcycle of reduced volume and intensity.

When prescribing a progressive resistive exercise (PRE) regimen, the clinician should consider the individual's current health and fitness status, goals, access to appropriate equipment, and time available for training.[40] Training programs prescribed for competitive athletes, which often include exercises designed specifically to improve the development of explosive power, are generally inappropriate for children, untrained adults, elderly persons, or patients with chronic disease(s). Exercise progression in the orthopaedic population, including the post surgical population, is determined by the stage of healing and the degree of irritability of the structure, which are factors of patient response, as healing relates to signs and symptoms.

TABLE 12-4 Types of Training That Incorporate Variation

Circuit training	Circuit training or cross-training incorporates a wide variety of modes of training and uses high repetitions and low weight to provide a more general conditioning program aimed at improving body composition, muscular strength, and some cardiovascular fitness.
Interval training	Interval training includes an exercise period followed by a prescribed rest interval. It is perceived to be less demanding than continuous training and tends to improve strength and power more than endurance. With appropriate spacing of work and rest intervals, a significant amount of high-intensity work can be achieved and is greater than the amount of work accomplished with continuous training. The longer the work interval, the more the anaerobic system is stressed and the duration of the rest period is not important. In a short work interval, a work recovery ratio of 1:1 or 1:5 is appropriate to stress the aerobic system.

CLINICAL PEARL

Three terms are commonly used with resistance training prescriptions:

- ***Repetitions.*** The number of times a specific movement or exercise is repeated.
- ***Repetition maximum (RM).*** The RM is the maximum number of reps an individual can perform at a given weight. For example, a 10 RM is the weight the patient can lift a maximum of 10 times.
- ***Set.*** A particular number of reps. Whatever exercise progression is used to achieve an increase in the total number of reps while maintaining a sufficient effort, the number of sets must also be increased. This increase in sets must occur in conjunction with a reduction in the number of reps per set by 10–20%[22] or a reduction in the amount of resistance. Generally speaking, no more than three to five sets are used.

Specificity of Training

It appears that the muscle response to resistance training for people who have a broad range of conditions and who might consult a physical therapist is similar to muscle responses reported in young people without impairment.[41] Resistance training can have a beneficial effect in populations where pain is a particular problem, such as people with low back pain and people with osteoarthritis. In addition, resistance training can have a beneficial effect on conditions such as high blood pressure, fracture rehabilitation, and cardiovascular disease. The effect of resistance training on other impairment parameters, such as bone mineral density, fat mass, and aerobic capacity, remains inconclusive.[41] There is also evidence to suggest that improvements in the ability to generate muscle force can carry over into an improved ability to do everyday tasks. However, the effects are generally quite modest, and there are a number of examples in the literature where significant improvements in activity were not demonstrated after resistance training.[41] Part of the problem with drawing conclusions from the literature is the lack of details provided as to the specifics of the exercises prescribed. Specificity of training is an accepted concept in physical therapy rehabilitation. This concept involves the principle of the specific adaptation to imposed demand (SAID). Thus, the focus of the exercise prescription should be to improve the strength and coordination of functional or sports-specific movements with exercises that approximate the demands of the desired activity (speed, agility, strength, power, endurance, etc.).

CLINICAL PEARL

The principle of overload states that a greater than normal stress or load on the body is required for training adaptation to take place. To increase strength, the muscle must be challenged at a greater level than it is accustomed to. High levels of tension will produce adaptations in the form of hypertrophy and recruitment of more muscle fibers.

Three important concepts are related to the SAID principle:[26]

- Overload. When cells, tissues, and organs are loaded beyond what they normally are required to do, they will adapt to permit them to deal with these new loads more effectively. These training effects are specific to the energy supply systems that have been utilized, the locale of the stimulus, the specific muscle groups, the joint action(s), the type of contraction, and the speed of contraction. When loads are applied they should be specific to the desired effect (SAID), and be appropriate to the individual in terms of frequency, intensity, and duration. It is important to remember that once an adaptation has taken place to a specific load, this load is no longer an "overload" and the load must be progressively increased to get further improvements.
- Underload. When cells, tissues, and organs are loaded at a level below what is normally performed, the body will adapt by decreasing its ability in the underloaded component (detraining). Detraining occurs quickly after the cessation of training—a reduction in the VO_2 max can be detected within four weeks of detraining.

CLINICAL PEARL

An overprescription of resistance training exercise may result in overstress injuries, whereas underprescription will result in a failure to achieve the necessary or desired strength improvement.

- Overtraining. Overtraining occurs because of an inappropriate amount of rest, recovery, and unloading. It is manifested as an inability to recover from exercise, lowered resistance to injury, and chronic fatigue or exhaustion, and is caused by a loss in the body's adaptive capability after chronic high-volume loading or in response to a too large increase in either duration or intensity of training. The signs and symptoms of overtraining include loss of appetite, inability to sleep, lethargy, muscle soreness, chronic fatigue, declining performance, and altered metabolism.[42–44]

The SAID principle can be applied by exercising the muscles along each extremity and within the trunk in functional patterns.[45] The exercise component of the intervention should be as specific as the manual technique used in the clinic. Muscles can be classified into tonic and phasic groups according to how muscles develop from the myotomes[46] (Table 12-5).

CLINICAL PEARL

In general, tonic muscles function as endurance (postural) muscles, whereas phasic muscles function as the power muscles.[47,48]

Speed-strength training applies the principles of specificity of training and is typically used with highly conditioned

TABLE 12-5 The Various Muscle Types and Their Primary Innervation

Muscle Type	Characteristics	Primary Innervation	Examples
Type I	Tonic	Type 1a phasic nerve endings	Extensors
	Slow twitch		External rotators
	Small neuron		Abductors
Types IIa and IIb	Phasic	Anterior divisions of the nerve plexus	Flexors
	Fast twitch		Adductors
	Large neuron		Two-joint muscles

Data from Wilk KE, Voight ML, Keirns MA, et al.: Stretch-shortening drills for the upper extremities: theory and clinical application. *J Orthop Sports Phys Ther* 17:225–239, 1993.

athletes who want to take their performance to the next level. Speed-strength training involves taking some of the basic movements of a task and increasing the resistance. For sports, such as baseball and golf, athletes can use devices, such as an oversized ball or weighted golf club, to train the arms and trunk to work against a greater resistance. Sprinters have long benefited from the use of a small parachute to increase wind resistance, or by dragging a tire fastened by a rope. The theory behind speed-strength training is that once the higher resistance is removed the athlete's speed is improved when they perform the activity under normal resistance. Wherever possible, strength testing by the clinician should assess the function of a muscle. If a power muscle is assessed, its ability to produce power should be assessed. In contrast, an endurance muscle should be tested for its ability to sustain a contraction for a prolonged period, such as occurs with sustained postures.

In addition to speed-strength training, agility drills, rapid reflex, and specific skill training should form the core of many sport-specific exercise programs.

CLINICAL PEARL

The principles of resistance training can be easily remembered by the acronym PROS—progression, regularity, overload, and specificity.

Delayed Onset Muscle Soreness

Familiar to most individuals at some time, muscular soreness is one of the drawbacks to participating in an exercise program involving activity beyond what one usually experiences. The purpose of the recovery phase is to restore the muscles in the body to preexercise levels through promotion of venous turn and removal of metabolites from muscle, reestablishment of fluid balance, replacement of depleted fuel energy reserves, and relaxation in muscles that were active.[26] The recovery period is also necessary to replenish muscle glycogen following prolonged exercise of the continuous or integral nature. If the recovery period is insufficient, acute or DOMS can result. Acute soreness is apparent during the later stages of an exercise bout and during the immediate recovery period.[38] This results from an accumulation of end products that occurs with exercise, H+ ions, and lactate, but generally disappears between 2 minutes and 1 hour after cessation of exercise.[38] DOMS, on the other hand, appears 24–56 hours after the exercise bout.[49] DOMS can exhibit as anything, from minor muscle soreness to debilitating pain and swelling, but is most commonly described as causing a reduction in joint range of motion, shock attenuation, and peak torque.[50] A recent review of DOMS confirms that the mechanisms, treatment strategies, and impact on athletic performance remain uncertain.[51] Recognized mechanisms include lactic acid and potassium accumulation, muscle spasms, mechanical damage to the connective tissues, inflammation, enzyme efflux secondary to muscle cell damage, and edema.[51] There is certainly a marked increase in the proportion of disrupted muscle fibers after eccentric as compared with concentric exercise, which has been roughly correlated to the degree of DOMS.[52] Eccentric exercise is also linked to morphologic and metabolic signs of muscle alteration: myofibrillar damage along the Z-band,[53,54] mitochondrial swelling,[53,54] increased intramuscular pressure,[53,54] and impaired glycogen resynthesis.

Given the role of eccentric exercise in DOMS, prevention of DOMS involves the careful design of any eccentric program, which should include preparatory techniques, accurate training variables, and appropriate aftercare, including a cool-down period of low-intensity exercise to facilitate the return of oxygen to the muscle. It is a widely held belief among athletes and coaches that massage is an effective therapeutic modality that can enhance muscle recovery and reduce soreness following intense physical activity.[55] However, the actual scientific literature does not tend to support the positive efficacy of manual massage as a postexercise therapeutic modality in the athletic setting.[55–57]

To help prevent DOMS, there is some controversy as to whether a cool-down or warm-up should be used. A number of studies advocate a short (5–10 minutes) low-intensity warm-up (30–65% of VO_2 max) to assist in maintaining venous return and removal of metabolites above levels in passive rest.[58,59] However, one randomized controlled trial found that whereas a 10 minute warm-up reduced perceived muscle soreness (measured on a 100-mm visual analogue scale) 48 hours after exercise (mean effect of 13 mm, 95% CI 2 to 24 mm), a 10 minute cool-down had no apparent effect (mean effect of 0 mm, 95% CI 11 to 11 mm).[60]

If the prevention of DOMS is unsuccessful, the intervention should include, as appropriate, rest, local measures to reduce edema (e.g., cryotherapy, elevation of the involved limb(s)), drug therapy (typically nonsteroidal anti-inflammatory agents), or further exercise (aerobic submaximal exercise with no eccentric component, e.g., swimming, biking, or stepper machine, pain-free flexibility exercises, and high-speed [300 degrees per second] concentric-only isokinetic training).[21,61]

Types of Resistance Used in Exercise Programs

Resistance-training programs have the potential for many positive benefits provided the training is appropriately progressed to meet the needs of a person as his or her strength increases. Resistance can be applied to a muscle by any external force or mass, including any of the following.

Gravity

Gravity alone can supply sufficient resistance for a weakened muscle. With respect to gravity, muscle actions may occur

- in the same direction as gravity (downward);
- in the opposite direction to gravity (upward);
- in a direction perpendicular to gravity (horizontal);
- in the same or opposite direction to gravity, but at an angle.

The direction in which the muscle is working determines the role that gravity plays and the role that the muscle must play in order to counteract the forces of gravity. For example, if an arm muscle is working to lower a book to a table, the biceps muscle works eccentrically against the force of gravity to control the speed of the lowering. If the muscle works to lift

the book from the table, the biceps muscle must work concentrically against the force of gravity.

CLINICAL PEARL

Active range of motion exercises are designed to work against gravity, whereas active assisted exercises are typically performed perpendicular to gravity.

Body Weight

A wide variety of exercises have been developed that do not require any equipment but rely solely on the patient's body weight for the resistance (e.g., push-up).

Small Weights

Cuff weights, dumbbells, and surgical tubing (elastic resistance) are economical ways of applying resistance. Small weights are typically used to strengthen the smaller muscles or to increase the endurance of larger muscles by increasing the number of reps. Free weights also provide more versatility than exercise machines, especially for three-dimensional exercises, as the movements do not occur in a straight line or plane. The disadvantage of free weights is that they offer no variable resistance throughout the range of motion and so the weakest point along the length–tension curve of each muscle limits the amount of weight lifted. According to a recent study, 96% of rehabilitation professionals use elastic resistance with their patients, and 85% of home exercise programs prescribed by rehabilitation professionals require elastic-resistance bands or tubing.[9,32,62–67] Elastic resistance offers a unique type of resistance that cannot be classified within the traditional subcategories of strengthening. The amount of variable resistance offered by elastic bands or tubing is a factor of the internal tension produced by the material. This internal tension is a factor of the elastic material's coefficient of elasticity, the surface area of the elastic material, and how much the elastic material is stretched.[32] It is commonly believed that the resistance provided by these bands or tubing increases exponentially at the end range of motion. However, the forces produced by elastic resistance are linear until approximately 500% elongation, at which point the forces increase exponentially.[32] As the elastic resistance is not stretched more than 300% in prescribed exercises, the exponential increase should not be attained. In addition, the torque production of elastic-resistance exercises is similar to that produced by a concentric/eccentric dumbbell exercise: a bell-shaped curve.[68]

Medicine Balls

Medicine balls provide the opportunities to improve strength, balance, and coordination through dynamic movements by training the body as a functional unit and strengthening the core and trunk musculature. Both upper and lower body medicine ball exercises can be performed using a variety of speeds, and medicine ball weights and sizes.

Exercise Machines

In situations where the larger muscle groups require strengthening, and where exercises need to be performed in straight and supported lines, a multitude of specific exercise machines can be used. These machines are most often used in the more advanced stages of a rehabilitation program when more resistance can be tolerated, but can also be used in the earlier stages depending on the size of the muscle undergoing rehabilitation. Examples of these machines include the multi-hip, the lat pull-down, the leg extension, and the leg curl machine. Exercise machines are often fitted with an oval-shaped cam or wheel that mimics the length of tension curve of the muscle (Nautilus, Cybex). Although these machines are a more expensive alternative to dumbbell or elastic resistance, they do offer some advantages:

- They provide more adequate resistance for the large muscle groups that cannot be achieved with free weights/cuff weights, or manual resistance.
- They are typically safer than free weights as control/support throughout the range is provided.
- They provide the clinician with the ability to quantify and measure the amount of resistance that the patient can tolerate over time (as compared with elastic resistance).

The disadvantages of exercise machines are as follows:

- the inability to modify the exercise to be more functional or three-dimensional and
- the inability to modify the amount of resistance at particular points of the range.

Manual Resistance

Manual resistance is a type of active exercise in which another person provides resistance manually. An example of manual resistance is proprioceptive neuromuscular facilitation (PNF) (see Chap. 10).

The advantages of manual resistance, when applied by a skilled clinician, are as follows[69]:

- Control of the extremity position and force applied. This is especially useful in the early stages of an exercise program when the muscle is weak.
- More effective reeducation of the muscle or extremity, using diagonal or functional patterns of movement.
- Critical sensory input to the patient through tactile stimulation and appropriate facilitation techniques (e.g., quick stretch).
- Accurate accommodation and alterations in the resistance applied throughout the range. For example, an exercise can be modified to avoid a painful arc in the range.
- Ability to limit the range. This is particularly important when the amount of range of motion needs to be carefully controlled (postsurgical restrictions).

The disadvantages of manual resistance include the following:

- The amount of resistance applied cannot be measured quantitatively.
- The amount of resistance is limited by the strength of the clinician/caregiver or family member.

- Difficulty with consistency of the applied force throughout the range, and with each rep.

Improving Muscle Performance

Progression is defined as "the act of moving forward or advancing toward a specific goal over time until the target goal has been achieved."[23] A progressive program is recommended to condition the patient for a return to activity and to prevent overload injuries. Such a program should address the following areas:[70–74]

- ***Flexibility.*** Attempts should be made to improve general body flexibility, with an emphasis on the specific activity or exercise. The general flexibility exercises should address the entire kinematic chain and not just the joint in question (e.g., shoulder rotation and elbow motion in the arm, low back, hip rotation, and hamstrings in the legs).
- ***Strengthening.*** The exercises to improve strength should be applied in appropriate amounts and locations to address sport- or functional-specific activities.
- ***Power.*** Power is incorporated through the use of rapid movements in appropriate planes with weights and ballistic activities.
- ***Endurance.*** Endurance can be built up with aerobic exercises.

Optimal resistance training progressions should always be based on sound rationale and should always be individualized to meet specific training goals. Each progression is made more challenging by altering one of the parameters of exercise including the intensity, duration, and frequency which are modified according to patient response.

Increasing Strength

Strengthening of a muscle occurs when the muscle is forced to work at a higher level than that to which it is accustomed. The extent of the functional and health benefits from exercise training depends on several factors including initial performance and health status, along with the exercise prescription variables previously discussed such as frequency, duration, intensity, variation, and rest intervals.[75]

To increase muscle strength most effectively, a muscle must work with increasing effort against progressively increasing resistance.[3,76] In a strength training program, the term *load* refers to the amount of weight used in a specific exercise. Most strength and conditioning programs describe the load as a percentage of a RM. The RM can be expressed as the greatest amount of load lifted one time (1 RM). As the load becomes heavier, the number of times an individual can lift (perform a rep) the load decreases, whereas if the load becomes lighter, more reps can be accomplished. If resistance is applied to a muscle as it contracts so that the metabolic capabilities of the muscle are progressively overloaded, adaptive changes occur within the muscle, which make it stronger over time.[4,77] These adaptive changes include the following[2,3,78–82]:

- ***An increase in the size of the muscle (hypertrophy).*** In normal individuals, an increase in strength after a resisted exercise program is thought to initially occur as a result of neural adaptation, followed by hypertrophy of muscle fibers if the exercise program is continued for a longer period. *Mitochondria* are the main subcellular structures that determine the oxygen demand of muscle. There is consensus that there is a dilution of mitochondrial volume density through an increase in myofibrillar (i.e., contractile protein) volume density as a consequence of strength-type exercise training.[14,83] This increase in myofibrillar volume density, or hypertrophy that occurs with strength training is regarded as the main cause for the overall increase in the anatomical cross-sectional area (CSA) of an entire muscle group. The fiber hypertrophy is typically greater for fast- than for slow-twitch muscle fibers.[84]
- ***An increase in the force per unit area.*** Strength training has also been shown to lead to an increase in the force per unit CSA of the muscle. This effect has been attributed either to an increase in neural drive[85] or to an actual increase in muscle specific tension due to a denser packing of muscle filaments.[86] A denser packing of contractile tissue along the tendon could theoretically increase the angle of pennation of muscle fibers.[87]
- ***A reduction in the time to peak force.***[88] This can be defined as the time from the onset of muscle activation until peak force is attained.
- ***An increase in the efficiency of the neuromuscular system.*** This increased efficiency results in
  - an increase in the number of motor units recruited,
  - an increase in the firing rate of each motor unit,
  - an increase in the synchronization of motor unit firing, and
  - an improvement in the endurance of the muscle.
- ***Stimulation of slow-twitch fibers (when performing workloads of low intensity) and stimulation of fast-twitch IIa fibers (when performing workloads of high intensity and short duration).***
- ***Rhythmic activities increase blood flow to the exercising muscles via contraction and relaxation.***
- ***The power of the muscle improves.***
- ***Improved bone mass (Wolff's Law).***
- ***Increase in metabolism/calorie burning/weight control.***
- ***Increased intramuscular pressure results from a muscle contraction of about 60% of its force generating capacity.***
- ***Cardiovascular benefits when using large muscle groups.*** Strength training of specific muscles has a brief activation period and uses a relatively small muscle mass, producing less cardiovascular metabolic demands than vigorous walking, swimming, etc.
- ***An increase in the rate of force development.***[88]
- Conversely, a muscle can become weak or atrophied through:
  - *Disease.*
  - *Neurologic compromise.*
  - *Immobilization.* Continuous immobilization of skeletal muscle tissues can cause some undesirable consequences.

These include weakness or atrophy of muscles. Muscle atrophy is an imbalance between protein synthesis and degradation. After modest trauma, there is a decrease in whole body protein synthesis rather than increased breakdown. With more severe trauma, major surgery, or multiple organ failure, both synthesis and degradation increase, the latter being more enhanced.

- *Disuse.*

Strengthening Exercises Based on Contraction Type

As outlined earlier in the chapter, a muscle can contract in a variety of ways. Each type of contraction has its advantages and disadvantages.

Isometric Exercises. Studies have demonstrated that a 6-second hold of 75% of maximal resistance is sufficient to increase strength when performed repetitively.[89,90] Isometric exercises have an obvious role when joint movement is restricted, either by pain or by bracing and casting. The primary role in this regard is to prevent atrophy and a subsequent decrease of ligament, bone, and muscle strength. Isometric exercises have the following disadvantages:

- Strength gains are not increased throughout the range (unless performed at multiple angles).
- They do not activate all of the muscle fibers (primary activation is of slow-twitch fibers).
- There are no flexibility or cardiovascular fitness benefits.
- Peak effort can be injurious to the tissues because of vasoconstriction and joint compression forces.
- There is limited functional carryover.[12]
- Considerable internal pressure can be generated, especially if the breath is held during contraction. This can prove injurious to patients with weakness in the abdominal wall (hernia) or cardiovascular impairment (increase in blood pressure through the Valsalva maneuver)[91] even if performed correctly.

Concentric Exercises. These contractions are commonly used in the rehabilitation process and in activities of daily living. The biceps curl and the lifting of a cup to the mouth are examples, respectively. Concentric exercises are dynamic and allow the clinician to vary the load from constant, using free weights, to variable, using an exercise machine. The speed of contraction can also be manipulated depending on the goal of the intervention. A number of programs have been designed for the progression of concentric exercise programs. Some of these PRE programs are summarized in Tables 12-6 and 12-7. Determining the RM is dependent upon the goals of the individual and his or her functional demands. A 10 RM testing load is often recommended to estimate the 1 RM. The rehabilitation program designed by DeLorme is based on a rep maximum of 10 (10 RM).[79] The Oxford technique[92] reverses the percentage of maximum in the three sets (Table 12-6), whereas the MacQueen technique[93,94] differentiates between beginning, intermediate, and advanced levels. In contrast, the program designed by Sanders is based on a formula that uses a percentage of body weight to determine starting weights.[95] The daily adjusted progressive resistive exercise (DAPRE) program, designed by Knight, allows for individual differences in the rates at which patients progress in

TABLE 12-6 Exercise Progressions

	Set(s) of 10	Amount of Weight	Repetitions
DeLorme program	1	50% of 10 RM	10
	2	75% of 10 RM	10
	3	100% of 10 RM	10
Oxford technique	1	100% of 10 RM	10
	2	75% of 10 RM	10
	3	50% of 10 RM	10
MacQueen technique	3 (beginning/intermediate)	100% of 10 RM	10
	4–5 (advanced)	100% of 2–3 RM	2–3
Sander program	Total of 4 sets (3 times per week)	100% of 5 RM	5
	Day 1: 4 sets	100% of 5 RM	5
	Day 2: 4 sets	100% of 3 RM	5
	Day 3: 1 set	100% of 5 RM	5
	2 sets	100% of 3 RM	5
	2 sets	100% of 2 RM	5
Knight DAPRE program	1	50% of RM	10
	2	75% of RM	6
	3	100% of RM	Maximum
	4	Adjusted working weight	Maximum
Berger's adjustment technique	3	100% of 10 RM	6–8

DAPRE, daily adjustable progressive resistive exercise; RM, repetition maximum.

TABLE 12-7 Adjustment Sequence for DAPRE Program

Number of Repetitions Performed During Set	Adjusted Working Weight for Fourth Set (lb)	Next Exercise Session (lb)
0–2	−5–10	−5–10
3–4	0–5	Same weight
5–6	Same weight	+5–10
7–10	+5–10	+5–15
11	+10–20	+10–20

DAPRE, daily adjustable progressive resistive exercise.

their rehabilitation programs.[96] (Table 12-7) Finally, the Berger technique[97] selects an amount of weight that is sufficient to allow 6–8 RM in each of the three sets (the initial selection of a starting weight typically requires some trial and error), with a recovery period of 60 to 90 seconds between sets. If at least three sets of 6 RM cannot be completed, the weight is considered too heavy and is reduced. Conversely, if it is possible to do more than three sets of 8 RM, the weight is considered too light and is increased.

CLINICAL PEARL

The *1 RM equivalent* is a formula that takes into account the weight lifted and reps multiplied by a numeric equivalent.

1 RM = (weight lifted × number of reps × 0.03) + weight lifted.

For example, a patient who has lifted 100 pounds for a bench press a total of 12 reps, his or her RM equivalent will be equal to (100 × 12 × 0.03) + 100 = 136

A typical exercise prescription for high school, collegiate, and professional athletes includes three or more sets of a 6–12 RM per exercise performed 3 days/week.[40] For others, a 10–15 RM is generally recommended.[23] Initially, the strengthening exercises are performed on a daily basis, with the variables dependent on the patient's response to the exercise. This is progressed to every other day, and then to at least three times per week, but no more than four times per week.

CLINICAL PEARL

To determine how much weight should be increased for a particular exercise the *2 for 2 rule* method is recommended as it is relatively conservative. The rule states that the load should increase, if the individual can perform two or more reps over the assigned reps for that particular exercise over two consecutive workouts.

Eccentric Exercises. The clinical indications for the use of eccentric exercise are numerous[21] (Table 12-8).

CLINICAL PEARL

Functional strength is the ability of the neuromuscular system to perform combinations of concentric and eccentric contractions in the performance of activities that relate to a patient's needs and requirements in a multiplanar environment (see section "Specificity of Training").[98] Effective rehabilitation targets specific muscles with regard to functional muscle activity patterns and overall conditioning and uses a progression of increased activity, while preventing further trauma.[99] Incremental gains in function should be seen as strength increases.

TABLE 12-8 Clinical Indications for Eccentric-Biased Exercise

Mechanical, reproducible joint pain
Joint pain resistant to modality intervention
Unidirectional joint crepitus or pain arc
Deconditioned or low endurance patients
Plateaus in strength gains
Tendonitis presentations
Late-stage rehabilitation and performance training

Isokinetic Exercises. An isokinetic exercise is one in which the length of the muscle is changing while the contraction is performed at a constant velocity.[100] Isokinetic exercise requires special equipment that produces an accommodating and variable resistance. The main principle behind isokinetic exercise is that peak torque (the maximum force generated through the range of motion) is inversely related to angular velocity, the speed that a body segment moves through its range of motion. Put more simply, the resistance provided by an isokinetic machine moves at some pre-set speed, regardless of the torque applied to it by the individual, thus, the key to isokinetic exercise is not the resistance but the speed at which the resistance can be moved.[101]

Advantages for this type of exercise:

- Both high-speed/low-resistance and low-speed/high-resistance regimens result in excellent strength gains.[7–10]
- Both concentric and eccentric resistance exercises can be performed on the machines.
- Provides objective and quantifiable measurements of muscular strength.
- The machines provide maximum resistance at all points in the range of motion as a muscle contracts.
- The gravity-produced torque created by the machine adds to the force generated by the muscle when it contracts resulting in a higher torque output than it actually created by the muscle.

Disadvantages of this type of exercise:

- Expense. Isokinetic machines, which rely on hydraulic, pneumatic, and mechanical pressure systems, are very

expensive, with purchase prices ranging between $50,000 and $80,000.
- Requires maximal effort to work effectively.
- The increased potential for impact loading and incorrect joint axis alignment.[11]
- Questionable functional carryover.[12]

Increasing Muscle Endurance

It is well established that endurance training results in enhanced performance and delayed onset of fatigue during endurance exercise. Endurance exercise training also leads to a shift of skeletal muscle mitochondria toward an increased use of lipids as a substrate source both at the same absolute and at the same relative exercise intensity.[14,102]

Muscular endurance training is typically prescribed during the general preparation phase of training to prepare the body for the increased work demands that will be required, and to program the body's neuromuscular coordination systems. It is worth remembering that working at a level to which the muscle is accustomed improves the endurance of that muscle but does not increase its strength.

To increase muscle endurance, exercises are performed against light resistance for many reps (no fewer than 20 per set) so that the amount of energy expended is equal to the amount of energy supplied. The amount of weight used during muscular endurance training can be determined by using a RPE scale, in which 1 is very light exertion and 10 is intense exertion. Using the example of a bench press, if an athlete plans to work at around level 3 and his maximum weight for the bench press is 220 pounds, he should reduce his workout weight by 70% (154 pounds) and increase the number of reps.

The number of reps used is a factor of the speed of one rep, and how many reps the athlete can complete in 60 seconds. For example, if under normal training conditions the athlete takes 3 seconds to raise the weight during a biceps curl and 3 seconds to lower it, the muscle is under tension for 6 seconds and the athlete is working at a speed of 10 reps per minute. By increasing the speed of the rep to 4 seconds (the time the muscle is under tension), the athlete must achieve at least 15 reps in order to build muscular endurance.

The major drawback of muscular endurance training is the increased potential for overuse injuries. This can be offset by manipulating one or more of the training variables, such as sets, loads, tempo, rest periods between sets, number of exercises, hand position, and grip width.

Increasing Muscle Power

Power is increased by having a muscle work dynamically against resistance within a specified period. In the context of rehabilitation, plyometric training can be viewed as the bridge between pure strength and sports-related exercises.[103]

Plyometrics. It has been demonstrated that when a concentric contraction is preceded by a phase of active or passive stretching, elastic energy is stored in the muscle. This stored energy is then used in the subsequent contractile phase. For example, during some functional activities, such as jumping, the movement involves an eccentric loading of a muscle or muscle group, followed immediately by a concentric muscle action, as part of a stretch-shortening cycle.[81] The eccentric/concentric actions utilize the stretch reflex or stretch-shortening cycle in which the muscle is preloaded with energy during the eccentric phase (much like stretching a rubber band apart) and the release of that stored energy for subsequent muscular actions (releasing the rubber band).[104] The stored elastic energy within the muscle is used to produce more force than can be provided by a concentric contraction alone (see later).[105–107]

The goal of plyometric training is to decrease the amount of time required between the yielding eccentric muscle contraction and the initiation of the overcoming concentric contraction.[108]

The training system of plyometrics is credited to Yuri Verhoshanski,[109] the renowned Soviet jump coach of the late 1960s, although the actual term *plyometrics* was first introduced in the mid-1970s by an American track coach Fred Wilt.[110] The term *plyometrics*, when broken down to the roots of the words, is a little confusing. *Plyo* comes from the Greek word *pleythein*, which means to increase, and *metric*, which means to measure. Plyometrics is associated with an enhancement of the ability of the muscle–tendon unit to produce maximal force in the shortest amount of time through activation of the myotatic reflex.[106,111–113] The tendon portion of the muscle–tendon unit has been found to be the main contributor to muscle–tendon unit length changes and the storage of elastic potential energy.[114]

Movement patterns in both athletics and activities of daily living involve repeated stretch-shortening cycles, in which an eccentric movement must be stopped and converted into a concentric movement in the opposite direction. When a muscle contracts in a concentric fashion, most of the force produced comes from the muscle fiber filaments sliding past one another. Force is registered externally by being transferred through the series elastic component of the muscle, and as the muscle lengthens like a spring during the eccentric contraction, the series elastic component is also stretched and contributes to the overall force production.[108]

Acceleration and deceleration are the most important components of all task-specific activities.[22] These activities use variable speed and resistance throughout the range of contraction, stimulating neurologic receptors and increasing their excitability. The nerve receptors involved in plyometrics are the muscle spindle, the Golgi tendon organ, and the joint capsule/ligamentous receptors (see Chap. 3). These neurologic receptors play an important role in fiber recruitment and physiologic coordination. Plyometric activities serve to improve the reactivity of these receptors. Two other reflex mechanisms, which result from neural signals generated by muscle receptors that project back to the muscle of origin as well as other muscles, can be initiated during plyometric exercise and may assist with motor coordination and joint stability:[115]

- ***Length feedback.*** These signals, generated by muscle stretch, occur around the same time frame as the stretch reflex, and serve to link muscles that are synergists through excitatory feedback and those with opposite actions by reciprocal inhibition.[116] Length feedback also links

monoarticular muscles with excitatory feedback and contributes to joint stiffness.[116]

- ***Force feedback***. These are signals generated by muscle force, which are provided by stimulation of the Golgi tendon organ, and which connect muscles that cross different joints and exert torque in different directions through inhibitory feedback. Force feedback regulates coupling between joints.[116]

Together, length and force feedback induced during the loading phase of a plyometric activity have the potential to improve neuromuscular control.[115]

The physiology of plyometrics can be broken down into a number of phases:

1. A loading phase (eccentric, deceleration, setting, yielding, or cocking phase), in which the muscle–tendon units of the prime movers and synergists are stretched as a result of kinetic energy or loading applied to the joint and begin to perform negative work.[115] Stretching of the muscle–tendon unit during this phase elicits the stretch-shortening cycle, which results in enhanced force production and performance when compared to the absence of stretch.[46] Stretch of active muscle during the loading phase elicits two mechanisms associated with the stretch-shortening cycle: muscle "potentiation" and activation of the muscle spindle[115]:
   - *Muscle potentiation*. An alteration of the muscle contractile properties that leads to higher force production through an increase in the proportion of cross-bridges attached to actin and a decrease in the cross-bridge detachment rate.
   - *Muscle spindle activation*. Sensory information from the muscle spindle is passed through a monosynaptic reflex loop to provide excitatory feedback to the same muscle (see Chap. 3). This results in short-latency reflex muscle activity (myotatic or stretch reflex). However, the stretch reflex may not be elicited in all muscles that are stretched during a plyometric activity. Monoarticular muscles are consistently activated, but biarticular muscles are not. Differences in reflex muscle activity between monoarticular and biarticular muscles may be explained by differences in muscle length changes during loading. In certain activities, some of the fascicles of biarticular muscles undergo lengthening (eccentric action), while the other muscle fascicles act nearly isometrically. This suggests that monoarticular muscles may benefit more than biarticular muscles from stretch reflex force augmentation for enhanced work output.
2. A coupling (amortization, transmission, pay-off, or reversal) phase: This phase marks the transition between the loading phase and the unloading phase.[46] The coupling phase, the definitive phase of plyometric exercise, is generally a period of quasi-isometric muscle action.[115] If this transition phase is not continuous, the activity will no longer be considered plyometric because the benefits of the stretch-shortening cycle will be lost.[115]
3. An unloading phase: The unloading (rebound, shortening, push-off, or propulsion) phase of a plyometric exercise occurs immediately after the coupling phase and involves shortening of the muscle–tendon unit. In the biphasic analysis of plyometric jumps, the unloading phase begins at the start of upward movement of the center of mass and ends when ground contact ceases.[117] Most plyometric activities terminate in a momentum phase, during which body segments continue to move as a result of the forces generated in the unloading phase.[115]

By reproducing these stretch-shortening cycles at positions of physiologic function, plyometric activities stimulate proprioceptive feedback to fine-tune muscle activity patterns. Stretch-shortening exercise trains the neuromuscular system by exposing it to increased strength loads and improving the stretch reflex[46] (see Chap. 3). The degree of performance enhancement during the momentum phase is dependent on the magnitude of the forces and quickness of movement during the plyometric activity.[115] In particular, higher forces are associated with a shorter coupling phase[118] and greater energy storage in the series elastic component.[119] Performance is also a consequence of the total contact duration (loading through unloading phases), because as the contact duration becomes shorter, higher forces and joint moments are generated[120] and the tendon contribution to work is increased.[115,121]

The mechanisms by which performance is enhanced during plyometric exercise depend on a number of factors:

- The activity must impart higher forces and faster speeds of movement.
- Prolonged contact times should be avoided. The goal of plyometric training is to decrease the amount of time required between the loading phase and the initiation of the overcoming concentric contraction. Prolonged contact times may result when the intensity is too high during the loading phase or when the transition between the loading and unloading phases is not continuous.[115]
- Plyometric exercises must be initiated at a lower intensity and progressed to more difficult, higher-intensity levels according to tolerance. Before initiating plyometric exercises, the clinician must ensure that the patient has an adequate strength and physical condition base.[46] Initially, the patient is instructed to perform fewer sets and reps. Later, the patient is permitted to do more sets, but not more reps.

Plyometric exercises were traditionally designed to enable lower extremity muscles—primarily the thighs, quadriceps, hamstrings, and calves—to attain maximal power using high-intensity workouts in short spurts of hops, leaps, or bounds. Therefore, care should be taken when applying the physiological principles derived from lower extremity investigations to upper-body and trunk applications, as it is unknown whether the upper extremity and trunk will respond in similar manner.[115] Plyometrics are typically introduced into the rehabilitation program in the later stages as many plyometric exercises, even at low intensities, expose joints to substantial forces and movement speeds.[115] Plyometric exercise is indicated for those patients who desire to return to activities that include explosive movements. Contraindications for initiating plyometric exercise are acute inflammation

or pain, immediate postoperative status, and joint instability.[46] Joint pathologies such as arthritis, bone contusion, or chondral injury are relative contraindications, depending on the ability of the tissue to tolerate the high forces and joint loading required in many plyometric activities.[115] Musculotendinous injury is also a relative contraindication until the tissue is able to handle the rapid and high forces of a plyometric exercise.[115]

Guidelines for initiating plyometric exercise in rehabilitation are poorly developed. Most of the criteria have been established for high-intensity exercise in uninjured athletes and are grounded in opinion rather than research.[115] For example, it has been suggested that plyometric exercise should be initiated only after achieving the ability to perform one rep of a parallel squat with a load of 1.5–2.5 times body mass on the back and/or squat 60% of body mass 5 times within 5 seconds (lower extremity), and a bench press with one-third of body weight and/or perform five hand clap pushups (upper extremity).[103] In addition, success in the static stability tests[91] (Table 12-9) and dynamic stability tests (vertical jump for the lower extremities and medicine ball throw for the upper extremities) have also been used as a measure of preparation.[21]

Many different activities and devices can be used in plyometric exercises. Plyometric exercises may include diagonal and multiplanar motions with tubing or isokinetic machines. These exercises may be used to mimic any of the needed motions and can be performed in the standing, sitting, or supine positions. Generally, 48–72 hours of rest is recommended for recovery between plyometric training sessions.[122]

Lower Extremity Plyometric Exercises. Lower extremity plyometric exercises involve the manipulation of the role of gravity to vary the intensity of the exercise (Table 12-10). Thus, plyometric exercises can be performed horizontally or vertically.

- Horizontal plyometrics are performed perpendicular to the line of gravity. These exercises are preferable for most initial clinical rehabilitation plans because the concentric force is reduced and the eccentric phase is not facilitated.[21] Examples of these types of exercises include pushing a sled against resistance, and a modified leg press that allows the subject to push off and land on the foot plate.
- Vertical plyometric exercises (against or with gravitational forces) are more advanced. These exercises require a greater

level of control.[21] The drop jump is an example—the subject steps off a box, lands, and immediately executes a vertical jump.

The footwear and landing surfaces used in plyometric drills must have shock-absorbing qualities, and the protocol should allow sufficient recovery time between sets to prevent fatigue of the muscle groups being trained.[123]

Upper Extremity Plyometric Exercises. Plyometric exercises for the upper extremity involve relatively rapid movements in planes that approximate normal joint function. For example, at the shoulder this would include flexion or abduction at the shoulder, trunk rotation and diagonal arm motions, and rapid external and internal rotation exercises.

Plyometrics should be performed for all body segments involved in the activity. Hip rotation, knee flexion and extension, and trunk rotation are power activities that require plyometric activation. Plyometric exercises for the upper extremity include push-offs (Fig. 12-3), corner push-ups, and weighted ball throws (Fig. 12-4). Medicine and other weighted balls are very effective plyometric devices. The weight of the ball creates a prestretch and an eccentric load when it is caught. This combination creates resistance and demands a powerful agonist contraction to propel it forward again. The exercises can be performed using one arm or both arms at the same time. The former emphasizes trunk rotation and the latter emphasizes trunk extension and flexion, as well as shoulder motion.

A variety of positive changes in athletic performance and neuromuscular function have been attributed to plyometric training, predominantly in the lower extremity:[115]

- Increased maximal vertical jump height.[124]
- Increased leg strength, especially when combined with weight training.[124]
- A faster rate of force development during jumping.[125]
- Delayed onset of muscle fatigue during jumping.[126]
- Correction of neuromuscular imbalances.[127]

Due to the scarcity of research on upper extremity performance plyometric training, the improvements in upper extremity performance remain largely anecdotal. It is also unknown whether patients recovering from injury will respond to plyometric exercise in a manner similar to uninjured subjects.[115]

Contraindications to Strengthening, Endurance, and Power Exercises

Absolute contraindications to exercise include unstable angina, uncontrolled hypertension, uncontrolled dysrhythmias, hypertrophic cardiomyopathy, and certain stages of retinopathy. Patients with congestive heart failure, myocardial ischemia, poor left ventricular function, or autonomic neuropathies must be carefully evaluated before initiating an exercise program.

A number of precautions need to be taken when exercising patients who have a compromised cardiovascular or pulmonary system (see Chap. 15):

- An appropriate level of intensity must be chosen.
- Too high a level can overload the cardiorespiratory and muscular systems and potentially cause injuries.
- Exercising at the level it is too high causes the cardiorespiratory system to work anaerobically, not aerobically.

- A sufficient period of time should be allowed for warm-up and cool-down to permit adequate cardiorespiratory and muscular adaptation.

Increasing Joint Stabilization

According to Voight,[128,129] the standard progression for stabilization exercises involves:

- Static stabilization exercises with closed chain loading and unloading (weight shifting). This phase initially employs isometric exercises around the involved joint on solid and even surfaces, before progressing to unstable surfaces. The early training involves balance training and joint repositioning exercises, and is usually initiated (in the lower extremities according to weight-bearing restrictions) by having the patient placing the involved extremity on a 6–8 inch stool, so that the amount of weight bearing can be controlled more easily. The proprioceptive awareness of a joint can also be enhanced by using an elastic bandage, orthotic, or through taping.[130–135] As full weight bearing through the extremity is restored, a number of devices such as a mini-trampoline, balance board, stability ball, and wobble board can be introduced. Exercises on these devices are progressed from double limb support, to single leg support, to support while performing sports-specific skills.

CLINICAL PEARL

A stability ball creates an unstable base, which challenges the postural stabilizer muscles more than using a stable base. It is important to choose the correct and appropriate size of stability ball, which is dependent upon patient size

45 cm ball: shorter than 5′

55 cm ball: 5′ to 5′ 8″

65 cm ball: 5′ 9″ to 6′3″

75 cm ball: taller than 6′3″

With the patient sitting on the ball with both feet firmly planted on the ground, the patient's thigh should be parallel to the floor (the knee may be slightly above the hips).

- Pumping up the ball to increase firmness increases the level of difficulty in any given exercise.
- The further away the ball is from the support points, the greater the demand for core stability.
- Decreasing the number of support points increases the difficulty of the exercise.

- Transitional stabilization exercises. The exercises during this phase involve conscious control of motion without impact, and replace isometric activity with controlled concentric and eccentric exercises throughout a progressively larger range of functional motion. The physiological rationale behind the exercises in this phase is to stimulate dynamic postural responses, and to increase muscle stiffness. Muscle stiffness (see Chap. 2) has a significant role in improving dynamic stabilization around the joint, by resisting and absorbing joint loads.[136]
- Dynamic stabilization exercises. These exercises involve the unconscious control and loading of the joint, and introduce both *ballistic* and *impact* exercises to the patient.

A delicate balance between stability and mobility is achieved by coordination between muscle strength, endurance, flexibility, and neuromuscular control.[137]

The neuromuscular mechanism that contributes to joint stability is mediated by the articular mechanoreceptors (see Chap. 3). These receptors provide information about joint position sense and kinesthesia.[134,135,138,139] Initially, closed-chain exercises are performed within the pain-free ranges or positions. Open chain exercises may be built upon the base of the closed chain stabilization to allow normal control of joint mobility.

The emphasis during these exercises is to concentrate on functional positioning during exercise rather than isolating open and closed chain activities.[137] The activities should involve sudden alterations in joint positioning that necessitate reflex muscular stabilization coupled with an axial load.[135,137] Such activities include rhythmic stabilization (an isometric contraction of the agonist followed by an isometric contraction of the antagonist) performed in both a closed and an open chain position,[140] and in the functional position of the joint.[137] The use of a stable, and then unstable, base during closed chain exercises encourages co-contraction of the agonists and antagonists.[140]

Weight shifting exercises are ideal for this. For example, the following weight shifting exercises may be used for the upper extremity:

- Standing and leaning against a treatment table or object.
- In the quadruped position, rocking forward and backward with the hands on the floor or on an unstable object.
- Kneeling forward in the three-point position (with one hand on the floor). A Body Blade® can be added to this exercise to increase the difficulty (Fig. 12-5).
- Kneeling in the two-point position (high-kneeling) (Fig. 12-6).
- Weight shifting on a Fitter® while in a kneeling position (Fig. 12-7).
- Weight shifting on a Swiss ball with the feet elevated on a support, and both hands on the Swiss ball in the push-up position (Fig. 12-8). The exercise can be made more difficult by raising the height of elevation of the feet, such as placing the feet on a chair.
- Slide board exercises in the quadruped position moving hands forwards and backwards, in opposite diagonals and in opposite directions.

Integration of the Entire Kinematic Chain

Although force-dependent motor firing patterns should be reestablished, special care must be taken to completely integrate all of the components of the kinetic chain to generate and funnel the proper forces to the appropriate joint. It should be

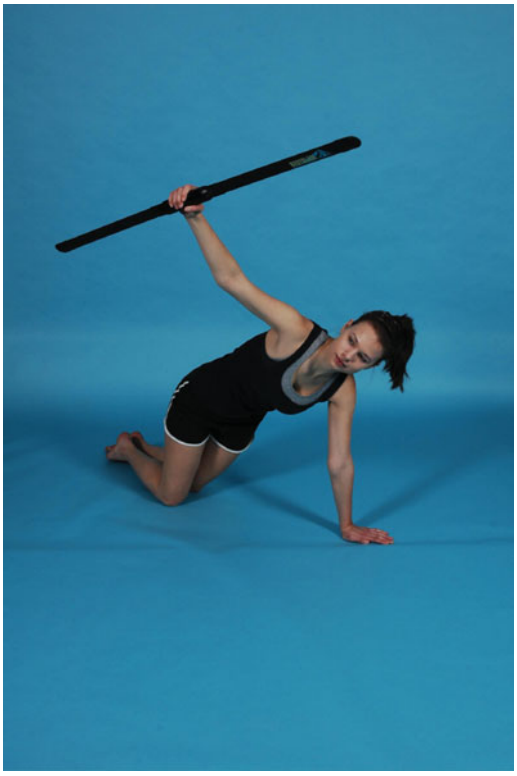

FIGURE 12-5 Three point kneeling with Bodyblade.

FIGURE 12-7 Weight shifting on a Fitter® while in a kneeling position.

clear that for a kinematic chain to operate efficiently, there must be an optimal sequential activation of the limb segments involved. This then allows for an efficient generation and transfer of force along the kinematic chain.[141] When choosing a mode of kinematic exercise, the variables of each type of exercise must be considered. The clinician should understand the principles of exercise application and the differences between open kinematic chain (OKC) and closed kinematic chain (CKC) movements, in order to accomplish a specific intervention goal (Table 12-11). A number of studies have

FIGURE 12-6 Hi-kneeling.

FIGURE 12-8 Weight shifting on a Swiss ball.

TABLE 12-11 Differential Features of OKC and CKC Exercises

Exercise Mode	Characteristics	Advantages	Disadvantages
Open kinematic chain	1. Single muscle group 2. Single axis and plane 3. Emphasizes concentric contraction 4. Non–weight-bearing	1. Isolated recruitment 2. Simple movement pattern 3. Isolated recruitment 4. Minimal joint compression	1. Limited function 2. Limited function 3. Limited eccentrics 4. Less proprioception and joint stability with increased joint shear forces
Closed kinematic	1. Multiple muscle groups 2. Multiple axes and planes 3. Balance of concentric and eccentric contractions 4. Weight-bearing exercise	1. Functional recruitment 2. Functional movement patterns 3. Functional contractions 4. Increase proprioception and joint stability	1. Difficult to isolate 2. More complex 3. Loss of control of target joint 4. Compressive forces on articular surfaces

Data from Greenfield BH, Tovin BJ: The application of open and closed kinematic chain exercises in rehabilitation of the lower extremity. *J Back Musculoskel Rehabil* 2:38–51, 1992.

illustrated the importance of the sequential activation of these links.[142,143] The benefit of closed kinematic chain exercises (CKCE) over open kinematic chain exercises (OKCE) is based on the premise that CKCEs, particularly in the lower extremities, appear to replicate functional tasks better than OCKEs. This is because the CKCEs appear to allow the entire linkage system of the kinematic chain to be exercised together.[45,74,144–150] In addition, CKCEs have been shown to enhance joint congruency, decrease the shearing forces, and stimulate the articular mechanoreceptors using axial loading and increased compressive forces.[147,151–155] Thus, CKC activities are purported to help reinforce the synchronization of the necessary muscle-firing patterns for both antagonist and agonist muscle groups used during stabilization and ambulation.[45] However, there also appears to be much in the literature to suggest that OKCEs have a beneficial effect on function,[8,156,157] especially when combined with specific closed chain exercises or when used to strengthen individual muscles.[144]

A comprehensive rehabilitation program thus should integrate the entire kinematic chain, using a blend of OKCEs and CKCEs. This integration must occur during functional exercises, with the emphasis determined by the activity to be restored.

CLINICAL PEARL

The rehabilitation of the kinematic chain should address the strength and flexibility of the entire kinematic chain, using the principle of specificity, with the specific elements of the rehabilitation program being determined by both the existing pathology and the functional goals of the patient.[144,158]

In addition, under the concept of specificity, rather than isolating OKCEs or CKCEs, it may be wise to emphasize functional positioning during the exercise training, while striking a balance between mobility and stability.[144,159]

Several objectives must be met if the rehabilitation of the functional kinematic chain is to be comprehensive.[144]:

1. The first objective in the rehabilitation program, the healing phase, is the restoration of functional stability, which is the ability to control the translation of the joint during dynamic functional activities, through the integration of both the primary and the secondary stabilizers.[160]
2. The second objective, the functional phase, is to restore sports- or functional-specific movement patterns. The functional phase begins once the patient has near-full, pain-free ROM.
3. The final objective is assessing the readiness of the patient to return to his or her prior level of function or level of athletic performance.

REVIEW QUESTIONS*

1. What are the four biomechanical properties of skeletal muscle?
2. Give three examples of a muscle that cross two or more joints.
3. What are the three main types of muscle contraction?
4. Define the characteristics of an isotonic contraction.
5. True/false: Rapid lengthening contractions generate more force than do slower lengthening contractions.

*Additional questions to test your understanding of this chapter can be found in the Online Learning Center for Orthopaedic Assessment, Evaluation, and Intervention at www.duttononline.net.

Improving Range of Motion and Flexibility

CHAPTER 13

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Define the different types of range of motion (ROM).
2. Describe strategies to increase ROM.
3. Describe the indications and contraindications for the various types of ROM exercises.
4. Define active insufficiency and passive insufficiency of a muscle.
5. Outline the indications and contraindications for continuous passive motion (CPM).
6. Define flexibility and describe its importance in rehabilitation.
7. List and describe two types of flexibility.
8. Describe strategies to increase flexibility using different techniques.

OVERVIEW

The terms *range of motion* and *flexibility* are often used synonymously by clinicians, yet they are not the same.

- Range of motion (ROM) refers to the distance and direction a joint can move. Each specific joint has a normal ROM that is expressed in degrees. Within the field of physical therapy, goniometry is commonly used to measure the total amount of available motion at a specific joint. ROM of a joint may be limited by the shape of the articulating surfaces and by capsular and ligamentous structures surrounding that joint.
- Flexibility refers to the ability to move a joint or series of joints through a full, nonrestricted, injury, and pain-free ROM. Flexibility is dependent on a combination of joint ROM, muscle flexibility, and neuromuscular control. When injury occurs, there is almost always some associated loss of the ability to move normally due to the pain, swelling, muscle guarding, or spasm. The subsequent inactivity results in a shortening of connective tissue and muscle, loss of neuromuscular control, or a combination of these factors.[1]

A decrease in ROM and/or in the flexibility of one joint can affect the entire kinetic chain. For example, a decreased ROM or flexibility in the shoulder can impact the function of the entire arm. In order to provide a treatment for a loss of movement, the clinician must make the determination as to the specific cause i.e., loss of ROM or decreased flexibility. For example, is the specific cause due to joint effusion, adaptive shortening of connective tissue structures, changes in bony architecture, or alignment of the articular surfaces?

RANGE OF MOTION AND FLEXIBILITY

Normal flexibility and ROM are necessary for efficient movement. Joint movement may be viewed as the amount of joint ROM, the arthrokinematic glide that occurs at the joint surfaces, termed *joint play*, whereas flexibility is determined by the degree of extensibility of the periarticular and connective tissues that cross the joint. A number of anatomic factors can limit the ability of a joint to move through a full, unrestricted ROM. These include

- muscles and their tendons
- connective tissue
- bone
- adipose tissue
- skin
- neural tissue

When referring to ROM, three major movements are recognized:[1]

- Active range of motion (AROM). AROM, also called dynamic flexibility, refers to the degree to which a joint can be moved by a single muscle contraction, usually through the mid range of movement. Active ROM does not maintain or increase strength, or develop skill or coordination except in the movement patterns used.

- Active assisted range of motion (AAROM). AAROM is AROM where the effect of gravity has been removed. For example, performing shoulder abduction while lying supine.
- Passive range of motion (PROM). PROM refers to the degree to which a joint can be passively moved to the endpoint in the ROM. PROM is important for injury prevention. Passive ROM does not prevent muscle atrophy, increase strength or endurance, or assist circulation to the same extent that active, voluntary muscle contraction does.

When referring to flexibility, two types are recognized, static and dynamic.

CLINICAL PEARL

In the early stages of the rehabilitation process, ROM exercises are performed in the following sequence: PROM→AAROM→AROM. It is important to remember when making the transition from PROM to AAROM or AROM, that gravity has a significant impact especially in individuals with weak musculature. These individuals may require assistance when the segment moves up against gravity, or moves downward, with gravity.

- Static flexibility. Static flexibility is defined as the range or motion available to a joint or series of joints.[2,3] Increased static flexibility should not be confused with joint hypermobility, or laxity, which is a function of the joint capsule and ligaments. Decreased static flexibility indicates a loss of motion. The end-feel encountered may help the clinician differentiate the cause among adaptive shortening of the muscle (muscle stretch), a tight joint capsule (capsular), and an arthritic joint (hard). Static flexibility can be measured by a number of tests, such as the toe touch and the sit and reach, both of which have been found to be valid and reliable.[4,5]
- Dynamic flexibility. Dynamic flexibility refers to the ease of movement within the obtainable ROM. Dynamic flexibility is measured actively. The important measurement in dynamic flexibility is *stiffness*, a mechanical term defined as the resistance of a structure to deformation.[6,7] An increase in ROM around a joint does not necessarily equate to a decrease in the passive stiffness of a muscle.[8–10] However, strength training, immobilization, and aging have been shown to increase stiffness.[11–14] The converse of stiffness is pliability. When a soft tissue demonstrates a decrease in pliability, it has usually undergone an adaptive shortening, or an increase in tone, termed *hypertonus.* There is a growing research to suggest that the limiting factors to preventing increases in ROM are not only the connective tissues but are also the result of neurophysiological phenomena controlled by the higher centers of the central nervous system (CNS).[15]

ENHANCING RANGE OF MOTION AND FLEXIBILITY

A number of factors influence connective tissue deformation:

- Sensory receptors. Two sensory receptors that monitor muscle activity, the muscle spindle and Golgi tendon organs (GTOs) (see Chapter 3), play an important role when attempting to increase flexibility through stretching. These two receptors can activate both spinal reflexes and long-loop pathways involving supraspinal centers. When a muscle is stretched, both the muscle spindles and the GTOs immediately begin sending a stream of sensory impulses to the spinal cord. Initially, impulses coming from the muscle spindles notify the CNS that the muscle is being stretched. Impulses return to the muscle from the spinal cord, causing the muscle to reflexively contract, thus resisting the stretch.[1] The GTOs respond to the change in length and the increasing tension by firing off sensory impulses of their own to the spinal cord and, if the stretch of the muscle continues for an extended period of time (at least 6 seconds), impulses from the GTOs begin to override muscle spindle impulses and cause a reflex relaxation of the antagonist muscle (autogenic inhibition).[1]

CLINICAL PEARL

In any synergistic muscle group, a contraction of the agonist causes a reflex relaxation in the antagonist muscle, allowing it to stretch and protect it from injury—this phenomenon is referred to as reciprocal inhibition.[1]

- Tissue temperature. At temperatures above 37°C (98.6°F), the cross-links between collagen fibrils are broken more easily and more rapidly, with the most profound changes occurring between 40–45°C (104–113°F).[16,17] A number of key points must be remembered by the clinician in order to effectively manipulate temperature:[18]
  - The amount of force required to attain/maintain a desired deformation decreases as temperature increases.
  - The time required to deform collagen to the point of failure is inversely related to temperature.
  - The higher the temperature, the greater the load collagen is able to tolerate before failure.
  - The higher the temperature, the greater the amount of deformation possible before failure.

It is important to make a distinction between stretching and warm-up as the two are not synonymous but often confused by the layman. While stretching places neuromusculotendinous units and their fascia under tension, a warm-up requires the performance of an activity that raises total body and muscle temperatures to prepare the body for exercise.[19] Research has shown that warm-up prior to stretching results in significant changes in joint ROM.[20] Anecdotally, it would make sense not to perform stretching at the beginning of the warm-up routine because the tissue

temperatures are too low for optimal muscle–tendon function, and are less compliant and less prepared for activity. Some advocate stretching after an exercise session, citing that the increased musculotendinous extensibility leads to the potential for improved joint flexibility.[21] In one study, static stretching was done before, after, and both before and after each workout. All produced significant increases in ROM.[22]

- The amount of force used. Viscoelastic changes are not permanent, whereas plasticity changes, which are more difficult to achieve, result in a residual or permanent change in length. The key factor for any change in connective tissue length is the deforming force, in particular the magnitude and velocity applied. The application of low-load, long duration forces is recommended. A muscle usually requires a greater stretching force initially, possibly to break up adhesions or cross-linkages, and to allow for viscoelastic and plastic changes to occur in the collagen and elastin fibers.[23] Frequent stretching ensures that the lengthening is maintained before the muscle has the opportunity to recoil to its shortened state.[24]
- The direction of the stretch. To stretch a muscle appropriately, the stretch must be applied parallel to the muscle fibers. The orientation of the fibers can be determined by palpation. Typically, in the extremities, the muscle fibers run parallel to the bone.

A variety of stretching techniques can be used to increase the extensibility of the soft tissues.

Static Stretching. Static stretching involves the application of a steady force for a sustained period (Table 13-1). The stretch should be performed at the point just shy of the pain, although some discomfort may be necessary to achieve results.[23] Small loads applied for long periods produce greater residual lengthening than heavy loads applied for short periods.[25] Restoration of normal length of the muscles may be accomplished using the guidelines outlined in Table 13-1. Weighted traction or pulley systems may be used for this type of stretching. It is important for the patient to realize that the initial session of stretching may increase symptoms.[26] However, this increase in symptoms should be temporary, lasting for a couple of hours, at most.[24,27]

Dynamic Stretching. Dynamic stretching involves stretching by a muscular contraction to increase or decrease the joint angle where the muscle crosses, thereby elongating the musculotendinous unit as the end ROM is obtained[21] Dynamic stretching is a specific warm-up using activity-specific movements to prepare the muscles by taking them through the movements used in a particular sport.[21] Dynamic stretching does not incorporate end-range ballistic movements but rather the use of controlled movements through a normal ROM.[21]

There is some debate as to whether the static or dynamic method is better to stretch a muscle. Static stretching is considered the gold standard in flexibility training.[28] However, recent studies have found that static stretching is not an effective way to reduce injury rates,[29,30] and may actually inhibit athletic performance.[31] This is likely because the nature of static stretching is passive and does nothing to warm a muscle.[32] More dynamic methods of stretching involve either a contraction of the antagonist muscle group thus allowing the agonist to elongate naturally in a relaxed state, or eccentrically training a muscle through its full ROM.[28] The latter method would appear to address the problem that most injuries occur in the eccentric phase of activity.[29] A study by Nelson[28] that compared the immediate effect of static stretching, eccentric training, and no stretching/training on hamstring flexibility in high school and college athletes (75 subjects) found the flexibility gains in the eccentric training group to be significantly greater than the static stretch group.

TABLE 13-1 Static Stretching Guidelines

- Heat should be applied to increase intramuscular temperature prior to, and during, stretching[1–4] This heat can be achieved with either through low-intensity warm-up exercise, or through the use of thermal modalities. The application of a cold pack following the stretch is used to take advantage of the thermal characteristics of connective tissue, by lowering its temperature and thereby theoretically prolonging the length changes—the elasticity of a muscle diminishes with cooling.[1–4]
- Effective stretching, in the early phase, should be performed every hour, but with each session lasting only a few minutes.
- With true muscle shortness, stronger resistance is used to activate the maximum number of motor units, followed by vigorous stretching of the muscle.
- Stretching should be performed at least three times a week using:
  - Low force, avoiding pain
  - Prolonged duration.
  - Rapid cooling of the muscle while it is maintained in the stretched position

Proprioceptive Neuromuscular Facilitation. The proprioceptive neuromuscular facilitation (PNF) techniques of contract–relax (CR), an agonist contraction (AC), or a contract-relax-agonist contraction sequence (CRAC) can be used to actively stretch the soft tissues:[1]

- CR. CR stretching begins as does static stretching in that the clinician supports the patient and brings a limb to the end of ROM until gentle stretching is felt. At that point, the clinician asks the patient to provide an isometric contraction of the muscle being stretched (the antagonist) for approximately 2 to 5 seconds after which the patient is asked to relax the muscle. The clinician moves the limb passively into the new range until a limitation is again felt and repeats the procedure two to four times.
- AC. AC stretching uses the principle of reciprocal inhibition. The clinician moves the limb to the position of gentle stretch and asks the patient for a contraction of the

muscle opposite the muscle being stretched (the antagonist). For example, when stretching the hamstring muscles, a simultaneous contraction of the quadriceps muscles can facilitate the stretch of the hamstrings. The contraction is held for 2 to 5 seconds and the technique is repeated 2 to 4 times.

- CRAC. This technique combines the CR and AC stretches. The clinician takes the limb to the point of gentle stretch and performs a CR sequence (i.e., resistance applied against the muscle being stretched). After contracting the muscle being stretched, the patient is asked to relax this muscle while contracting the opposing muscle group (antagonist), thus facilitating the stretch. For example, when stretching the hamstring muscles, the hamstrings are brought to a position stretch, the hamstrings are then contracted against resistance, and then relaxed, and then the quadriceps are contracted.

The majority of studies have shown the PNF techniques to be the most effective for increasing ROM through muscle lengthening when compared to the static or slow sustained, and the ballistic or bounce techniques,[33–37] although one study found it to be not necessarily better.[38]

Other techniques that can assist in lengthening of contractile tissue through relaxation include the following:

- The application of heat, which increases the extensibility of the shortened tissues, will allow the muscles to relax in length and more easily, reducing the discomfort of stretching. Heat without stretching has little or no effect on long-term improvement in muscle flexibility, whereas the combination of heat and stretching produces greater long-term gains in tissue length than stretching alone.
- Massage, which increases local circulation to the muscle and reduces muscle spasm and stiffness.
- Biofeedback, which teaches the patient to reduce the amount of tension in a muscle.

Ballistic Stretching. This technique of stretching uses bouncing movements to stretch a particular muscle. The muscle is stretched by momentum created from the bouncing movement of the body supplying the tensile force used for the stretch.[21] The patient quickly relaxes the muscle when reaching the end of ROM. This is performed in a cyclical bouncing motion and repeated several times, thus engaging a neurological component called active resistance—the contraction of muscles that resist elongation in the form of muscle reflex activity.[21,39] In comparisons of the ballistic and static methods, two studies[40,41] have found that both produce similar improvements in flexibility. However, the ballistic method appears to cause more residual muscle soreness or muscle strain, than those techniques that incorporate relaxation into the technique.[42–44]

Further research is needed to determine the appropriate stretching frequency and duration for long-lasting changes in flexibility. Researchers have reported that techniques utilizing cyclic and sustained stretching for 15 minutes on five consecutive days increased hamstring muscle length, and that a significant percentage of the increased length was retained 1 week posttreatment.[45] Other researchers have reported that after using four consecutive knee flexor static stretches of 30 seconds, the new knee ROM was maintained for 3 minutes but had returned to prestretch levels after 6 minutes.[46] A similar study using a sequence of five modified hold–relax stretches reported producing significantly increased hamstring flexibility that lasted 6 minutes after the stretching protocol ended.[47] The specific duration, frequency, and number of stretching repetitions vary in the literature. Evidence to date has shown that stretches are generally held anywhere from 10 to 60 seconds, with the research recommending that stretches be held between 15 and 30 seconds.[21,48,49] In contrast, little research has been conducted on the number of repetitions of a stretch in exercise session, although it has been determined that 80% of the length changes occur in the first four stretches of 30 seconds each.[21,50] Current American College of Sports Medicine Guidelines recommend three to five repetitions for each stretching exercise.[51]

SELF-STRETCHING

Self-stretching techniques include any stretching exercise that is carried out independently by the patient after instruction and supervision. Self-stretching techniques are included at the end of each of the joint chapters.

CONTINUOUS PASSIVE MOTION

CPM refers to passive motion performed by a mechanical device that moves the joint slowly and continuously through a controlled ROM.[52] CPM machines have been designed for use on many body parts, including the hip, knee (most common), ankle, shoulder, elbow, wrist, and hand. The subject of CPM device use following surgery has been debated for years, with some surgeons advocating, and others opposing its use.

CLINICAL PEARL

CPM protocols vary significantly, ranging from 24 hours a day for as long as 1 month, to as little as 6 hours a day after surgery.

The CPM machine is calibrated in degrees of motion and cycles per minute.

The use of a CPM device has been promoted as a means to facilitate a more rapid recovery by improving ROM, decreasing length of hospital stay, and lowering the amount of narcotic use.[53–63] However, studies have shown that the effect of CPM devices on analgesia consumption, ROM, hospital stay, and complications has been variable:

- Data support the use of CPM to decrease the rate of manipulation for poor ROM after total knee arthroplasty (TKA).
- The use of CPM has not been shown to result in more long-term increases in ROM than other methods of early movement and positioning.

- Although it appears that the use of a CPM device does help regain knee flexion quicker post TKA, it is not as effective in the enhancement of knee extension.
- Knee impairments or disability are not reduced with the use of a CPM at discharge from hospital.
- Because of standardized inpatient hospital clinical pathways, the length of hospital stay is not decreased by the use of a CPM device but, depending on the hospital involved, the overall cost is not increased.
- Wound complications probably are not increased with the use of CPM, provided good technique is used in wound closure.

CLINICAL PEARL

- It is still not clear whether ROM is achieved faster and whether the prevalence of deep vein thrombosis (DVT) and analgesics use are decreased with CPM.

Indications

- Decrease soft tissue stiffness
- Increase short-term ROM, which may result in early discharge from the hospital
- Promote healing of the joint surfaces (promotes cartilage growth) and soft tissue.
- Prevention of adhesions and contractures and thus joint stiffness
- Decrease postoperative pain

Contraindications

- Nonstable fracture sites
- Excessive edema
- Patient intolerance

Application and Patient Preparation

The procedure is explained to the patient. Any wound area must be covered. The clinician adjusts the unit so that the patient's anatomical joint is aligned with the mechanical hinge joint of the machine. The patient's limb is secured in the machine using the safety straps. The clinician sets the beginning and end ROM degrees, and then turns the unit on. Typically a low arc of 20–30 degrees is used initially and is progressed 10–15 degrees per day as tolerated. The rate of motion is typically one cycle per 45 seconds to two minutes. The patient is monitored during the first few minutes to ensure correct fit and patient comfort. Treatment duration varies from one hour three times a day to 24 hours a day.

Improving Neuromuscular Control

CHAPTER 14

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Define the components of neuromuscular control.
2. Describe ways in which neuromuscular control can be improved through physical therapy.
3. Describe a number of exercises that can be used to improve neuromuscular control.
4. Provide examples to enhance balance retraining.
5. Explain the concepts related to stabilization retraining.

OVERVIEW

The entire rehabilitation process is focused on restoring function as quickly and as safely as possible. An important component of function is neuromuscular control. Neuromuscular control involves the detection, perception, and utilization of relevant sensory information in order to perform specific tasks. Successful performance of a task requires the intricate coordination of various body parts using information provided by peripheral receptors located in and around the articular structures (see chap. 3). This feedback provides information that assists with proprioception, balance, and neuromuscular control. It is now well accepted that neuromuscular control impairment can change movement patterns and increase the risk of musculoskeletal injury.

Neuromuscular rehabilitation (NMR) is a method of training the enhancement of these unconscious motor responses, by stimulating both the afferent signals and the central mechanisms responsible for dynamic joint control.[1] The aims of NMR are to improve the ability of the nervous system to generate a fast and optimal muscle-firing pattern, to increase joint stability, to decrease joint forces, and to relearn movement patterns and skills.[1] Before developing a neuromuscular training program, the faulty movement pattern or absent motor skill must be identified.[2] In addition, before initiating a neuromuscular training program, individuals must have adequate muscle strength to perform training exercises correctly. If weaknesses are present, training activities must begin at a more baseline level that includes weight training, technique instruction, and performing single plane versus multiplanar movements.[2] The three major components of NMR are proprioceptive retraining, balance retraining, and stabilization retraining.

PROPRIOCEPTIVE RETRAINING

Because afferent input is altered after joint injury, proprioceptive training must focus on the restoration of proprioceptive sensibility to retrain these altered afferent pathways and enhance the sensation of joint movement.[3] In designing exercises to improve three-dimensional dynamic lower extremity postural stability, the clinician should consider the following: [4]

- Postural differences between patients
- Lower extremity loading pathomechanics
- Hip, knee, and ankle joint positions for optimal muscle moment arm lengths
- The interplay between global and local proprioceptive mechanisms
- The concept of rehabilitating movements that facilitate the development of synergistic lower extremity muscle function

Although ROM and progressive resistance exercises (PREs) help reestablish joint proprioception, they are not as effective in restoring function as exercises that involve technique or task training. Technique or task training involves the performance of specific movements with an emphasis on proper technique, with the primary chosen movement being one that results in a large percentage of injuries, such as changing direction, transferring from sit to stand, or more advanced techniques such as performing a cut maneuver.[2] According to Voight,[3,5] the standard progression for proprioceptive retraining involves:

1. ***Static stabilization exercises with closed-chain loading and unloading (weight shifting).*** This phase initially employs isometric exercises around the involved joint on solid and even surfaces, before progressing to unstable surfaces. The early training involves balance training and joint repositioning exercises and usually is initiated (in the

lower extremities) by having the patient place the involved extremity on a 6–8-inch-high stool, so that the amount of weight bearing can be controlled more easily. The proprioceptive awareness of a joint can also be enhanced by using an elastic bandage or orthotic, or through taping.[6–11] As full-weight-bearing through the extremity is restored, a number of devices, such as a minitrampoline, balance board, Swiss ball, and wobble board, can be introduced. Exercises on these devices are progressed from double-limb support to single-leg support to full support while performing sports-specific skills.

2. ***Transitional stabilization exercises.*** The exercises during this phase involve conscious control of motion without impact and replace isometric activity with controlled concentric and eccentric exercises throughout a progressively larger range of functional motion. The physiologic rationale behind the exercises in this phase is to stimulate dynamic postural responses and increase muscle stiffness. Muscle stiffness has a significant role in improving dynamic stabilization around the joint, by resisting and absorbing joint loads.[12]
3. ***Dynamic stabilization exercises.*** These exercises involve the unconscious control and loading of the joint and introduce both ballistic and impact exercises to the patient.

A delicate balance between stability and mobility is achieved by coordination among muscle strength, endurance, flexibility, and neuromuscular control.[13] The neuromuscular mechanism that contributes to joint stability is mediated by the articular mechanoreceptors (see Chap. 3). These receptors provide information about joint position sense and kinesthesia.[10,11,14,15] The objective in NMR is to restore proximal stability, muscle control, and flexibility through a balance of proprioceptive retraining and strengthening.

Initially, closed kinetic chain exercises (CKCEs) are performed within the pain-free ranges or positions. Open kinetic chain exercises (OKCEs), including mild plyometric exercises, may be built upon the base of the closed-chain stabilization to allow normal control of joint mobility (see Chap. 12).

The neuromuscular emphasis during these exercises is on functional positioning during exercise rather than isolating open- and closed-chain activities.[13] The activities should involve sudden alterations in joint positioning that necessitate reflex muscular stabilization coupled with an axial load.[11,13] Such activities include rhythmic stabilization performed in both a closed- and an open-chain position[16] and in the functional position of the joint (see Chap. 12).[13] The use of a stable, and then an unstable, base during CKCEs encourages co-contraction of the agonists and antagonists.[16]

Following treatment of any joint, retraining of the muscles must be carried out to reestablish coordination. Proprioceptive neuromuscular facilitation (PNF) techniques are especially useful in this regard. PNF techniques require motions of the extremities in all three planes.[17] PNF techniques that use combinations of spiral and diagonal patterns are designed to enhance coordination and strength.[18] The diagonal patterns 1 and 2 (see Chap. 10) are appropriate, with resistance being added as appropriate.

BALANCE RETRAINING

Balance retraining focuses on the ability to maintain a position through both conscious and subconscious motor control. There are many factors to consider when developing an intervention program for balance impairment. As outlined in Chapter 3, impaired balance can be caused by injury or disease to any structures involved in the stages of information processing: somatosensory input, visual and vestibular input, sensory motor integration, and motor output generation.[19] The clinician needs to consider the patient's impairments across all systems and decide which impairments can be rehabilitated and which require compensation or substitution.

It is also important to determine the cause of the impairment—whether the problem results from musculoskeletal, neuromuscular, sensory, or cognitive (e.g., fear of falling) impairment.[20] The key elements of a comprehensive evaluation of individuals with balance problems include the following:[21]

- A thorough history of falls, including whether the onset of falls are sudden versus gradual; the frequency and direction of the falls; the environmental conditions, activities, presence of dizziness, vertigo, and lightheadedness at time of falls; current and past medications, and the presence of a fear of falling.
- Assessments to identify sensory input and/or sensory processing deficits, abnormal biomechanical and motor alignment, poor muscle strength and/or endurance, and decreased range of motion and/or flexibility. Of particular importance is core strength.[20]
- Assessment of coordination, and awareness of posture and the position of the body in space.
- Tests and observations to determine the impact of balance control system deficits on functional performance.
- Environmental assessments to determine full-risk hazards in a person's home.

Studies have shown that proprioception and kinesthesia do improve following rehabilitation.[10,11] For example, habituation exercises have proven beneficial for patients with acute unilateral vestibular loss, and adaptation and balance exercises have produced positive outcomes in patients with chronic bilateral vestibular deficits.[22] The type of intervention will depend on the deficits found during the clinical examination, and typically involves improving one or more of the following categories:[21]

- Static balance control
- Dynamic balance control
- Anticipatory balance control
- Reactive balance control
- Sensory reorganization
- Vestibular rehabilitation

Because balance training often involves activities that challenge the patient's limits of stability, it is important that the clinician takes steps to ensure the patient's safety. This includes the use of a gait belt, performing the exercises near

TABLE 14-1 Agility and Perturbation Training Examples

Activity	Progression
Sidestepping: the patient steps sideways, moving right to left and then left to right, approximately 10–20 feet, repeating two times in each direction for a total of four times.	The width of steps and the speed of steps are progressed every 1 to 2 sessions. The activity is initiated on a level surface and progressed to sidestepping over low obstacles when the patient is able to sidestep on level surfaces without difficulty.
Braiding activities: the patient combines front and back crossover steps while moving laterally (walking carioca). During each activity, the patient moves right to left and then left to right, approximately 10–20 feet, repeating two times in each direction for a total of four times.	The activity is progressed by increasing the width of steps and the speed of steps every 1 to 2 sessions.
Front and back crossover steps during forward ambulation: the patient crosses one leg in front of the other, alternating legs with each step, while walking forward approximately 10–20 feet. The patient then walks backwards to the start position while crossing one leg behind the other, alternating legs with each step.	Two repetitions are performed, beginning with partial crossover steps and progressing to full crossover steps when the patient's performance improves. The width of steps and the speed of steps can be progressed every 1 to 2 sessions.
Shuttle walking: plastic pylon markers are placed at distances of 5, 10, and 15 feet. The patient walks forward to the first marker, then returns to the start by walking backward. The patient then walks forward to the 10-foot marker, then returns to the 5-foot marker walking backward. The patient then walks to the 15-foot marker, returns to the 10-foot marker walking backward, then finishes by walking to the 15-foot marker.	The activity is progressed by increasing the width of steps and the speed of steps every 1 to 2 sessions.
Multiple changes in direction on command during walking: the clinician directs the patient to either walk forward, backwards, sideways, or on a diagonal by cueing the patient randomly with hand signals.	The duration of the exercise bout is approximately 30 seconds.
Double leg foam balance activity: the patient stands on a soft firm surface with both feet on the ground and the clinician attempts to perturb the patient's balance in a random fashion.	The duration of the activity is approximately 30 seconds. The difficulty is progressed as the patient improves by progressing to ball catching with the clinician perturbing the patient's balance while standing on foam and progressing to single-leg support if tolerated.
Tilt board balance training: the patient stands on a tilt board with both feet on the board. The clinician perturbs the tilt board in forward and backward and side to side directions for approximately 30 seconds each.	The difficulty of the activity is progressed by adding ball catching during the perturbations and progressing to single limb support perturbations based on patient tolerance.
Rollerboard and platform perturbations: the patient stands with one limb on a stationary platform and the other limb on a rollerboard. The clinician perturbs the rollerboard in multiple directions, at random, and the patient attempts to resist the perturbations. The activity lasts approximately 30 seconds and is then repeated by changing the limbs on the platform and the rollerboard.	If the patient has difficulty doing the activity in full standing, the activity may begin with the patient in a semi-seated position, with the hips resting on the bed. The activity is progressed to the full standing position as tolerated.

Data from: Fitzgerald GK, Piva SR, Gil AB, et al: Agility and Perturbation Training Techniques in Exercise Therapy for Reducing Pain and Improving Function in People With Knee Osteoarthritis: A Randomized Clinical Trial. Physical therapy, 2011.

a railing, and closely guarding the patient. Examples of agility and perturbations activities are outlined in Table 14-1. Balance training to promote static balance control involves changing the base of support of the patient while performing various tasks, first with their eyes open and then with the eyes closed. The lower the center of gravity, the more stable the patient feels. Thus, the prone or supine positions provide the lowest center of gravity and the most support, sitting the next, with standing providing the highest center of gravity and the least support. The usual progression employed in balance retraining involves a narrowing of the base of support while increasing the perturbation and changing the weight-bearing surface from hard to soft or from flat to uneven.

CLINICAL PEARL

It is important for the clinician to be aware of a number of factors that can affect balance and increase the risk of fall:

- Medications: the risk of falling can be increased when the patient is prescribed sedatives and antidepressants.

- Low vision: patients with balance issues should be advised to have regular eye examinations and to avoid areas with poor lighting.
- Sensory loss: sensory loss in the lower extremities can result in difficulties when walking on soft or uneven surfaces.

- Balance training for adults usually begins in the short sitting position, which allows the feet to provide anterior support. This position can be made more challenging by placing a wobble board or Swiss ball under the patient's buttocks. The patient is then progressed to quadruped, through tall kneeling, and finally to the standing position.
- Balance training for the pediatric population usually begins in the "W" sitting position, then to "Indian-style sitting," then to quadruped, through tall kneeling, and finally to the standing position.

Once the patient is able to stand, the structured sequence such as the one that follows is recommended.

- Static control of the trunk without extremity movement. These exercises involve closed chain loading/unloading. The patient is positioned in standing, with the feet positioned approximately shoulder-width apart. The purpose of the starting position is to provide a stable base from the proximal segments and trunk onto which challenges can be superimposed. For example:
  - Manual perturbations to a stable trunk. The clinician applies gentle perturbations to the patient's trunk in different directions.
  - Weight shifting while maintaining postural equilibrium. Initially, the patient, with the feet positioned approximately shoulder-width apart, is instructed to alternate transferring weight through one lower extremity then the other. Then the patient is asked to put one foot in front of the other and to transfer the weight from the rear foot to the front foot and back again.
- Dynamic control of trunk without extremity movement. For example, maintaining both feet on the ground while bending at the waist. As indicated, the range of motion is increased from a small range to a larger range.

Once this is mastered, the progression moves to exercises that incorporate static control of the trunk with extremity movement(s) superimposed using the following progression:

- Standing with the feet positioned approximately shoulder-width apart, the patient is asked to flex the hip and knee, so that the foot is approximately 6–8 inches off the floor. The exercise is repeated using the other leg. To add a challenge to the exercise, the patient can be trained with the eyes closed, or the patient can stand on an unstable surface.
- Standing with the feet positioned approximately shoulder-width apart, the patient grasps resistive-tubing with one hand and pulls the tubing toward the body using a smooth, comfortable motion (Fig. 14-1). This produces a forward weight shift that is stabilized with an isometric counterforce consisting of hip extension, knee extension, and ankle plantarflexion.[23]

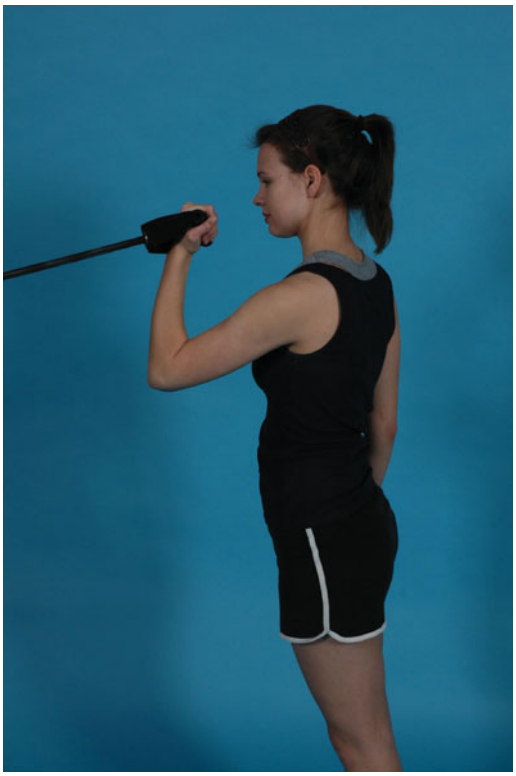

FIGURE 14-1 Forward weight shift exercise.

- The patient stands sideways to the resistive-tubing. The tubing is pulled by one hand in front of the body and the other hand behind the body to equalize the force and minimize the rotation (Fig. 14-2). This causes a lateral weight shift, which is stabilized with an isometric

FIGURE 14-2 Lateral weight shift exercise.

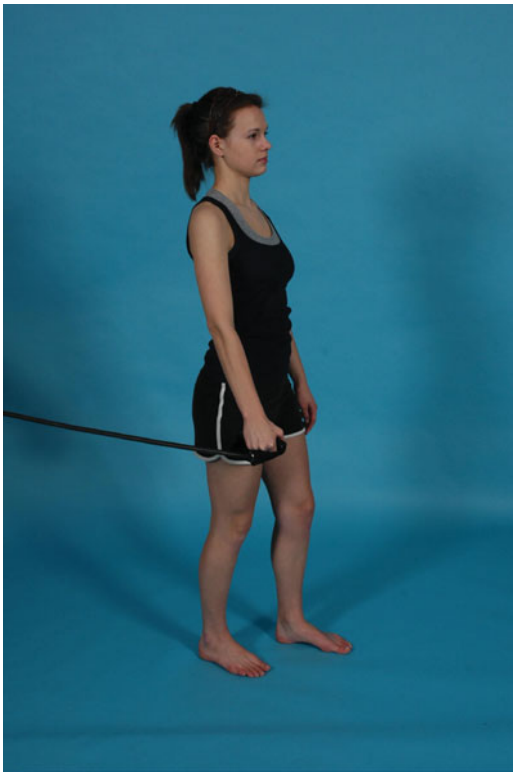

FIGURE 14-3 Posterior weight shift exercise.

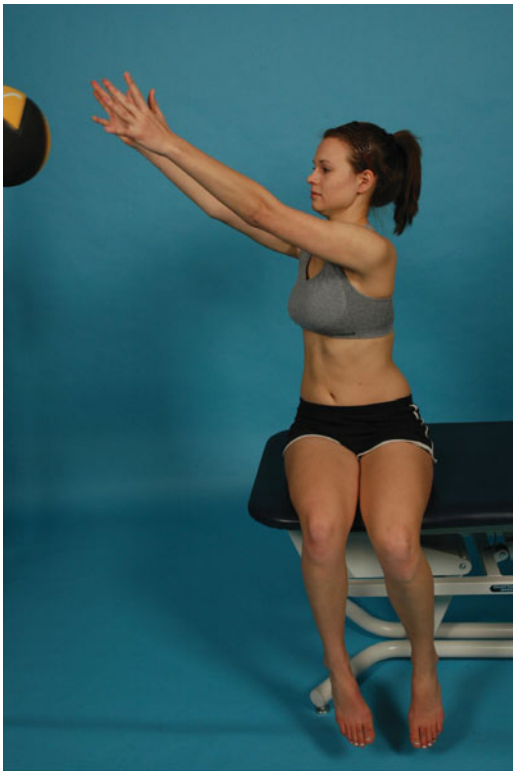

FIGURE 14-4 Medicine ball throw in sitting.

counterforce consisting of hip abduction, knee cocontraction, and ankle eversion.[23]

- The patient stands with his/her back to the tubing in the frontal plane (Fig. 14-3). The tubing is pulled to the body from behind, causing a posterior weight shift, which is stabilized by an isometric counterforce consisting of hip flexion, knee flexion, and ankle dorsiflexion.[23]

The aforementioned single plane exercises are progressed to multiplanar exercises in the following manner:

- PNF movement patterns are initiated using resistive-tubing. Initially the patient stands with both feet shoulder-width apart, and then the exercises are progressed so that the patient is standing on one leg. In addition to using resistive-tubing, medicine balls can be used.
- Ballistic extremity movements while maintaining trunk stability are introduced, first in sitting and then in standing. For example, maintain the sitting position while throwing a medicine ball (Fig. 14-4).

At the earliest opportunity functional tasks must be incorporated. A typical functional activity progression includes:

- Closed-chain activities (squats, lunges) initially, then open-chain activities superimposed on the closed chain by adding extremity motions to the squats and lunges (Fig. 14-5).
- Sit–stand–sit activities focusing on moving the body mass forward over the base of support, extending the lower extremities and raising the body mass over the feet, and then reversing the procedure.
- Stand–to–sit transitions focusing on balance control while pivoting and changing direction.
- Floor to standing raises using progression of side-sit to quadruped to kneeling to half kneeling to standing.
- Gait activities: ambulating forwards, backwards, sideward at varying speeds and base of support widths (narrow to wide). Resisted walking and/or running can also be used.

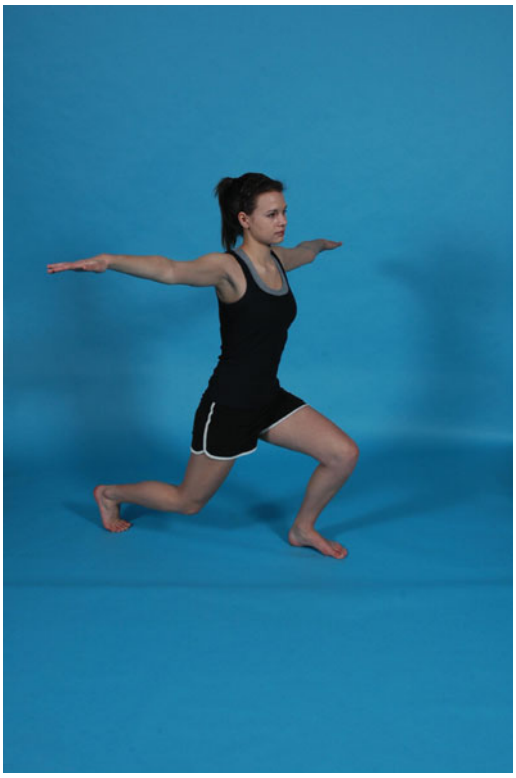

FIGURE 14-5 Lunge with arms raised out to sides.

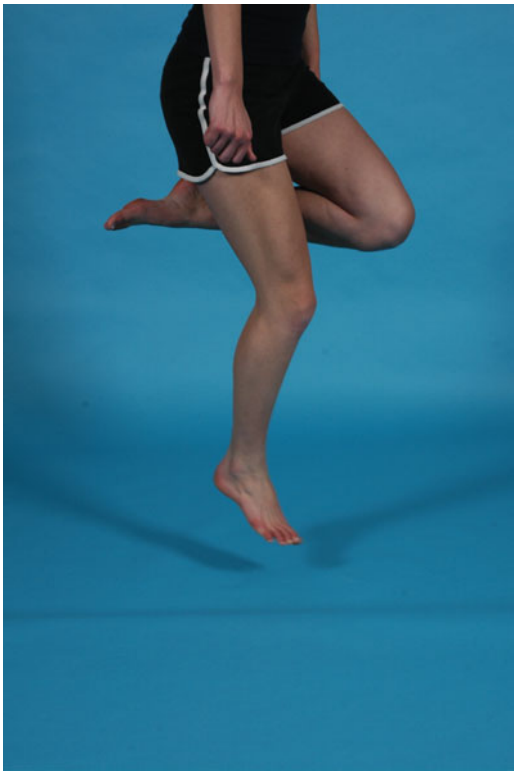

FIGURE 14-6 Hopping on one leg.

FIGURE 14-7 Minitrampoline standing on one leg.

- As appropriate, multidirectional drills including jumping (two-foot takeoff followed by two-foot landing), hopping (one-foot takeoff followed by landing on the same foot) (Fig. 14-6), and bounding (one-foot takeoff followed by an opposite-foot landing).[23]

CLINICAL PEARL

Various clinical devices have been designed to assist with proprioceptive training for the upper and lower extremity. These include, but are not limited to:

- Minitrampoline (Fig. 14-7)
- Biomechanical ankle platform system (BAPS)®
- Foam rollers
- Wobble board
- Kinesthetic ability training device (KAT)®
- Fitter®, Rocker boards, or foam balance mats

STABILIZATION RETRAINING

Stability normally involves the interaction of three systems—the neurological or central control system, the passive or inert tissues (e.g., ligaments, capsule), and the contractile (muscular) or active system (see Chap. 3).[24]

The *neutral zone* is a term used to define a region of laxity around the neutral resting position of a joint (see Chap. 2).[25] The neutral zone refers to the position of a joint in which minimal loading is occurring in the passive structures (all of the noncontractile elements of the joint including the ligaments, fascia, joint capsules, and non-contractile components of muscle), and the contribution of the active system (the muscles and tendons which surround and control joint motion) is most critical.[26,27]

CLINICAL PEARL

The size of the neutral zone is determined by the integrity of the passive restraint and active control systems, which in turn are controlled by the neural system.[25] Studies have demonstrated that a larger than normal neutral zone caused by injury or microtrauma is related to a lack of segmental muscle control, and is associated with injury.[25,28–31] Unfortunately, there is as yet no *clinical* method to measure the size of the neutral zone.

In both the spine and the extremities, certain muscles work as either mobilizers or stabilizers. The peripheral stabilizers rely on stabilization of the two primary dynamic bases or core structures—the pelvis and the scapula. The pelvis acts as a base for the whole body, especially for the spine and the lower limbs, whereas the scapula acts as a base for its respective upper limb.[24] During peripheral joint movement, the peripheral stabilizer muscles normally contract first to stabilize the core structures from which the mobilizers work.[24,32] The mobilizers then contract, resulting in a controlled movement pattern. For example, during upper extremity activity, the scapular stabilizers contract first to stabilize the scapula before the other shoulder muscles move the upper extremity into a functional position. However, with injury, a pathologic process, or other abnormality, an abnormal stabilizer recruitment pattern can

develop, resulting in a dominance of the mobilizer muscles and eventual weakening of the local stabilizers.[24,32]

For stabilization retraining to be effective, the clinician must, therefore, ensure that a stable base is present from which the mobilizers can act. Once the stabilizer muscles are functioning efficiently, training of the mobilizer muscles can begin using the following sequence: isometric to concentric, to eccentric, and ecocentric (pseudo-isometric) contractions, and finally to functional movement (see Chap. 12).[24]

CLINICAL PEARL

An ecocentric contraction occurs when a two-joint muscle shortens at one end, while lengthening at the other end. An example involves the hamstrings when moving from standing to sitting.

The body has several natural stabilization methods including muscle contraction, muscle spasm, osteophyte formation, scar tissue formation, and adaptive shortening of inert tissue or muscle.[24] While the clinician cannot impact some of these natural stabilization methods such as muscle spasm, osteophyte and scar tissue formation, the clinician can use muscle contraction and adaptive shortening to the patient's advantage.

Stabilization retraining involves approximately 6 stages with 12 steps:[24,32,33]

- Stage 1. This stage typically occurs in the acute phase of healing.

  Step 1: Decrease pain. This can be accomplished through muscle relaxation techniques, patient education on joint resting positions and proper body mechanics, the use of electro physical agents, working in the pain-free range, and the use of medication.[34]

  Step 2: Allow freedom of movement and proper arthrokinematic movement of the joint. This can be accomplished through joint mobilization (joint capsule), prolonged passive stretch (inert tissue and muscle), muscle energy techniques (muscle), active release techniques (muscle), manipulation (joint), and neurodynamic techniques (nerve), depending on the tissue causing the restriction.[24]

- Stage 2. This stage is initiated once pain is under control and normal arthrokinematics are restored.

  Step 1: Ensure that the individual muscles will contract when and how they should, starting with an isometric contraction of the isolated muscle (stabilizers first). The initial emphasis is directed toward strengthening any weak stabilizer muscles using the inner range or muscle test position.

  Step 2: Ensure proper muscle recruitment and reeducation so that the muscles contract in the correct order—stabilizers first, then mobilizers. Once the patient can contract the muscle isometrically, concentric movement within the range that the patient has control using the mobilizers can be initiated, but only if the stabilizer muscles function properly.[24] Finally, training progresses to the use of eccentric contractions which allow the patient to maintain control of the base while lengthening during functional movements or slowing down a particular motion.[24]

  Step 3: Ensure muscle imbalance between muscle groups to ensure that the various force couples work together correctly and function to enable control and eliminate incoordination. In general, to correct muscle length, one should exercise lengthened muscles in the inner range to shorten them, and stretch short muscles to lengthen them.[24]

- Stage 3. This stage should only be initiated when the patient has learned to statically control the core structures.

  Step 1: Correct endurance and strength discrepancies. Exercises for stabilizer muscles may involve high-load, low-repetition training, although the focus should be on lower loads and high repetitions to build up resistance to fatigue.

- Stage 4. This stage is typically initiated at the same time the stage 3, provided the patient has successfully completed stages one and two and can demonstrate control of the core.

  Step 1: Retrain proprioception. Proprioceptive retraining is outlined at the beginning of the chapter.

- Stage 5. This stage involves the integration of five different steps into the program.[35]

  Step 1: Reeducate stabilizing muscle statically. This is achieved by ensuring proximal stabilization of the core while allowing distal movement through the extremities. Short arc movements are performed initially while the clinician observes for the expected proper sequence of muscle contractions (stabilizers then mobilizers), correct force-couple action, and good muscle cocontraction (static stabilization).

  Step 2: Teach advanced static stabilization exercises. This involves taking the patient into the mechanism of injury position and asking him or her to hold the position statically against resistance.

  Step 3: Teach dynamic stabilization exercises. This involves the use of controlled movement patterns to ensure the development of proper movement patterns (engrams—see Chap. 3) and voluntary control. Exercises during this step involve movement of the core, with the control muscles acting eccentrically while distal joints are moved concentrically through the full range of movement.

  Step 4: Teach advanced dynamic stabilization exercises. Exercises during this step include multidirectional stability training that require control of functional speeds, progressive eccentric exercises at functional speeds, and stressing of functional diagonal patterns used in the activities to which the person plans to return.

  Step 5: Teach functional stabilization. Functional activities are initially broken down into their component parts before performing the whole movement.

- Stage 6

  Step 1: Maintain or restore fitness throughout. Depending on the location of the injury, endurance exercises are prescribed for the upper extremities or lower extremities to improve or maintain cardiovascular fitness (see Chap. 15).

  Step 2: Return to sport or heavy manual labor as appropriate. In order to return to sport or heavy manual labor, there should be:[24]

  - Complete resolution of acute signs and symptoms
  - Sufficient dynamic, functional range of motion of all joints involved in the activity

- Adequate strength, endurance, and proprioceptive/kinesthetic sense to perform the expected skills successfully
- No alteration of the patient's normal mechanics that could predispose him or her to reinjury

Improving Cardiovascular Endurance

CHAPTER 15

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Explain the importance of cardiovascular endurance in the overall health of an individual.
2. Describe the physiology of the cardiovascular system.
3. Describe the various types of energy and how each is generated.
4. Explain how the various muscle types are involved with endurance and aerobic activities.
5. Outline the precautions with aerobic conditioning.
6. Discuss the various methods by which aerobic conditioning can be enhanced through a rehabilitation program.

OVERVIEW

Physical activity has been defined as "any bodily movement produced by skeletal muscles that results in energy expenditure."[1] When a person undertakes work or exercise, a number of body systems adapt to the demands of the required tasks, particularly the cardiorespiratory and neuromuscular systems.[2] The maximum work capacity of the cardiorespiratory system is a factor of the maximal amount of oxygen that can be taken in and used by the body, or VO_{2max}, whereas the capacity of the neuromuscular system is a factor of the maximum tension that can be developed by the working muscle, or muscles—the maximal voluntary contraction. Assessment of the cardiovascular system provides the clinician with the justification for monitoring or not monitoring activities during a patient's rehabilitation or providing modifications in the exercise prescription.[3]

Whenever possible, the clinician should address the impact on the patient resulting from the loss of physical activity. This loss of activity affects both the cardiovascular and the musculoskeletal systems and can occur very rapidly. Thus, it is important that the rehabilitation program includes exercises that maintain, or improve, the patient's cardiovascular endurance, while monitoring safety concerns. If our sedentary society is to change to one that is more physically active, clinicians must play their role in communicating to their patients the amounts and types of physical activity that are needed to prevent disease and promote health, because patients respect their advice.[4,5] Patients should be routinely counseled to adopt and maintain regular physical activity. Inadequate reimbursement, limited knowledge of the benefits of physical activity, and a lack of training in community physical activity counseling are barriers to achieving these goals. While policy makers work to improve reimbursement for preventive services, clinicians should develop effective ways to teach physical activity counseling.[5] The personal physical activity practices of health professionals should not be overlooked. Health professionals should be physically active, not only to benefit their own health but also to make more credible their endorsement of an active lifestyle.[5]

PHYSICAL FITNESS

According to the Department of Health and Human Services, physical fitness is a set of attributes a person has in regards to his/her ability to perform physical activities that require aerobic fitness, endurance, strength, or flexibility and is determined by a combination of regular activity and genetically inherited ability.[6] Although commonly associated with the state of the cardiorespiratory system, which includes the ability to perform work or participate in activity over time using the body's oxygen uptake, delivery, and energy release mechanisms,[7] physical fitness also encompasses a number of attributes including:[8]

- Muscle strength, which is the ability of muscles to exert or resist a force.
- Muscle endurance, which is the ability of the muscle to perform work.
- Muscle power, which is the ability of a muscle to exert high force at high speed.
- Balance, which is the ability to maintain equilibrium when the body is static or moving.
- Agility, which is the ability to perform functional or powerful movements in opposite directions.
- Flexibility, which is the ability to stretch, easily bend, or be pliable.

PHYSICAL ACTIVITY

Physical activity is closely related to, but distinct from, the subsets of exercise and physical fitness. Exercise is defined as "planned, structured, and repetitive bodily movement done to improve or maintain one or more components of physical fitness."[1] This differs from the definition of physical fitness, which is "a set of attributes that people have or achieve that relates to the ability to perform physical activity."[1] Regular physical activity has long been regarded as an important component of a healthy lifestyle, and it is well established from controlled experimental trials that active individuals have high levels of cardiorespiratory fitness. Intermittent activity, provided it is continued, also confers substantial benefits.[9–11] Studies have demonstrated that within a few weeks of discontinuing an endurance training program, the positive effects of exercise are almost completely lost, with approximately half of that loss occurring within the first 2 weeks.[12,13]

Clinical experience and limited studies suggest that people who maintain or improve their levels of physical activity may be better able to perform daily activities, may be less likely to develop pain, and may be better able to avoid disability, especially as they advance into older age.[5] Regular physical activity may also contribute to better balance, coordination, and agility, which in turn may help prevent falls in the elderly.[14] Epidemiologic research has demonstrated protective effects of physical activity and risk for several chronic diseases, including coronary heart disease,[9,15,16] hypertension,[17,18] non–insulin-dependent diabetes mellitus,[19,20] osteoporosis,[21,22] colon cancer,[23] and anxiety and depression.[24] Patterns of physical activity appear to vary with demographic characteristics. Men are more likely than women to engage in regular activity,[25] vigorous exercise, and sports.[26] The total amount of time spent engaging in physical activity normally declines with age.[27,28] Adults at retirement age (65 years) show some increased participation in activities of light to moderate intensity, but, overall, physical activity declines continuously as age increases.[27,29] Elderly African Americans, and other ethnic minority populations, are less active than white Americans,[25,29,30] and this disparity is more pronounced for women.[30] People with higher levels of education participate in more leisure-time physical activity than do people with less education.[25] Differences in education and socioeconomic status account for most, if not all, of the differences in leisure-time physical activity associated with race and ethnicity.[31]

CARDIOVASCULAR PHYSIOLOGY

Oxygen is a vital component for life and the cardiovascular system provides a means by which oxygen is supplied to the various tissues of the body via the heart, blood vessels, blood, and lungs.

CLINICAL PEARL

The basal metabolic rate (BMR) is the amount of energy required to sustain the body at rest in a supine position. Thus, physical activity is measured as a ratio between the BMR and the rate required to perform a particular task. This ratio is measured as a metabolic equivalent (MET) of the task. Moderate physical activity is activity performed at an intensity of 3–6 METs and is the equivalent of brisk walking at 3–4 mph for most healthy adults.[5]

By definition, cardiorespiratory endurance is the ability to perform whole body activities (walking, jogging, swimming, etc.) for extended periods of time without unwarranted fatigue. The maximal amount of oxygen that can be used during exercise is referred to as maximal aerobic capacity (VO_{2max}). It is also common to see aerobic capacity expressed in METs.

A number of adaptations occur within the circulatory system in response to exercise:

- Heart rate. As the body begins to exercise, the working tissues require an increased supply of oxygen to meet increased demand. Monitoring heart rate (HR) is an indirect method of estimating oxygen consumption as, normally, these two factors have a linear relationship (this relationship is consistent at very low and very high intensity exercise). If a physical therapy intervention requires an increase in systemic oxygen consumption expressed as either an increase in MET levels, kcal, or VO_2, then HR should also be seen to increase.[32] Increases in HR produced by exercise are met by a decrease in diastolic filling time. The extent at which the HR increases with escalating workloads is influenced by many factors including age, fitness level, type of activity being performed, body position, presence of disease, medications, blood volume, and environmental factors such as temperature, humidity, and altitude. Failure of the HR to increase with increasing workloads, referred to as chronotropic incompetence, should be of concern, even if the patient is taking beta blockers—beta blockers slow the HR, which can prevent the increase in HR that typically occurs with exercise.[32]
- Stroke volume. Stroke Volume (SV) is the amount of blood pumped out by the left ventricle of the heart with each beat (the difference between end-diastolic volume and end-systolic volume). The volume of blood being pumped out with each beat increases with exercise, but only to the point when there is enough time between beats for the heart to fill up (approximately 110–120 beats per minute). In the normal heart, as workload increases, SV increases linearly up to 40–50% of aerobic capacity, after which it increases only slightly. Factors that influence the magnitude of change in SV include exercise intensity, body position, and ventricular function.
- Cardiac output. Cardiac output (CO) is the amount of blood (approximately 5L) discharged by each ventricle (not both ventricles combined) per minute, usually expressed as liters per minute. CO, the product of HR and SV, increases linearly with workload because of the increases in HR and SV in response to increasing exercise intensity. During exercise, CO increases to approximately 4 times than that experienced during rest. Factors that influence the magnitude of change in CO include age, posture, body size, presence of disease, and level of physical conditioning. A long-term beneficial training effect that occurs with regard

to HR is a reduced resting HR and reduced HR at a standard exercise load. This occurs because the heart becomes more efficient—the SV increases, brought about by increased venous return, and increased contractile conditions in the myocardium.

- Blood flow. The amount of blood flowing to the various organs increases during exercise, but there is a change in overall distribution of the CO—it is increased to active skeletal muscle, but decreased to nonessential organs. Total peripheral resistance, the sum of all forces that resist blood flow within the circulatory system, decreases during exercise primarily because of the vessel vasodilation in the active skeletal muscles.[33]
- Blood pressure. Blood pressure (BP) is defined as the pressure exerted by the blood on the walls of the blood vessels, specifically *arterial blood pressure* (the pressure in the large arteries). Systolic BP normally increases in proportion to oxygen consumption and CO, while diastolic BP normally shows little or no increase, or may decrease. Long-term aerobic training can result in reduced systolic and diastolic BP. Failure of the systolic BP to rise with an increase in intensity, referred to as exertional hypotension, is considered abnormal, and may occur in patients with cardiovascular problems. The minimal change in diastolic BP is due primarily to the vasodilation of the arteries from the exercise bout. Thus, the expansion in artery size may lower BP during the diastolic phase.[32]
- Oxygen consumption rises rapidly during the first minutes of exercise and levels off as the aerobic metabolism supplies the energy required by the working muscles.
- Mitochondria: An increase in size and number of the mitochondria.
- Hemoglobin concentration. Oxygen is transported throughout the system attached to hemoglobin, an iron containing protein that has the capability of easily accepting or giving up molecules of oxygen as needed.[33] The concentration of hemoglobin in circulating blood does not change with training; it may actually decrease slightly.[33] However, because training for improving cardiovascular endurance produces an increase in total blood volume, there is a corresponding increase in the amount of hemoglobin.
- Myoglobin: Increased myoglobin content.
- The use of fat and carbohydrates: Improved mobilization and use of fat and carbohydrates.
- Lung changes that occur due to exercise.
  - An increase in the volume of air that can be inspired in a single maximal ventilation. Ventilation is the process of air exchange in the lungs.
  - An increase in the diffusing capacity of the lungs.

THE ENERGY FOR MOVEMENT

During physical exercise, energy turnover in skeletal muscle may increase by 400 times compared with muscle at rest and muscle oxygen consumption may increase by more than 100 times.[34] The energy required to power muscular activity is derived from the hydrolysis of ATP to ADP and inorganic phosphate (P_i). Despite the large fluctuations in energy demand just mentioned, muscle ATP remains practically constant and demonstrates a remarkable precision of the system in adjusting the rate of the ATP generating processes to the demand.[35] There are three energy systems that contribute to the resynthesis of ATP via ADP rephosphorylation. These energy systems are as follows:

- ***Phosphagen system.*** The phosphagen system is an anaerobic process—can proceed without oxygen (O_2). Within the skeletal muscle cell at the onset of muscular contraction, phosphocreatine (PCr) represents the most immediate reserve for the rephosphorylation of ATP. The phosphagen system provides ATP primarily for short-term, high-intensity activities (i.e., sprinting) but is active at the start of all exercises regardless of intensity.[36] One disadvantage of the phosphagen system is that because of its significant contribution to the energy yield at the onset of near maximal exercise, the concentration of PCr can be reduced to less than 40% of resting levels within 10 seconds of the start of intense exercise.[37]
- ***Glycolysis system.*** The glycolysis system is an anaerobic process that involves the breakdown of carbohydrates—either glycogen stored in the muscle or glucose delivered through the blood—into pyruvate to produce ATP. Pyruvate is then transformed into lactic acid. Because this system relies upon a series of nine different chemical reactions, it is slower to become fully active. However, glycogenolysis has a greater capacity to provide energy than does PCr, and therefore it supplements PCr during maximal exercise and continues to rephosphorylate ADP during maximal exercise after PCr reserves have become essentially depleted.[36] The process of glycolysis can be in one of the two ways, termed fast glycolysis and slow glycolysis, depending on the energy demands within the cell. If energy must be supplied at a high rate, fast glycolysis is used primarily. If the energy demand is not so high, slow glycolysis is activated. The main disadvantage of the fast glycolysis system is that during very high-intensity exercise, hydrogen ions dissociate from the glycogenolytic end product of lactic acid.[35] The accumulation of lactic acid in the contracting muscle is recognized in sports and resistance training circles. An increase in hydrogen ion concentration is believed to inhibit glycolytic reactions and directly interfere with muscle excitation–contraction and coupling, which can potentially impair contractile force during exercise.[36] This inhibition occurs once the muscle pH drops below a certain level, prompting the appearance of phosphofructokinase (PFK), resulting in local energy production ceasing until replenished by oxygen stores.

CLINICAL PEARL

Lactic acid is the major energy source for providing the muscle with ATP during exercise bouts that last 1 to 3 minutes (e.g., running 400 to 800 m).

- ***Oxidative system.*** As its name suggests, the oxidative system requires O_2 and is consequently termed the "aerobic" system. The oxidative system is the primary source of ATP

at rest and during low-intensity activities. It is worth noting that at no time during either rest or exercise does any single energy system provide the complete supply of energy. While being unable to produce ATP at an equivalent rate to that produced by PCr breakdown and glycogenolysis, the oxidative system is capable of sustaining low-intensity exercise for several hours.[36] However, because of an increased complexity, the time between the onset of exercise and when this system is operating at its full potential is around 45 seconds.[38]

The relative contribution of these energy systems to ATP resynthesis has been shown to depend upon the intensity and duration of exercise, with the primary system used being based on the duration of the event:[39]

- 0–10 seconds: ATP–PCr
- 10–30 seconds: ATP–PCr plus anaerobic glycolysis
- 30 seconds–2 minutes: anaerobic glycolysis
- 2–3 minutes: anaerobic glycolysis plus oxidative system
- >3 minutes and rest: oxidative system

RECOVERY

The performance of any activity requires a certain rate of oxygen consumption, so that an individual's ability to perform an activity is limited by the maximal amount of oxygen the person is capable of delivering into the lungs.[33] Fatigue and recovery from fatigue are complex processes that depend on physiologic and psychological factors. The physiologic factors include the adequacy of the blood supply to the working muscle and the maintenance of a viable chemical environment, whereas the psychological factors include motivation and incentive.[2] After an intense exercise session, anaerobic energy sources must be replenished before they can be called on again to provide energy for muscular contraction. The anaerobic energy sources of ATP–PCr and lactic acid are ultimately replenished by the oxidative energy system. The extra oxygen that is taken and used to replenish the anaerobic energy sources after cessation of the exercise effort was previously referred to as the *oxygen debt*, but is now more accurately referred to as *excess postexercise oxygen consumption* (EPOC).

The patient who is injured while performing an activity or exercise is likely to return to that activity once the symptoms subside.[5] Thus, the body needs to be prepared for a resumption of the stresses and demands that the activity or exercise will place upon it. If not, when the patient returns to competitive sports or functional and work activities, fatigue may result in alterations in efficient movements making the individual susceptible to injury.

PRECAUTIONS WITH AEROBIC CONDITIONING

Before beginning any exercise program, the clinician should perform a health screening check or risk factor assessment as part of the initial assessment to identify individuals who should consult a physician before initiating an exercise program. The following are considered risk factors for cardiovascular disease:[40]

- High BP: >140 mm Hg systolic or >90 mm Hg
- Smoking
- Elevated serum cholesterol: a total serum level >200, LDL >160 (individuals without heart disease, >100 in individuals with heart disease), or HDL <40 in men or <50 in women
- Lack of regular exercise (three or more times per week of regular exercise or moderate physical activity)
- Family history (mother or father with heart disease or stroke before age 60)
- Stress (particularly personality factors of anger and hostility)
- Diabetes
- Obesity
- Sex: men are at greater risk than women until women reach menopause, then equal risk
- Age: increasing age increases risk

CLINICAL PEARL

In cases of severe pulmonary disease, the cost of breathing can reach 40% of the total exercise oxygen consumption, thereby decreasing the amount of oxygen available for the exercising muscles.

Obese individuals should exercise at longer durations and lower intensities—they should be able to exercise while maintaining a conversation (talk test). In addition, to reduce stresses on weight-bearing joints, these individuals should perform exercises where their weight is supported (e.g., recumbent bike, swimming, etc.)

All patients should be monitored (i.e., HR, BP, and symptoms) during the initial assessment if they have been determined unsafe to exercise based on any risk factor or healthy lifestyle assessment.

During exercise, the clinician should note normal clinical responses to progressively increasing aerobic exercise. The magnitude of the change in cardiovascular responses during aerobic exercise is related to the physical activity status of the patient. For example, a patient whose HR takes longer than 5 minutes to return to resting levels after 2 minutes of exercise has poor cardiovascular function.[41] Once the individual has demonstrated normal vital signs and lack of symptoms with the activities, it may not be necessary to monitor further activities.

A number of precautions need to be taken when exercising patients who have been determined unsafe to exercise. These include:

- An appropriate level of intensity must be chosen:
  - Too high a level can overload the cardiorespiratory and muscular systems and potentially cause injuries or severe complications.
  - Exercising at a level which is too high causes the cardiorespiratory system to work anaerobically, not

aerobically. Initially the patient should be exercising at a level with the HR at 60% of his or her maximum (220–age of patient). If the patient is exercising within their target HR, they should be able to carry on a conversation.

- A sufficient period of time should be allowed for warm-up and cool-down to permit adequate cardiorespiratory and muscular adaptation.

CLINICAL PEARL

Conditioned individuals have a cardiovascular and pulmonary system that is more capable of delivering oxygen to sustain aerobic energy production at increasingly higher levels of intensity.

A rapid decline in cardiorespiratory fitness occurs during the first few weeks of deconditioning; for example, one study reported that 20 days of bed rest was associated with a 28% decrease in aerobic capacity.[42] The aforementioned decline in aerobic capacity after 20 days of bed rest was greater than that found after three decades of aging in the same subjects.[43]

Signs and symptoms of exercise intolerance include, but are not limited to:

- BP:
  - Systolic BP >200 to 210 mm Hg
  - Drop in systolic BP >20 mm Hg
  - Diastolic BP >110 mm Hg
- HR:
  - Increase in HR >50 bpm with low level activity
  - Significant arrhythmias
- Chest pain
- Nausea, vomiting
- Unusual or severe fatigue
- Syncope or moderate dizziness
- Marked dyspnea (2 +/4+)
- Severe claudication (grade III/IV)
- Cyanosis or severe pallor

CLINICAL PEARL

Currently, only a few studies have examined the acute effect of resistance exercise on cardiovascular function.[44,45] From these studies it has been found that the magnitude and directional change in cardiac volume and function during resistance exercise are, for the most part, opposite to those that occur during aerobic exercise.

TECHNIQUES FOR IMPROVING, MAINTAINING, AND MONITORING CARDIORESPIRATORY ENDURANCE

Aerobic conditioning is especially valuable for those who participate in sports that involve endurance.[46] Nirschl[47,48] recommends general body conditioning for patients, which provides the following benefits:

- Increased regional perfusion
- Neurophysiologic synergy and overflow
- Neurologic stimulation
- Minimization of the domino effect of weakness of adjacent structures
- Minimization of negative psychological effects
- Obesity control

A number of different training factors must be considered when attempting to maintain or improve cardiorespiratory endurance:

- Continuous training—the F.I.T.T. (Frequency, Intensity, Time, and Type) principle:
  - Frequency: to see at least minimal improvement in cardiorespiratory endurance, it is necessary for the average person to engage in no less than three sessions per week.
    - If the intensity is kept constant, there appears to be no additional benefit from twice a week versus four times or three times a week versus five times per week.
    - If the goal is weight loss, 5 to 7 days per week increases the caloric expenditure more than 2 days per week.
  - Intensity: the recommendations regarding training intensity (overload) vary. Relative intensity for an individual is calculated as a percentage of the maximum function, using $VO_{2\ max}$ or maximum HR (HR max). It is now recognized that an individual's perception of effort (relative perceived exertion or RPE) is closely related to the level of physiological effort (see Chap. 12).[49,50] For aerobic activities, the exercise intensity should be at a level that is 40–85% maximal aerobic power ($VO_{2\ max}$) or 55–90% of maximal HR.[51]

CLINICAL PEARL

If an individual is taking medications that may affect HR and BP responses (e.g., beta blockers), the Borg rating of perceived exertion is the only method for prescribing exercise intensity.

Two other common methods of monitoring intensity are employed:

- Monitoring HR—two formulas are commonly used:
  - Maximum heart rate reserve (MHRR): this method uses the difference between the maximum heart rate (MHR) and the resting heart rate (RHR), referred to as the maximum heart rate reserve (MHRR). When using this formula, the recommended intensity level range is 50–85% of $VO_{2\ max}$. For example, for a 40-year-old with a RHR of 65 bpm who wants to train at an intensity of 70%:
  - 220–40 = 180 bpm (MHR)
  - 180–65 = 115 bpm (MHRR)
  - (115 × 0.7) + 65 = 145 bpm

TABLE 15-1 Comparison of Physiologic Adaptations to Resistance Training and Aerobic Training

Variable	Result Following Resistance Training	Result Following Endurance Training
Performance		
Muscle strength	Increases	No change
Muscle endurance	Increases for high-power output	Increases for low-power output
Aerobic power	No change or increases slightly	Increases
Maximal rate of force production	Increases	No change or decreases
Vertical jump	Ability increases	Ability unchanged
Anaerobic power	Increases	No change
Sprint speed	Improves	No change or improves slightly
Muscle fibers		
Fiber size	Increases	No change or increases slightly
Capillary density	No change or decreases	Increases
Mitochondrial density	Decreases	Increases
Fast heavy-chain myosin	Increases in amount	No change or decreases in amount
Enzyme activity		
Creatine phosphokinase	Increases	Increases
Myokinase	Increases	Increases
Phosphofructokinase	Increases	Variable
Lactate dehydrogenase	No change or variable	Variable
Metabolic energy stores		
Stored ATP	Increases	Increases
Stored creatine phosphate	Increases	Increases
Stored glycogen	Increases	Increases
Stored triglycerides	May increase	Increases
Connective tissue		
Ligament strength	May increase	Increases
Tendon strength	May increase	Increases
Collagen content	May increase	Variable
Bone density	No change or increase	Increases
Bone composition		
Percentage body fat	Decreases	Decreases
Fat-free mass	Decreases	No change

ATP, adenosine triphosphate.
Data from Clancy WG: Specific rehabilitation for the injured recreational runner. *Instr Course Lect* 38:483-486, 1989.

- The age-adjusted maximum heart rate (AAMHR)[52]: MHR = 220 – patient's age. For example, for a 40-year-old, the MHR is 220–40 = 180. The recommended level of intensity when using this formula is a range between 60–90% of an individual's MHR Therefore, the target heart range (60–90%) for a MHR of 180 is between 180 × 60% and 180 × 90% = 108 to 162 bpm.

CLINICAL PEARL

Tanaka and colleagues recently revealed that the AAMHR equation underestimates the actual maximal HR by 6 to 15 bpm for individuals between 60 and 90 years of age.[53] Based on these findings a new formula has been derived to estimate the age-predicted maximal HR: 208 – (0.7 × age).[54]

Regardless of which formula is used, the clinician should keep in mind that formulas are merely estimations (and highly inaccurate when used with patients taking prescribed medications that may affect HR and BP responses), and therefore, it is more important to be conservative in prescribing exercise intensity for any sedentary individual, elderly individual, or someone at moderate to high risk for cardiovascular disease.[3]

- Type of exercise: the type of activity chosen in continuous training must be aerobic—involving large muscle groups activated in a repetitive and rhythmic manner. Examples of aerobic activities are running, cycling, swimming, and cross-country skiing. Aerobic exercises allow the individual to speed up or slow down the pace to maintain the HR at a specified or target level.[33] Cross-training exercises, including cycling, upper body ergometer (UBE), and water running, increase cardiovascular endurance.

However, it must be remembered that although cross training can produce a similar cardiovascular effort as the original sport, it does not necessarily produce the same musculoskeletal effects (Table 15-1).

- Time (duration): duration is increased when intensity is limited, e.g., by initial fitness level. For minimal improvement to occur, the patient must participate in continuous activity for at least 20 minutes with a HR elevated to its working level. Three to five minutes per day produces a training effect in poorly conditioned individuals, whereas 20 to 60 minutes, 3 to 5 times a week is optimal for conditioned people. Generally, the greater the duration of the workout, the greater the improvement in cardiovascular endurance.[33] A number of pieces of exercise equipment can be used with continuous training:
  - Treadmill walking: progressing from slow to fast and short distances to longer distances with or without an incline.
  - Ergometers: these come in a variety of forms for both the upper extremities and the lower extremities. The pace progression is from slow to fast and the goal is to increase the time spent exercising.
  - Free weights and elastic resistance: the use of low resistance and high repetitions can produce an aerobic effect.

CLINICAL PEARL

Discontinuous training, also known as interval training, involves the use of repeated high-intensity exercise bouts that are interspersed with rest intervals. Although endurance levels can be improved with this method, more benefits are seen in the development of strength and power.

CHAPTER 16 The Shoulder

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joints, ligaments, muscles, blood, and nerve supply that comprise the shoulder complex.
2. Describe the biomechanics of the shoulder complex, including the open- and close-packed positions, muscle force couples, and the static and dynamic stabilizers.
3. Describe the relationship between muscle imbalance and functional performance of the shoulder.
4. Describe the purpose and components of the tests and measures for the shoulder complex.
5. Perform a comprehensive examination of the shoulder complex, including history, systems review, palpation of the articular and soft tissue structures, specific passive mobility tests, passive articular mobility tests, and special tests.
6. Evaluate the key findings from the examination data to establish a physical therapy diagnosis and prognosis.
7. Summarize the various causes of shoulder dysfunction.
8. Describe and demonstrate intervention strategies and techniques based on the clinical findings and any established goals.
9. Evaluate the intervention effectiveness to determine progress and modify an intervention as needed.
10. Plan an effective home program and instruct the patient in its use.

OVERVIEW

The shoulder is the most rewarding joint in the body because when a limited or painful movement is found, the finding is seldom ambiguous and often implicates the offending structure.

—James Cyriax, MD (1904–1985)

The primary function of the shoulder complex is to position the hand in space, thereby allowing an individual to interact with his or her environment and to perform fine motor functions. An inability to position the hand results in profound impairment of the entire upper extremity.[1]

Secondary functions of the shoulder complex include the following:

- Suspending the upper limb.
- Providing sufficient fixation so that motion of the upper extremity or trunk can occur.
- Serving as a fulcrum for arm elevation. Three types of arm elevation are recognized: an upward motion of the upper extremity in the scapular plane (*scaption*) and the motions in either the coronal plane (*abduction*) or in the sagittal plane (*flexion*).

The shoulder is endowed with a unique blend of mobility and stability. The degree of mobility is contingent on a healthy articular surface, intact muscle–tendon units, and supple capsuloligamentous restraints. The degree of stability is dependent on intact capsuloligamentous structures, proper function of the muscles, and the integrity of the osseous articular structures.[1] Optimal functioning of the shoulder and arm can only take place if a delicate balance between mobility and stability is maintained.

ANATOMY

The shoulder complex functions as an integrated unit, involving a complex relationship between its various components. The components of the shoulder joint complex consist of (Fig. 16-1):

- three bones (the humerus, the clavicle, and the scapula);
- three joints (the sternoclavicular (S-C), the acromioclavicular (A-C), and the glenohumeral (G-H) joints);
- one "pseudojoint" (the articulation between the scapula and the thorax);
- one physiological area (the suprahumeral or subacromial space).

For optimal function to occur at the shoulder, motion also has to be available at the cervicothoracic junction and at the connections between the first three ribs and the sternum and spine.

GLENOHUMERAL JOINT

The G-H joint is a true synovial-lined diarthrodial joint that connects the upper extremity to the trunk, as part of the upper kinetic chain. The G-H joint is described as a ball and socket joint—the humeral head forms roughly half a ball or sphere (Fig. 16-1), whereas the glenoid fossa forms the socket.

The head of the humerus faces medially, posteriorly, and superiorly with the axis of the head forming an angle of 130–150 degrees with the long axis of the humerus.[2] In the frontal plane, the head of the humerus is angled posteriorly (retroverted) by 30–40 degrees.[3,4] The joint capsule of the G-H joint is lax inferiorly to permit full elevation of the arm.

The glenoid fossa of the scapula faces laterally, superiorly, and anteriorly at rest and inferiorly and posteriorly when the arm is in the dependent position (Fig. 16-2).[5] The glenoid fossa is flat and covers only one-third to one-fourth of the surface area of the humeral head. This arrangement allows for a great deal of mobility but little in the way of articular stability (Fig. 16-3). However, the glenoid fossa is made approximately 50% deeper (doubling the depth of the glenoid fossa across its equatorial line)[6] and more concave by a ring of fibrous cartilage[7] and dense fibrous collagen[8] called a labrum. The labrum forms a part of the articular surface and is attached to the margin of the glenoid cavity and the joint capsule.[9] It is also attached to the lateral portion of the biceps anchor superiorly.[10] In addition, approximately 50% of the fibers of the long head of the biceps (LHB) brachii originate from the superior labrum (the remainder originates from the superior glenoid tubercle),[8] with four different variations identified,[11] and continue posteriorly to become a periarticular fiber bundle, making up the bulk of the labrum.[10,12] The labrum enhances joint stability by increasing the humeral head contact areas to 75% vertically and 56% transversely.[5,9] The humeral–glenoid contact area provides two primary functions[13]: it spreads the joint loading over a broad area, and it permits movement of opposing joint surfaces with minimal friction and wear.[14] However, because the humeral head is larger than the glenoid, at any point during elevation, only 25–30% of the humeral

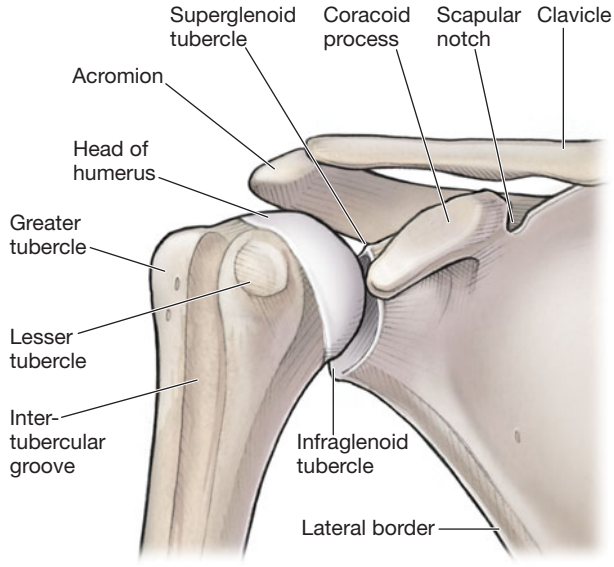

FIGURE 16-3 Glenohumeral joint. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy*. McGraw-Hill, 2011)

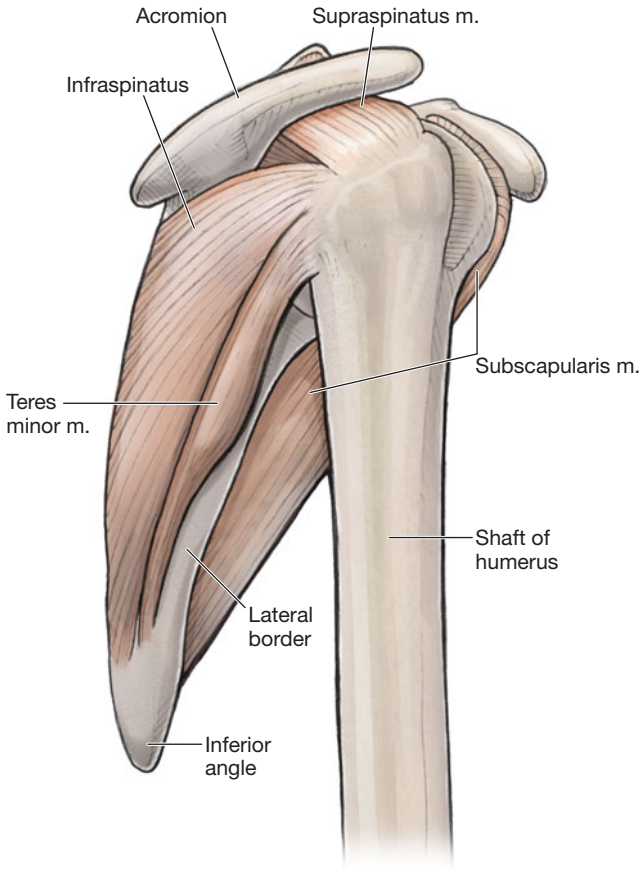

FIGURE 16-4 Rotator cuff muscles. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy*. McGraw-Hill, 2011)

head is in contact with the glenoid, with the greatest contact occurring during elevation rather than at the extremes. Contact between the humeral head and glenoid fossa is significantly reduced when the humerus is positioned in[15–17]

- adduction, flexion, and internal rotation (IR);
- abduction and elevation;
- adducted at the side, with the scapula rotated downward.

Although the labrum provides some stability for the G-H joint, additional support is provided by both dynamic and static mechanisms. The dynamic mechanisms include the muscles of the rotator cuff (supraspinatus, infraspinatus, teres minor, and subscapularis muscles) (Fig. 16-4) and a number of muscle force couples described later. The static mechanisms, which include reinforcements of the joint capsule, joint cohesion and geometry, and ligamentous support, are also described later.

The scapula (Fig. 16-1) functions as a stable base from which G-H mobility can occur. The scapula is a flat blade of bone that is oriented to contribute to stability: it lies along the thoracic cage at 30 degrees to the frontal plane, 3 degrees superiorly relative to the transverse plane to augment functional reaching motions above shoulder height,[18] and 20 degrees forward in the sagittal plane.[19–21] This orientation results in arm elevation occurring in a plane that is 30–45 degrees anterior to the frontal plane. When elevation of the arm occurs in this plane, the motion is referred to as *scapular plane abduction* or *scaption*.

CLINICAL PEARL

It has been recommended that many strengthening exercises for the shoulder joint complex be performed in the scapular plane. Reasons for this include the following:

- When the limb is positioned in the plane of the scapula, the mechanical axis of the G-H joint is in line with the mechanical axis of the scapula and movement of the humerus in this plane is less limiting than in the frontal or sagittal planes because the G-H capsule is not twisted.[22,23]
- Since the rotator cuff muscles originate on the scapula and attach to the humerus, the length–tension relationship of these muscles is enhanced in this position.

The scapula's wide and thin configuration allows for its smooth gliding along the thoracic wall and provides a large surface area for muscle attachments both distally and proximally.[24] In all, 16 muscles gain attachment to the scapula (Table 16-1). Six of these muscles, including the trapezius, rhomboids, levator scapulae, and serratus anterior, support and move the scapula, while nine of the others are concerned with G-H motion.[25–27]

Posteriorly, the scapula is divided by the elevated scapula spine into two unequally sized muscle compartments. The supraspinous fossa is small and serves as the site of origin for the supraspinatus muscle (see Fig. 16-4). The infraspinous fossa gives attachment for the downward-acting infraspinatus and teres minor muscles, important muscles for the stabilization of the humeral head (see "Muscles of the Shoulder Complex" section). The spine of the scapula (see Fig. 16-1) provides a continuous line of attachments for the supporting trapezius muscle along its upper border, whereas the deltoid muscle, which suspends the humerus, gains origin from its lower border. The undersurface of the scapula is covered by the subscapularis muscle, which also assists in stabilizing the humeral head against the glenoid fossa.

A prominent feature of the scapula is the large overhanging acromion (see Fig. 16-3), which, along with the coracoacromial ligament and the previously mentioned labrum, functionally enlarges the G-H socket. The position of the acromion also places the deltoid muscle in a dominant position to provide muscular support during elevation of the arm. Bigliani et al.[21,28] introduced the following acromion types:

TABLE 16-1 Muscles of the Scapula

Trapezius	Subscapularis
Levator scapulae	Coracobrachialis
Long and short head of the biceps	Pectoralis minor
Rhomboid major	Serratus anterior
Rhomboid minor	Long head of triceps
Supraspinatus	Teres major
Infraspinatus	Teres minor
Deltoid	Omohyoid

- Type I has a relatively flat undersurface
- Type II is slightly convex
- Type III is hooked

CLINICAL PEARL

Acromial morphology and the mechanical effect of the acromion is a strong predictor of rotator cuff impingement.[21] Cadaveric studies have confirmed a 70% incidence of rotator cuff tears in patients with a Type III acromial shape and only a 3% incidence in patients with a Type I acromion.[28,29]

The distance, or angle, between the scapula and the clavicle is variable and depends on function. While the shoulder is protracted, the angle is 50 degrees. At rest, the angle is approximately 60 degrees, and with retraction the angle increases to 70 degrees.[3]

Along the medial border of the scapula arise three muscles: the two rhomboid muscles and the serratus anterior (Fig. 16-5), all of which aid with scapular stability during arm elevation (see later). The coracoid process (see Fig. 16-3) projects forward like a crow's beak, for which it is named. This forward position provides an efficient lever whereby the small pectoralis muscle can help to stabilize the scapula. In addition, the process serves as a point of origin for the coracobrachialis and the short head of the biceps muscle.

The lateral attachment of the voluminous joint capsule of the G-H joint attaches to the anatomical neck of the humerus (Fig. 16-6).[6] Medially, the capsule is attached to the periphery of the glenoid and its labrum. The overall strength of the joint capsule bears an inverse relationship with the patient's age; the older the patient, the weaker the joint capsule. The fibrous portion of the capsule is very lax and has several recesses, depending on the position of the arm. At its inferior aspect, the capsule forms an axillary recess, which is both loose and redundant. The recess permits normal elevation of the arm, although it can also be the site of adhesions when the shoulder is immobilized in adduction. The anterior aspect of the joint capsule is reinforced by three ligaments (Z ligaments), which are described in the next section. The tendons of the rotator cuff (supraspinatus, infraspinatus, teres minor, and subscapularis) reinforce the superior, posterior, and anterior aspects of the capsule, as does the LHB tendon.

An inner synovial membrane lines the fibrous capsule and secretes synovial fluid into the joint cavity. The synovium typically lines the joint capsule and extends from the glenoid labrum down to the neck of the humerus. It also forms variously sized bursae, the largest of which, the subacromial or subdeltoid bursa, lies on the superior aspect of the joint (see later).

The greater and lesser tuberosities (see Fig. 16-1), which serve as attachment sites for the tendons of the rotator cuff muscles, are located on the lateral aspect of the anatomical neck of the humerus, an imaginary line that separates the humeral head from the rest of the humerus. The lesser tuberosity serves as the attachment for the subscapularis. The greater tuberosity serves as the attachment for the supraspinatus, infraspinatus, and teres minor. The greater and lesser tuberosities are separated by the intertubercular groove (see Fig. 16-1), through which passes the tendon of the LHB on its route to attach to the superior rim of the glenoid fossa. This groove has wide variance in the angle of its walls, but 70% fall within a 60–75-degree range.[30] Certain shoulder disorders, including rotator cuff and bicipital tendinitis, have been associated with anomalies of this groove.[31] As the tendon of the LHB (Fig. 16-7) passes over the humeral head from its origin, it makes a right-angle turn to lie in the anterior aspect of the humerus. This abrupt turn may permit abnormal wearing of the tendon at this point.

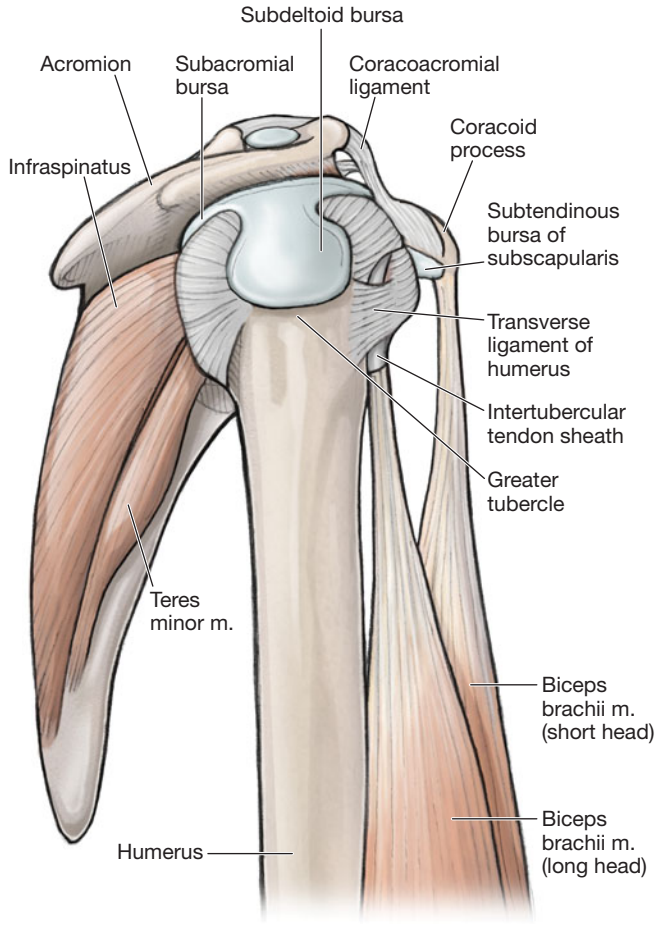

FIGURE 16-7 Soft tissue structures of the shoulder. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy.*McGraw-Hill, 2011)

The roof of this groove is formed by the transverse ligament. The transverse humeral ligament (Fig. 16-7), which runs perpendicular over the biceps tendon, was once thought to function as a restraint to the biceps tendon within the intertubercular groove. However, this appears to be the role of the coracohumeral ligament.[31]

The region below the greater and lesser tuberosities, where the upper margin of the humerus joins the shaft of the humerus, is referred to as the surgical neck (Fig. 16-1). The axillary nerve and posterior humeral circumflex artery lie in close proximity to the medial aspect of the surgical neck.

CLINICAL PEARL

Fractures of the surgical neck of the humerus occur more frequently than fractures of the anatomical neck, and they are most likely to cause damage to the axillary nerve.

Ligaments

A number of structures function as static stabilizers during motion of the arm to reciprocally tighten and loosen, thereby limiting translation and rotation of the G-H joint surfaces in a load-sharing fashion.[32] These include the G-H ligaments and the posterior capsule. Further static stabilization is provided by the glenoid labrum. The posterior capsule is under tension when the shoulder is in flexion, abduction, IR (in particular, the superior and middle segments), or in any combination of these.

At the anterior portion of the outer fibers of the joint capsule, three local reinforcements are present: the superior, middle, and inferior G-H ligaments (Fig. 16-6). Together with the coracohumeral ligament, these ligaments form a Z-pattern on the anterior aspect of the shoulder (Fig. 16-6).[33] In the midrange of rotation, the G-H ligaments are relatively lax and stability is maintained primarily by the action of the rotator cuff muscle group compressing the humeral head into the conforming glenoid articulation.[32] The G-H ligaments appear to produce a major restraint during shoulder flexion, extension, and rotation[34]:

- The anterior G-H ligament is under tension when the shoulder is in extension, abduction, and/or external rotation (ER).
- The posterior G-H ligament is under tension in flexion and ER.
- The inferior G-H ligament is the most important of the G-H ligaments. It is under tension when the shoulder is abducted, extended, and/or externally rotated. In addition, this ligament is a primary restraint against both anterior and posterior dislocations of the humeral head, and is the most important stabilizing structure of the shoulder in the overhead athlete.[35] At 0-degree abduction, the subscapularis muscle, the labrum, and the superior G-H ligament are the

primary restraints against anterior translation. At 45-degree abduction, the subscapularis muscle and the middle and inferior G-H ligaments, along with labrum, prevent anterior translation. When the arm is abducted more than 90 degrees, which is the most common position of anterior dislocation, the anterior fibers of the inferior G-H ligament are the primary restraint anterior movement.[9,36]

- The middle G-H ligament is under tension when the shoulder is flexed and externally rotated. In addition, the middle G-H ligament and the subscapularis tendon limit ER from 45 to 75 degrees of abduction, and are important anterior stabilizers.

Other ligaments (Fig. 16-6) help provide stability to the G-H joint. These include the following:

- ***The coracohumeral ligament.*** The coracohumeral ligament (see Fig. 16-6) arises from the lateral end of the coracoid process and runs laterally, where it is split into two bands by the presence of the biceps tendon. The posterior band blends with the supraspinatus tendon to insert near the greater tuberosity, and the anterior band blends with the subscapularis tendon to insert near the lesser tuberosity. The coracohumeral ligament covers the superior GH ligament anterosuperiorly and fills the space between the tendons of the supraspinatus and subscapularis muscles, uniting these tendons to complete the rotator cuff in this area. Tears of the cuff usually extend longitudinally between the supraspinatus and coracohumeral ligament so that the hood action of the cuff is lost. It is generally agreed that the posterior band of the coracohumeral ligament limits flexion, whereas the anterior band limits extension of the G-H joint.[37] Both the bands also limit inferior and posterior translation of the humeral head, strengthening the superoanterior aspect of the capsule.[37,38]
- ***The coracoacromial ligament.*** The coracoacromial ligament (see Fig. 16-6) is often described as the roof of the shoulder. It is a very thick structure that runs from the coracoid process to the anteroinferior aspect of the acromion, with some of its fibers extending to the A-C joint. The ligament consists of two bands that join near the acromion, and it is ideally suited, both anatomically and morphologically, to prevent separation of the A-C joint surfaces. The coracoclavicular ligaments and the costoclavicular ligament are described in the A-C joint section and the S-C joint section, respectively.

Coracoacromial Arch

The coracoacromial arch (Fig. 16-6) is formed by the anteroinferior aspect of the acromion process, and the coracoacromial ligament, which connects the coracoid to the acromion and the inferior surface of the A-C joint.[39–41] A number of structures are located in the subacromial space (Fig. 16-7) between the coracoacromial arch superiorly and the humeral head inferiorly, and the coracoid process, anteromedially. These include (from inferior to superior) the following:

- the head of the humerus,
- the long head of biceps tendon (intra-articular portion),
- the superior aspect of the joint capsule,
- the supraspinatus and upper margins of subscapularis and infraspinatus,
- the subdeltoid–subacromial bursae,
- the inferior surface of coracoacromial arch.

In normal individuals, the suprahumeral space averages 10–11 mm in height with the arm adducted to the side.[42,43] Elevating the arm decreases this space, and the space is at its narrowest between 60 and 120 degrees of scaption.[44] During overhead motion in the plane of the scapula, the supraspinatus tendon, the region of the cuff most involved in overuse syndromes of the shoulder, can pass directly underneath the coracoacromial arch. If the arm is elevated while internally rotated, the supraspinatus tendon passes under the coracoacromial ligament, whereas if the arm is externally rotated, the tendon passes under the acromion itself.[45]

Muscle imbalances or capsular contractures can cause an increase in superior translation of the humeral head, narrowing the subacromial space. For example, if the rotator cuff muscles are weak or injured, increased translation occurs between the humeral head and the glenoid labrum.[46] This increase in translation may lead to increased wear on the labrum, increased reliance on the static restraints (e.g., ligaments, capsule), and eccentric overloading of the dynamic (muscle) restraints, which in turn can result in instability and/or a condition termed "subacromial impingement syndrome (SIS)."[47,48]

Bursae

Approximately eight bursae are distributed throughout the shoulder complex. The subdeltoid–subacromial bursae (see Fig. 16-7) are collectively referred to as the subacromial bursa because they are often continuous in nature. The subacromial bursa is one of the largest bursae in the body and provides two smooth serosal layers, one of which adheres to the overlying deltoid muscle and the other to the rotator cuff lying beneath. This bursa is also connected to the acromion, greater tuberosity, and coracoacromial ligament. As the humerus elevates, it permits the rotator cuff to slide easily beneath the deltoid muscle. There are also smaller bursae interposed between most of the muscles in contact with the joint capsule:

- ***The subcoracoid bursa.*** This bursa is located under the coracoid process.
- ***The subscapular bursa.*** This bursa is located between the subscapular muscle tendon and the anterior neck of the scapula and protects the tendon as it passes under the coracoid process.

Neurology

The shoulder complex is embryologically derived from C5 to C8, except the A-C joint, which is derived from C4 (Fig. 16-8). The sympathetic nerve supply to the shoulder originates primarily in the thoracic region from T2 down as far as T8.[49]

One study[50] attempted to determine the variability of the course and the pattern of these nerves and found that the peripheral nerves contributing to the anterior shoulder joint included the axillary (C5–6), subscapular (C5–6), and lateral pectoral (C5–6). The same study found that the nerves

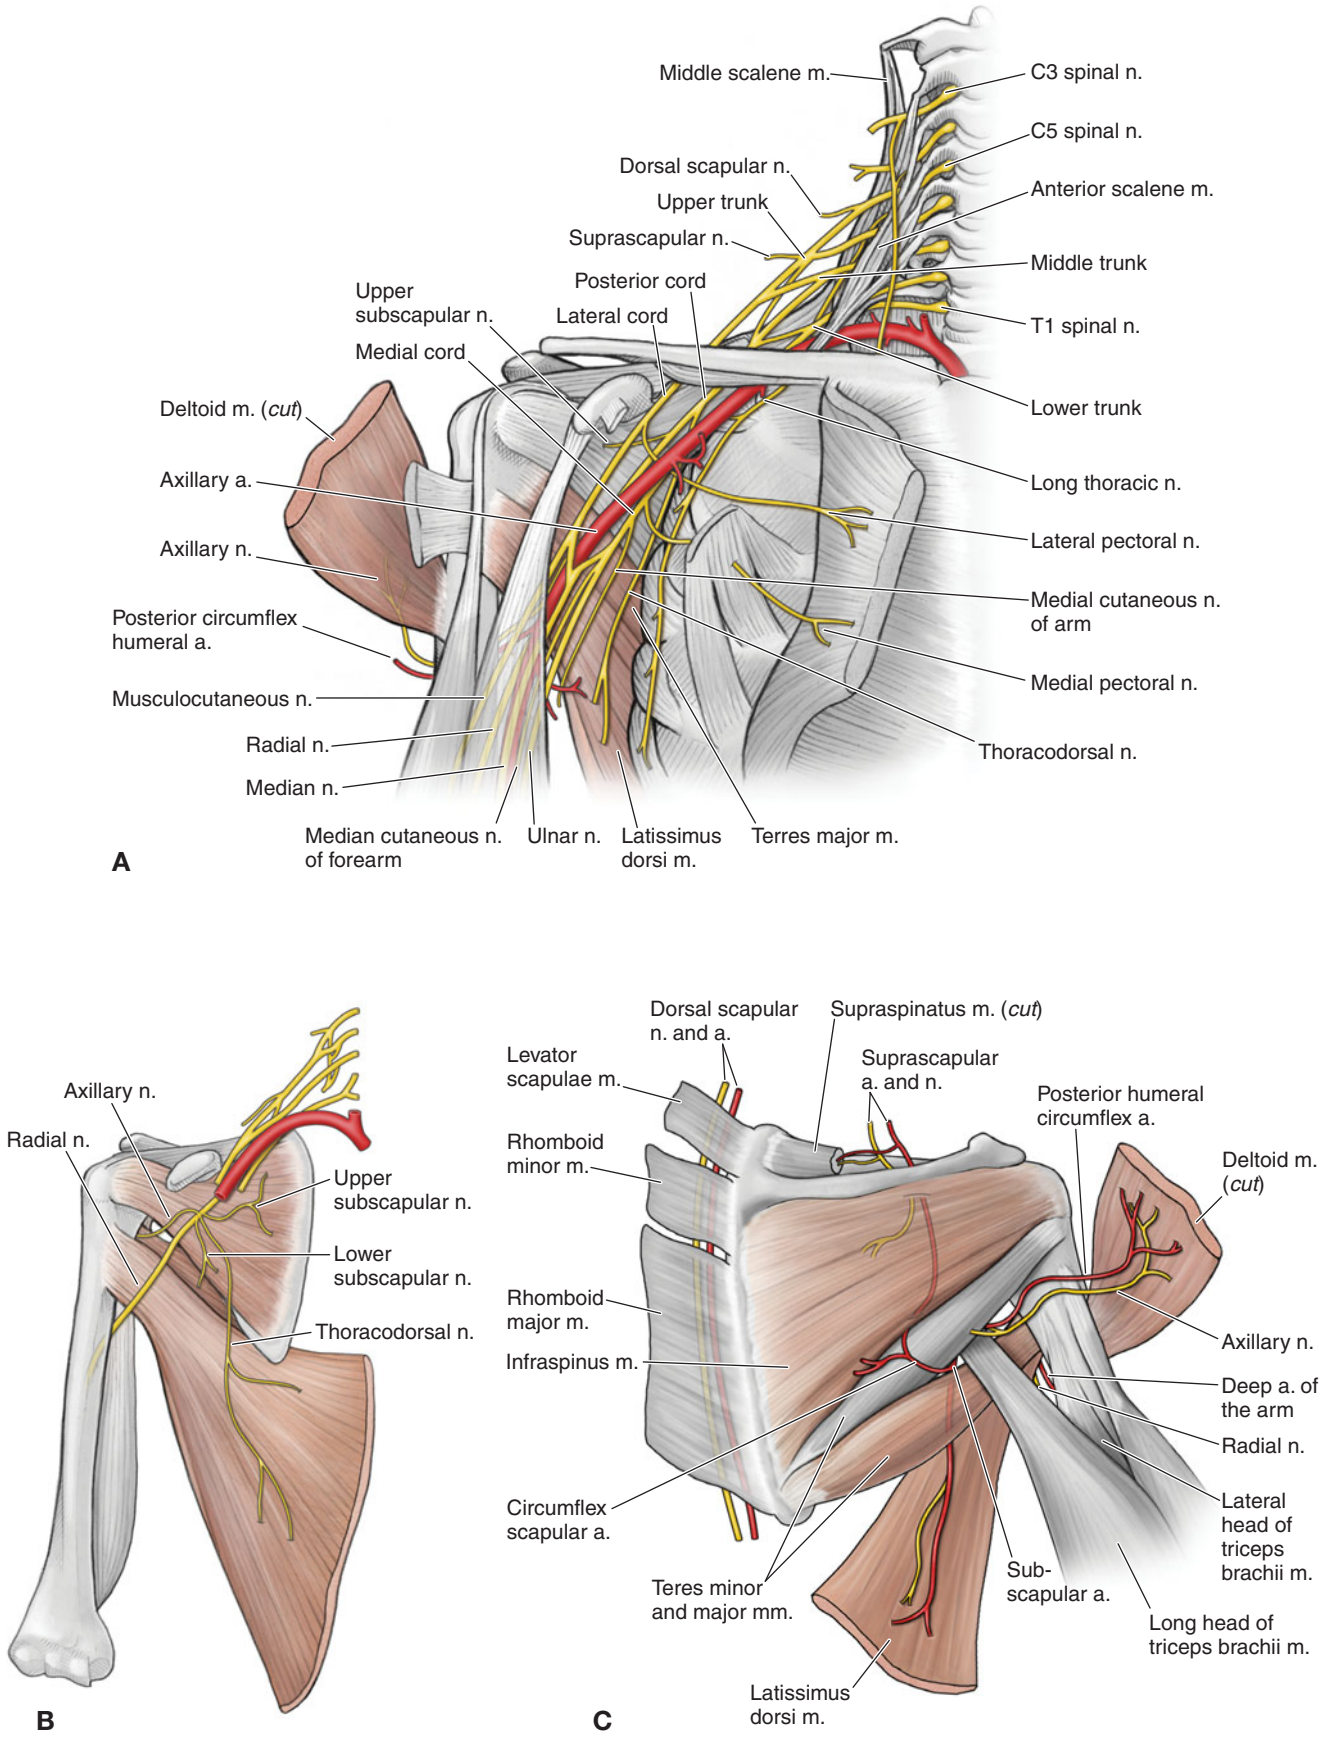

FIGURE 16-8 Neurological and vascular structures of the shoulder. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy.* McGraw-Hill, 2011)

contributing articular branches to the posterior joint structures are the suprascapular nerve (C5–6) and small branches of the axillary nerve.[50] The pathways of these nerves are described in Chapter 3.

Other nerves innervate the muscles that act upon the shoulder. These include the long thoracic nerve (C5–7), which innervates the serratus anterior, the spinal accessory nerve (cranial nerve XI and C3–4), which innervates the sternocleidomastoid (SCM) and trapezius muscles, and the musculocutaneous nerve (C5–7), which innervates the coracobrachialis, biceps brachii, and brachialis, before dividing into its cutaneous branches.

CLINICAL PEARL

Shoulder pain that persists despite extensive conservative approaches could be of neural origin, as the peripheral nerves that innervate the ligaments, capsule, and bursae of the shoulder joint may have been subject to damage, either at the time of initial trauma or through subsequent surgical intervention.[50–52]

Vascularization

The vascular supply to the shoulder complex is primarily provided by branches off the axillary artery (Fig. 16-9), which begins at the outer border of the first rib as a continuation of the subclavian artery. The axillary artery is commonly divided into three parts: above, behind, and below the pectoralis minor muscle. The axillary artery meets the more deeply placed brachial plexus in the neck, and here they are encased in the axillary sheath, together with the axillary vein.[53] The lateral, posterior, and medial cords of the brachial plexus descend behind the first portion of the artery and then take up their respective locations at the second portion of the artery (behind the pectoralis minor muscle). The branches off these cords also maintain their respective positions. Compression of the axillary artery (or, to a lesser degree, the axillary vein) can result in shoulder dysfunction and most commonly occurs in the posterior fossa around the shoulder and against the humerus with shoulder elevation.[53] The G-H joint receives its blood supply from the anterior and posterior circumflex humeral as well as the suprascapular and circumflex scapular vessels.[54] The vascular supply to the labrum arises mostly from its peripheral attachment to the capsule and is from a combination of the suprascapular circumflex scapular branch of the subscapular and posterior circumflex humeral arteries.[8]

The brachial artery provides the dominant arterial supply to each of the two heads of the biceps brachii. The artery travels in the medial intermuscular septum and is bordered by the biceps muscle anteriorly, the brachialis muscle medially, and the medial head of the triceps muscle posteriorly.[55]

The microvasculature of the rotator cuff has been the subject of much discussion and consists of three main sources: the thoracoacromial, suprahumeral, and subscapular arteries.[54] The supraspinatus receives its primary supply from the thoracoacromial arteries. The subscapularis receives its supply from the anterior humeral circumflex and the thoracoacromial arteries. The posterior rotator cuff muscles, the infraspinatus and teres minor, receive their blood supply from the posterior humeral circumflex and suprascapular artery. The circulation of the rotator cuff is unidirectional with no flow traversing the tide mark at the insertion of the supraspinatus.[56] The supraspinatus and biceps tendons appear to be particularly vulnerable to areas of relative avascularity, referred to as *critical zones*. The vascular compromise of the supraspinatus is thought to be due to a number of factors:

- It can be directly compressed by the subacromial structures. With the arm adducted to the side, the vessels within the supraspinatus tendon are poorly perfused.[57] Other arm positions, such as raising the arm above 30 degrees, have been shown to increase intramuscular pressure in the supraspinatus muscle to an extent that may impair normal blood perfusion.[57,58]
- Its blood vessels travel parallel to the tendon fibers, which make them vulnerable to stretch.[59] Avascularity appears to increase with age beginning as early as 20 years.[60]
- The presence of a critical zone just proximal to the supraspinatus insertion point.[57] Two early studies noted a critical zone that lies slightly proximal to the supraspinatus insertion point.[61,62] Since then, it has been determined that the critical zone is more likely a zone of anastomoses between the vessels supplying the bone and the tendon and is not less vascular except in certain positions.[57,63,64]

Although it is possible that sustained isometric contractions, prolonged adduction of the arm or increase in subacromial pressure[65] may reduce the microcirculation, it is unlikely that frequent abduction or elevation of the arm would produce selective avascularity of the supraspinatus or biceps tendon.

Close-Packed Position

The close-packed position for the G-H joint is 90 degrees of G-H abduction and full ER or full abduction and ER, depending on the source.

Open-Packed Position

Without IR or ER occurring, the open-packed position of the G-H joint has traditionally been cited as 55 degrees of semi-abduction and 30 degrees of horizontal adduction.[66] More recently, a cadaver study, which examined the point in the range at which maximal capsular laxity occurred in seven subjects, determined the open-packed position to be 39 degrees of abduction in the scapular plane or at the point which is 45% of the maximal available abduction range of motion (ROM).[67] This finding suggests that the open-packed position may be closer to neutral and that joint mobility testing and joint mobilizations of the G-H joint should be initiated according to a smaller angle of abduction than the traditionally cited open-packed position.[67]

The zero position for the G-H joint is the arm relaxed by the side, which, relative to the scapula, averages approximately 0 degree of abduction, 12 degrees of flexion, and 10 degrees of ER.[68]

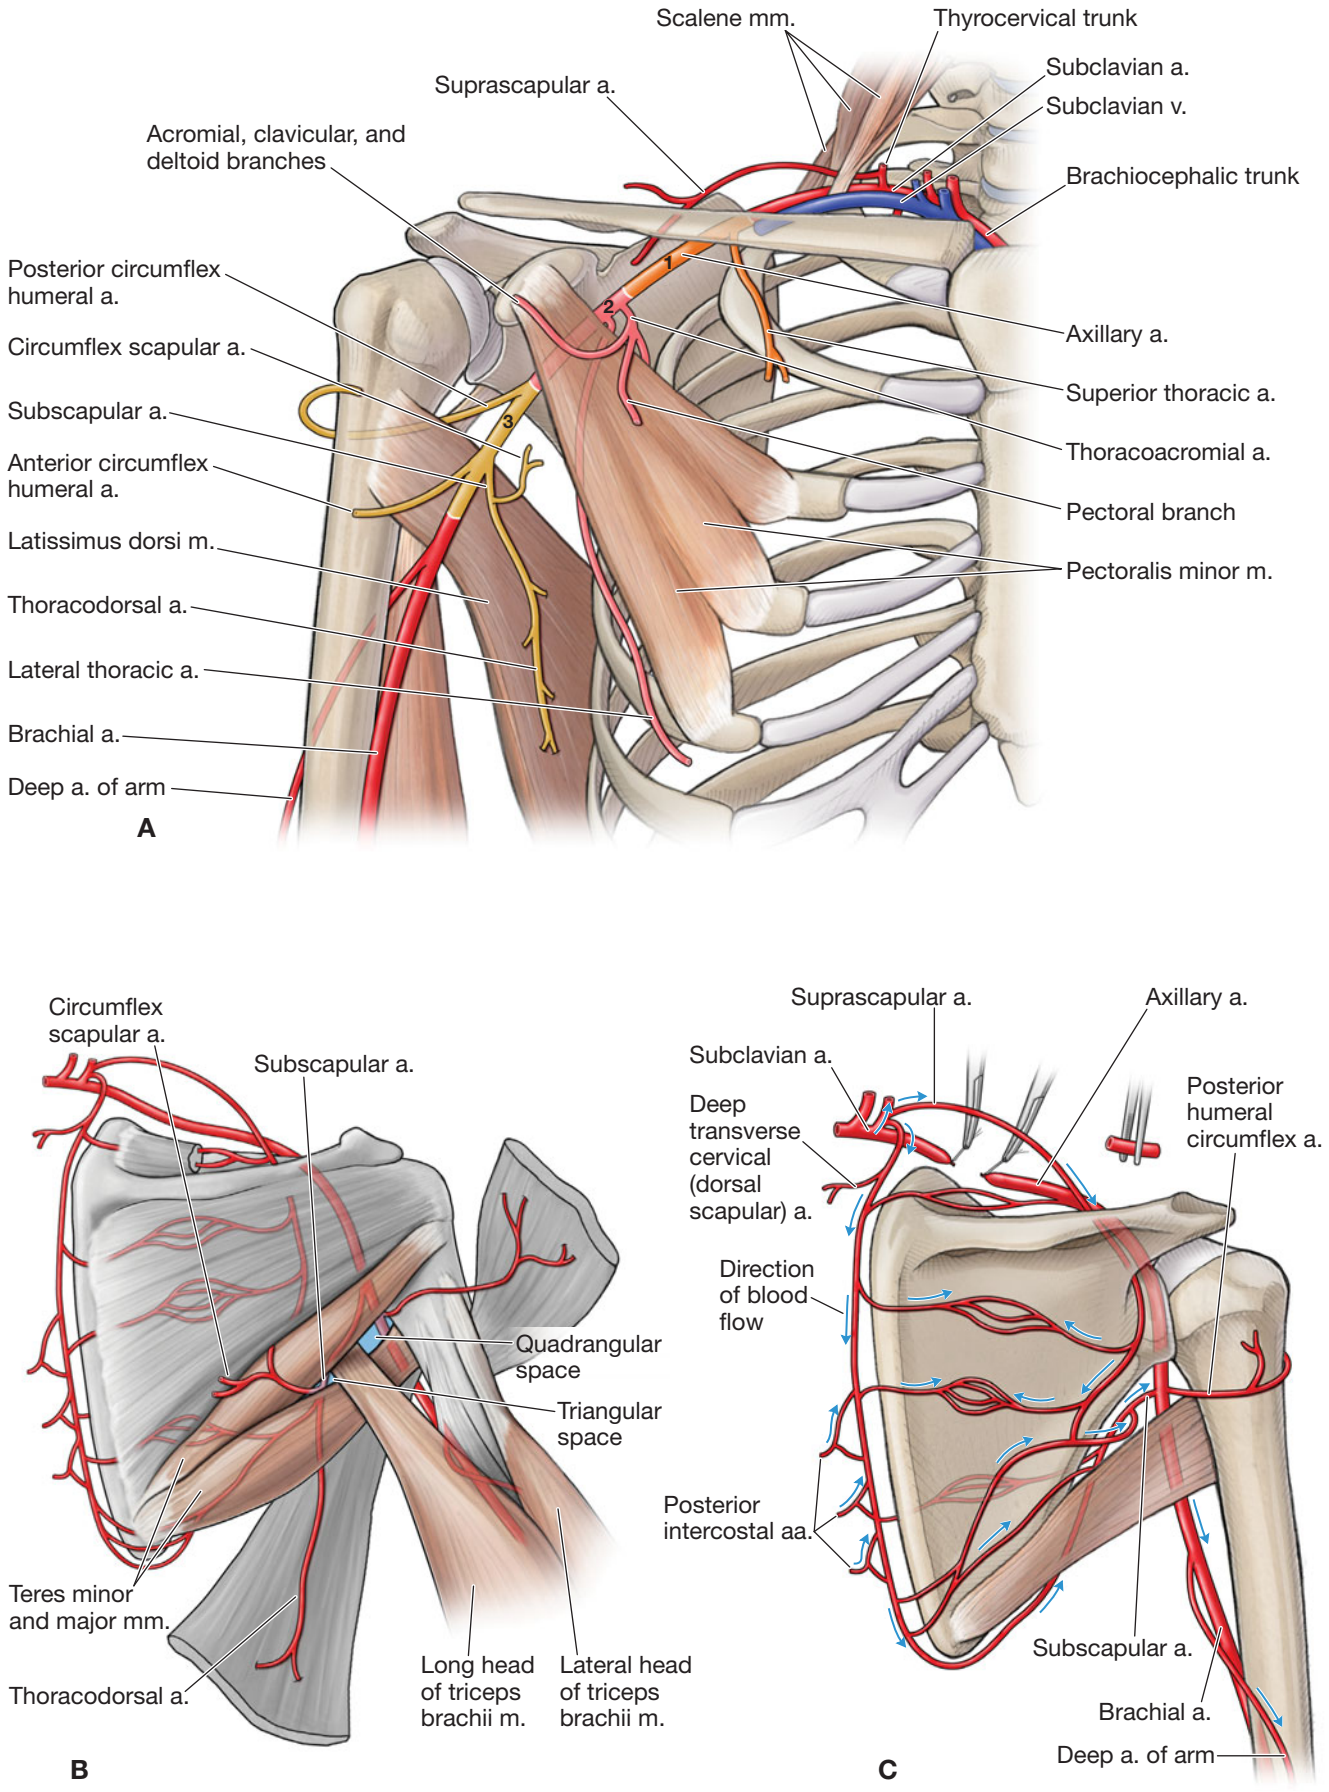

FIGURE 16-9 Vascularization of the shoulder. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy.* McGraw-Hill, 2011)

Capsular Pattern

According to Cyriax,[69] the capsular pattern for the G-H joint is that ER is the most limited, abduction the next most limited, and IR the least limited in a 3:2:1 ratio, respectively. However, this pattern only appears to be consistent with adhesive capsulitis of the shoulder. IR, rather than ER or abduction, appears to be the most limited motion in conditions with selected capsular hypomobility.[70]

THE ACROMIOCLAVICULAR JOINT

The A-C joint is a diarthrodial joint, formed by the medial margin of the acromion and the lateral end of the clavicle. The A-C joint is most often described as a gliding or plane joint, but the joint surfaces can vary from flat to slightly convex or concave, corresponding with the articulating surface of the acromion. In the early stages of development, the articular surfaces of the A-C joint are lined with hyaline cartilage, which changes to fibrocartilage at approximately 17 years of age on the acromial side of the joint, and until approximately 24 years of age on the clavicular side.[71] Within the A-C joint, there is variable presence of a thumbtack-shaped intra-articular fibrous disk that projects superiorly into, and incompletely divides, the A-C joint. This disk is subject to tearing.[71] When viewed from above, the clavicle is convex anteriorly in the medial two-thirds and convex posteriorly in the lateral one-third (see Fig. 16-1). Variability in the inclination of the joint is common and can be anywhere from 10 to 50 degrees, but the anteromedial border of the acromion usually faces anteriorly, medially, and superiorly.[72] This variability may account for the differences in vulnerability to separation seen among people.[73]

The A-C joint serves as the main articulation that suspends the upper extremity from the trunk, and it is at this joint about which the scapula moves. The clavicle serves as the lever by which the upper extremity acts on the torso and as an attachment site for many soft tissues.[71,74] The joint has a thin capsule lined with synovium, which is strengthened anteriorly, posteriorly, inferiorly and superiorly by A-C ligaments (see Fig. 16-6). The superior A-C ligament (see Fig. 16-6) gives support to the capsule and serves as the primary restraint to posterior translation and posterior axial rotation at the joint.[71] Other support structures for the joint include the costoclavicular, coracoclavicular (conoid and trapezoid) ligament, the pectoralis major, SCM, deltoid, and trapezius muscles (see Fig. 16-10).[74,75]

CLINICAL PEARL

Degenerative changes of the A-C joint, including narrowing of the joint space and the formation of inferior osteophytes, can predispose an individual to SIS.[41,76,77]

Ligaments

The coracoclavicular ligament (conoid and trapezoid portions) (see Fig. 16-6) is the primary support for the A-C joint and runs from the coracoid process to the inferior surface of the clavicle. The conoid ligament (see Fig. 16-6) is

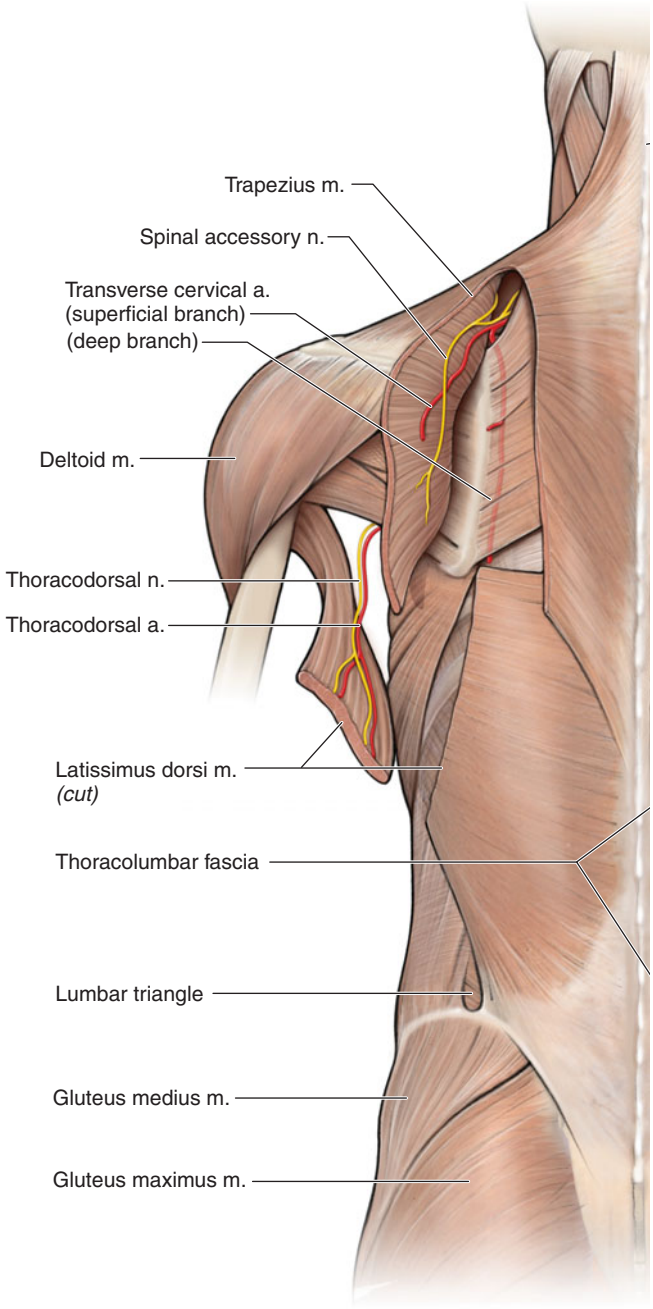

FIGURE 16-10 Muscles of the shoulder. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy*. McGraw-Hill, 2011)

fan shaped with its apex pointing inferiorly. It lies in the frontal plane and is the more medial of the two ligaments. This ligament functions to block coracoid movement away from the clavicle inferiorly.[78] The trapezoid ligament arises from the medial border of the upper surface of the coracoid process and runs superiorly and laterally to insert into the inferior surface of the clavicle. It is larger, longer, and stronger than the conoid and forms a quadrilateral sheet that lies in a plane that is at right angles to the plane formed by the conoid ligament. The function of this ligament is unclear, although its orientation suggests that it may block medial movement of the coracoid[78] or act as a restraint to superior or posterior displacement of the clavicle.[79] In

addition, as the clavicle rotates upward, the coracoclavicular ligament dictates scapulothoracic rotation by virtue of its attachment to the scapula.[80]

CLINICAL PEARL

The conoid and trapezoid ligaments provide mainly vertical stability, with control of superior and anterior translation as well as anterior axial rotation.[71,78,81]

Neurology

Innervation to this joint is provided by the suprascapular, lateral pectoral, and axillary nerves (Fig. 16-8).[82]

Vascularization

The A-C joint receives its blood supply from branches of the suprascapular and thoracoacromial arteries (Fig. 16-9).

Capsular Pattern

Joints such as the A-C joint, which are not controlled by muscles, lack true capsular patterns. However, anecdotal clinical evidence suggests that the capsular pattern for the A-C joint is pain at the extremes of ROM, especially horizontal adduction and full elevation.

Close-Packed Position

The close-packed position for this joint is probably only achievable in the below-30 age group and clinically seems to correspond to 90 degrees of G-H joint abduction.

Open-Packed Position

The open-packed position for this joint is undetermined, although it is likely to be when the arm is by the side. This positions the clavicle in approximately 15–20 degrees of retraction relative to the coronal plane and elevated approximately 2 degrees from the horizontal plane.[83]

The motions available at the A-C joint occur around three axes:

- Rotation in an anteroposterior (A-P) direction around a longitudinal axis that projects through the A-C and S-C joints, and rotation in a superoinferior (vertical) direction. The A-P rotation occurs during arm elevation. The superoinferior rotation, which occurs around the costoclavicular ligament, is involved during protraction (anterior movement of the acromial end of the clavicle) and retraction (posterior motion of the acromial end). The A-P rotation of the clavicle on the scapula is three times greater than that of the superoinferior rotation. The clavicle can rotate approximately 30–50 degrees in the A-P direction, most of which is contributed by the mobile S-C joint. The A-C joint only contributes approximately 5–8 degrees to the rotation.[84] The type of glide and rotation that occurs with clavicular motion depends on the shoulder motion and the shape of the articular surfaces. If the lateral end of the clavicle presents a concave surface, an anterior glide is combined with an anterior rotation. If the lateral end presents a convex surface, an anterior glide is combined with a posterior rotation.

CLINICAL PEARL

The clavicle must rotate approximately 40–50 degrees for full elevation to occur; otherwise elevation would be limited to approximately 110 degrees.[84]

- Pure spin/rotation. A pure spin occurs during abduction/adduction (lateral and medial rotation of inferior scapula angle) motions.
- Glides. Glides of the clavicle can occur in an A-P and superoinferior direction.

The A-C joint is predisposed to chronic stress injury, especially in the situations in which it is subjected to repetitive high demand.[71,85] The joint can also be affected by direct trauma and by nontraumatic factors such as degenerative arthritis and inflammatory arthropathies.[74] Table 16-2 contains the pathologies and dysfunctions that may affect the A-C joint.

STERNOCLAVICULAR JOINT

The S-C joint represents the articulation between the enlarged medial end of the clavicle, the clavicular notch of the manubrium of the sternum, and the cartilage of the first rib, which forms the floor of the joint. The articulating surfaces of the S-C joint are covered with fibrocartilage. The S-C joint is angulated slightly upward approximately 20 degrees in a posterior and lateral direction. The clavicle presents with an irregularly shaped surface to the meniscus, and this lateral part of the joint acts as an ovoid. If held vertically, the proximal end of the clavicle is convex whereas the manubrium surface is concave (see Fig. 16-1). If held

TABLE 16-2 Pathologies and Dysfunctions that May Affect the A-C Joint

Traumatic conditions	Separation/dislocation (types I–VI) fracture
Infectious conditions	Septic arthritis
Inflammatory conditions	Rheumatoid arthritis Systemic lupus erythematosus Ankylosing spondylitis Subacromial bursitis Rotator cuff pathology
Degenerative joint disease	Osteoarthritis Osteolysis
Metabolic conditions	Gout

Data from Powell JW, Huijbregts PA: Concurrent criterion-related validity of acromioclavicular joint physical examination tests: A systematic review. *J Man Manip Ther* 14:E19–E29, 2006.

anteroposteriorly, the proximal end of the clavicle is concave and the manubrium is convex. A very thick meniscus is the key to the joint curvature. The disk is attached to the upper and posterior margin of the clavicle, and to the cartilage of the first rib by an intra-articular disk ligament, which functions to help prevent medial displacement of the clavicle, and completely divides the joint into two cavities: a larger one that is above and lateral to the disk, and a smaller one that is medial and below the disk. Greater movement occurs between the clavicle and the disk than between the disk and the manubrium. The S-C joint has very little bony stability and relies heavily on support from the surrounding capsule and ligaments.

Some confusion seems to exist about classification of the S-C joint—it has been classified as a ball and socket joint,[82] a plane joint,[86] and as a saddle joint.[82] These classifications depend on whether anatomy or function is being considered. For example, when its function is considered, the S-C joint acts similar to a ball and socket joint, allowing for motion in almost all planes, including rotation.

CLINICAL PEARL

During normal shoulder motion, the S-C joint permits 30–35 degrees of upward elevation, 35 degrees of combined forward and backward movement, and 45–50 degrees of rotation about the long axis of the clavicle.[3,87]

Ligaments

Because of its bony arrangement, the S-C joint itself is extremely weak, but is held securely by strong ligaments that hold the sternal end of the clavicle downward and toward the sternum. These ligaments include the following:

Capsular-Ligamentous Structures

Capsular Ligament. This ligament represents the inner aspect of the joint capsule. The anterior portion is heavier and stronger, and it covers the anterior aspect of the joint running obliquely from the proximal end of the clavicle to the sternum in an inferior and medial direction. The posterior component, which covers the posterior aspect of the joint, also runs obliquely from the proximal end of the clavicle to the sternum in an inferior and medial direction. The capsular ligament is considered the most important and strongest ligaments of the S-C joint and is most responsible for preventing upward displacement of the medial clavicle in the presence of a downward force on the distal end of the shoulder.[88]

Interclavicular. This ligament connects the superomedial sternal ends of each clavicle with the capsular ligaments and the upper sternum. Together, these structures help to hold up the shoulder. This function can be demonstrated by placing a finger in the superior sternal notch; the ligament is lax with elevation of the arm but becomes taut when both arms are hanging by the sides.

Costoclavicular (rhomboid ligament). This short and strong ligament, which runs from the upper border of the first rib to the inferior surface of the clavicle, consists of two laminae: fibers of the anterior lamina run superiorly and laterally and check elevation and lateral movement (upward rotation) of the clavicle.[88] The posterior lamina fibers run superiorly and medially and check downward rotation of the clavicle.[88]

Due to the support provided by the ligaments, the S-C joint is very stable and trauma to the clavicle usually results in a fracture rather than a joint dislocation.[89] Gross motions occur here as with the A-C joint. The SCM, which can be seen clearly with rotation of the head, has a tendinous sternal and clavicular insertion. The subclavius (C5–6) has a questionable function but may function as a dynamic ligament, which contracts and pulls the clavicle toward the manubrium.

Two types of translation also occur at this joint: anterior to posterior and superior to inferior, with the former exceeding the latter motion by 2:1.[90] These translations allow for three degrees of freedom (DOF): the movements of elevation, depression; protraction, retraction; and upward (backward) and downward (forward) motion.

- ***Protraction/retraction.*** Approximately 15–20 degrees of protraction and retraction of the clavicle are available. With protraction, the concave surface of the medial clavicle moves on the convex sternum, producing an anterior glide of the clavicle, and an anterior rotation of the lateral clavicle.[90] With retraction to the neutral position, the medial clavicle articulates with a flat surface and tilts/swings, causing an anterolateral gapping, and a posterior rotation at the lateral end.[90]
- ***Elevation/depression of the clavicle.*** There are 35–40 degrees of elevation and approximately 15 degrees of depression available,[3,87,90] involving the convex clavicle gliding on the concave sternum.

As the clavicle elevates and rolls upward on the manubrium, an inferior glide is produced, with the reverse occurring with depression. Elevation and depression movements at the S-C joint are associated with reciprocal motions of the scapula because of the lateral attachment of the clavicle to the scapula at the A-C joint.[75]

Rotation around the long axis produces a spin of the clavicle on the manubrium. Approximately 40 degrees of upward rotation and 5 degrees of downward rotation are available and are necessary to allow upward scapular rotation.[3,87]

CLINICAL PEARL

For the scapular to abduct and upwardly rotate throughout 180 degrees of humeral abduction, clavicular movement must occur at both the S-C and A-C joints.

Close-Packed Position

The close-packed position for the S-C joint is maximum arm elevation and protraction.

Open-Packed Position

The open-packed position for the S-C joint has yet to be determined, but is likely to be when the arm is by the side.

Capsular Pattern

Similar to the A-C joint, the S-C joint is not controlled by muscles and therefore lacks a specific capsular pattern. One possibility, seen clinically, is pain at the extreme ranges of motion, especially full arm elevation and horizontal adduction.

Neurology

Pain can be referred from this joint to the throat, anterior chest, and axillae. The neural supply to this joint is primarily from the following[91]:

- The anterior supraclavicular nerve
- The nerve to the subclavius (medial accessory phrenic) C5–6
- The T1 spinal nerve root

Vascularization

The S-C joint receives its blood supply from the internal thoracic and suprascapular arteries.[92]

SCAPULOTHORACIC JOINT

This articulation is functionally a joint, but it lacks the anatomic characteristics of a true synovial joint. However, the movement of the scapula on the wall of the thoracic cage is critical to shoulder joint motion. A lack of ligamentous support at this "joint" delegates the function of stability fully to the muscles that attach the scapula to the thorax.

An altered position of the scapula or an abnormal motion at this joint due to muscle imbalances have both been linked with shoulder complex dysfunction.[24,93,94] Motions at this joint are described according to the movement of the scapula relative to the thorax. Available motion consists of approximately 60 degrees of upward rotation of the scapula, 40–60 degrees of IR/ER, and 30–40 degrees of anterior and posterior tipping of the scapula.[95] Other motions occurring here include elevation and depression and adduction and abduction of the scapula (Fig. 16-11).

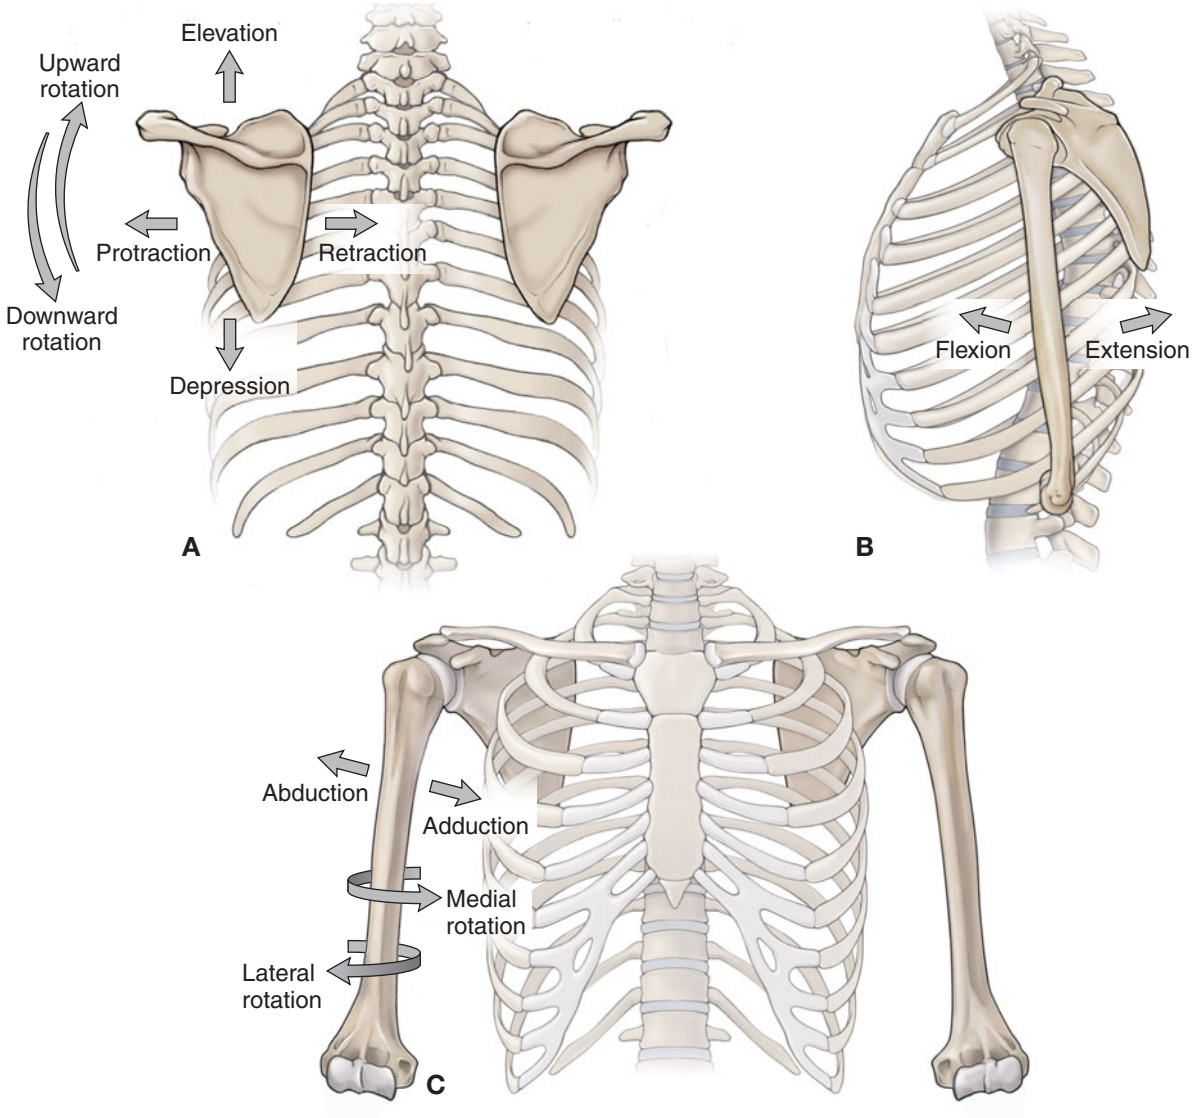

FIGURE 16-11 Movements of the scapula and upper extremity. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy*. McGraw-Hill, 2011)

Close-Packed and Capsular Pattern

Since the scapulothoracic joint is not a true joint, it does not have a close-packed position or a capsular pattern.

Open-Packed Position

Relative to the thorax, when the arm is by the side, the scapula is in an average of 30–45 degrees of IR, and slight upward rotation, and approximately 5–20 degrees of anterior tipping.[68,95]

Bursae

There are a number of bursae located in and around the scapulothoracic articulation. The scapulothoracic bursa is located between the thoracic cage and the deep surface of the serratus anterior.[96] The subscapular bursa is most often located between the superficial surface of the serratus anterior and the subscapularis.[96]

The scapulotrapezial bursa lies between the middle and lower trapezius fibers and the superomedial scapula.[96] The purpose and clinical significance of the scapulotrapezial bursa are not known. It may encourage smooth gliding of the superomedial angle of the scapula against the undersurface of the trapezius during scapular rotation in the same manner that the scapulothoracic bursa (between the serratus attachment at the anteromedial surface of the superior angle) encourages smooth gliding against the underlying ribs.[96] It is possible that inflammation of either of these bursae, directly or as a consequence of injury, may result in painful clicking at the superomedial angle of the scapula.[96]

The relationship of the spinal accessory nerve to the scapulotrapezial bursa may also have clinical importance, especially as it is closely applied to the superficial wall of the scapulotrapezial bursa.[96] The spinal accessory nerve receives afferent fibers from C3 and C4, which are thought to be proprioceptive, before reaching the deep surface of the trapezius.[96,97] As a consequence of their proximity, inflammation and fibrosis within the bursa may cause irritation and pain of the nerve, or interference with the normal proprioceptive feedback mechanism provided by the nerve.[96]

MUSCLES OF THE SHOULDER COMPLEX

A number of significant muscles control motion at the shoulder and provide dynamic stabilization. Rarely does a single muscle act in isolation at the shoulder. For simplicity, the muscles acting at the shoulder may be described in terms of their functional roles: scapular pivoters, humeral propellers, humeral positioners, and shoulder protectors (Table 16-3).[98]

TABLE 16-3 Muscles of the Shoulder Complex

Shoulder protectors
Rotator cuff (supraspinatus, infraspinatus, teres minor, and subscapularis)
Long head of the biceps brachii

Scapular Pivoters

The scapular pivoters comprise the trapezius, serratus anterior, levator scapulae, rhomboid major, and rhomboid minor.[98] As a group, these muscles are involved with motions at the scapulothoracic articulation, and their proper function is vital to the normal biomechanics of the whole shoulder complex. The scapular muscles can contract isometrically, concentric, or eccentrically, depending on the desired action and whether the action involves stabilization, acceleration, or deceleration. To varying degrees, the serratus anterior and all parts of the trapezius cooperate during the upward rotation of the scapula.

Trapezius

The trapezius muscle (Fig. 16-10) originates from the medial third of the superior nuchal line, the external occipital protuberance, the ligamentum nuchae, the apices of the seventh cervical vertebra, all the thoracic spinous processes, and the supraspinous ligaments of the cervical and thoracic vertebrae. The upper fibers descend to attach to the lateral third of the posterior border of the clavicle. The middle fibers of the trapezius run horizontally to the medial acromial margin and superior lip of the spine of the scapula. The inferior fibers ascend to attach to an aponeurosis gliding over a smooth triangular surface at the medial end of the spine of the scapula to a tubercle at the scapular lateral apex.

It has been suggested that the upper fibers of this muscle have a different motor supply than that to the middle and lower portions.[99,100] Recent clinical and anatomical evidence seems to suggest that the spinal accessory nerve provides the most important and consistent motor supply to all portions of the trapezius muscle, and although the C2–4 branches of the cervical plexus are present, no particular elements of innervation within the trapezius have been determined.[101]

One of the functions of the trapezius is to produce shoulder girdle elevation on a fixed cervical spine. For the trapezius to perform its actions, the cervical spine must first be stabilized by the anterior neck flexors to prevent simultaneous occipital extension from occurring. Failure to prevent this occipital extension would allow the head to translate anteriorly, resulting in a decrease in the length, and therefore the efficiency, of the trapezius[102] and an increase in the cervical lordosis.

CLINICAL PEARL

Complete paralysis of the trapezius usually causes moderate-to-marked difficulty in elevating the arm over the head. The task, however, can usually be completed through full range as long as the serratus anterior remains totally innervated.[103]

Serratus Anterior

The muscular digitations of the serratus anterior (see Fig. 16-5) originate from the upper eight to ten ribs and fascia over the intercostals. The muscle is composed of three functional components[104,105]:

- The upper component originates from the first and second ribs and inserts into the superior angle of the scapula.
- The middle component arises from the second, third, and fourth ribs and inserts into the anterior aspect of the medial scapular border.
- The lower component is the largest and most powerful, originating from the fifth through ninth ribs. It runs anterior to the scapula and inserts into the medial border of the scapula.

The serratus anterior is activated with all shoulder movements, but especially during shoulder flexion and abduction.[105] Working in synergy with the trapezius, as part of a force couple (see later), the main function of the serratus anterior is to protract and upwardly rotate the scapula,[106,107] while providing a strong, mobile base of support to position the glenoid optimally for maximum efficiency of the upper extremity.[108] Its lower fibers draw the lower angle of the scapula forward to rotate the scapula upward while maintaining the scapula on the thorax during arm elevation.[109] This moves the coracoacromial arch out of the path of the advancing greater tuberosity and opposes the excessive elevation of the scapula by the levator scapulae and trapezius muscles.[110] Without upward rotation and protraction of the scapula by the serratus anterior, full G-H elevation is not possible. In fact, in patients with complete paralysis of the serratus anterior, Gregg et al.[108] reported that abduction is limited to 110 degrees.

Dysfunction of the serratus anterior muscle causes winging of the scapula as the patient attempts to elevate the arm.[4,111] Scapulothoracic dysfunction can also contribute to G-H instability, as the normal stable base of the scapula is destabilized during abduction or flexion.[4,112,113]

The serratus anterior muscle is innervated by the long thoracic nerve (C5–7).

CLINICAL PEARL

Paralysis or weakness of the serratus anterior muscle results in disruption of normal shoulder kinesiology. The disability may be slight with partial paralysis or profound with complete paralysis. As a rule, persons with complete or marked paralysis of the serratus anterior cannot elevate the arms above 90 degrees of abduction.[103]

Levator Scapulae

The levator scapulae muscle (see Fig. 16-10) originates by tendonous strips from the transverse processes of the atlas, axis, and C3 and C4 vertebrae, and descends diagonally to insert into the medial superior angle of the scapula.

The levator scapulae can act on the cervical spine (see Chap. 23) and on the scapula. If it acts on the cervical spine, it can produce extension, side flexion, and rotation of the cervical spine to the same side.[114] When acting on the scapula during upper extremity flexion or abduction, the levator scapula muscle acts as an antagonist to the trapezius muscle, and provides eccentric control of scapular upward rotation in the higher ranges of motion.[115]

Both the trapezius and levator scapulae muscles are activated with increased upper extremity loads.[102,105,116]

The levator scapulae muscle is innervated by the posterior (dorsal) scapular nerve (C3–5).

Rhomboids

The rhomboid major muscle (Fig. 16-10) originates from the second to fifth thoracic spinous processes and the overlying supraspinous ligaments. The fibers descend to insert into the medial scapular border between the root of the scapular spine and the inferior angle of the scapula.

The rhomboid minor muscle (see Fig. 16-10) originates from the lower ligamentum nuchae, and the seventh cervical and first thoracic spinous processes, and attaches to the medial border of the scapula at the root of the spine of the scapula.

The rhomboid muscles help control scapular positioning, particularly with horizontal flexion and extension of the shoulder complex.[115]

The rhomboid muscles are innervated by the posterior (dorsal) scapular nerve (C4–5).

Humeral Propellers

The total muscle mass of the shoulder's internal rotators (subscapularis, anterior deltoid, pectoralis major, latissimus dorsi, and teres major) is much greater than that of the external rotators (infraspinatus, teres minor, and posterior deltoid).[103] This fact explains why the shoulder internal rotators produce approximately 1.75 times greater isometric torque than the external rotators.[117] Peak torques of the internal rotators also exceed the external rotators when measured isokinetically, under both concentric and eccentric conditions.[103,118]

Latissimus Dorsi

The latissimus dorsi muscle (see Fig. 16-12) originates from the spinous processes of the last six thoracic vertebrae, the lower three or four ribs, the lumbar and sacral spinous processes through the thoracolumbar fascia, the posterior third of the external lip of the iliac crest, and a slip from the inferior scapular angle. The scapular slip allows the latissimus dorsi to act at the scapulothoracic articulation. The latissimus dorsi inserts into the intertubercular sulcus of the humerus. The muscle functions as an extensor, adductor, and powerful internal rotator of the shoulder, and also assists in scapular depression, retraction, and downward rotation.[119] It is innervated by the thoracodorsal nerve (C6–8).

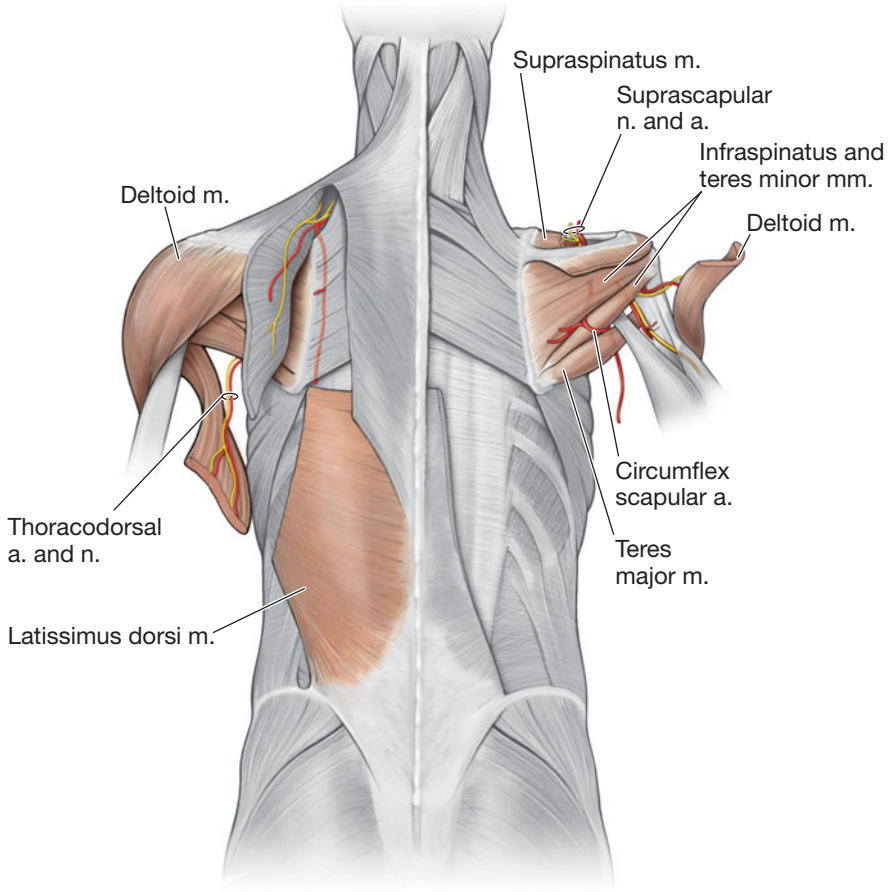

FIGURE 16-12 Latissimus dorsi. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy.* McGraw-Hill, 2011)

Teres Major

The teres major (see Fig. 16-12) originates from the inferior third of the lateral border of the scapula and just superior to the inferior angle. The teres major tendon inserts into the medial lip of the intertubercular groove of the humerus. The teres major functions to complement the actions of the latissimus dorsi in that it extends, adducts, and internally rotates the G-H joint. It is innervated by the lower subscapular nerve (C5, C6).

Pectoralis Major

The pectoralis major (see Fig. 16-13) originates from the sternal half of the clavicle, half of the anterior surface of the sternum to the level of the sixth or seventh costal cartilage, the sternal end of the sixth rib, and the aponeurosis of the obliquus externus abdominis. The fibers of the pectoralis major converge to form a tendon that inserts into the lateral lip of the intertubercular sulcus of the humerus. Although this muscle does not insert into the scapula, it does act upon the scapulothoracic articulation through its insertion on the humerus. The function of the pectoralis muscle depends on which fibers are activated:

- Upper fibers (clavicular head)—IR, horizontal adduction, flexion, abduction (once the humerus is abducted 90 degrees, the upper fibers assist in further abduction), and adduction (with the humerus below 90 degrees of abduction) of the G-H joint.
- Lower fibers (sternal head)—IR, horizontal adduction, extension, and adduction of the G-H joint.

The pectoralis major is innervated by the medial (lower fibers) and lateral (upper fibers) pectoral nerves (C8–T1 and C5–7, respectively).

CLINICAL PEARL

The pectoralis major and latissimus dorsi muscles are referred to as *humeral propeller* muscles as they have been shown to be the only muscles in the upper extremity to have a positive correlation between peak torque and velocity during the propulsive phase of the swim stroke.

Pectoralis Minor

The pectoralis minor (see Fig. 16-9) originates from the outer surface of the upper margins of the third to fifth ribs near their cartilage. The fibers of the pectoralis minor ascend laterally, converging to a tendon that inserts into the coracoid process of the scapula.

The pectoralis minor muscle is innervated by the medial pectoral nerve (C6–8).

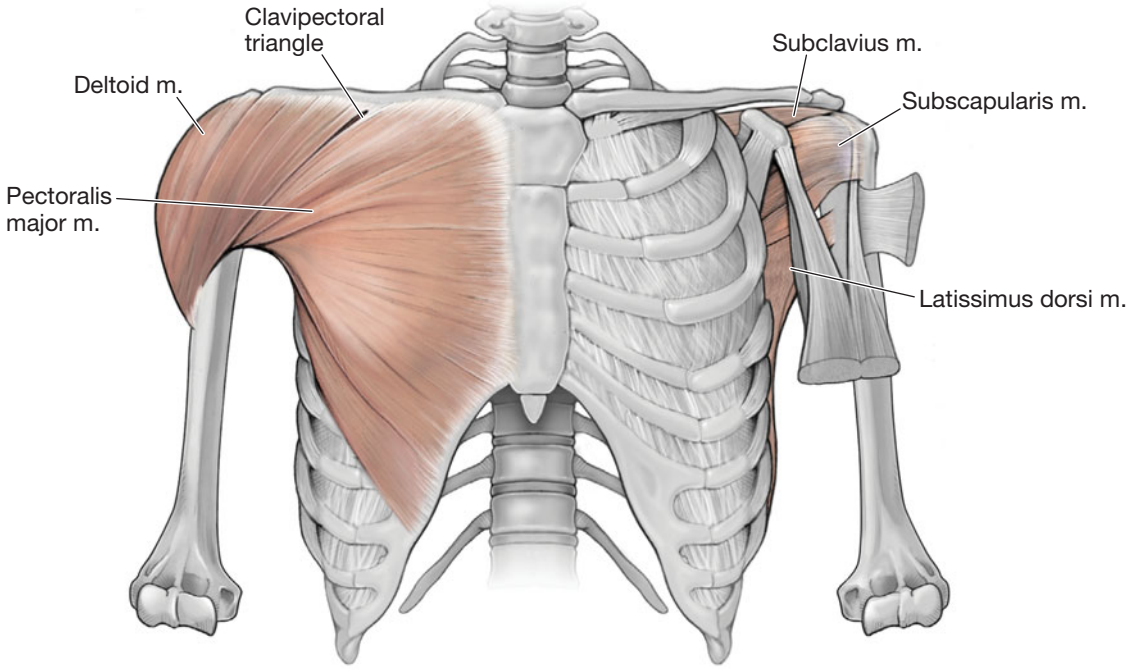

FIGURE 16-13 Pectoralis major muscle. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy.* McGraw-Hill, 2011)

Humeral Positioners

Deltoid

The deltoid muscle originates from the lateral third of the clavicle, the superior surface of the acromion, and the spine of the scapula (Fig. 16-13). It inserts into the deltoid tuberosity of the humerus. The deltoid can be described as three separate muscles—anterior, middle, and posterior—all of which function as humeral positioners, positioning the humerus in space.[98]

The deltoid muscle is innervated by the axillary nerve (C5–6).

Shoulder Protectors

Rotator Cuff

The rotator cuff muscles (Fig. 16-4), which consist of the supraspinatus, infraspinatus, teres minor, and subscapularis, are commonly involved with shoulder pathology. The anatomy of these muscles was described previously (see "Glenohumeral Joint" section). These muscles are referred to as the protectors of the shoulder since, in addition to actively moving the humerus, they fine-tune the humeral head position during arm elevation.[98] Compared with most joints that have a single axis on which torques are generated, the shoulder is very different, because it has no fixed axis. As a result, each muscle activation creates a unique set of rotational moments, which necessitates precise coordination in the timing and magnitude of muscle contractions.[73] Jenp et al.[120] used electromyography (EMG) to detect the most specific positions of highest activation for the individual rotator cuff muscles. The greatest activation of the subscapularis was with the arm in the scapular plane at 90 degrees of elevation and neutral humeral rotation. The subscapularis has also been shown to be an effective humeral head depressor in ER, whereas it produces almost no A-P translation in abduction and ER. The infraspinatus–teres minor muscles are very effective humeral head depressors with the arm in the sagittal plane and the humerus elevated to 90 degrees in the midrange of external/IR (the so-called "hornblower's" position). The supraspinatus could not be effectively isolated.

The rotator cuff muscles have an important role in the function of the shoulder and serve the following:

- *Assist in the rotation of the shoulder and arm.* At the G-H joint, elevation through abduction of the arm (Table 16-4) requires that the greater tuberosity of the humerus pass under the coracoacromial arch. For this to occur, the humerus must externally rotate, and the acromion must elevate.[121] ER of the humerus is produced actively by a contraction of the infraspinatus and teres minor, and by a twisting of the joint capsule. A force couple exists in the transverse plane between the subscapularis anteriorly and the infraspinatus and teres minor posteriorly in which cocontraction of the infraspinatus, teres minor, and subscapularis muscles both depresses and compresses the humeral head during overhead movements.

CLINICAL PEARL

The importance of the ER during humeral elevation (Table 16-5) can be demonstrated clinically. If the humerus is held in full IR, only approximately 60 degrees of G-H abduction is passively possible before the greater tuberosity impinges against the coracoacromial arch and blocks further abduction. This helps explain why individuals with marked IR contractures cannot abduct fully, but can elevate the arm in the forward plane.

TABLE 16-4 Contributors to Glenohumeral Abduction

Degree of Abduction	Biomechanics Involved
0–90	The concerted action of the active stabilizers (deltoid, biceps, and rotator cuff muscles) and the passive restraints (articular surfaces, osseous structures, and ligaments) is necessary for purposeful function. The supraspinatus contracts to initiate abduction of the glenohumeral joint.[a] The remaining rotator cuff muscles also contract to pull the humeral head into the glenoid fossa. At approximately 20 degrees of humeral abduction, scapular upward rotation begins with concurrent clavicular elevation and axial rotation.[b,c] At approximately 90 degrees, or a little more in females, the upper extreme of G-H abduction is reached, and clavicular elevation ceases due to tension of the costoclavicular ligament.[d] Continued abduction of the humerus requires continued upward rotation of the scapula, which by this point has rotated through a range of approximately 30 degrees.[e]
90–150	As the scapula continues to upwardly rotate, the glenoid fossa faces superiorly and laterally, and its inferior angle moves laterally through approximately 60 degrees. The scapular contribution peaks between 90 and 140 degrees.[f] The scapular upward rotation is accommodated at both the S-C and A-C joints by a posterior axial rotation of the clavicle of 30–40 degrees and a clavicular elevation of approximately 30–36 degrees.[c] The muscles producing this movement are the serratus anterior and trapezius, acting as a force couple on the scapulothoracic joint. The movement is limited by the acromion and S-C joint, and by the scapular and humeral adductors (notably the latissimus dorsi and pectoralis major).
150–180	Abduction beyond 150 degrees requires adequate motion at the vertebral joints of the upper thorax and cervical spine.[g] Bilateral abduction demands that the thoracic spine extends and the lumbar lordosis increases.

However, in clinical practice, shoulders having large rotator cuff tears and good function are frequently encountered. In the coronal plane, there is another force couple between the deltoid and the inferior rotator cuff muscles (infraspinatus, subscapularis, and teres minor). With the arm fully adducted, contraction of the deltoid produces a vertical force in a superior direction, resulting in an upward translation of the humeral head relative to the glenoid. Cocontraction of the inferior rotator cuff muscles produces both a compressive force and a downward translation of the humerus that counterbalances the force of the deltoid, thereby stabilizing the humeral head.

EMG studies have shown that during casual elevation of the arm in normal shoulders, the deltoid and the rotator cuff act continuously throughout the motion of abduction, each

TABLE 16-5 Contributors to Glenohumeral Elevation

Degree of Elevation and Main Contributor	Biomechanics Involved
0–60 degrees: glenohumeral elevation	A combined motion of flexion, abduction, and external rotation occurs at the glenohumeral joint, produced by the anterior deltoid, coracobrachialis, and the clavicular fibers of pectoralis major. Motion is limited by the increasing tension in the posterior coracohumeral ligament and the stretching of the shoulder extensors, adductors, and external rotators.[a]
60–120 degrees: sternoclavicular and acromioclavicular elevation	The scapula depresses, protracts, and abducts on the posterior thoracic wall, such that the glenoid fossa faces anteriorly and superiorly and its inferior angle faces laterally and anteriorly. This motion is accommodated by the S-C and A-C joints. The scapulothoracic motion is produced in the same manner as with abduction, by the serratus anterior and trapezius, and is limited by the ligaments of the two joints, and the tension in the shoulder extensor and adductor musculature.[a]
120–180 degrees—costospinal elevation	Kapandji[b] states that the extreme of flexion is the same as the extreme of abduction. That is, during unilateral elevation, the lateral displacement is produced by the contralateral spinal muscles while bilateral abduction requires an exaggeration of the lumbar lordosis to bring the arms vertical. In addition, the medial attachments of the first and second ribs descend while those of the fourth to sixth ascend and the third acts as the axis. Bilateral abduction demands that the thoracic spine extends and the lumbar lordosis increases.

[a]Data from Pettman E: Level III course notes. Berrien Springs, Michigan, North American Institute of Manual Therapy, Inc., 2003.
[b]Data from Kapandji IA: *The Physiology of the Joints, Upper Limb*. New York, Churchill Livingstone, 1991.

reaching a peak of activity between 120 and 140 degrees of abduction.[13,122] However, during more rapid and precise movements, such as those involved with throwing, a more selective pattern emerges with specific periods of great intensity.[123] Weakening of the rotator cuff appears to allow the deltoid to elevate the proximal part of the humerus in the absence of an adequate depressor effect from the rotator cuff, resulting in a decrease in the subacromial space and impingement of the rotator cuff on the anterior aspect of the acromion.[124,125]

- *Reinforce the G-H capsule.* The rotator cuff muscles, together with the coracohumeral ligament, and the LHB (often referred to as the fifth rotator cuff muscle) function as contractile ligaments. For example, firing of the rotator cuff muscles increases the tension of the middle G-H ligament when the arm is abducted to 45 degrees and externally rotated.[37]
- *Control much of the active arthrokinematics of the GH joint.* Contraction of the horizontally oriented supraspinatus produces a compression force directly into the glenoid fossa.[124] This compression force holds the humeral head securely in the glenoid cavity during its superior roll, which provides stability to the joint and also maintains a mechanically efficient fulcrum for elevation of the arm.[124] In the shoulder midrange position, when all of the passive restraints are lax, joint stability is achieved almost entirely by the rotator cuff. In addition, as previously mentioned, without adequate supraspinatus force, the near vertical line of force of a contracting deltoid tends to jam or impinge the humeral head superiorly against the coracoacomial arch.[103]

Long Head of the Biceps Brachii

The biceps brachii muscle is a large fusiform muscle in the anterior compartment of the upper extremity, which has two tendinous origins from the scapula (Fig. 16-7). The medial head and LHB normally originate from the coracoid process and supraglenoid tubercle of the scapula, respectively. However, a great deal of research has noted that the origin of the biceps tendon varies, not only in the type of insertion (single, bifurcated, or trifurcated), but also in the specific anatomical location where it inserts.[11,73] The proximal LHB tendon receives an arterial supply from labral branches of the suprascapular artery.[126] As it leaves its origin, the LHB tendon is surrounded by a synovial sheath, which ends at the distal end of the bicipital groove, making the tendon an intra-articular but extrasynovial structure.[73] As the LHB tendon moves between the greater and lesser tuberosities, it is stabilized in position by the tendoligamentous sling comprising the coracohumeral ligament, superior G-H ligament, and fibers from the supraspinatus and the subscapularis.[73,127] Once in the bicipital groove, the LHB tendon passes under the transverse humeral ligament, which bridges the groove.[128] After coursing through the groove, the two heads join to form the biceps muscle belly at the level of the deltoid insertion.[129] The medial tendon is interarticular, lying inside the G-H capsule.[39–41] This tendon is not as common a source of shoulder pain as the long tendon, and it rarely ruptures.[39–41]

The function of the biceps as a forearm supinator and secondarily as an elbow flexor is well known.[130] At the shoulder joint, however, the function of the LHB tendon is less clear, with most references regarding it as a week flexor of the shoulder.[131] Cadaveric studies have suggested that the LHB tendon functions as a humeral head depressor (in full ER), an anterior stabilizer, a posterior stabilizer, a limiter of ER, a lifter of the glenoid labrum, and a humeral head compressor of the shoulder.[132–135] The muscle has also been described as having an important role in decelerating the rapidly moving arm during activities such as forceful overhand throwing.[73] In the anatomical position, the biceps has no ability to elevate the humerus. If the arm is rotated 90 degrees externally, the tendon of the long head lines up with the muscle belly to form a straight line across the humeral head. As the biceps contracts in this position, the humeral head rotates beneath the tendon, resisting ER of the humeral head and increasing the anterior stability of the G-H joint.[86,136,137] Contraction of the LHB in this position fixes the humeral head snugly against the glenoid cavity, as the resultant force passes obliquely through the center of rotation of the humeral head and at right angles to the glenoid.[136] The humeral head is prevented from moving upwards by the hood-like action of the biceps tendon (Fig. 16-7), which exerts a downward force and assists the depressor function of the cuff.[138–140] Interestingly, the biceps tendon was found to be wider in cuff-deficient shoulders in one study.[141]

The biceps brachii muscle is innervated by the musculocutaneous nerve.

CLINICAL PEARL

A number of pathological conditions have been associated with the LHB tendon including LHB tendon degeneration, superior labrum anterior and posterior (SLAP) lesions, LHB tendon anchor abnormalities, and LHB tendon instability.[128]

Biomechanics

The G-H joint has three DOF: flexion/extension, abduction/adduction, and internal/ER. Available ranges of motion *at the G-H joint* are approximately as follows:

- ***Flexion and abduction.*** Approximately 100–120 degrees are available, with females demonstrating slightly more motion than males.
- ***External rotation.*** Approximately 60–80 degrees are available, with females demonstrating slightly more motion than males.
- ***Internal rotation.*** Approximately 80–90 degrees are available, with females demonstrating slightly more motion than males.
- ***Extension.*** Great variability exists with extension, with ranges existing from 10 to 90 degrees.

G-H motions (Table 16-11) consist of a combination of glides and rolls based on the concave–convex rule (see Chap. 10). At the G-H joint, the concave–convex rule dictates that the articulating surface moves in the opposite direction of the shoulder motion (Table 16-6). Motions at this joint do not occur in isolation, but rather as coupled motions.[142] For

TABLE 16-6 Glenohumeral Joint Motions and Their Appropriate Axis and Accessory Motions

Plane/Axis of Motion	Physiologic Motion	Accessory Motion
Sagittal/mediolateral	Flexion/extension	Spin
Coronal/anteroposterior	Abduction	Inferior glide
Transverse/longitudinal	Adduction	Superior glide
	Internal rotation	Posterior glide
	External rotation	Anterior glide

example, ER and abduction occur with flexion, and ER and adduction accompany extension.[75]

Complete movement at the shoulder girdle involves a complex interaction between the G-H, A-C, S-C, scapulothoracic, upper thoracic, costal, and sternomanubrial joints, the upper thorax, and the lower cervical spine. Within the joints of the shoulder complex, there appear to be no well-defined points within the range where one joint's motion ends and another begins. Rather, they all blend into a smooth harmonious movement during arm raising (see Tables 16-4 and 16-5).

During shoulder rotation and arm activities, the scapula invariably acts as a platform upon which the activities are based. It is worth noting that the supporting structures of the G-H joint are only effective if the scapula can maintain its ROM with the humerus (see "The Dynamic Scapula" section).

The G-H joint has been described as being similar to a golf ball on a tee due to the size relationships. A more accurate biomechanical description is that the G-H joint is like a ball on a seal's nose.[143] As the ball or humeral socket moves, the seal's nose, or the scapula, needs to move to maintain the position of the ball on the glenoid. The orientation of the G-H joint causes motions at this joint to occur in the scapular plane. The shoulder has the greatest ROM of any joint, with a vast array of muscles producing those motions.[1] The correct function of these muscles is dependent on length–tension relationships and coordinated activation.[48] Over 1,600 different positions in three-dimensional space can be assumed by the shoulder.[144,145] Due to this wide ROM, the G-H joint is faced with the task of maintaining equilibrium between functional mobility and adequate stability during normal activities of daily living.[146] When sport is added to the equation, extremely high forces can be generated at the shoulder. For example, the angular velocity of an overhead throw reaches over 7,000 degrees per second, which is the fastest recorded human movement.[147]

CLINICAL PEARL

It has been estimated that the anterior translation forces generated with pitching are equal to one-half body weight during the late cocking phase, and there is a distraction force equal to body weight during the deceleration phase.[148]

The complex kinematics of this region probably account for the fact that strains and sprains may remain symptomatic for much longer than in other joints.[1]

TABLE 16-7 Static Restraints to Inferior Translation (Dependent on the Position of the Arm)

Degrees of Glenohumeral Abduction	Restraining Structures
0	Superior G-H and coracohumeral ligaments
90	Inferior G-H ligament (posterior band in external rotation, anterior band in internal rotation)

Data from Warner JJP, Deng XH, Warren RF, et al: Static capsuloligamentous restraints to superior-inferior translation of the glenohumeral joint. *Am J Sports Med* 20:675–685, 1992; Turkel SJ, Panio MW, Marshall JL, et al: Stabilizing mechanisms preventing anterior dislocation of the glenohumeral joint. *J Bone Joint Surg Am* 63:1208–1217, 1981.

Full elevation of the arm occurs through an arc of approximately 180 degrees and can occur in an infinite number of body planes.[149] Locally, this motion is a result of abduction of the G-H joint and upward rotation of the scapulothoracic joint. During abduction of the shoulder, the G-H joint is reported to contribute up to 120 degrees of the total arc of motion, with the remaining 60 degrees occurring at the scapulothoracic joint (see "The Dynamic Scapula" section). Arm elevation beyond 90 degrees requires motion in other, more distal joints such as the A-C and S-C joints (see "The Dynamic Scapula" section) and the vertebral joints of the upper thorax and lower cervical spine (Tables 16-8 and 16-9).

Glenohumeral Joint Arthrokinematics

Flexion at the G-H joint involves a pure spin if it occurs strictly in the sagittal plane; no roll or slide is necessary. Tension within the surrounding capsular structures, particularly the posterior structures, may cause a slight anterior translation of the humerus at the extremes of flexion.[46] However, although flexion in the sagittal plane involves a pure spin, elevation of the arm in the scapular plane involves a combination of flexion, abduction, and ER. Thus, at the joint surface of the G-H joint during arm elevation in the scapular plane, the head of the humerus spins (flexion component), glides inferiorly

(abduction component), and glides anteriorly (ER component) (Table 16-6).

Functional Movements

Depending on the type of function performed, motions of the shoulder complex involve both local motions and motions at other joints.

Kibler[150] labels the motions that occur in other joints of the body during an activity such as throwing (i.e., trunk and hip rotation) as *distant functions*. In contrast, those motions occurring at the shoulder during the same activity (i.e., G-H ER) are termed *local functions*.

Distant Functions

The majority of shoulder motions involve a series of sequentially activated links in a kinetic chain of body segments.[145,150] For those motions requiring more force, the number of links in the kinetic chain increases—the sequence of activation starts as a ground reaction force (GRF) and moves up through the knees and hips to the trunk, and into the shoulder. Approximately 50% of the total kinetic energy and force occurring at the G-H joint originate from a combination of the GRF and the forces from the legs and hips.[145,150,151] At the shoulder, G-H, A-C, S-C, and scapulothoracic joints, motion occurs simultaneously as a result of muscle action and ligamentous tension in these joints. The specific sequence of muscle activation in the upper extremity depends on the activity, although the direction of activation is usually from proximal to distal as this is the most efficient method for producing large forces and accelerations to the arm. As part of this activation sequence, specific muscle activation patterns and joint positions are developed depending on the activity. Any changes to this sequence of activation can produce an abnormal movement pattern, involving substitution or compensation from the more distal links.[47,152] For example, a throwing athlete with decreased trunk rotation due to stiffness has to rely more on the shoulder to provide the force for the throw. These adaptive patterns eventually result in either decreased performance or increased injury risk.

Local Functions

The G-H joint accounts for approximately two-thirds of all shoulder motions, with the remainder provided by the scapulothoracic joint.[87] For full motion to occur, a complex interaction between the deltoid, rotator cuff, LHB, G-H capsule, glenoid articulating cartilage, and scapular pivoters (trapezius, serratus anterior, levator scapulae, and rhomboids) is required.[153]

Stabilization of the Static Shoulder

The dependent shoulder requires very little muscular support. Its vertical stability is a result of the inferior lateral projection and upward inclination of the glenoid fossa, which is maintained by a mild contraction of the fibers of the trapezius. It was traditionally theorized that the humeral head was prevented from rolling off of this lateral projection by a moderate contraction of the supraspinatus and the deltoid.[134,154] More recent studies have demonstrated that the muscle tone of the rotator cuff is not a significant contributor to the static inferior stability of the dependent shoulder with light loads, but that maintenance of the intra-articular pressure and the adhesion and cohesion properties of the articular surfaces are far more significant.[155,156] However, the rotator cuff does provide a passive restraint to translation, especially to posterior translation, during the early-to-midranges of elevation.[157]

During the mid and end ranges of motion, a combination of several different static restraints create a vector that keeps the humeral head securely seated in the glenoid, through concavity compression—negative articular pressure (see Tables 16-7–16-9).[144,153,155,158–160] Static restraint is also provided by the anatomic curvature of the humerus and glenoid, the extra depth of the labrum, and ligamentous restraints (see Tables 16-7 and 16-8).[161] The ligamentous restraints contribute especially at the end ranges of motion[162] and are assisted with concomitant muscle activity (see Table 16-9).

Stabilization of the Dynamic Shoulder

Dynamic stability of the shoulder complex is dependent on a variety of mechanisms including the optimal alignment of the scapula, correct G-H orientation, and the quality of the length–tension relationship of the involved muscles, and correct functioning of the static restraints (Table 16-9).

The deltoid, pectoralis major, latissimus dorsi, and teres major muscles are prime movers of the G-H joint. EMG studies have shown that these muscles function along the line of pull, creating the potential for infinite lines of pull that may allow an almost 360 degrees arc of motion.[13,163] Indeed, like the temporomandibular joint, the G-H joint enjoys the benefit that all of its prime movers compress the joint surface, thus optimizing joint stability. The secondary movers of the G-H joint are the LHB, and the triceps.

CLINICAL PEARL

The LHB and the triceps muscles are major dynamic stabilizers of the G-H joint, predominately functioning as "shunt" muscles (muscles that produce a compression at the joint surfaces of the joints they cross) during high-velocity activities.

As motion occurs at the G-H joint, the glenoid cavity of the scapular adopts a diverse number of reciprocal positions. It is likely that these scapular positions are based on both the functional task and the placement of the hand. The scapular stabilizers include the serratus anterior, latissimus dorsi, trapezius, rhomboids, levator scapulae, and the pectoralis minor. Dysfunction or inhibition of any of these muscles can alter the position of the glenoid significantly, resulting in abnormal centering of the humeral head within the glenoid.[24,164,165]

The function of the rotator cuff in normal and pathologic conditions has been the subject of several studies.[12,99,138–141] Until recently, EMG or cadaver studies have been the primary method of evaluating the contribution of each rotator cuff and shoulder muscle to a particular motion or exercise.[12,99,138,142–145] For example, using cadavers, Keating et al.[146] determined that the subscapularis contributes 53% of the cuff moment and believed it to be the most important muscle in humeral head stabilization.

Magnetic resonance imaging (MRI) is now being used to show increases in muscle signal intensity detected immediately following exercise.[147–149] On the basis of the level of signal intensity, this so-called exercise-induced enhancement seen on MRI can determine which muscles are used for a given exercise.[140,147,148,150–152] For example, one study of the shoulder[149] demonstrated that side-lying abduction produced the greatest signal intensity in the supraspinatus, infraspinatus, and subscapularis muscles. Surprisingly, scaption with internal rotation (SIR), previously associated with isolation of the supraspinatus muscle, did not provide the highest increase in any muscle of the rotator cuff.[149] However, caution must be used in drawing conclusions from single studies, and further research is certainly warranted in this area.

As previously mentioned, the role of the capsuloligamentous complex in stabilizing the G-H joint during dynamic activities is complex and varies with both shoulder position and the direction of the translation force.[166] The posterior capsule is the main restraint against posterior translation of the humerus on the glenoid fossa with the arm below 90 degrees of abduction.[167] With the arm at 90 degrees of abduction, the inferior G-H ligament and the posteroinferior capsule become the main restraint.[167] The posterior band of the inferior G-H ligament resists inferior translation when the arm is at 90 degrees of abduction.

The Dynamic Scapula

The synchronized motions that occur between the scapula and the humerus during elevation are a combination of scapulothoracic motion and scapulohumeral motion.

Scapulohumeral Motion. The angle between the glenoid and the moving humeral head has to be maintained within a safe zone of 30 degrees of angulation during activities to decrease shear and translatory forces.[168] For this to occur, the scapula must be positioned muscularly in relation to the moving humerus and must also act as a stable base of muscle origin for the rotator cuff muscles. If the scapula cannot be controlled, the glenoid cannot be positioned correctly to allow for the optimal length–tension relationships within the shoulder complex.[110,112,161,169] This synchronized motion between the glenoid cavity and the humerus is referred to as *scapulohumeral rhythm* (Fig. 16-14). Proper rhythm involves a rotation of the scapula during arm elevation. By allowing the glenoid to stay centered under the humeral head, the strong tendency for a downward dislocation of the humerus is resisted and the glenoid is maintained within a physiologically tolerable range (Fig. 16-14). At full abduction, the glenoid completely supports the humerus.

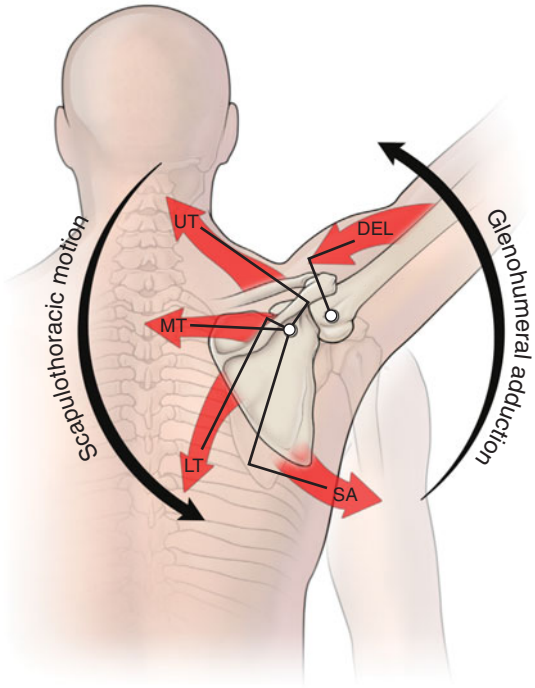

FIGURE 16-14 The scapulohumeral rhythm.

Several studies have examined the scapulohumeral rhythm three dimensionally.[25,26,87,170,171] An early study by Inman[87] determined that a 2:1 ratio existed between the motion occurring at the G-H joint and scapula, respectively. However, more recent studies have shown that this ratio is not consistent throughout the ROM.[21,107,153] As the humerus elevates to 30 degrees (setting phase), there is minimal movement of the scapula. In this initial portion of abduction, G-H motion predominates and the ratio has been found to be 4.4 degrees of G-H motion for every degree of scapular motion (4.4:1 ratio). From 30 to 90 degrees, the scapula abducts and upwardly rotates, and the ratio becomes 5 degrees of G-H motion to 4 degrees of scapular motion (5:4 ratio). As the shoulder moves above 90 degrees of abduction to full abduction, the scapula abducts and upwardly rotates 1 degree for every 1 degree of humeral elevation (1:1 ratio).[25,115,170] However, it must be kept in mind that these ratios are based on two-dimensional radiographic projections of angular rotations taken at discrete positions of elevation, whereas in reality, the arm moves in three dimensions, and that the scapulohumeral rhythm has also been found to change with external loading of the arm.[171]

CLINICAL PEARL

A reverse scapulohumeral rhythm, in which the scapula moves more than the humerus, occurs in conditions such as adhesive capsulitis.

Scapulothoracic Motion. Scapulothoracic motion is a vital component of shoulder function and consists of rotation and translation around approximately three axes of motion. These axes are considered to be embedded in the scapula.[172]

- Anterior and posterior tipping occurs around an axis parallel to the scapula.
- Protraction and retraction of the scapula occur through protraction and retraction of the clavicle at the S-C joint.
- IR and ER occur around an axis running through the scapula from superior to inferior.
- Elevation and depression of the scapula occurs through elevation and depression of the clavicle at the S-C joint. Throughout the 180 degrees of arm elevation, a total of 30–35 degrees of clavicle elevation occurs, in addition to rotation of the clavicle (30–35 degrees) around its longitudinal axis.[74,173] This clavicular elevation and rotation occur in two main phases of shoulder abduction. Assuming a 2:1 scapulohumeral rhythm, shoulder abduction up to 90 degrees occurs as a summation of 60 degrees of G-H abduction, and 30 degrees of scapulothoracic upward rotation. The 30 degrees of upward rotation occurs predominantly through a synchronous 20–25 degrees of clavicular elevation at the S-C joint and 5–10 degrees of upward rotation at the A-C joint.[103] The elevation of the clavicle raises the acromion during arm elevation allowing for the subacromial structures to pass under the coracoacromial arch.[24] Shoulder abduction from 90 to 180 degrees occurs as a summation of an additional 60 degrees of G-H joint abduction and an additional 30 degrees of scapulothoracic upward rotation.[103] During this late phase, the clavicle elevates only an additional 5 degrees at the S-C joint, whereas, at the A-C joint, the scapula upwardly rotates 20–25 degrees. Thus, by the end of 180 degrees of abduction, the 60 degrees of scapulothoracic upward rotation can be accounted for by 30 degrees of elevation at the S-C joint and 30 degrees of upward rotation at the A-C joint.[103] The motion at the A-C joint is controlled by tension in the coracoclavicular ligaments. Finally, the clavicle has been demonstrated in vivo to posteriorly rotate around its long axis during the late phase of shoulder abduction.[24] It is, as yet, unclear whether this posterior rotation occurs at the S-C or at the A-C joint. The rotation of the clavicle, though, is controlled by tension in the coracoclavicular ligaments and the clavipectoral fascia.

  Elevation of the arm in the scapular plane in healthy subjects is accompanied by posterior tipping and upward rotation of the scapula.[172] The upward rotation of the scapula occurs about an axis that passes through the base of the spine of the scapula and occurs in various phases (see Tables 16-4 and 16-5). Rotation of the scapula about the vertical axis shows a somewhat more variable pattern,[172] with some studies showing ER occurring predominantly at higher elevation angles,[68,174,175] whereas others demonstrate IR.[176–178]
- Upward and downward rotation occurs around an axis perpendicular to the plane of the scapula that travels through the A-C joint and S-C joint.[71] The upward rotation of the scapula during shoulder abduction helps to maintain an effective length–tension relationship between the three groups (force couples) of muscles that attach to the scapula. A *force couple* is defined as two forces that act in opposite directions to rotate a segment around its axis of motion.[86,179]

During the first 30 degrees of upward rotation of the scapula, the serratus anterior muscle and the upper and lower divisions of the trapezius muscle are considered the principal upward rotators of the scapula. Together these muscles form two force couples; one formed by the upper trapezius and the upper serratus anterior muscles (Fig. 16-14) and the other by the lower trapezius and lower serratus anterior muscles.[6,87,180]

The prime muscles that abduct the G-H joint are the middle deltoid and the supraspinatus muscles.[103] Elevation of the arm through flexion is performed primarily by the anterior deltoid, coracobrachialis, and LHB brachii.[103] The trapezius appears to be more critical for controlling the scapula during the initial phases of abduction, whereas the serratus has been found to be the most effective upward rotator of the scapula.[87,181] The lower trapezius contributes during the later phase of shoulder abduction by preventing tipping of the scapula and assisting in the stabilization of the scapula through eccentric control of the scapula during scapular upward rotation.[115,170]

CLINICAL PEARL

During approximately the first 150 degrees of arm elevation through flexion

- the upper and lower fibers of the trapezius contract concentrically,
- the fibers of the lower serratus anterior contract concentrically,
- the levator scapulae contracts eccentrically,
- the rhomboids contract eccentrically.

Approximately from 150 to 180 degrees

- the lower fibers of the serratus anterior contract isometrically,
- the lower fibers of the trapezius contract concentrically,
- the pectoralis minor contracts eccentrically,
- the upper fibers of the serratus anterior contract eccentrically.

The middle trapezius and rhomboids may also contribute to the scapular motions involved during arm elevation.[182] The antagonists are the pectoralis major, teres major, latissimus dorsi, and coracobrachialis, all working eccentrically. Normal motion of the scapula on the thorax is believed to include consistent contact between the thoracic wall, the medial border, and inferior angle of the scapula.[180,182] Loss of this contact has been clinically implicated as evidence of abnormal scapular kinematics. These abnormal scapular kinematics may result in additional stress on the anterior shoulder stabilizers.[183–185]

The appropriate force couples for the acromial elevation that occurs during G-H abduction are the lower trapezius and serratus muscles working together, paired with the upper trapezius and rhomboid muscles (Fig. 16-14).[24]

The EMG activity of the levator scapula muscle, upper and lower trapezius muscles, and serratus anterior muscle during arm elevation increases progressively as the humeral angle increases.[68] Activities that maintain an upwardly rotated scapula while accentuating scapular protraction, such as a push-up plus, elicit the greatest serratus anterior EMG activity.[75]

The last few degrees of shoulder elevation consist of upper thoracic movement once full G-H joint and shoulder girdle motion have been completed.[186] As the arm continues to elevate beyond the 150-degree mark, the thorax begins to extend and ipsilaterally rotate and side flex.

The scapula also functions during retraction and protraction along the thoracic wall (see Fig. 16-11).[24] Protraction occurs as the serratus anterior at the scapula and the pectoralis major at the humerus contract simultaneously. Retraction is produced by the combined action of the trapezius and rhomboids.[187] A 15–18-cm translation of the scapula around the thoracic wall occurs during retraction and protraction, depending on the size of the individual and the vigorousness of the activity.[24,151] This retraction and protraction is used during activities such as reaching and pulling, respectively.[24]

Lastly, the scapula functions to transfer the large forces and energy from the legs, hips, back, and trunk to the actual delivery mechanism, the arm and hand.[24,150,188,189]

EXAMINATION

The intervention strategies for the common pathologies of the shoulder complex are detailed after the examination section. An understanding of both is necessary. As mention of the various pathologies occurs with reference to the examination and vice versa, the reader is encouraged to alternate between the two. Shoulder complex conditions are often multifaceted, and patients with the same shoulder condition often present with diverse physical findings. It is critical that the clinician consider the shoulder girdle as a whole, rather than as a series of isolated articulations, and as a part of the whole kinetic chain. In the presence of shoulder complex dysfunction (assuming systemic or serious causes have been ruled out) there are three likely causes:

- Compromise of the passive restraint components of the shoulder girdle.
- Compromise of the neuromuscular system's production or control of shoulder girdle motion.
- Compromise to one or more of the neighboring joints that contribute to shoulder girdle motion, including
  - the A-C joint,
  - the S-C joint,
  - the joints of the upper thoracic spine and ribs,
  - the joints of the lower cervical spine.

Due to this complexity, all of the above-mentioned joints must be selectively tested in a specific sequence before proceeding with a more detailed examination of the suspected joint or joints.

HISTORY

A good history is the cornerstone of proper diagnosis, especially since shoulder pain has a broad spectrum of patterns and characteristics. A body chart can be used to record the patient's symptom distribution (see Chap. 4). The body chart is a symptomatic representation of a patient's complaints and can be an important element in guiding both the history and the tests and measures.

The history should begin with a brief outline of the patient's profile including age, occupation, hand dominance, recreational pursuits, work requirements, and activities of daily living (ADL).[190] Age is occasionally significant[191]:

- Children and adolescents may have an epiphysitis of the humerus, or an osteogenic sarcoma.
- Calcific deposits in the shoulder are more common between 20 and 40 years of age.
- Chondrosarcomas usually occur after age 30.
- Rotator cuff degeneration usually occurs in the 40s and 50s.
- A frozen shoulder is more common in those aged 45–60 years and is associated with medical conditions such as diabetes mellitus and ischemic heart disease.[190]

The exact mechanism of injury should be determined as it can help with a preliminary diagnosis[192]:

- Overhead exertion involving repetitive motions is a common mechanism for subacromial pathology, encompassing subacromial bursitis,[61] SIS,[40] rotator cuff tendinitis,[40,193] and rotator cuff tear.[194] It is also a common cause of bicipital tendinitis.
- A fall on an outstretched hand ("FOOSH" injury) can result in a sprain or strain injury to the wrist, elbow, and shoulder. More serious injuries from such a fall include fractures of the wrist and elbow, A-C separations, clavicular fractures, and G-H fractures and dislocations.
- A fall on the tip of the shoulder is a common mechanism for A-C separation. In addition, this mechanism can result in a compression periostitis (bone contusion) or a cervical spine injury, both of which appear remarkably similar to an A-C separation especially in the early stages.
- Forced horizontal extension of the abducted, externally rotated arm is a common mechanism for anterior dislocation.

It is important to establish the patient's chief presenting complaint (which is not always pain) as well as defining their other symptoms. The most common complaints associated with shoulder pathology include pain, instability, stiffness, deformity, locking, and swelling.[190] Patients sometimes complain of catching, clunking, grinding, or popping of the shoulder with various movements. These sounds and sensations may be asymptomatic and nonpathologic. However, they may also indicate pathology including labral disorders, rotator cuff tears, snapping scapular, subacromial bursitis, or biceps tendon disorders, especially if the sound or sensation is associated with pain or instability.[190] Periscapular pain is often associated with local muscle strain but may be referred.[1]

The quality of the pain is also important. Radicular pain tends to be sharp, burning, and radiating. Bone pain is deep, boring, and localized. Muscle pain can be dull, aching, and hard to localize. Tendon pain tends to be hot and burning. Vascular pain can be diffused, aching, and poorly localized and may be referred to other areas of the body. The intensity of pain may wax and wane with particular motions associated with specific activities. Common complaints with a rotator cuff tear include difficulty with elevation of the arm in abduction, as well as ER, and when patients attempt to put their hand behind their head or back.[195] Patients who report difficulty tucking in their shirts may have limited IR from posterior capsular stiffness.[196] The hallmark of posterior capsular contracture is symmetric loss of active and passive IR. Posterior capsular stiffness may occur independent of rotator cuff disease. Stiffness or loss of motion at the shoulder may be the chief complaint in conditions such as adhesive capsulitis.[190] A-C joint pain tends to occur with arm motion above 90 degrees of abduction and with horizontal abduction. Pain associated with an idiopathic frozen shoulder tends to be constant, but is particularly bad at night and frequently awakens the patient.[53]

Weakness may be the chief complaint, leading to some diagnostic confusion. It is important to distinguish true weakness from weakness secondary to pain, both in terms of history and examination findings.[197] Painless weakness is usually due to neurological problems or myopathies, although peripheral nerve injuries can be painful (Table 16-10). Shoulder weakness may be caused by a rotator cuff tear or nerve injury (suprascapular, axillary, long thoracic, or thoracodorsal nerves, or cervical nerve root injury) (see Table 16-10).[111]

TABLE 16-10 Peripheral Nerve Lesions

Spinal accessory nerve	Inability to abduct the arm beyond 90 degrees Pain in the shoulder with abduction
Musculocutaneous nerve	Weak elbow flexion with forearm supinated
Long thoracic nerve	Pain on flexing a fully extended arm Inability to fully flex an extended arm Winging of the scapula at 90 degrees of forward shoulder flexion
Suprascapular nerve	Increased pain on forward shoulder flexion Pain increased with scapular abduction Pain increased with cervical rotation to the opposite side
Axillary nerve	Inability to abduct the arm with neutral rotation
Thoracodorsal nerve	Marked difficulty to resist shoulder extension Marked difficulty to resist shoulder internal rotation
Cervical spinal nerve root	Varies according to the level involved, so can include various combinations of the above

Symptoms that are not associated with movement should alert the clinician to a more serious condition (see "Systems Review" section). Pain that is worse at night, but increased when rolling onto the shoulder, points to a periarticular mechanical problem.[195]

Determining the location of pain is important. Anterior shoulder pain suggests bicipital tendinitis, whereas posterior shoulder pain might be due to a posterior labral tear.[53] Posterior neck pain may be indicative of a cervical radiculopathy, as neither the A-C joint nor a subacromial irritation refers pain to this area.[74,198]

CLINICAL PEARL

Pain due to rotator cuff pathology and impingement is usually felt over the anterior or lateral part of the shoulder, is characterized by radiation down the upper arm, and is aggravated with overhead activities.[190,199] Pain that radiates beyond the elbow is far less likely to be due to shoulder pathology, particularly if it is associated with any sensory disturbance in the limb such as distal radiation of pain, numbness, or paresthesias.[190] In such cases, the clinician should rule out thoracic outlet syndrome (TOS), cervical radiculopathy, or referred pain from neighboring areas.

Pain due to A-C joint pathology is usually located at the superior region of the shoulder or well localized at the A-C joint itself, and there is often a clear history of injury to this region. Severe pain on top of the shoulder with an associated deformity could indicate an A-C joint sprain.

The clinician should determine which positions or movements relieve the pain, as these can provide helpful information[192]:

- Pain relieved with arm elevation overhead could indicate a cervicogenic cause.[200]
- Pain relieved with the elbow supported is suggestive of A-C separation and rotator cuff tears.
- Pain relieved by circumduction of the shoulder with an accompanying click or clunk could indicate an internal derangement or subluxation.
- Pain relieved with arm distraction is suggestive of bursitis or rotator cuff tendinitis.
- Pain relieved when the arms are held in a dependent position suggests TOS.

An inquiry about general health, any existing medical conditions, medications, and allergies should be made. Corticosteroid use can cause osteoporosis and tendon atrophy and affects wound healing; therefore a history of its use may alter the differential diagnosis.[190,195] The use of anticoagulant medication should be noted. Patients who are undergoing renal dialysis are at increased risk for tendon tears, as are patients who are 80 years of age or older.[195] Bilateral shoulder involvement is not uncommon in these groups.

Past physical therapy interventions, previous injections, and previous surgery are important to document, as are previous shoulder injuries and what relationship, if any, they have with the present symptomatology.[190]

Systems Review

The clinician should be able to determine the suitability of the patient for physical therapy. If the clinician is concerned with any signs or symptoms of a visceral, vascular, neurogenic, psychogenic, spondylogenic, or systemic disorder (see Chap. 5) that is out of the scope of physical therapy, the patient should be referred back to his or her physician or another appropriate healthcare provider.

Scenarios related to the shoulder that may warrant further investigation by the clinician include an insidious onset of symptoms and complaints of numbness or paresthesia in the upper extremity.

The most common causes of numbness in the shoulder and arm are due to cervical or upper thoracic involvement, with either the segmental roots involved or the brachial plexus. The patient should be questioned about recent changes in work requirements or environment, and the presence of neck pain.[39–41,201] In studies where normal cervical ligaments and muscles,[202] cervical zygapophyseal joints,[203] and disks[204] have been stimulated, subjects have reported pain in the head, anterior and posterior chest wall, shoulder girdle, and upper limb depending on the cervical level stimulated.[115]

The Cyriax scanning examination (see Chap. 4) may demonstrate subtle weakness of the cervical root innervated muscles. Depressed or absent upper extremity reflexes are also frequently noted. Finally, reproduction of the patient's pain with cervical motion and not with shoulder movement is a strong indicator of cervical origin.

In addition to the cervical and upper thoracic spine, the related joints referring symptoms to the shoulder require clearing. These include the temporomandibular joint, costosternal joint, costovertebral and costotransverse joint, thoracic spine, and the elbow and forearm.[70,199]

Systemic causes of insidious shoulder pain include rheumatoid arthritis. Rheumatoid arthritis often affects the shoulders and hips in older individuals and can be difficult to distinguish from polymyalgia rheumatica. Morning stiffness lasting for more than 1 hour, constitutional signs, and physical signs of joint inflammation are all indicative of an inflammatory disease.[195] Other systemic sources of shoulder pain include lupus erythematosus and gallbladder and liver disease.[70] These latter conditions are associated with other signs and symptoms that are not related to movement and are systemic in nature. Chronic respiratory and cardiovascular conditions must also come into consideration.[190] The shoulder is very close to the chest and its viscera; therefore reference of symptoms to the shoulder from these structures is common (see Chap. 5). It is vital that questions be asked that would reveal a relationship between the onset of symptoms and local movements versus general exercise, the latter of which could implicate the lung, heart, or diaphragm.

CLINICAL PEARL

Severe progressive pain not affected by movement, which is persistent throughout the day and night, and is associated with systemic signs, may indicate referred pain from a malignancy. The exception to this may be adhesive capsulitis (frozen shoulder), which is often characterized by boring, unrelenting, aching pain, even at rest.[205]

Finally, a vascular examination should be performed and should include an assessment of general skin texture, color, temperature, hair growth, and alteration of sensation about and distal to the shoulder.[53] Autonomic signs and symptoms are suggestive of complex regional pain syndrome (CRPS) (refer to Chap. 18). Neurovascular compression or TOS tests are described in "Special Test" section in Chapter 25.

TESTS AND MEASURES

The physical examination of the shoulder complex should be focused and thorough, using the clinical impression gleaned from the history and systems review as a guide.

Observation

Observation of the patient begins when the patient enters the clinic. The clinician observes how the patient holds the arm, the overall position of the upper extremity, and the willingness of the patient to move the arm. During gait, an upper extremity should swing in tandem with its opposite lower extremity. Once in the examination room, the patient is appropriately disrobed and the shoulder is systematically inspected from anterior, lateral, and posterior positions. Total body alignment is examined for overall posture, the relative rotation of the humerus, structural malalignment such as kyphosis, the presence of scars, color changes, and swelling.[190] For example, a hollowed infraspinatus fossa is a hallmark of a rotator cuff tear, although a suprascapular nerve lesion should also be considered.[53] Anterior prominence of the humeral head or a high-riding outer clavicle suggest G-H dislocation or A-C separation, respectively.[53] The relative heights of the shoulder girdles should be assessed. The height of the shoulder may or may not be significant. If the shoulders are elevated, the neck appears short. If they are depressed, the A-C joint is seen to be lower than the S-C joint.[206] Elevation of the clavicle can be due to shortness of the upper trapezius such that the lateral end of the clavicle appears appreciably higher than its medial aspect.[206] A low shoulder can result from[192]

- adaptive laxity of the shoulder,
- leg length discrepancy,
- scoliosis,
- soft-tissue hypertonicity,
- mechanical dysfunction of the pelvis,
- hand dominance—the shoulder on the dominant side may be slightly lower and more muscular than the nondominant side; this is a normal finding.

Deformity is a common complaint with injuries of the A-C joint and fractures of the clavicle. For example, a second-degree sprain or severe first-degree sprain of the A-C joint can be seen as a high-riding lateral clavicle (elevation of the distal end) causing a step-off to form between the clavicle and acromion.[17,207] It is frequently referred to as a tent-pole deformity. The fountain sign describes swelling that is anterior

to the A-C joint that is indicative of degeneration that has caused communication between the AC joint and a swollen subacromial bursa underneath. Other causes of deformity include an anterior dislocation of the shoulder, which may produce a squaring of the shoulder, as the deltoid is no longer rounded out over the humeral head.

Observation of muscle symmetry should be noted. Specific atrophy can imply certain diagnoses. For example, muscle weakness or atrophy, especially posttraumatic, might indicate peripheral nerve damage[208]:

- Atrophy of the deltoid from axillary nerve neuropathy can result in a squared appearance of the lateral shoulder,[207,208] which is best observed from the front.[17]
- Atrophy of the posterior deltoid can occur in patients with multidirectional instability.[208]
- Atrophy at the infraspinatus or supraspinatus fossa is a hallmark of a rotator cuff tear[16] or suprascapular nerve entrapment. Wasting of the supraspinati and infraspinati can be determined by pushing the examining finger into the respective muscle bellies.
- Atrophy of the trapezius may indicate compromise of the spinal accessory nerve. Atrophy of the trapezius is characterized by the appearance of a shoulder girdle that droops in association with a protracted inferior border of the scapula and an elevated acromion.[24,110,209]
- Atrophy of the serratus anterior muscle can create a prominent superior medial border of the scapula and a depressed acromion.

A balled-up muscle may indicate a muscle rupture, the most common of which are of the biceps and infraspinatus. Rupture of the LHB can be noticed by the change in contour of the anterior arm with bunching of the muscle (the "Popeye" appearance).[190]

Observable swelling in the shoulder may indicate a serious problem or damage.

The position and attitude of the scapula, both statically and dynamically, should be noted (see later). In standing, with their arms by the sides, the patients' medial (vertebral) border of the scapula should be 5–8 cm lateral to the thoracic spinous processes,[191,210] the medial end of the spine of the scapula should be level with the T3 spinous process, and the inferior angle of the scapula should be level with the T7 spinous process. The superior aspect of the medial border of the scapula begins at the level of the spinous process of T2 and extends to the level of the spinous process of T7. Excessive prominence of the scapular spine may indicate atrophy of the infraspinatus and supraspinatus.[208] Two conditions, which may present with deformity of the scapula as their main symptom, are Sprengel's deformity and winging of the scapula.[190]

Sprengel's deformity is the most common congenital abnormality affecting the shoulder. It is characterized by the presence of a hypoplastic, incorrectly rotated scapula, which sits abnormally high on the posterior chest wall. The condition results from a failure of the normal descent of the scapula, which occurs in utero, and is commonly associated with other significant musculoskeletal and visceral congenital abnormalities.[190]

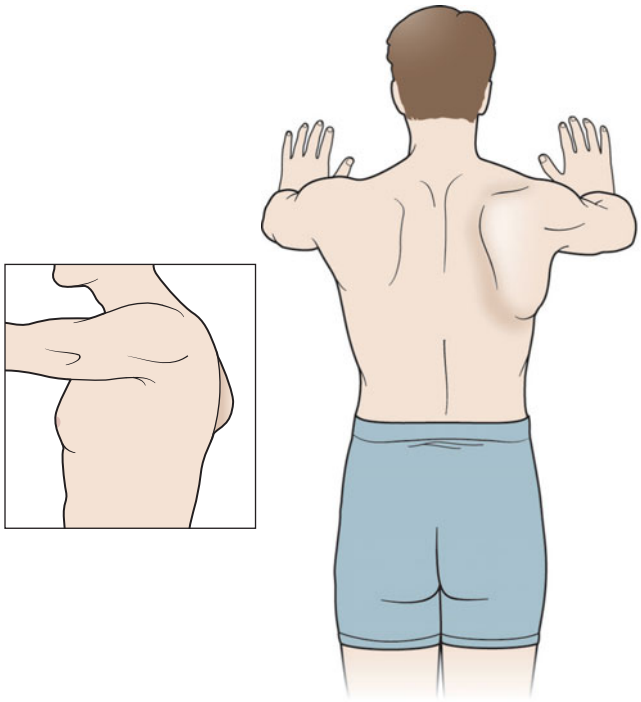

FIGURE 16-15 Scapular winging.

Winging of the scapula (Fig. 16-15) is due to a loss of the normal scapular stability. Subtle forms of scapular winging, usually evident at the inferior border, occur commonly with many shoulder disorders such as G-H joint stiffness and shoulder instability.[112] In cases of G-H joint stiffness, there is passive limitation of G-H motion, while with instability there is evidence of excessive movements or positive apprehension signs. Scapular winging may occur as the result of serratus anterior weakness, trapezius palsy,[209] excessive shortening of the pectoralis minor muscle,[2] or myopathies.[190,211–213] Scapular winging may also be caused by G-H joint stiffness, shoulder instability, and rotator cuff disease (see "Analysis of the Static Shoulder" section).

Gait

Gait is evaluated to observe freedom of the arm swing, reciprocal upper extremity movement, position of the arms and scapulae, and motion of the trunk and lower extremities (see Chap. 6).[70,199]

Posture

An analysis of posture prompts the clinician as to the area of movement disturbance or excessive stresses. Postural dysfunctions of the upper quarter are a common cause of shoulder pain. A wide variety of structural changes can produce shoulder pain.[183,214,215] Poor positioning of the cervical or thoracic spine may alter the position of the shoulder girdle.[216,217] For example, thoracic kyphosis, scoliosis, or neck lordosis can result in excessive protraction of the scapula, producing interscapular pain.[24,218] In the older patient (aged over 50 years), an increased thoracic kyphosis may be related to a decrease in shoulder elevation.[219]

The relationship of the humeral head to the acromion should be observed. One-third of the humeral head should be anterior to the acromion. A finding of less than one-third

TABLE 16-11 Common Muscle Imbalances of the Shoulder Complex	
Muscles Prone to Tightness	**Muscles Prone to Inactivity or Lengthening**
Upper trapezius	Middle and lower trapezius
Levator scapulae	Rhomboids
Pectoralis major and minor	Serratus anterior
Upper cervical extensors	Deep neck flexors
Sternocleidomastoid	Supraspinatus
Scalenes	Infraspinatus
Teres major and minor	
Subscapularis	

may indicate a tight posterior capsule or adaptive shortening of the external rotators.[220]

The patient's hands and arms should also be observed. Normally, the thumb faces anterior or slightly medial. If the posterior aspect of the hand faces anteriorly, there may be excessive adaptive shortening of the internal rotators.[220]

Muscle balances in the upper quadrant can cause a characteristic postural pattern of the forward head position.[221] The most common muscle imbalances are outlined in Table 16-11. The clinician should observe the trunk and neck positions in sitting and standing, as well as the relationship of the scapulae relative to the trunk and the humerus relative to the acromion. Any change in the scapular position has an impact on the A-C and S-C joint and can also alter the length–tension relationship of the scapular muscles.

The forward head and rounded shoulder posture include an abducted and elevated position of the scapula and an internally rotated humerus,[24,102,217,222] and is more common in patients presenting with shoulder pain[223] and interscapular pain.[223] Forward head posture (FHP) in the presence of abducted scapulae and protracted shoulders results in a decrease in the size of the subacromial space, which may predispose the patient to rotator cuff disorders.[224] This posture results in an adaptive shortening of the upper trapezius, levator scapulae, and pectoralis, with weakening and lengthening of the deep neck flexors and lower scapular stabilizers.[102,223,225]

If the pectoralis major is tight or strong, the muscle will be prominent. If there is an imbalance present, it will lead to rounded and protracted shoulders and a slight IR of the humerus.[226,227] The altered position of the scapulae can distort the course of the suprascapular nerve, placing it at risk for a traction injury during upper extremity movements.[228–230]

Normally, the insertion of the SCM is barely visible. If the clavicular insertion is prominent, it may indicate adaptive shortening of the SCM.[226] A groove along the SCM is an early sign of weakness of the deep neck flexors. A weakening and atrophy of the deep neck flexors has been proposed as a sign to estimate biological age.[231] The change in the anatomical relationship of the clavicle associated with this weakness and atrophy, decreases the width of the thoracic inlet, rendering the brachial plexus vulnerable to compression (refer to Chap. 25).[228,232,233]

A loss of bulk in the interscapular muscles may indicate tightness in the trapezius and levator scapula.

Analysis of the Static Scapula

An abnormal position of the scapula at rest is common in patients with shoulder overuse injuries.[102,206,223,225] The scapular position is initially examined with the arms by the side. The clinician notes any signs of winging, elevation, depression, adduction, abduction, and rotation of the scapula. Abnormalities in alignment include a flattening of the interscapular area and an increase in the distance between the thoracic spinous processes and the medial border of the scapula. When the scapula is abducted (more than 8 cm from the midline of the thorax), it is also rotated more than 30 degrees anterior to the frontal plane and produces a medial rotation of the humerus.[206]

Tipping of the scapula, in which the inferior angle protrudes away from the rib cage, often results from a weakness of the lower trapezius and positions the glenoid fossa so that it faces a more inferior direction.[115] This alignment is often associated with shortness of the pectoralis minor muscle or biceps brachii muscle.[206]

Adaptive shortening of the rhomboids and levator scapulae muscles, in the presence of a lengthened upper trapezius and serratus anterior, results in an elevation of the scapulae at the superior angle, and a downward rotation of the scapula. This causes the G-H joint to move into a position of abduction.[206,234] In addition, if the levator scapula adaptively shortens, both cervical and shoulder motions occur sooner than normal because the starting position of the scapula is changed. This modification to the starting position of the scapula for shoulder-elevated tasks presumably has an effect on the timing of the scapular muscles responsible for upward rotation. This results in an end position of arm elevation that is lower than usual (see "Examination of the Dynamic Scapula" section).[115]

Extremity dominance can affect the orientation of the scapula, with the greater degree of unilateral activity producing the greater changes. A bilateral comparison should be made and allowances made for the dominance. Bilateral comparisons do not always highlight dysfunctions. For example, the symmetrical effects of an adaptive shortening of the anterior chest and shoulder musculature, and lengthening of the posterior musculature that occurs in the forward head and rounded shoulder posture, will not be confirmed until during the mobility tests.

A number of static tests for the scapular position exist. The amount of scapular protraction available can be measured clinically using the method described by Diveta et al.,[235] who advocate two linear measurements with a piece of string. The distance in centimeters between the root of the scapular spine and the inferior angle of the acromion (scapular width) is divided into the distance from the third thoracic spinous process to the inferior angle of the acromion (scapular protraction). The resulting ratio provides a measurement of scapular protraction corrected for scapular size (normalized scapular protraction). This method of measurement of scapular protraction has been found to be both reliable and valid when compared with radiographic measurements.[223,235,236]

Palpation

Palpation must be performed in a systematic manner and must focus on specific anatomical structures (refer to

Figs. 16-1 through 16-13). The degree and location of tenderness is often a reliable physical sign leading to an accurate diagnosis.[53] For example, tenderness over the anterior acromion and greater tuberosity is suggestive of impingement, whereas tenderness over the posterior joint line could indicate joint pathology such as G-H arthritis or a torn posterior labrum.[53] Traditionally, palpation has been viewed as a static process. However, palpation is a dynamic process and should be performed along with other aspects of the examination. The optimal methods of palpating the shoulder tendons occur in regions where there is the least amount of overlying soft tissue.[237]

It is best to divide the shoulder complex into compartments for palpation as symptoms reproduced by palpation in these compartments are frequently associated with a specific underlying pathology.

Anterior and Superior Compartment

The clinician should begin anteriorly, with palpation of the contours of the clavicle. The anterior and superior aspects of the clavicle are covered by the platysma muscle. The sternal end of the clavicle, which projects cranially over the border of the manubrium, is covered by the SCM. The following areas related to the clavicle should be palpated for tenderness, swelling, or symptom reproduction:

- The supraclavicular fossa, bordered medially by the SCM and laterally by the omohyoid.
- The infraclavicular fossa, between the pectoralis major, deltoid, and clavicle. The coracoid process is located in the infraclavicular fossa, especially if the arm is placed in extension. Several palpable ligaments and muscles attach here including the coracoclavicular, on the conoid tubercle, the coracoacromial ligament, the pectoralis minor, the coracobrachialis, and the short head of the biceps. A prominent coracoid could indicate a posterior dislocation of the shoulder.
- The subclavius and costoclavicular ligament.
- The suprasternal (jugular) notch—this indentation on the superior border of the sternal manubrium is an important reference point. Three centimeters above the notch is the inferior border of the larynx, while the sternal bellies of the SCM form the sides of the notch. The interclavicular ligament is located within the notch. Disruption of the normal contours of the notch is associated with S-C dislocations.
- The S-C joint and joint line—arthrotic changes of the S-C joint are evidenced by crepitus at the joint during IR/ER of the humerus with the arm abducted to 90 degrees. The contours of the S-C joint are palpated and a comparison should be made with the contralateral side. Thickening of the S-C, or an S-C dislocation, produces an inability to abduct the arm.
- The A-C joint—injuries and arthritis of this joint are common, and focal tenderness is an important sign of A-C pathology.[190] Changes in the size and shape of the joint may indicate past or present separation, fracture, or osteoarthritis.

With the arm hanging by the side and the palm facing the body, the greater tuberosity lies laterally, and the lesser tuberosity lies anteriorly with respect to each other. They are separated by a bicipital groove. The bicipital groove is made more accessible for palpation with IR of the arm to 15–20 degrees.[237,238] Within this groove lies the biceps tendon, which should be palpated for tenderness. If the arm at rest appears slightly abducted and externally rotated, an anterior dislocation might be present. An adducted and internally rotated arm suggests many shoulder conditions, including a posterior dislocation.

The lesser tuberosity (shaped like an inverted teardrop) is palpated during passive IR and ER of the humerus at a point lateral to the coracoid process. The subscapularis can be palpated deep in the deltopectoral triangle at its insertion into the lesser tuberosity. This is accomplished by positioning the arm by the side in neutral rotation, and palpating just lateral to the coracoid.[237]

The greater tuberosity is located directly anterior to the acromion. It is best located with the patient in side-lying, facing the clinician, with the upper arm in front in approximately 60 degrees of shoulder flexion. The clinician palpates laterally along the spine of the scapula until contact is made with the superior facet of the greater tuberosity. The supraspinatus and posterior coracohumeral ligament insert into the superior facet, the infraspinatus on its middle facet, and the teres minor on its inferior facet. The supraspinatus, located just distal to the anterolateral corner of the acromion, can be made more discernible by positioning the patient's arm behind the back in slight extension.[237,239]

The subacromial–subdeltoid bursa can be palpated by putting the the patient in the prone position, and passively stretching the arm into extension before palpating anterior to the A-C joint. Tenderness reported with shoulder extension and relieved with shoulder flexion is indicative of an inflammation of this bursa.

The anterior joint capsule can be located by palpating one fingerbreadth lateral to the coracoid process with the arm by the side. Persistent tenderness at this point with IR and ER of the arm suggests capsular involvement.[240]

The muscle bellies, origins, and insertions of the upper trapezius, supraspinatus, and levator scapula should be palpated for tenderness or asymmetries.

Lateral Compartment

The deltoid muscle belly and insertion should be palpated for tenderness or atrophy.

Posterior Compartment

The spine of the scapula should be located. The clinician should be able to locate the inferior pole of the scapula, the medial border of the scapula, and the posterior angle of the acromion. The superior angle of the scapula should be level with the second rib, the spine of the scapula with the level of T3, and the inferior border with the level of T7.

The infraspinatus can be palpated just distal to the posterolateral acromion with the arm at 90-degree flexion and 10-degree adduction.[237] The teres minor is isolated and palpated using the same patient position.[237] To help locate the teres minor, the long head of the triceps is palpated by placing the patient's arm at 90 degrees of abduction followed by extension.

Once the long head of the triceps is located, the patient is repositioned and the teres minor, now superior to the long head of the triceps, can be palpated. Tenderness of the posterior capsule suggests capsular laxity.

Inferior Compartment

The lymph nodes in the axilla are palpated for swelling or tenderness. Also located in the inferior compartment are the anterior coracohumeral ligament, G-H ligament, transverse humeral ligament, and pectoralis major. The latissimus dorsi tendon can be palpated deep in the axilla.

The teres major tendon is palpated medial to the supeior part of the latissimus dorsi tendon insertion. It can be differentiated from the latissimus dorsi by using a combination of isometric IR and adduction with the patient's shoulder positioned at 90 degrees of abduction and maximum ER.

The subscapularis tendon is palpable between the serratus anterior and the latissimus dorsi while the patient's arm is elevated.

Active and Passive Range of Motion

Due to the complex nature of the arthrokinematics, osteokinematics, and myokinetics of this region, the results from the active and passive movements can be misleading; therefore care must be taken with interpretation of the findings. Passive testing should be performed when active motion is incomplete. Pain with end-range stress is an important clinical finding. Crepitus can be soft with rotator cuff pathology or harsh with G-H arthritis. Active motion testing provides the clinician with information regarding the following:

- Overall functional capacity of the shoulder.
- Painful or hesitant initiation or termination of movement. Such a hesitation may be a subtle sign of instability or rotator cuff dysfunction.[241]
- Quantity of movement (Table 16-12). Estimation of true G-H motion is performed by fixing the scapula at its inferior border.
- Developed trick movements or modifications to the movement, such as an altered plane, the use of trunk movements, or abnormal recruitment of muscles.
- Associated signs and symptoms not reproduced with nonfunctional motion testing.
- Presence of a capsular pattern (Table 16-13).
- Detection of a "painful arc."
- End-feels (see Table 16-12), if passive overpressure is applied.

McClure and Flowers[242] classify limited shoulder motion into two categories:

- Decreased ROM secondary to changes in the periarticular structures, including shortening of the capsule, ligaments, or muscles, as well as adhesion formation. Clinical findings for this category include a history of trauma,[243–245] immobilization,[243–245] presence of a capsular pattern,[246] capsular end-feel,[246] and no pain with the isometric testing.[246]
- Decreased ROM due to nonstructural problems, including the presence of pain, protective muscle spasm, or a loose body within the joint space.[247] Clinical findings for this

TABLE 16-12 Normal Ranges for Movements of the Shoulder Complex and Potential Causes of Pain

Motion	Range Norms (Degrees)	End-Feel	Potential Source of Pain
Elevation–flexion	170–180	Tissue stretch	▸ Suprahumeral impingement ▸ Stretching of G-H, A-C, S-C joint capsule ▸ Triceps tendon if elbow flexed
Extension	50–60	Tissue stretch	▸ Stretching of G-H l joint capsule ▸ Severe suprahumeral impingement ▸ Biceps tendon if elbow extended
Elevation–abduction	170–180	Tissue stretch	▸ Suprahumeral impingement ▸ A-C joint arthritis at terminal abduction
External rotation	80–90	Tissue stretch	▸ Anterior G-H instability
Internal rotation	60–100	Tissue stretch	▸ Suprahumeral impingement ▸ Posterior G-H instability

TABLE 16-13 Close Packed, Open Packed, and Capsular Patterns of the Shoulder Complex

	Close Packed	Open Packed	Capsular Pattern
Glenohumeral	90 degrees of G-H abduction and full external rotation; or full abduction	55-degree abduction, 30-degree horizontal adduction external rotation	External rotation, abduction, internal rotation
Acromioclavicular	90-degree abduction	Arm resting by side	Pain at extremes of range, especially horizontal adduction and full elevation
Sternoclavicular	Full arm elevation and shoulder protraction	Arm resting by side	Pain at extremes of range, especially horizontal adduction and full elevation

patient include a history of trauma or overuse, and the presence of a noncapsular pattern of motion restriction.

Riddle et al.[248] examined the intratester and intertester reliabilities for clinical goniometric measurements of shoulder passive ROM (PROM) using two different sizes of universal goniometers. Patients were measured without controlling therapist goniometric placement technique or patient position during measurements. Repeated PROM measurements of shoulder flexions **VIDEO**, extension **VIDEO**, abduction **VIDEO**, shoulder horizontal abduction, horizontal adduction, external rotation **VIDEO**, and internal rotation **VIDEO** were taken for two groups of 50 subjects each. The intratester intraclass correlation coefficients (ICCs) for all motions ranged from 0.87 to 0.99. The ICCs for the intertester reliability of PROM measurements of horizontal abduction, horizontal adduction, extension, and internal rotation ranged from 0.26 to 0.55. The intertester ICCs for PROM measurements of flexion, abduction, and external rotation ranged from 0.84 to 0.90. Goniometric PROM measurements for the shoulder appear to be highly reliable when taken by the same physical therapist, regardless of the size of the goniometer used.

The patient is asked to bring the arm actively through the ranges of motion. These motions include flexion, extension, abduction, IR (Fig. 16-43), ER, horizontal adduction, and shrugging of the shoulders.

Arm Elevation

The clinician should view the patient carefully as he or she attempts arm elevation. Elevation in the frontal plane (Fig. 16-16) and scapular plane is assessed. Typically, 170–180 degrees of elevation is possible in both of these planes, with the upper portion of the arm being able to be placed adjacent to the head. If the patient is unable to achieve 170–180 degrees, the clinician must determine where and why movement is not occurring. The presence of pain with arm elevation can provide the clinician with valuable information (Fig. 16-17). A common cause of pain with arm elevation is rotator cuff tendinopathy. If there is an arc of pain, the point in the range where the arc of pain occurs can be diagnostic in implicating the cause.

- Pain that occurs between 70 and 110 degrees of abduction is deemed a "painful arc" and may indicate rotator cuff impingement, or tearing, or subacromial bursitis.[76]
- Pain which occurs in the 120–160/160–180-degree range may indicate involvement of the A-C joint.[76]

CLINICAL PEARL

One study[76] attempted to differentiate various types of painful arcs and proposed that adding ER to the painful range indicated subscapularis involvement, or possibly supraspinatus and/or infraspinatus involvement when the pain was increased. Adding IR to the painful range, the supraspinatus and/or infraspinatus was more likely the source of involvement.[76]

Kibler[24] advocates the use of the "muscle assistance" or "scapular assistance" test (SAT) to assess scapular motion and position during elevation and lowering of the arm to see if the impingement may be due to a lack of acromial elevation (Fig. 16-18). As the patient elevates the arm, the clinician pushes laterally and superiorly on the inferior medial border of the scapula to simulate the serratus anterior/lower trapezius force couple. The test is considered positive if the manual

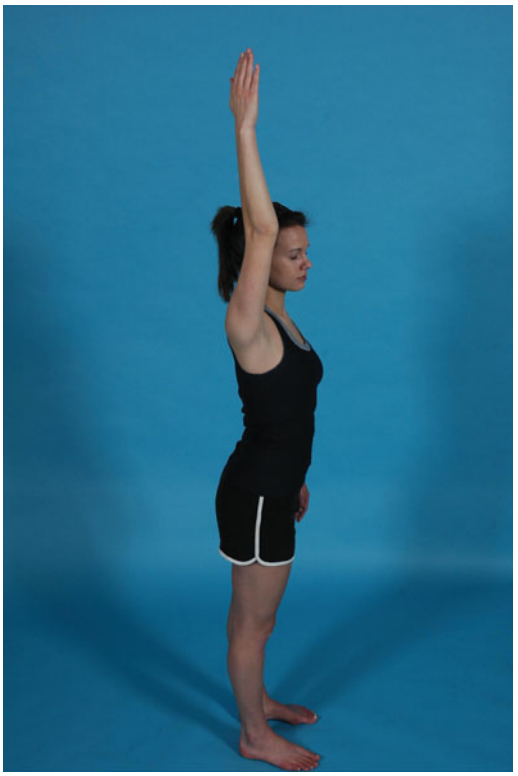

FIGURE 16-16 Elevation in the frontal plane.

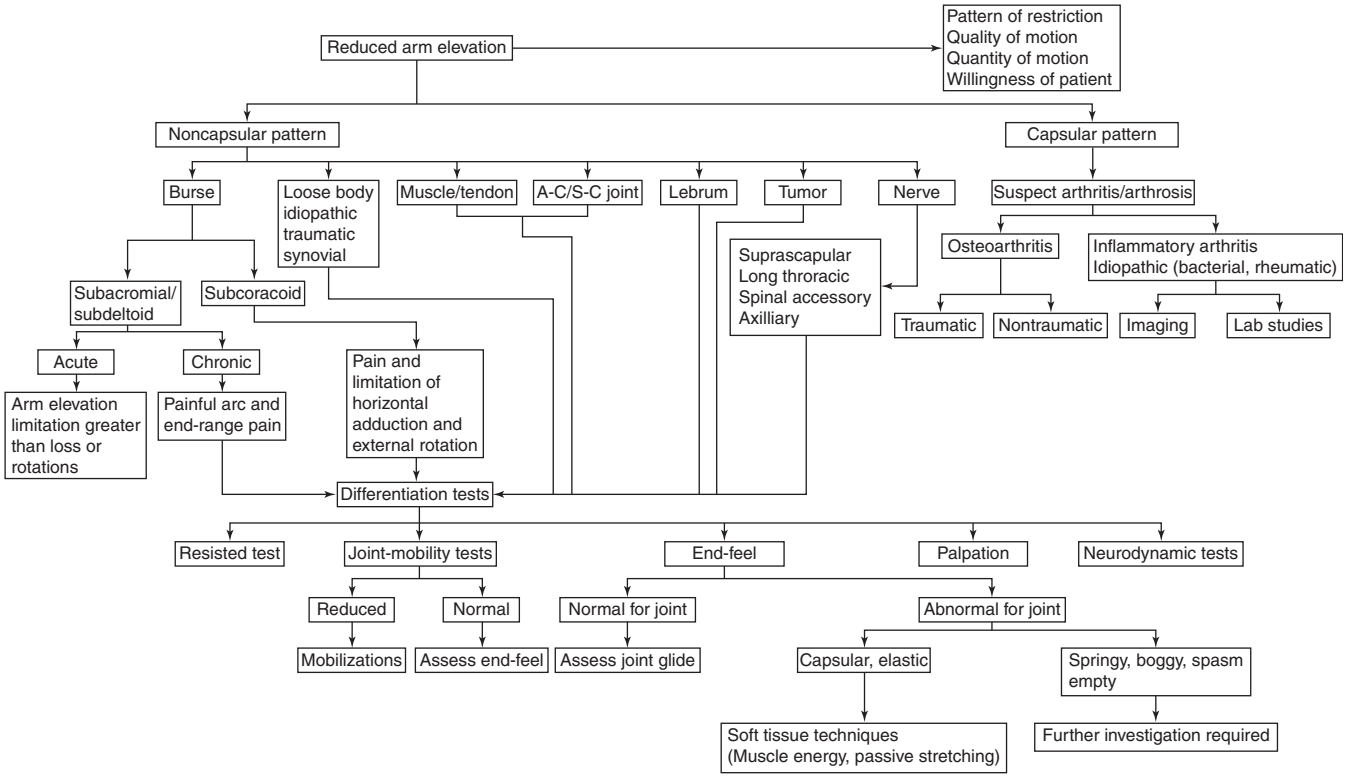

FIGURE 16-17 Causes of painful arm elevation.

assistance diminishes or abolishes the impingement symptoms.[24] The SAT is presumed to indirectly measure the function of the scapula rotators; however, other factors, such as thoracic posture and pectoralis minor length, have also been hypothesized to affect scapular rotation, and it is possible that these could be affected by the manual pressure provided during the SAT.[172,249,250] More importantly, the SAT is used to directly assess the influence of scapular motion on shoulder pain. In a study by Rabin et al.,[172] a modified version of the SAT, which included assisting posterior tipping of the scapula in addition to assisting upward rotation of the scapula, was found to possess acceptable interrater reliability for clinical use to assess the contribution of scapular motion to shoulder pain. The κ coefficient and percent agreement were 0.53 and 77%, respectively, when the test was performed in the scapular plane, and 0.62 and 91%, respectively, when the test was performed in the sagittal plane. In the modified version, the clinician places one hand on the superior aspect of the involved scapula, with the fingers over the clavicle. The other hand is placed over the inferior angle of the scapular so that the heel of the hand is just over the inferior angle and the fingers are wrapped around the lateral aspect of the thorax. The patient is asked to actively elevate his or her arm in the scapular plane, and during the movement the clinician facilitates upward rotation of the scapula by pushing upward and laterally on the inferior angle, as well as tilting the scapula posteriorly by pulling backwards on the superior aspect of the scapula.

FIGURE 16-18 Scapular assist.

Weakness of the serratus anterior muscle, due to palsy or disuse, produces winging of the scapula as the patient attempts to elevate the arm.[4,111,113] In addition to winging, serratus anterior dysfunction presents with loss of scapular protraction during attempted shoulder elevation and the inferior tip of the scapula becomes prominent.[110]

Abduction of the shoulder requires a greater use of the upper and lower trapezius muscles, whereas shoulder flexion is more likely to recruit the serratus anterior muscle.[87,181]

Although lesions to the deltoid are rare, imbalances of the deltoid and the rotator cuff are common. When the deltoid becomes dominant, the humeral head is seen to glide superiorly during arm elevation because the downward pull of the rotator cuff muscles is insufficient to counterbalance the upward pull of the deltoid (*humeral superior glide syndrome*).[206] This alteration in the G-H force couple usually occurs during the middle phase of elevation[170] (between 80 and 140 degrees), because the upward translation force of the deltoid peaks during this phase, requiring more compressive and depressive forces from the rotator cuff muscles.[251,252]

An anterior glide of the humeral head, which occurs during arm elevation (*humeral anterior glide syndrome*)[206] suggests that the posterior deltoid has become the dominant external rotator.[206] This syndrome should be suspected if the pain is located in the anterior or anterior medial aspect of the shoulder and is increased by G-H IR, shoulder hyperextension, and horizontal abduction, and is decreased when the humeral head is prevented from moving anteriorly during shoulder rotation and flexion movements.[206]

When compared, the range achieved for unilateral elevation should be greater than that achieved when bilateral arm elevation is attempted. This is because the joints of the cervicothoracic junction have to be permitted to rotate toward the elevating arm. The clinician should observe the smoothness of the scapulohumeral rhythm during elevation and the ratio between the scapular upward rotation and G-H elevation (see "Examination of the Dynamic Scapula" section).

Compressive forces across the A-C joint occur mainly in the terminal 60 degrees of abduction. This often causes pain during this range if pathology exists at this joint.[190]

Extension

Active extension (Fig. 16-19) is normally 50–60 degrees. Care must be taken when measuring this motion as substitutions can occur to seemingly increase extension by bending forward at the waist or by retracting the scapula. Asymmetry of shoulder extension can indicate weakness of the posterior deltoid in one arm (swallowtail sign).

Rotation

The following arm positions can be used to assess IR and ER:

- The arm at shoulder level (at 90 degrees of shoulder abduction, 90 degrees of elbow flexion and with the palm parallel to the floor). Normal ER (Fig. 16-20), which is performed by rotating the hand toward the floor, is 90 degrees or beyond. Assessing ER in this position is helpful in determining the presence of a fracture of the greater tuberosity, or a decrement in the performance of a throwing athlete. IR is then carried out (Fig. 16-21), rotating the hand toward the hip, as if positioning it behind the body. Normal IR approaches 90 degrees. However, this test position is often uncomfortable and not very functional, except for pitchers.
- The arm to the side and the elbow flexed to 90 degrees. ER is performed by moving the hand away from midline (Fig. 16-22), and IR is performed by moving the hand toward the abdomen (Fig. 16-23). Again, it is important to assess active and passive range, because a loss of active motion alone may indicate muscular weakness.
- The arm at the side and the forearm behind the back (Apley scratch test). This measurement for IR is assessed by the position reached with the extended thumb up the posterior (dorsal) aspect of the spine using the spinous processes as landmarks (Fig. 16-24).[253] This is more of a functional test, and the thumb tip of normal subjects will reach the T5–T10 level.[190] Loss of motion with this test affects the patient's ability to perform toileting duties, hook bras behind the back, reach into a back pocket, and tuck in shirts.[254] The examination is made relative to the opposite side, as there is quite a large variation in range among normal subjects. In a study by Hoving et al.,[255] which assessed the intrarater and interrater reliability among rheumatologists of a

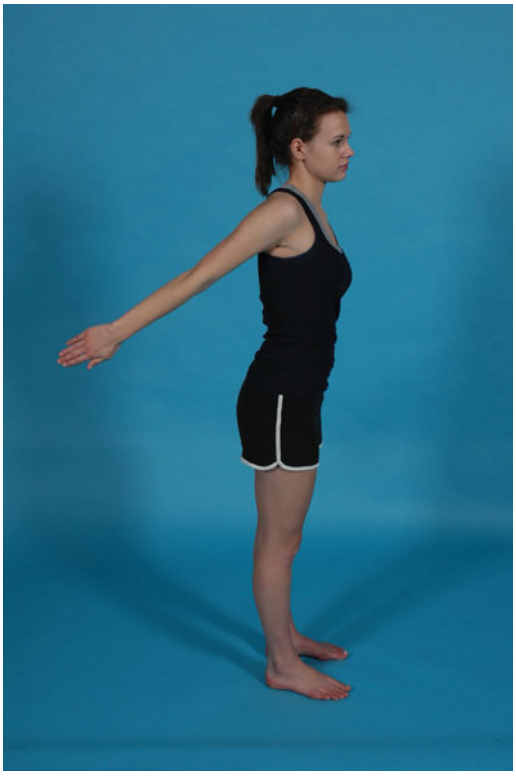

FIGURE 16-19 Shoulder extension AROM.

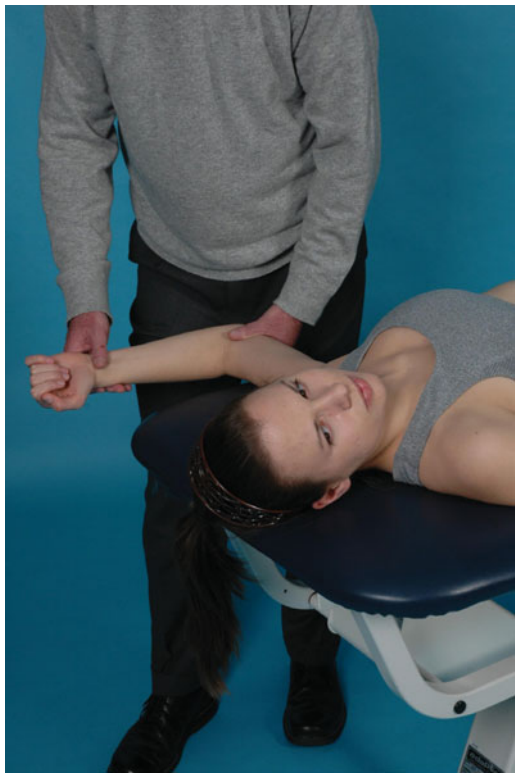

FIGURE 16-20 Shoulder external rotation in supine.

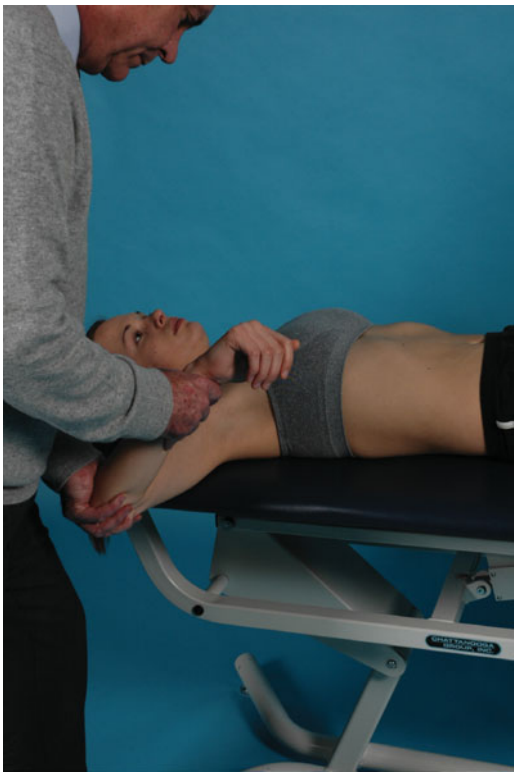

FIGURE 16-21 Shoulder internal rotation in supine.

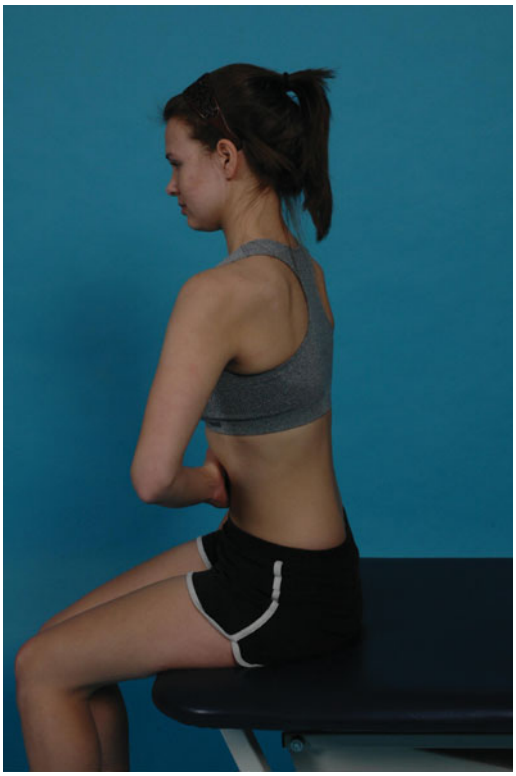

FIGURE 16-23 Shoulder internal rotation in sitting.

standardized protocol for measurement of shoulder movements, the movement of the hand behind the back (and total shoulder flexion) yielded the highest ICC scores for both intrarater reliability (0.91 and 0.83, respectively) and interrater reliability (0.80 and 0.72, respectively). However, in a study by Edwards et al.,[256] measurement of IR by vertebral level was not readily reproducible between observers.

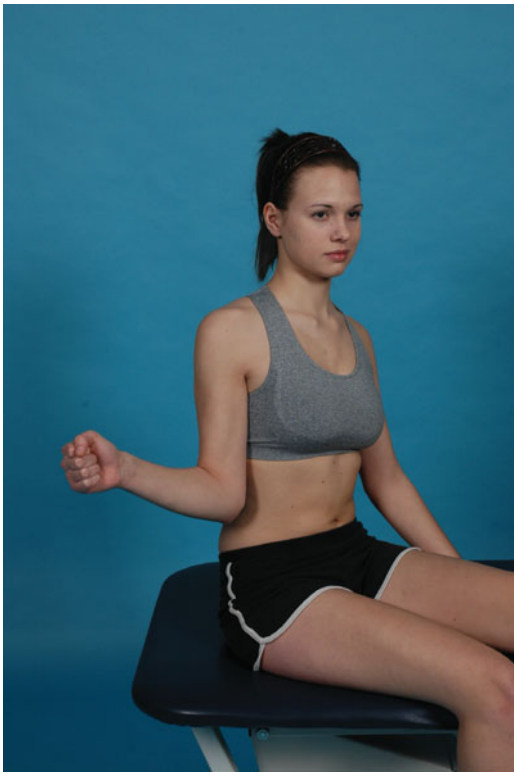

FIGURE 16-22 Shoulder external rotation in the upright position.

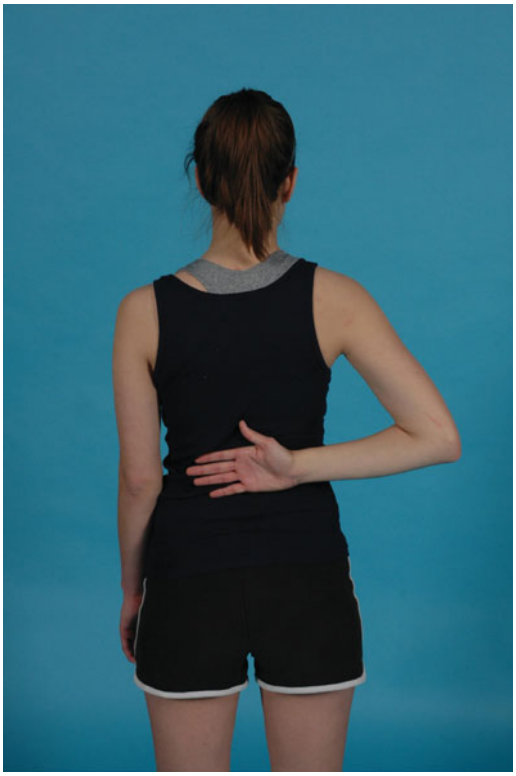

FIGURE 16-24 Apley scratch test.

FIGURE 16-25 Shoulder ER at 45-degree abduction.

- The arm at 45-degree abduction in the scapular plane (Fig. 16-25). This position is used to assess ER for overhead athletes.

Most overhead athletes exhibit excessive ER and decreased IR. The cause of this adaptation has not been established, with some authors[257–260] documenting humeral osseous retroversion as the cause, whereas others have theorized that excessive ER and limited IR are due to anterior capsular laxity and posterior capsule tightness,[261] although no clinical studies have confirmed these findings to date. G-H IR deficit (GIRD) and posterior shoulder tightness (PST) have been linked to shoulder dysfunction based on a study series by Burkhart et al.[261–263] In cadaveric studies, tightening the posterior capsule by plication has been shown to increase anterior G-H translation during flexion and cross-body adduction, cause superior G-H translation with flexion and ER of the G-H joint, and markedly decrease IR.[46,264,265] Similarly, GIRD and PST have been demonstrated in throwing athletes with internal impingement[266] and in patients with secondary impingement.[267] However, the theory of posterior capsule tightness has come into question from other researchers who have determined that ROM in baseball pitchers—specifically, a loss of IR—does not correlate with an alteration in posterior G-H translation.[268,269]

CLINICAL PEARL

Three terms can be used to describe the relationship between IR and ER of the G-H joint[261]:

- GIRD: defined as the difference in IR between the two shoulders. Normally the difference should be within 20 degrees. GIRD results from posterior capsule shortening and has been shown to predispose baseball pitchers to a higher potential for shoulder injury.
- Glenohumeral ER gain (GERG): defined as the difference in ER between two shoulders.
  - If the GIRD/GERG ratio is greater than one, the patient will likely develop shoulder problems.[262]
- Total rotational motion (TRM): determined by adding the amount of ER and IR at 90 degrees of abduction to determine the TRM arc.

It is important not to disregard the effect of muscle forces on these biomechanical changes. Reinold et al.[270] recently examined the PROM of the shoulder in 31 professional baseball pitchers, before and immediately after pitching. The researchers reported that rotational range of G-H motion was immediately affected by overhead throwing and that mean IR ROM after pitching significantly decreased (73 ± 16 degrees before, 65 ± 11 degrees after) and total rotational motion decreased (average, 9 degrees). Mean ER before throwing (133 ± 11 degrees) did not significantly change after throwing (131 ± 10 degrees). The researchers hypothesized that this decrease in IR ROM was due to large eccentric forces being generated in the external rotators during the follow-through phase of throwing that caused microscopic muscle damage in the posterior shoulder musculature. Previous studies examining the effect of repetitive eccentric contractions have shown a subsequent loss of joint ROM in the upper and lower extremities following testing.[271–273]

Wilk et al.[274] proposed the TRM concept, where the amount of ER and IR at 90 degrees of abduction are added and a TRM arc is determined. The authors reported that the TRM in the throwing shoulders of professional baseball pitchers is within 5 degrees of the nonthrowing shoulder[274] and that a TRM arc outside the 5-degree range may be a contributing factor to shoulder injuries and subsequent surgery.[275] Thus, although the dominant shoulder has greater ER and less IR, the combined total motion should be equal bilaterally.[270]

CLINICAL PEARL

It is likely that bilateral comparisons of ER and IR are not useful in the assessment of the overhead athlete.

Horizontal Adduction

Horizontal adduction is performed by bringing the arm across in front of the body (Fig. 16-26). Pain with horizontal adduction may indicate A-C joint pathology (see "Crossover Impingement/Horizontal Adduction Test" section). Horizontal adduction is normally 130 degrees compared with 50–75 degrees if the arm is brought in front of the body.

The patient then completes the motions of shoulder girdle elevation (shrug) and depression and shoulder protraction

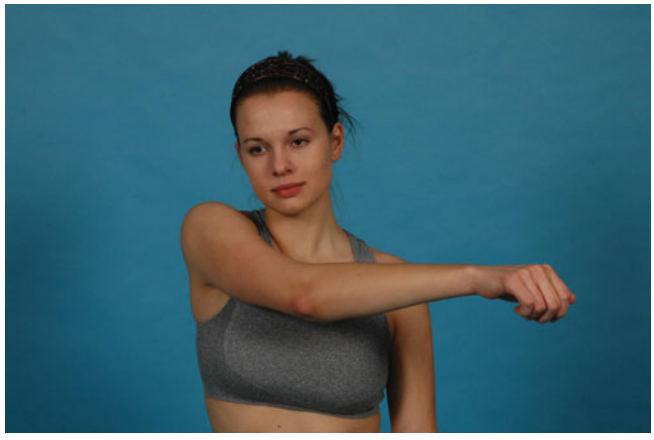

FIGURE 16-26 Horizontal adduction.

and retraction. An inability to shrug the shoulder may indicate a trapezius palsy.[110] Hiking of the shoulder and the scapular during arm elevation is often seen in patients with large rotator cuff tears.[195]

Movement combinations are assessed.

CLINICAL PEARL

If pain is reproduced when IR and extension are combined from a position of 90-degree abduction, the A-C joint, subcoracoid bursa, or subscapularis tendon may be implicated.

If the pain is reproduced with extension with the humerus at 90 degrees of flexion, the shoulder abductors, external rotators, and suprascapular nerve may be implicated. A jammed end-feel with this maneuver may indicate a thoracic dysfunction.

An isolated limitation of passive ER may indicate subcoracoid bursitis, which is aggravated by the pectoralis major muscle being stretched over it.[251]

PROM is performed if there is a deficiency in active motion to determine the end-feel.[246] Traditionally, PROM has been performed with the patient positioned in supine Given the importance of scapular motion during humeral elevation, care must be taken to not prevent the scapula from rotating during these tests.

A discrepancy between active and passive motion may indicate a painful periarticular condition.[227] Loss of active motion with preservation of passive motion is likely caused by a rotator cuff tear,[61] or rarely, suprascapular nerve injury.[201,276] A severely restricted active abduction pattern with no pain is suggestive of a rupture of the supraspinatus or deltoid. Loss of both active and passive motion is usually caused by adhesive capsulitis.[205]

A loss of PROM or active ROM (AROM) may be associated with a loss of flexibility in the passive restraints to motion. This can occur with both single plane motions and combined motions.[37,277–280] For example, if both IR and ER are restricted and muscle tightness has been ruled out as a cause, an adhesion of the middle G-H ligament is implicated.[280]

Examination of the Dynamic Scapula

Given the importance of the scapulothoracic joint to overall shoulder function, it is important to examine the scapulothoracic joint arthrokinematics and muscle power.[281]

A number of muscles play an important role in the kinematics of the scapula, including the trapezius and serratus anterior. Increased activity of the upper trapezius muscle, or imbalances between the upper and the lower trapezius muscle, during shoulder elevation may have adverse effects on the kinematics of the scapula.[93,115,183,282]

According to Sahrmann,[206] four abnormal clinical findings exist for the scapula:

- The scapular alignment is correct but its movement is impaired.
- The scapular alignment is impaired and its movement is impaired.
- The scapular alignment is impaired and its movement is of normal range, but does not correct or compensate for the impaired start position.
- The scapular alignment is impaired but its movement is sufficient to compensate for the impaired start position.

Kibler[24] recommends the use of the isometric "scapular pinch" test to examine the strength of the medial scapular muscles. This involves the patient squeezing his or her shoulder blades together (Fig. 16-27). Normally, the scapula can be held in this position for 15–20 seconds without difficulty. If a burning pain occurs in less than 15 seconds, Kibler suggests that scapular muscle weakness may be the cause.[24]

Observation of the scapulohumeral rhythm and scapulothoracic motion should reveal that the scapula stops its rotation when the arm has been elevated to approximately 140 degrees. Upon completion of the elevation, the inferior angle of the scapula should be in close proximity to the midline of the thorax, and the vertebral border of the scapular should be rotated 60 degrees. Movement beyond these points may indicate excessive scapular abduction.[206] At the end range of elevation, the scapula should slightly depress, posteriorly tilt, and adduct.[206] The motion of the scapula should be assessed carefully in patients with suspected multidirectional instability. A scapulothoracic dyskinesia (decrease in scapular abduction and ER with progressive arm abduction) is often observed in patients with anteroinferior instability.[283] Posteroinferior instability is characterized by excessive scapular retraction.[238] An inferior instability is characterized by a drooping of the lateral scapula or "scapular dumping."[238]

After positioning the patient in prone with his or her arm abducted to 90 degrees, ER is carried out to test the ability of the scapula to remain in its correct position rather than

FIGURE 16-27 Scapular pinch.

abducting due to excessive lengthening of the thoracoscapular muscles (trapezius and rhomboids) and shortening of the scapulohumeral muscles.[206]

Resistive Tests

In addition to pain, shoulder dysfunction is often caused or exacerbated by a loss of motion or weakness. The resistive tests assess function in the important muscle groups of the upper kinetic chain (Tables 16-14 and 16-15).

Localized, individual isometric muscle tests around the shoulder girdle can give the clinician information about patterns of pain and weakness and with information regarding weakness resulting from a spinal nerve root or peripheral nerve palsy. A general assessment of shoulder strength is initially performed, testing flexion, extension, abduction, adduction, IR, and ER. Weakness on isometric testing needs to be analyzed for the type—increasing weakness with repeated contractions of the same resistance indicating a palsy versus consistent weakness with repeated contractions, which could suggest a deconditioned muscle or a significant muscle tear—and the pattern (spinal nerve root, nerve trunk, or peripheral nerve). A painful weakness (see Chap. 5) is invariably a sign of serious pathology and, depending on the pattern, could indicate a fracture or a tumor. However, if a single motion is painfully weak, this could indicate muscle inhibition due to pain. The various motions of shoulder can be assessed through their arcs of motion both concentrically and eccentrically against resistance, as appropriate.

CLINICAL PEARL

Pain with isometric muscle testing is generally considered a sign of first- or second-degree musculotendinous lesion (see Chap. 4). According to Cyriax,[246] pain that occurs during a muscle contraction is more likely to indicate a lesion within a muscle belly, whereas pain that occurs on release of the contraction is more likely to indicate a lesion within a tendon.[251] However, because of the large amount of accessory joint gliding that occurs in the shoulder girdle joints with isometric contraction, the tests for inert tissue involvement must be negative before coming to the conclusion that only the musculotendinous structure is at fault.

TABLE 16-15 Shoulder Girdle Muscle Function and Innervation

Muscles	Peripheral Nerve	Nerve Root	Motions
Pectoralis major	Pectoral	C5–C8	Adduction, horizontal adduction, and internal rotation Clavicular fibers: forward flexion Sternocostal fibers: extension
Latissimus dorsi	Thoracodorsal	C7 (C6, C8)	Adduction, extension, and internal rotation
Teres major	Subscapular	C5–C8	Adduction, extension, horizontal abduction, and internal rotation
Teres minor	Axillary	C5(6)	Horizontal abduction (also a weak external rotator)
Deltoid	Axillary	C5(6)	Anterior: forward flexion, horizontal adduction Middle: abduction Posterior: extension, horizontal abduction
Supraspinatus	Suprascapular	C5(6)	Abduction
Subscapularis	Subscapular	C5–C8	Adduction, and internal rotation
Infraspinatus	Suprascapular	C5(C6)	Abduction, horizontal abduction, and external rotation

FIGURE 16-28 Jobe or empty-can test for supraspinatus.

FIGURE 16-29 Full-can test.

A number of resistive tests have been designed to isolate the muscles of the shoulder complex. Cyriax[275] believed that supraspinatus tendinitis is the most common cause of a painful arc. The supraspinatus can be tested using the Jobe test or empty-can position (Fig. 16-28) **VIDEO**. The patient's arm is positioned in IR within the scaption plane, at approximately 90 degrees of shoulder flexion. Manual resistance is then applied by the clinician in a direction toward the floor. The Jobe test can be performed similarly with the humerus externally rotated (full-can test) (Fig. 16-29) **VIDEO**. One study[284] found the empty-can test to have a high sensitivity of 86% and a low specificity of 50% in diagnosing supraspinatus tendon tears in a series of 55 patients. However, in another study,[285] the full-can test had higher specificity (74% vs. 68%) and an equal sensitivity of 77% when compared with the empty-can test in a series of 136 patients.

A partial rupture of the supraspinatus tendon will result in abduction that is both weak and painful.[69] A painless weakness with abduction could indicate a complete rupture of the supraspinatus tendon, although the deltoid cannot be ruled out. The tendon of the supraspinatus can be passively stretched by positioning it in adduction and IR to see if this increases the pain.[286]

It has been documented that if coracohumeral pain decreases with the addition of arm traction during resisted abduction, subacromial–subdeltoid bursitis or an A-C joint lesion should be suspected.[287] However, this was not found to be the case with ultrasonography.[288]

The test position for the *infraspinatus* and *teres minor* muscles is 90 degrees of G-H flexion and one-half full ER (Fig. 16-30).[120] If the pain is isolated to ER, then the infraspinatus is at fault. If ER and resisted adduction are painful, the teres minor is at fault, although isolated involvement of the teres minor is not common. To test the teres minor further, the muscle is placed on stretch by putting the patient in prone position with his or her upper arms vertical, adducted, and externally rotated to approximately 20 degrees. The patient is asked to lean toward the tested side to increase the adduction.

The *teres major* muscle can be tested by putting the patient in the prone position with his or her hand resting on his or her lower back (Fig. 16-31) **VIDEO**. The patient is asked to adduct and extend the humerus while the clinician applies resistance at the elbow into shoulder abduction.

FIGURE 16-30 Resisted test for infraspinatus and teres minor.

FIGURE 16-31 Resisted test for teres major.

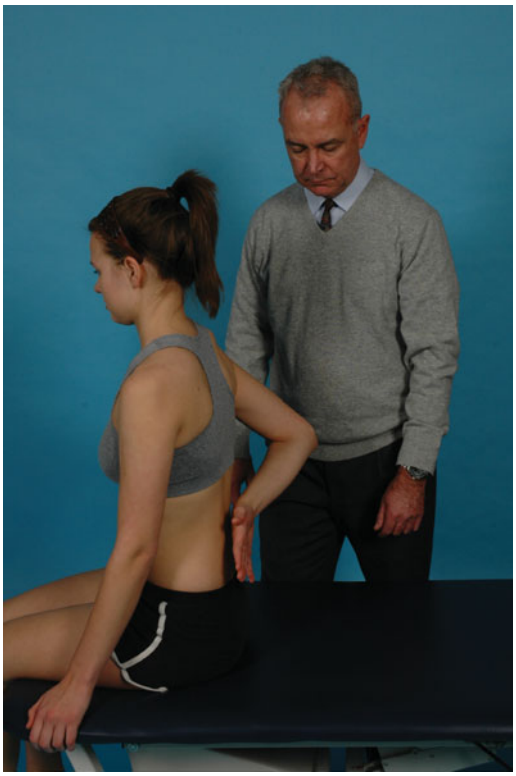

FIGURE 16-32 Lift-off test.

CLINICAL PEARL

A proper balance between agonist and antagonist muscle groups is necessary to provide dynamic stabilization to the shoulder joint.[289] For example to provide proper muscle balance, the G-H joint external rotator muscles should be at least 65% of the strength of the internal rotator muscles.[290] Ideally though, the ER–IR muscle strength ratio should be 66–75%.[290]

To assess for *rhomboid* dominance, the patient positions their arms by their side with their elbow flexed to approximately 90 degrees. Resisted ER in this position should not result in any scapular adduction, unless there is rhomboid dominance and poor control of G-H ER.[206] There should also be no superior or anterior gliding of the humerus during this test, unless deltoid dominance is occurring.[206]

Conditions to be ruled out if there is a painless weakness of ER include, but are not limited to, the following:

- A complete rupture of the infraspinatus tendon
- A C5 nerve root palsy
- A suprascapular nerve palsy
- Neuralgic amyotrophy

The *subscapularis* is best assessed using the lift-off test as described by Gerber and Krushell. The lift-off test is performed with the arm internally rotated so that the posterior surface of the hand rests on the lower back. Actively lifting the hand away from the back (Fig. 16-32) against a resisting force suggest integrity of the subscapularis. Failure to do so indicates a subscapularis tear. The test has been found to have a sensitivity of 80% and a specificity of 100% for a tear of the subscapularis.[291] A similar test is the IR lag sign test (see "Special Tests" section).

Resisted adduction is tested with the arm at 0 degree of abduction so that the subscapularis is not facilitated.[291] Pain with resisted adduction tends to be fairly rare, but could implicate the pectoralis major, latissimus dorsi, teres major, and teres minor.

CLINICAL PEARL

A patient with subacromial–subdeltoid bursitis, in the absence of a rotator cuff tear, will often demonstrate weakness of the rotator cuff secondary to pain if tested with the arm positioned in the arc of impingement. It will, however, show good strength if tested with the arm out of abduction. A patient with a significant cuff tear usually demonstrates profound weakness of the rotator cuff throughout various arm positions.

Testing of *deltoid* function is best done with resisted abduction with the arm at 90 degrees of abduction and neutral rotation (Fig. 16-33) **VIDEO**.[190] A painful arc cannot be produced by a lesion to the deltoid muscle due to its anatomical position.

Differential diagnosis will be needed to rule out several neurological disorders, which may provoke painless weakness on resisted abduction. These include an axillary nerve palsy, a suprascapular nerve palsy, or a fifth cervical root palsy.

The three components of the *trapezius* are assessed as follows:

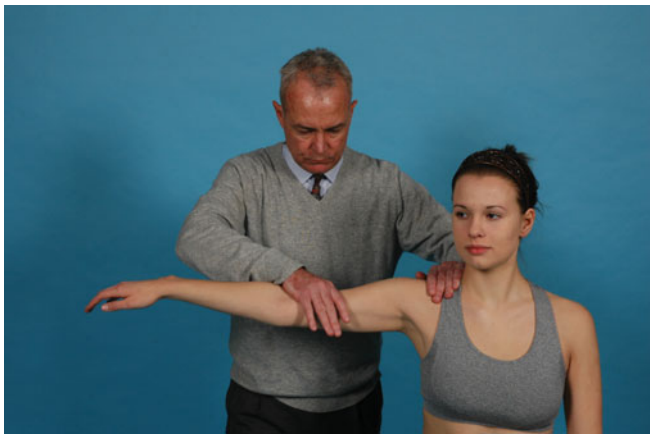

FIGURE 16-33 Resisted deltoid.

- ***Upper trapezius (and levator scapulae).*** Usually both sides are tested simultaneously. The patient is asked to shrug the shoulders to the ears. If the patient is unable to perform this action, he or she lies in the supine position to eliminate the effect of gravity and asked to repeat the test. Resistance is applied by the clinician in an attempt to depress the shoulders **VIDEO**. Unilateral resistance can be applied to the posterior lateral aspect of the head while stabilizing the shoulder.
- ***Middle trapezius.*** The patient lies in the prone position with the shoulder joint abducted to 90 degrees, elbow extended, and the forearm in maximum supination so that the thumb is pointing to the ceiling (Fig. 16-34) **VIDEO**. The clinician applies pressure on the humerus by pushing toward the floor.
- ***Lower trapezius.*** The patient lies in the prone position, with the upper limb supported in the elevated position and aligned in the direction of the lower trapezius muscle fibers (Fig. 16-35) **VIDEO**. Grades 0–2 are determined by the firmness of the muscle contraction. Grades 2+ and 3− are based on how far the limb is lifted from the table. Grades 3–5 require the application of resistance by the clinician.

As discussed in the biomechanics section, proper scapular movement and stability are imperative for asymptomatic shoulder function.[24] The *serratus anterior* can be assessed in a number of ways **VIDEO**, including using the wall push-up. A more sensitive test involves putting the patient in the supine position with his or her shoulder flexed to 90 degrees and their elbow flexed. The patient is asked to protract the shoulder by lifting the elbow to the ceiling. Resistance is applied by the clinician at the hand, pushing downward (Fig. 16-36). Given that the serratus anterior functions to control upward rotation of the scapula during arm elevation, this ability should also be assessed.

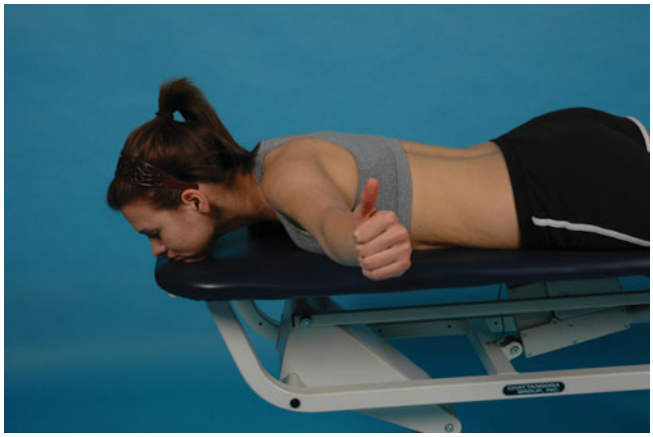

FIGURE 16-34 Middle trapezius test.

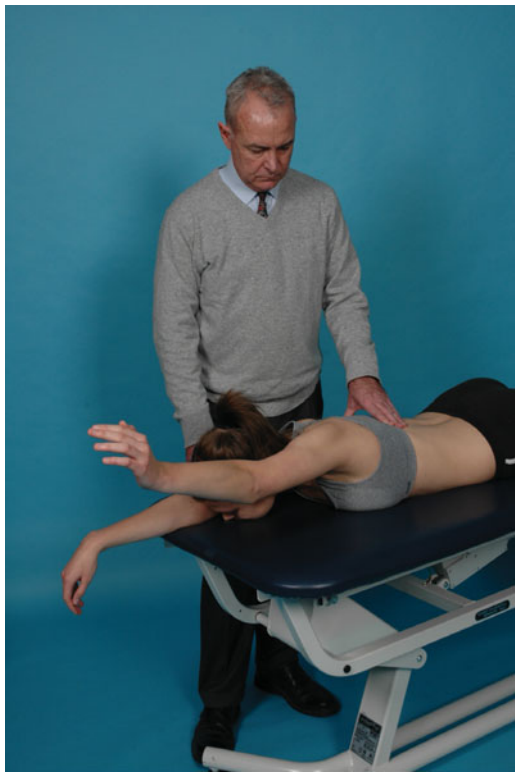

FIGURE 16-35 Lower trapezius test.

Finally, resisted elbow flexion and extension, as well as forearm supination (see Chap. 17), are examined to assess the *biceps* **VIDEO**, *brachialis* **VIDEO**, and *triceps* function **VIDEO**. Isometric elbow extension and flexion with the muscles in a stretched position will help exclude the biceps and triceps muscles. Pain reproduced with resisted elbow flexion could indicate a lesion to one or more of the elbow flexors, such as an intra-articular lesion of the LHB or a lesion in the sulcus of the LHB. The sulcus lesion can be tested with the patient side-lying, facing away from the clinician, and their arm hanging behind them. The clinician stabilizes the scapula and applies a longitudinal force along the humerus in a superior direction to drive the humerus superiorly. A positive sign is pain reproduced with this maneuver.

A painless weakness of elbow flexion can result from a fifth cervical root palsy, or a sixth cervical root palsy (a complete rupture of all of the elbow flexors is an extremely unlikely event.)

The wrist and hand are also evaluated for motor function as appropriate (see Chap. 18).

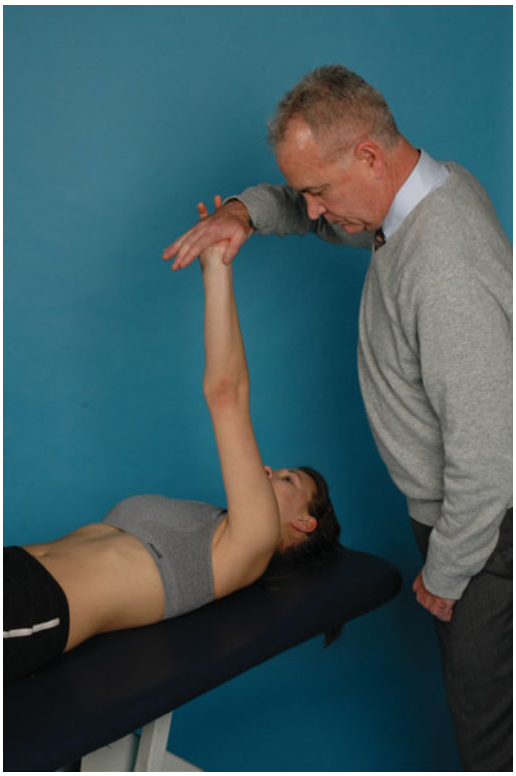

FIGURE 16-36 Serratus anterior test.

Examination of Movement Patterns

These tests are concerned with the coordination, timing, or sequence of activation of the muscles during movement. [206]

Serratus Anterior

The patient lies in the prone position and is asked to perform a push-up and then return to the start position extremely slowly. The clinician checks for the quality of scapula stabilization. If the stabilizers are weak, the scapula on the side of impairment will shift outward and upward with a resultant winging of the scapula.

Shoulder Abduction

The patient sits with his or her elbow flexed to control the humeral rotation. The patient is asked to slowly abduct the arm. Three components are evaluated:

- Abduction at the G-H joint
- Rotation of the scapula
- Elevation of the whole shoulder girdle—the abduction movement is stopped at the point at which the shoulder begins to elevate; this typically occurs at approximately 60 degrees of G-H abduction

Functional Testing

The assessment of shoulder function is an integral part of the examination of the shoulder complex. Functional testing of the shoulder complex can include tests designed to detect a biomechanical dysfunction or tests designed to assess the patient's ability to perform the basic functions of ADL. Given the number of different shoulder conditions that exist, it is important to remember that each of the following functional tests may have specific limited applications.

Biomechanical Function

There are only two functional motions within the shoulder girdle: arm elevation using a combination of flexion and abduction and arm extension with adduction. All other motions of the shoulder are parts or composites of these two basic functional sets.

Basic Function Testing

By referring to Table 16-16, the clinician can determine the functional status of the shoulder for basic functions simply by measuring the amount of available ROM. For example, humeral motions necessary for eating and drinking have been reported at 5–45 degrees of flexion, 5–35 degrees of abduction, and 5–25 degrees of IR relative to the trunk.[292] Combing hair has been found to require 112 degrees of arm elevation.[162]

Mannerkorpi[293] used three functional tests (hand-to-neck, hand-to-scapula, and hand-to-opposite scapula) to assess shoulder dysfunction in patients with fibromyalgia (Table 16-17). Yang and Lin[294] assessed the intertester and intratester reliability of these functional tests and found them to be reliable for documenting reduced function of the shoulder.

TABLE 16-16 Range of Motion Necessary at the Shoulder for Functional Activities

Activity	Necessary Range of Motion
Eating	70–100-degrees horizontal adduction 45–60-degrees abduction
Combing hair	30–70-degrees horizontal adduction 105–120-degrees abduction 90-degrees external rotation
Reach perineum	75–90-degrees horizontal abduction 30–45-degrees abduction 90-degrees or greater internal rotation
Tuck in shirt	50–60-degrees horizontal abduction 55–65-degrees abduction 90-degrees internal rotation
Position hand behind head	10–15-degrees horizontal adduction 110–125-degrees forward flexion 90-degrees external rotation
Put an item on a shelf	70–80-degrees horizontal adduction 70–80-degrees forward flexion 45-degrees external rotation
Wash opposite shoulder	60–90-degrees forward flexion 60–120-degrees horizontal adduction

TABLE 16-17 Function-Related Tests

Hand to back of neck (shoulder flexion and external rotation)[a]	0	The fingers reach the posterior median line of the neck with the shoulder in full abduction and external rotation without wrist extension
	1	The fingers reach the median line of the neck but do not have full abduction and/or external rotation
	2	The fingers reach the median line of the neck, but with compensation by adduction in the horizontal plane or by shoulder elevation
	3	The fingers touch the neck
	4	The fingers do not reach the neck
Hand to scapula (shoulder extension and internal rotation)[b]	0	The hand reaches behind the trunk to the opposite scapula or 5 cm beneath it in full internal rotation. The wrist is not laterally deviated
	1	The hand almost reaches the opposite scapula, 6–15 cm beneath it
	2	The hand reaches the opposite iliac crest
	3	The hand reaches the buttock
	4	Subject cannot move the hand behind the trunk
Hand to opposite scapula (shoulder horizontal adduction)[c]	0	The hand reaches to the spine of opposite scapula in full adduction without wrist flexion
	1	The hand reaches to the spine of the opposite scapula in full adduction
	2	The hand passes the midline of the trunk
	3	The hand cannot pass the midline of the trunk

[a]This test measures an action essential for daily activities, such as using the arm to reach, pull, or hang an object overhead or using the arm to pick up and drink a cup of water.
[b]This test measures an action essential for daily activities, such as using the arm to pull an object out of a back pocket or tasks related to personal care.
[c]This test measures an action important for daily activities, such as using the arm to reach across the body to get a car's seat belt or using the arm to turn a steering wheel.
Data from Mannerkorpi K, Svantesson U, Carlsson J, et al: Tests of functional limitations in fibromyalgia syndrome: A reliability study. *Arthritis Care Res* 12:193–199, 1999.

The assessment tool outlined in Table 16-18 can also be used as a functional test of the shoulder. Several generic and region-specific outcome tools have been developed and used to document outcomes of patients with shoulder pathologies.

Shoulder Outcome Scales

A number of shoulder scales have been developed. Five of the most commonly used shoulder outcome scales are the University of California–Los Angeles (UCLA) shoulder scale, the simple shoulder test (SST), the shoulder pain and disability index (SPADI), the disabilities of the arm, shoulder, and hand (DASH), and the Penn Shoulder Score (PSS).

University of California–Los Angeles (UCLA) Shoulder Scale. The self-report section of the UCLA Shoulder Scale consists of two single-item subscales, one for pain and the other for functional level (Table 16-19). The items are Likert-type (a psychometric scale) and scored from 1 to 10, with higher scores indicating less pain and greater function.[295]

The Simple Shoulder Test. Lippitt et al.[296] advocate the use of the SST (Table 16-20). The SST is a standardized self-assessment of shoulder function consisting of 12 yes/no questions. The SST has high test and retest reproducibility and is sensitive to a wide variety of shoulder disorders.[296] In addition, the SST has been shown to be a practical tool for documenting the efficacy of treatment for shoulder conditions. Patients without rotator cuff disease or other shoulder disorders are able to do all 12 functions of the SST.[196,297–299]

When compared with other available shoulder self-assessment questionnaires, the SST has the highest test/retest reliability, takes the shortest amount of time for a patient to complete, is the easiest to score, and has satisfactory responsiveness.[300,301] The questions can be asked at the initial visit and then at subsequent visits to track progress.

Shoulder Pain and Disability Index.[302] The SPADI consists of two self-report subscales of pain and disability. The items of both the subscales are visual analog scales (VASs). The five-item pain subscale asks people about their pain during ADL, and each item is anchored by the descriptors "no pain" (left anchor) and "worst pain imaginable" (right anchor). The eight disability items ask people about their difficulty performing ADL. These items are anchored with the descriptors "no difficulty" (left anchor) and "so difficult it required help" (right anchor). Each item is scored by measuring the distance from the left anchor to the mark made by the person. Subscales are scored in a three-part process. First, item scores within the subscale are summed. Second, this sum is divided by the summed distance possible across all items of the subscale to which the person responded. Third, this ratio is multiplied by 100 to obtain a percentage. Higher scores on the subscale indicate greater pain and greater disability. To obtain the SPADI total score, the pain and disability subscales scores are averaged.[302]

Disabilities of the Arm, Shoulder, and Hand. The acronym DASH was chosen to describe an outcome measure that reflects the impact on function of a variety of musculoskeletal

TABLE 16-18 Functional Testing of the Shoulder

Starting Position	Action	Functional Test
Sitting, cuff weight attached to wrist	Forward flex arm to 90 degrees, elbow extended	Raise 1–3-lb weight: functionally fair Raise arm without weight: functionally poor Cannot raise arm: nonfunctional
Sitting, cuff weight attached to wrist	Extend shoulder, elbow extended	Raise 4–5-lb weight: functional Raise 3–4-lb weight: functional fair Raise arm without weight: functionally poor Cannot extend arm: nonfunctional
Sitting with hand behind low back	Shoulder internal rotation	Raise 5-lb weight: functional Raise 1–3-lb weight: functional fair Raise arm without weight: functionally poor Cannot raise arm: nonfunctional
Side-lying, cuff weight attached to wrist	Shoulder external rotation	Raise 5-lb weight: functional Raise 3–4-lb weight: functional fair Raise arm without weight: functionally poor Cannot raise arm: nonfunctional
Sitting, cuff weight attached to wrist	Shoulder abduction to 90 degrees	Raise 5-lb weight: functional Raise 3–4-lb weight: functional fair Raise arm without weight: functionally poor Cannot raise arm: nonfunctional
Sitting, arm abducted to 145 degrees	Shoulder adduction	Pull 5-lb weight: functional Pull 3–4-lb weight: functional fair Pull 1–2-lb weight: functionally poor Cannot pull 1 lb: nonfunctional
Sitting	Shoulder elevation (shoulder shrug)	Five repetitions: functional Three to four repetitions: functional fair One to two repetitions: functionally poor Zero repetitions: nonfunctional
Sitting	Scapular depression	Five repetitions: functional Three to four repetitions: functional fair One to two repetitions: functionally poor Zero repetitions: nonfunctional

Data from Matsen FH III, Lippitt SB, Sidles JA, et al: *Practical Evaluation of Management of the Shoulder*. Philadelphia, PA: WB Saunders, 1994:19–150; Magee DJ: *Shoulder, Orthopaedic Physical Assessment*. diseases and injuries in the upper extremity.[303] Items covered by the DASH questionnaire are symptoms and functional status. The components included under the concept of symptoms are pain, weakness, stiffness, and tingling/numbness.[303] There are three dimensions under functional status: physical, social, and psychological status. Two versions of the DASH are available: a 30-item questionnaire that has optional three-question modules for sport/music and heavy work activities (Table 16-21), and a 15–20-item questionnaire suitable for office use.

Penn shoulder score

PSS is a condition-specific self-report measure that uses a 100-point scale consisting of three subscales, including pain, satisfaction, and function. The pain subscale consists of three pain items that address pain at rest, with no activities, and with strenuous activities (Table 16-22).[304] All are based on a 10-point numeric rating scale with end points of "no pain" and "worst possible pain." Points are awarded for each item by subtracting the number circled from the maximum of 10. Therefore a patient is awarded 30 points for complete absence of pain. If a patient is not able to use the arm for normal or strenuous activities, zero points are awarded for that item. Patient satisfaction with shoulder function is also assessed with a 10-point numeric rating scale (Table 16-23). The end points are "not satisfied" and "very satisfied." A maximum of 10 points for this section indicates that the patient is "very satisfied" with the current level of function of his or her shoulder. The total PSS maximum score of 100 indicates high

TABLE 16-20 The Simple Shoulder Test

1. Is your shoulder comfortable with your arm at rest by your side?
2. Does your shoulder allow you to sleep comfortably?
3. Can you reach the small of your back to tuck in your shirt with your hand?
4. Can you place your hand behind your head with the elbow straight out to the side?
5. Can you place a coin on a shelf at the level of your shoulder without bending your elbow?
6. Can you lift 1 lb (a full-pint container) to the level of your shoulder without bending your elbow?
7. Can you lift 8 lb (a full gallon container) to the level of the top of your head without bending your elbow?
8. Can you carry 20 lb at your side with the affected extremity?
9. Do you think you can toss a softball underhand 10 yards with the affected extremity?
10. Do you think you can throw a softball overhand 20 yards with the affected extremity?
11. Can you wash the back of your opposite shoulder with the affected extremity?
12. Would your shoulder allow you to work full time at your usual job?

Data from Matsen FA, Lippitt SB, Sidles JA, et al: Evaluating the shoulder. In: Matsen FA, Lippitt SB, Sidles JA, et al., eds. *Practical Evaluation and Management of the Shoulder.* Philadelphia, PA: WB Saunders, 1994:1–17.

function, low pain, and high satisfaction with the function of the shoulder. The PSS has been found to be a reliable and valid measure for reporting outcome of patients with various shoulder disorders.[304]

Other tests, which are designed to assess shoulder function, include the following:

One-Arm Hop Test

The one-arm hop test is a functional performance test for athletes, which can be used in preseason screens or to assist in return-to-play decisions. The test requires the patient to be in a one-arm push-up position on the floor (Fig. 16-37). The patient uses his arm to hop onto a 10.2-cm (4-inch) step and back to the floor. The time required to perform five repetitions of this movement as quickly as possible is recorded and compared with the uninvolved arm. With sufficient training, a time of under 10 seconds is considered normal.[305]

The one-arm hop test requires concentric and eccentric muscle strength and coordination while the distal portion of the upper extremity has a significant load placed upon it.[305]

Muscle Length Tests

Pectoralis Major

The patient lies in the supine position with the trunk stabilized. The clinician passively abducts the patient's arm and differentiates between the different bands of the pectoralis major.

Clavicular Portion. The patient's arm hangs loosely down over the edge of the table. The clinician moves the patient's shoulder down toward the floor. A slight barrier to the motion is normal, whereas a hard barrier is abnormal.

Sternal Portion. With the patient supine on a mat table, they actively abduct their arm fully. Their arm should maintain contact with the table throughout the range.

Pectoralis Minor

The patient lies in the supine position with the trunk stabilized. Adaptive shortening of the pectoralis minor is demonstrated if the lateral border of the spine of the scapula is more than 1 inch off the table.[206]

Latissimus Dorsi. The patient lies in the supine position with the trunk stabilized. The patient is asked to perform bilateral shoulder flexion. Under normal circumstances, the patient should be able to perform complete shoulder flexion without any increase in lumbar lordosis occurring.[206] Shoulder flexion that requires an increase in lumbar lordosis to complete is indicative of an adaptively shortened latissimus dorsi.

External Rotators

The patient lies in the supine position with the trunk stabilized. The shoulder is positioned at 90 degrees of abduction with the

TABLE 16-21 The DASH Questionnaire

Please rate your ability to do the following activities in the last week by circling the number below the appropriate response

	No Difficulty	Mild Difficulty	Moderate Difficulty	Severe Difficulty	Unable
1. Open a tight or new jar	1	2	3	4	5
2. Write	1	2	3	4	5
3. Turn a key	1	2	3	4	5
4. Prepare a meal	1	2	3	4	5
5. Push open a heavy door	1	2	3	4	5
6. Place an object on a shelf above your head	1	2	3	4	5
7. Do heavy household chores (e.g., wash walls, wash floors)	1	2	3	4	5
8. Garden or do yard work	1	2	3	4	5
9. Make a bed	1	2	3	4	5
10. Carry a shopping bag or briefcase	1	2	3	4	5
11. Carry a heavy object (over 10 lb)	1	2	3	4	5
12. Change a light bulb overhead	1	2	3	4	5
13. Wash or blow dry your hair	1	2	3	4	5
14. Wash your back	1	2	3	4	5
15. Put on a pullover sweater	1	2	3	4	5
16. Use a knife to cut food	1	2	3	4	5
17. Recreational activities which require little effort (e.g., cardplaying, knitting, etc.)	1	2	3	4	5
18. Recreational activities in which you take some force or impact through your arm, shoulder, or hand (e.g., golf, hammering, tennis, etc.)	1	2	3	4	5
19. Recreational activities in which you move your arm freely (e.g., playing frisbee, badminton, etc.)	1	2	3	4	5
20. Manage transportation needs (getting from one place to another)	1	2	3	4	5
21. Sexual activities	1	2	3	4	5

Disabilities of the arm, shoulder, and hand

	Not at all	Slightly	Moderately	Quite a Bit	Extremely
22. During the past week, to what extent has your arm, shoulder, or hand problem interfered with your normal social activities with family, friends, neighbors, or groups? (circle number)	1	2	3	4	5

	Not Limited at All	Slightly Limited	Moderately Limited	Very Limited	Unable
23. During the past week, were you limited in your work or other regular daily activities as a result of your arm, shoulder, or hand problem? (circle number)	1	2	3	4	5

Please rate the severity of the following symptoms in the last week (circle number)

	None	Mild	Moderate	Severe	Extreme
24. Arm, shoulder, or hand pain	1	2	3	4	5
25. Arm, shoulder, or hand pain when you performed any specific activity	1	2	3	4	5
26. Tingling (pins and needles) in your arm, shoulder, or hand	1	2	3	4	5
27. Weakness in your arm, shoulder, or hand	1	2	3	4	5
28. Stiffness in your arm, shoulder, or hand	1	2	3	4	5
29. During the past week, how much difficulty have you had sleeping because of the pain in your arm, shoulder or hand? (circle number)	1	2	3	4	5

(Continued)

	Strongly Disagree	Disagree	Neither Agree nor Disagree	Agree	Strongly Agree
30. I feel less capable, less confident, or less useful because of my arm, shoulder, or hand problem (circle number)	1	2	3	4	5

Scoring DASH function/symptoms: Add up circled responses (items 1–30); subtract 30; divide by 1.20 = DASH score.

Sports/performing arts module (optional)

The following questions relate to the impact of your arm, shoulder, or hand problem on playing your musical instrument or sport. If you play more than one sport or instrument (or play both), please answer with respect to that activity which is most important.

Please indicate the sport or instrument which is most important to you: _____

I do not play a sport or an instrument. (You may skip this section.)

Please circle the number that best describes your physical ability in the past week. Did you have any difficulty

	No Difficulty	Mild Difficulty	Moderate Difficulty	Severe Difficulty	Unable
1. Using your usual technique for playing your instrument or sport?	1	2	3	4	5
2. Playing your musical instrument or sport because of arm, shoulder, or hand pain?	1	2	3	4	5
3. Playing your musical instrument or sport as well as you would like?	1	2	3	4	5
4. Spending your usual amount of time practicing or playing your instrument or sport?	1	2	3	4	5

Work module (optional)

The following questions ask about the impact of your arm, shoulder, or hand problem on your ability to work (including homemakers if that is your main work role).

I do not work. (You may skip this section.)

Please circle the number that best describes your physical ability in the past week. Did you have any difficulty

	No Difficulty	Mild Difficulty	Moderate Difficulty	Severe Difficulty	Unable
1. Using your usual technique for your work?	1	2	3	4	5
2. Doing your usual work because of arm, shoulder, or hand pain?	1	2	3	4	5
3. Doing your work as well as you would like?	1	2	3	4	5
4. Spending your usual amount of time doing your work?	1	2	3	4	5

TABLE 16-22 The Penn Shoulder Score, Part 1: Pain and Satisfaction Subscales

Please Circle the Number Closest to Your Level of Pain or Satisfaction	Office Use Only
Pain at rest with your arm by your side: 0 1 2 3 4 5 6 7 8 9 10 No pain ... Worst pain possible	(10 —# circled)
Pain with normal activities (eating, dressing, bathing): 0 1 2 3 4 5 6 7 8 9 10 No pain ... Worst pain possible	(10 —# circled) (Score 0 if not applicable)
Pain with strenuous activities (reaching, lifting, pushing, pulling, throwing): 0 1 2 3 4 5 6 7 8 9 10 No pain ... Worst pain possible	(10 —# circled) (Score 0 if not applicable)
Pain score: =`30	
How satisfied are you with the current level of function of your shoulder? 0 1 2 3 4 5 6 7 8 9 10 No pain ... Worst pain possible	/10 (# circled)

Number of *X*s × 3 = ___(b), 60–___(b) = ___(c) (if no *X*s are circled, function score = total of columns)
Function score = ___(a) ± ___(c) = ___ × 60 ___/60

FIGURE 16-37 One arm push-up position.

elbow flexed to approximately 90 degrees. The patient is then asked to allow the shoulder to passively internally rotate. IR accompanied by an anterior tilt of the scapula, rather than the range of IR increasing, is indicative of adaptive shortness of the external rotators.[206] This is confirmed by having the patient perform the maneuver again while the clinician prevents the anterior tilt of the scapula from occurring. With the second test, there should be a decrease in the amount of passive IR available.

Passive Accessory Motion Tests

The passive accessory motion tests are performed at the end of the patient's available range to determine if the joint itself is responsible for the loss of motion. For all of these tests, the

FIGURE 16-38 Glenohumeral distraction.

joint is initially positioned in the resting or open-packed position, the patient lies in the supine position with their head supported on a pillow if required, while the clinician stands facing the patient.

Distraction of the G-H Joint

The clinician palpates and stabilizes the shoulder girdle and the anterior thorax. With one hand, the clinician gently grasps the proximal third of the humerus. The clinician distracts the G-H joint perpendicular to the plane of the glenoid fossa in a lateral, anterior, and inferior direction (30 degrees off the sagittal plane) (Fig. 16-38). The quantity of motion is noted and compared with the other side. Alternatively, if the arm is positioned so that the long axis of the humerus is perpendicular to the flattened concave surface of the glenoid, the technique can be performed by pulling on the upper arm (Fig. 16-39).

Inferior Glide of the G-H Joint

The clinician palpates and stabilizes the coracoid process of the scapula and the lateral clavicle. With the other hand, the clinician gently grasps proximal to the patient's elbow. The humerus is glided inferiorly at the G-H joint, parallel to the superoinferior plane of the glenoid fossa (Fig. 16-40). The quantity of motion is noted and compared with the other side.

FIGURE 16-39 Glenohumeral distraction using arm pull.

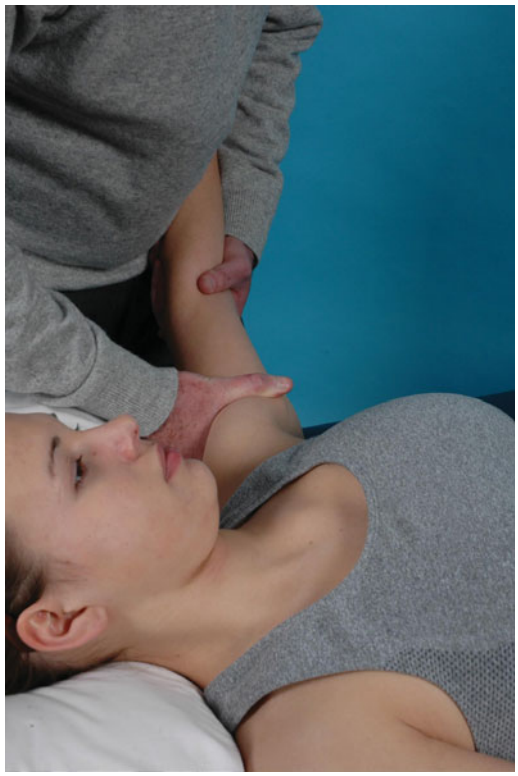

FIGURE 16-40 Inferior glide.

Posterior Glide of the G-H Joint

The clinician palpates and stabilizes the coracoid process and the lateral third of the clavicle. With the thenar eminence of the same hand, the clinician palpates the anterior aspect of the humeral head (Fig. 16-41). With the other hand, the clinician gently grasps the distal end of the humerus. From this position, the clinician glides the humerus posteriorly at the G-H joint, parallel to the A-P plane of the glenoid fossa. The quantity of motion is noted and compared with the other side.

Anterior Glide of the G-H Joint

There are two common variations for this technique, one with the patient in the supine position, and the other where the patient lies in the prone position:

- Patient supine. The clinician palpates the posterior aspect of the humeral head with one hand (Fig. 16-42). With the other hand, the clinician gently grasps the distal end of the humerus. From this position, the clinician glides the humerus anteriorly at the G-H joint, parallel to the A-P plane of the glenoid fossa. The quantity of motion is noted and compared with the other side.
- Patient prone. The clinician palpates the posterior aspect of the humeral head with one hand (Fig. 16-43). With the other hand, the clinician gently grasps the distal end of the humerus. From this position, the clinician glides the humerus toward the floor in an anterior direction, parallel to the A-P plane of the glenoid fossa. The quantity of motion is noted and compared with the other side.

The intervention for joint glide restrictions uses similar techniques and positioning as for the assessment except that the following:

FIGURE 16-41 Posterior glide.

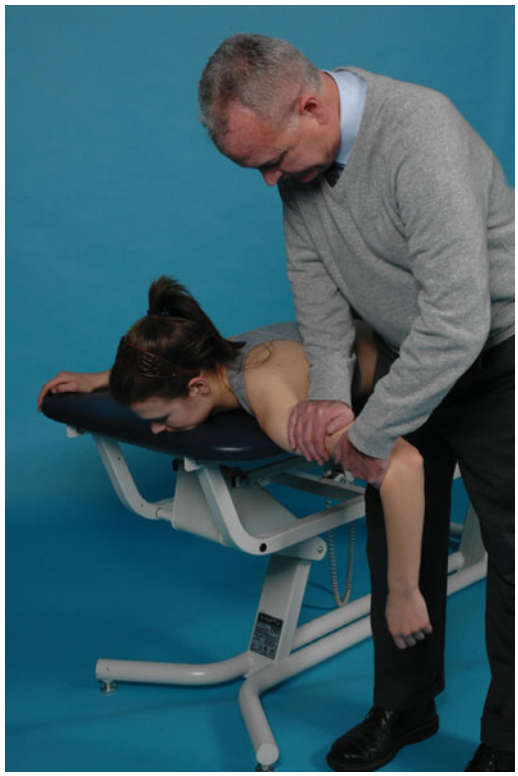

FIGURE 16-43 Anterior glide with patient prone.

- Grade I and II oscillations are used for pain and graded depending on the stage of healing.
- Grade III–V techniques are used to increase range.

Passive Accessory Motion Testing of the Scapulothoracic Joint

Distraction

The patient lies in the side-lying position. The patient's uppermost arm is placed in IR so that the posterior surface of the hand is positioned on the sacrum, if shoulder ROM allows. The clinician stands in front of the patient. The clinician places one hand over the acromion and the mobilizing hand is positioned adjacent to the inferior angle of the scapula. The clinician moves the scapula medially and inferiorly and then lifts the scapula away from the ribs (Fig. 16-44). The quantity and quality of motion is noted.

FIGURE 16-42 Anterior glide with patient supine.

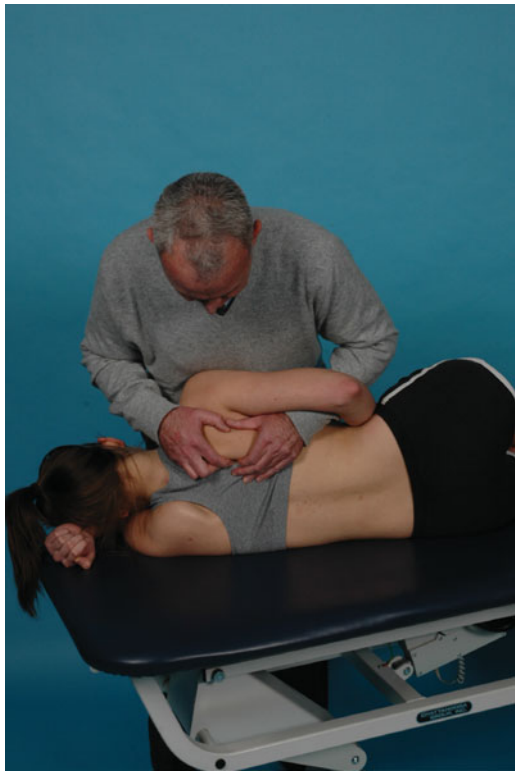

FIGURE 16-44 Distraction of scapulothoracic joint.

FIGURE 16-45 Superior glide of scapulothoracic joint.

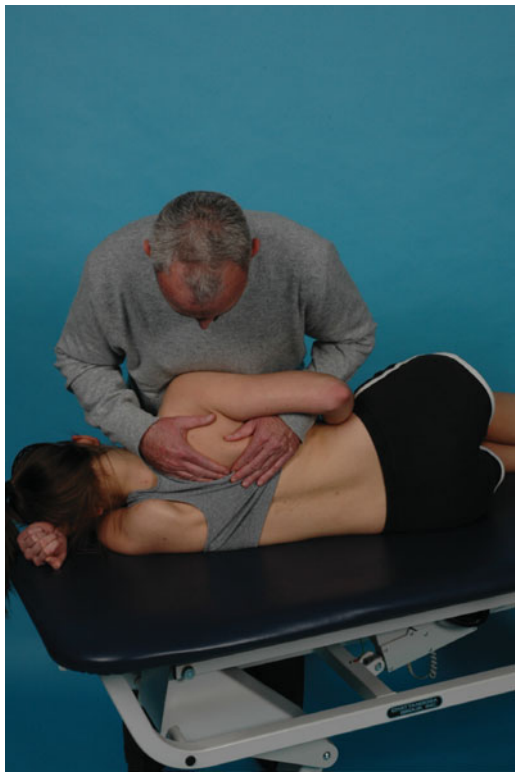

FIGURE 16-46 Inferior glide of scapulothoracic joint.

Superior Glide

The patient is positioned as for the scapulothoracic joint distraction technique, except the uppermost arm is positioned in neutral. Using the mobilizing hand, the clinician glides the scapula in a superior direction (Fig. 16-45).

Inferior Glide

The patient is positioned as for the scapulothoracic joint superior glide. Using the mobilizing hand, the clinician glides the scapula in an inferior direction (Fig. 16-46).

Medial Glide

The patient is positioned as for the superior glide of the scapulothoracic joint. The clinician positions both hands over the lateral surface of the scapula, with one hand over the axillary border and the other hand over the acromion. Using both hands the clinician glides the scapula in a medial direction (Fig. 16-47).

Lateral Glide

The patient is positioned as for the the medial glide of the scapulothoracic joint. The clinician places both hands and the fingertips over the vertebral border of the scapula and the scapula is glided in a lateral direction (Fig. 16-48).

Passive Accessory Motion Testing of the Acromioclavicular Joint

Anterior and Posterior Rotation of the Clavicle

During G-H abduction, or shoulder elevation, the lateral end of the clavicle moves superiorly, the medial end slides and rolls inferiorly, and the clavicle rotates anteriorly.[86] During G-H adduction, or shoulder depression, the lateral end of the clavicle moves inferiorly, while the medial end rolls and slides superiorly.[86] During this motion, the clavicle rotates posteriorly (see Table 16-24).[86]

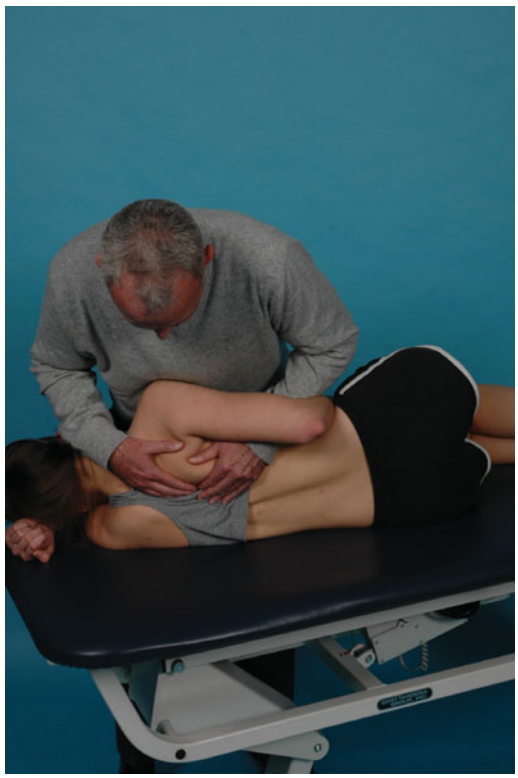

FIGURE 16-47 Medial glide of scapulothoracic joint.

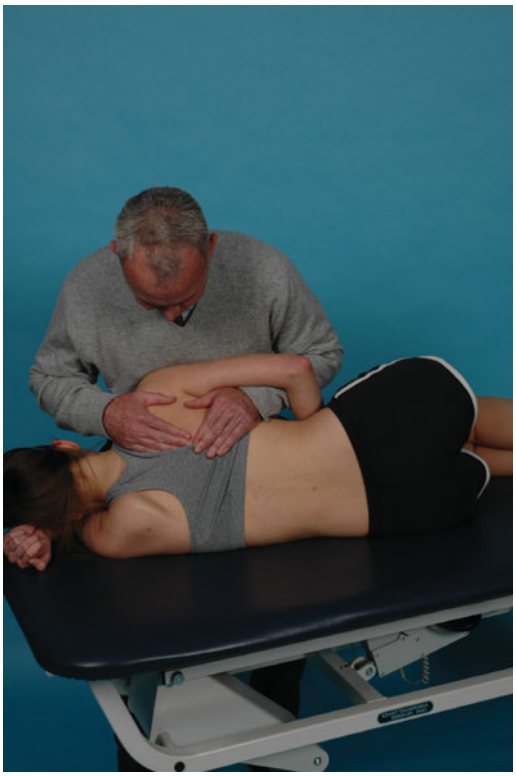

FIGURE 16-48 Lateral glide of scapulothoracic joint.

The patient lies in the side-lying or supine position. The clinician stabilizes the humerus with one hand and grasps the anterior and posterior aspects of the clavicle with the other hand, using the thumb, index, and middle fingers so that the fingers are hooked around the lateral aspect of the clavicle (Fig. 16-49). The clinician passively pulls the clavicle into the limit of anterior rotation and assesses the end-feel (see Fig. 16-49). The clinician then passively pushes the clavicle into the limit of posterior rotation and assesses the end-feel (see Fig. 16-49).

TABLE 16-24 Clavicle Motions in Relation to Other Motions

Moving Bone	Motion	Rotation
Ribs	Inspiration	Posterior
	Expiration	Anterior
Scapula	Protraction	Anterior
	Retraction	Posterior
	Elevation	Anterior
	Depression	Posterior
Head/neck	Ipsilateral rotation	Posterior
	Contralateral rotation	Anterior
	Ipsilateral flexion	Posterior
	Contralateral flexion	Anterior
	Flexion	Anterior
	Extension	Posterior

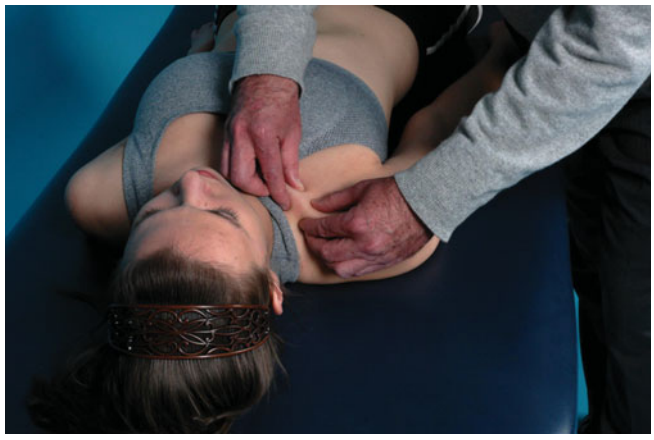

FIGURE 16-49 Anterior and posterior rotation of the clavicle.

Passive Accessory Motion Testing of the Sternoclavicular Joint

The patient lies in the supine position. It is assumed that the techniques are performed on the patient's right side.

Inferior Glide

Using one thumb, the clinician palpates the superior aspect of the medial end of the clavicle and the S-C joint and applies an inferior glide to the S-C joint (Fig. 16-50). The quantity and quality of motion is noted.

Superior Glide

Using the thumb and fingers of one hand, the clinician palpates the inferior aspect of the medial end of the clavicle and the S-C joint and applies a posterosuperior glide to the S-C joint (Fig. 16-51). The quantity and quality of motion is noted.

FIGURE 16-50 Inferior glide of S-C joint.

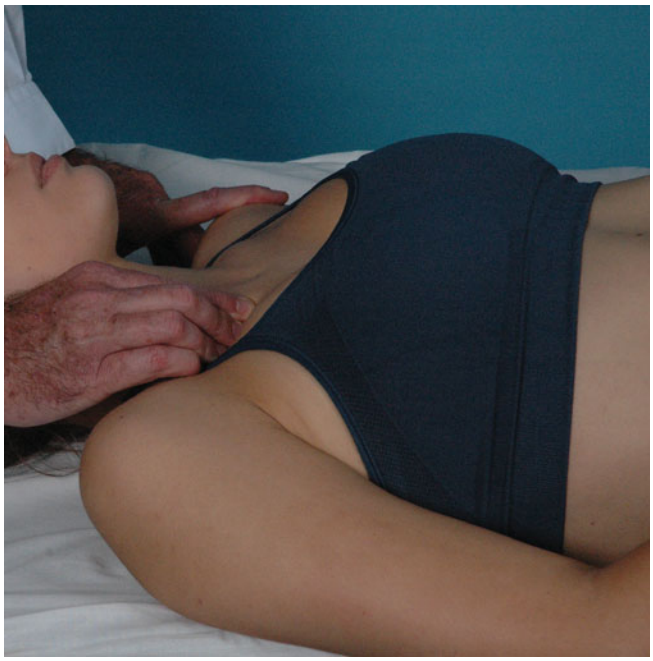

FIGURE 16-51 Superior glide of S-C joint.

Although some texts advocate assessing the anterior and posterior glides of this joint, both of these techniques can be uncomfortable for the patient, and provide little information for the clinician.

Special Tests

The special tests for the shoulder are divided into diagnostic categories. Selection for their use is at the discretion of the clinician and is based on a complete patient history and the findings from the physical examination. It is important to remember that rarely is a diagnostic test sensitive and specific enough to be used as the sole determinant, and multiple test may provide more diagnostic confidence.

Rotator Cuff Integrity and Subacromial Impingement Tests

The following tests have been described in the literature to assess rotator cuff integrity and the presence of SIS (Tables 16-24 and 16-25). Patients with SIS usually perceive pain when a compressing force is applied on the greater tuberosity and rotator cuff region.[306] Pain may also be elicited with shoulder

TABLE 16-25 Diagnostic Test Properties for Impingement and Rotator Cuff Tears

Diagnostic Test or Maneuver	Study Population	Sensitivity	Specificity	Positive Likelihood Ratio	Negative Likelihood Ratio

FIGURE 16-53 Hawkins Kennedy impingement test.

abduction in IR or ER.[306] It is important to remember that "impingement" is a broad diagnosis that encompasses a broad range of pathologies, making its diagnostic value questionable.

Neer Impingement Test. While scapular rotation is prevented by one hand of the clinician, the arm of the patient is passively forced into elevation at an angle between flexion and abduction by the clinician's other hand. Overpressure is applied with the G-H joint in neutral, IR, and then ER (Fig. 16-52). A positive Neer impingement test result is thought to represent impingement of the rotator cuff on the anterosuperior glenoid rim or coracoacromial ligament.[307] Post and Cohen[308] found the Neer test to have a sensitivity of 93% in the confirmation of subacromial impingement.

Hawkins–Kennedy Impingement Test.[309] The arm of the patient is passively flexed up to 90 degrees in the plane of the scapula. The arm is stabilized and the forearm is forced into IR (Fig. 16-53). In a cadaver study, Pink and Jobe[307] found that rotator cuff tendons were impinged under the acromion with the Hawkins–Kennedy test.

Ure et al.[310] found that the sensitivity of the Hawkins–Kennedy test was 62% and the sensitivity of the Neer test was 46% in 45 patients with stage II SIS, as determined using arthroscopy.

McDonald et al.[311] assessed the diagnostic accuracy of the Neer and Hawkins impingement signs for the diagnosis of subacromial bursitis or rotator cuff pathology in 85 consecutive patients undergoing shoulder arthroscopy by a single surgeon. The Neer sign was found to have a sensitivity of 75% for the appearance suggestive of subacromial bursitis; this compared with 92% for the Hawkins sign.[311] For rotator cuff tearing, the sensitivity of the Neer sign was 85% and that of the Hawkins sign was 88%. Specificity and positive predictive values for the two tests were low, being not much higher than pretest probability. The two tests had a high negative predictive value (96% for bursitis, 90% for rotator cuff tearing) when they were combined.[311]

Another study[312] found that the Hawkins–Kennedy test was more accurate than the Neer test in a series of 44 shoulders, with the former having a sensitivity of 78% and the latter a 0%.

Supine Impingement Test. The patient lies in the supine position with the clinician standing to the side of the patient's involved shoulder. The clinician grasps the patient's wrist and distal humerus and elevates the patient's arm to end range (170 degrees or greater). The clinician then moves the patient's arm into ER and then adducts the arm toward the patient's ear (Fig. 16-54). The clinician now internally rotates the patient's arm (Fig. 16-55). The test is considered positive if the patient reports a significant increase in shoulder pain. This test does not appear to be diagnostic but may have value as a screening test since a negative finding may rule out a rotator cuff tear (Table 16-25).

Internal Rotation Lag Sign (subscapularis tear). The patient sits or stands with the involved arm behind the back and the palm facing outward. The clinician grasps the patient's shoulder with one hand and the wrist with the other and then lifts the patient's arm off the back (Fig. 16-56). The clinician then asks the patient to maintain this position as the wrist is released (Fig. 16-57). A positive test, which is manifested with an inability of the patient to maintain his or her arm off of the back, indicates a subscapularis tear. A study by Hertel et al.[313] reported high sensitivity (97%) and specificity (96%) with this test (Table 16-25), but the study had a potential for bias.

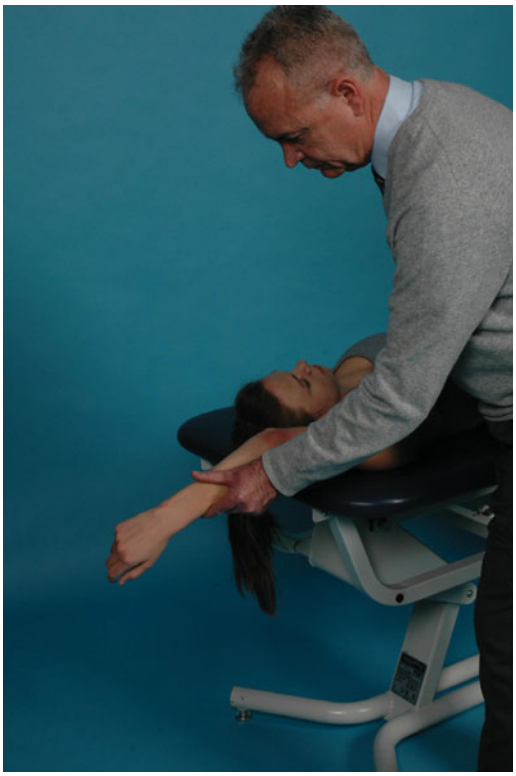

FIGURE 16-54 Supine impingement test—first position.

External Rotation Lag Sign (subscapularis tear). The patient sits with the clinician standing behind. The clinician grasps the patient's wrist and then places the elbow at 90 degrees of flexion and the shoulder at 20 degrees of elevation in the scapular plane. The clinician passively externally rotates the shoulder and, at the end range, asks the patient to maintain this position (Fig. 16-58) as the patient's wrist is released. A positive test, which is indicated by lag that occurs with the inability of the patient to maintain his or her arm near full ER (Fig. 16-59), indicates a supraspinatus/infraspinatus tear. A study by Hertel et al.[313] reported 70% sensitivity and 100% specificity with this test (Table 16-25), but the study had a potential for bias.

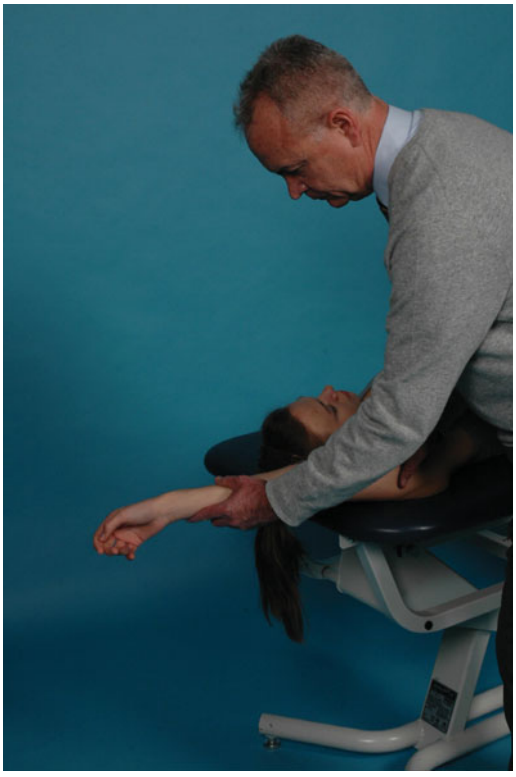

FIGURE 16-55 Supine impingement test—second position.

FIGURE 16-56 Internal rotation lag sign (subscapularis tear)—First position.

Belly Press Test.[291] The patient sits or stands with the elbow flexed to 90 degrees. The patient is asked to internally rotate the shoulder, causing the palm of the hand to be pressed into the stomach (Fig. 16-60). A positive test, which results in the elbow dropping behind the body into extension, indicates a subscapularis tear. The diagnostic value of this test, which was originally described as an alternative to the Lift-off test in those patients without adequate IR of the shoulder is as yet unknown.

The Posterior Impingement Sign. The patient lies in the supine position with the shoulder placed at 90–110 degrees of abduction and maximum ER (Fig. 16-61). A positive test is indicated by complaints of pain in the deep posterior shoulder and is indicative of a rotator cuff tear and/or a posterior labral tear (Table 16-25).

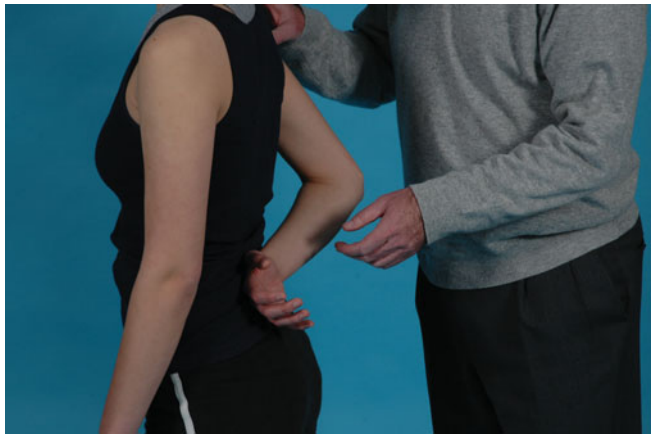

FIGURE 16-57 Internal rotation lag sign (subscapularis tear)—second position.

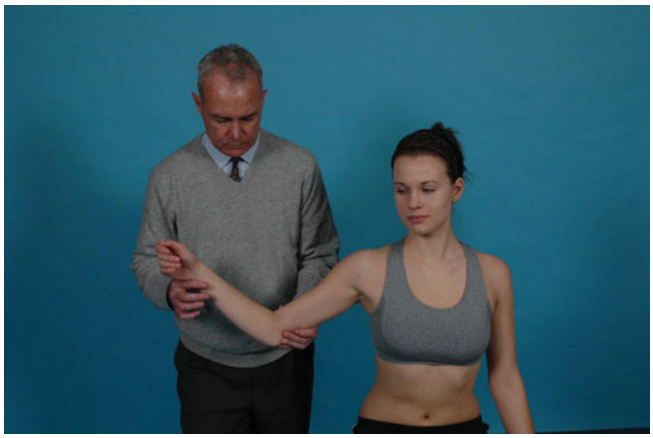

FIGURE 16-58 External rotation lag sign (subscapularis tear)—first position.

Internal Rotation Resisted Strength Test.[314] The patient lies in the supine position with the clinician standing behind the patient. The clinician places the patient's shoulder at 90 degrees of abduction and 80 degrees of ER, with the elbow at 90 degrees of flexion. The clinician first applies a manual resistance to the wrist to assess isometric ER, and then applies manual resistance to the wrist to assess isometric IR. A comparison is made of the two results. The IR-resisted strength test can be used to differentiate between outlet impingement (Fig. 16-62) and nonoutlet or internal impingement based on the apparent weakness of IR versus ER of the arm: if the IR strength is weaker than the ER, the test is considered positive and the patient has internal impingement, whereas a negative test (more weakness in ER) would suggest classic outlet impingement. A study by Zaslav[314] reported 88% sensitivity and 96% specificity with this test (Table 16-26), but the study had a potential for bias. (Table 16-24).[314]

Infraspinatus Test. The patient sits with the elbow at 90 degrees of flexion, neutral forearm rotation, the elbow adducted against the body, and the shoulder at end-range ER. The clinician stands to the side of the patient and provides an IR force against the patient's isometric resistance. A study by Park et al.[315] reported that a positive test, which indicates subacromial impingement (all stages), occurs if the patient gives way due to either pain or weakness, or if there is a positive ER lag sign. However, even when combining the results of two tests, the study demonstrated only a small effect on posttest probability (Table 16-25).

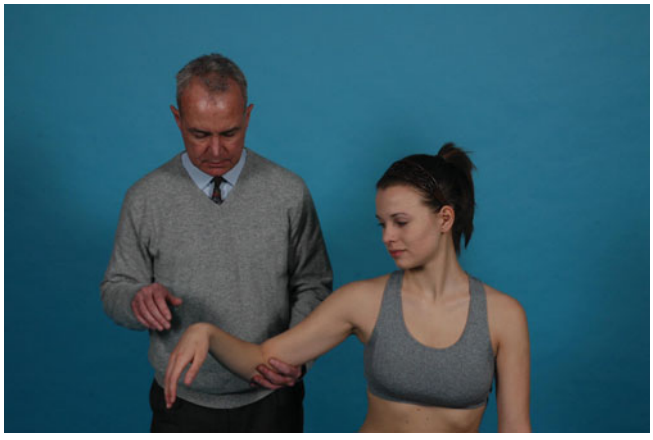

FIGURE 16-59 External rotation lag sign (subscapularis tear)—second position.

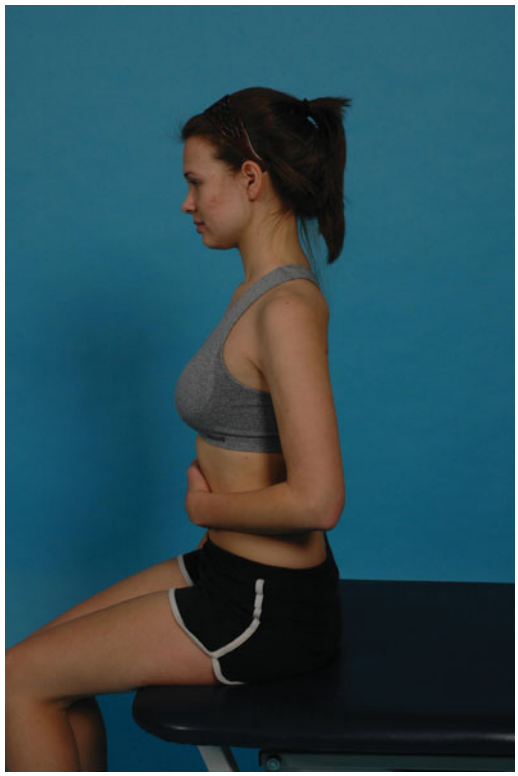

FIGURE 16-60 Belly press test.

Cross-body Adduction Test.[316] The patient sits and the clinician stands to the involved side of the patient. The patient is asked to elevate the arm to 90 degrees of shoulder flexion. The clinician then horizontally adducts the patient's arm to end range. A positive test for subacromial impingement or an A-C joint injury is indicated if shoulder pain is present (Table 16-25).

Painful Arc Test.[76] The patient stands and, while being observed by the clinician, is asked to actively abduct the involved shoulder. A positive test for subacromial

FIGURE 16-61 The posterior impingement sign.

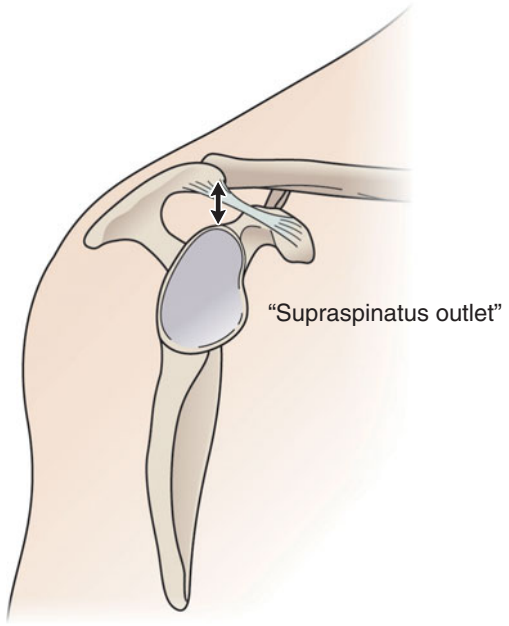

FIGURE 16-62 Supraspinatus outlet.

impingement is indicated if the patient reports shoulder pain in the 60–120-degree range. Pain outside this range is considered a negative test, and pain that increases in severity as the arm reaches 180 degrees is indicative of "a disorder of the A-C joint." Hermann et al.[317] found that the painful arc test was positive in 48.9% of 50 patients with degenerative impingement. Akgün et al.[318] observed 57.5% positive results with the test in stage II SIS patients. Although this test is good at detecting subacromial impingement, a positive finding is unlikely to aid the clinician in determining a specific diagnosis as there are a number of conditions that can be provoked with arm elevation (Table 16-25).

Transdeltoid Palpation (Rent Test).[319] The patient sits or stands with the involved arm relaxed and hanging on the side. The clinician stands behind the patient and holds the patient's distal arm with the patient's elbow flexed to 90 degrees (Fig. 16-63). The clinician then passively moves the patient's G-H joint into full extension, which allows greater palpation of the humeral head and tendons inserting into the greater tuberosity.[319] Palpation is performed at the anterior margin of the acromion. While palpating this area with the shoulder in the fully relaxed and extended position, the clinician moves the patient's arm into internal and external shoulder rotation to allow further palpation of the rotator cuff tendons (Fig. 16-64). In the presence of a complete rotator cuff tear, the eminence of the greater tuberosity appears quite prominent to palpation, and the torn area feels like a "sulcus," "rent," or soft-tissue defect (depression of approximately 1 finger-width) that has avulsed from the tuberosity.[319] Palpating the anterior and posterior margins of the cuff tear may elicit an avulsed edge.[319] It is recommended that this test be used to determine the absence or presence of a rotator cuff tear rather than the size of the tear (Table 16-25).

Yocum Test. The Yocum test is performed by having the patient lift the elbow to shoulder height while resting the hand on the opposite shoulder (Fig. 16-65). A study[284] comparing the Neer, Hawkins–Kennedy, and Yocum tests found all three to demonstrate a high sensitivity for diagnosing subacromial impingement.

Patte Test.[320,321] The Patte test, also known as the "hornblower's sign" (Fig. 16-30), is performed with the patient in the sitting or standing position. The patient's arm is supported at 90 degrees of abduction in the scapular plane, with the elbow flexed to 90 degrees. The patient is then asked to rotate the forearm externally against the resistance of the clinician's hand. If the patient is unable to externally rotate the shoulder in this position, the hornblower's sign is said to be present.

This test was found to have 100% sensitivity and 93% specificity in the diagnosis of irreparable degeneration of the teres minor muscle when compared with CT arthrography findings in a series of 54 shoulders scheduled for rotator cuff repair (Table 16-25).[322] The loss of integrity of the teres minor was confirmed at the time of surgery.

One study[284] attempted to determine the diagnostic value of three impingement tests (Yocum, Neer, and Hawkins–Kennedy), and four tests were used to determine the location of the specific rotator cuff lesion (Jobe empty can [see Resistive Tests], Gerber lift-off [see resisted tests], Patte test, and Speed's test [see later]) by comparing the clinical findings from the tests with the operative findings in a series of 55 patients with chronic shoulder pain and functional impairment.[323] The Neer test (89%), the Hawkins–Kennedy test (87%), and the Yocum test (78%), all demonstrated a high sensitivity for diagnosing subacromial impingement. Both the Jobe empty-can test (86%) and the Patte test (92%) demonstrated high sensitivity, but poor specificity (50 and 30%, respectively). Both the Gerber liftoff and the Speed's test demonstrated poor sensitivity (0 and 63%, respectively) and poor specificity (61 and 35%, respectively).[323]

Lock Test.[324,325] The Lock test is used to help differentiate the cause of symptoms when the patient complains of localized catching shoulder pain, and pain or restricted movement, when attempting to place the hand behind the back. Since the clinician controls the motion, this test can be a very sensitive test to help confirm the presence of an impingement of the supraspinatus tendon. It is assumed that the techniques are performed on the patient's right side.

The patient lies in the supine position with the right shoulder at the edge of the table, and the elbow positioned 10 degrees posterior to the frontal plane (Fig. 16-66). The clinician places his or her left hand under the scapula. The clinician's right hand is placed near the patient's right elbow.

After assessing the resting symptoms, the clinician slowly glides the patient's elbow anteriorly, noting the location of onset of resistance and/or pain in the available range. The end position for the test is achieved when the patient's right shoulder is in maximal humeral flexion with overpressure, and neither the patient nor the clinician can externally rotate the arm further while at this end range.

In the locking position, the greater tuberosity and its rotator cuff attachments are caught within the subacromial space. Further motion into ER, flexion, or abduction is not possible,

TABLE 16-26 Diagnostic Test Properties for Subacromial Impingement

Diagnostic Test or Maneuver	Study Population	Sensitivity	Specificity	Positive Likelihood Ratio	Negative Likelihood Ratio

unless the arm is allowed to move into less flexion. Positive findings for this test include reproduction of the patient's symptoms and a decrease in ROM compared with the uninvolved shoulder.

Dropping Sign.[326] The "dropping sign" is performed with the patient sitting or standing. The clinician places the patient's elbow and shoulder at 90 degrees of flexion. The shoulder is then externally rotated to near end range and the patient is then asked to maintain this position as the wrist is released. A positive test for an infraspinatus tear is indicated by a lag that occurs with an inability to maintain the position, and the arm drops to a neutral position of shoulder rotation. This is called the dropping sign. This test was found to have a 100% sensitivity and a 100% specificity for irreparable degeneration of the infraspinatus muscle (confirmed at the time of surgery), although the test was performed with the arm at the patient's side, which is not the original description (Table 16-25).[322]

Rotator Cuff Rupture Tests

Drop-arm (Codman's) Test. The clinician passively raises the patient's arm to 90 degrees of abduction. The patient is asked to lower their arm with their palm down (Fig. 16-67). If at any point in the descent, the patient's arm drops, it is indicative of a rotator cuff injury (Table 16-27).

Supraspinatus Tests

Two techniques described in the literature can be used to test the supraspinatus muscle. In a 1982 report, Jobe and Moynes[327] suggested that the best position for isolating the supraspinatus was the empty-can position—the elbow extended, the shoulder in full IR, and the arm in the scapular plane (thumbs-down

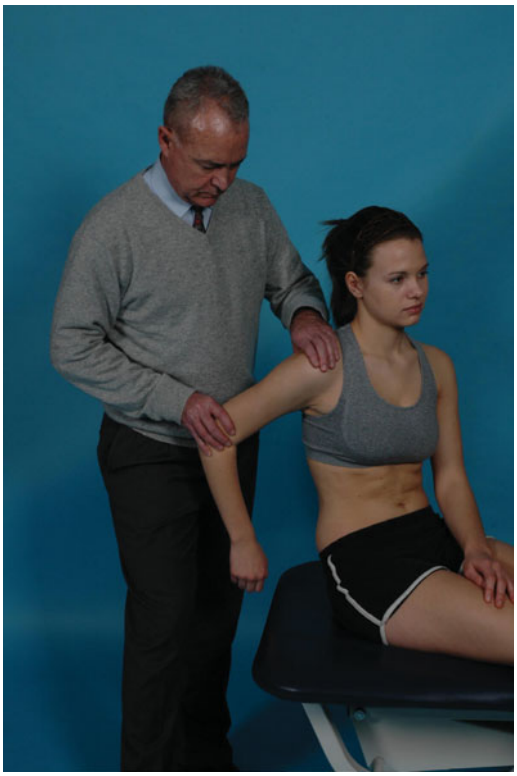

FIGURE 16-63 Transdeltoid palpation (Rent test)—first position.

position) (Fig. 16-28) (Table 16-25). In a 1990 article, Blackburn et al.[122] recommended testing in the prone position, in the full-can position—the elbow extended and the shoulder abducted to 100 degrees and externally rotated while the patient lifts the arm into abduction (thumbs-up position) (Fig. 16-29) (Table 16-25). Malanga et al.[328] noted that although both techniques

FIGURE 16-66 Lock test.

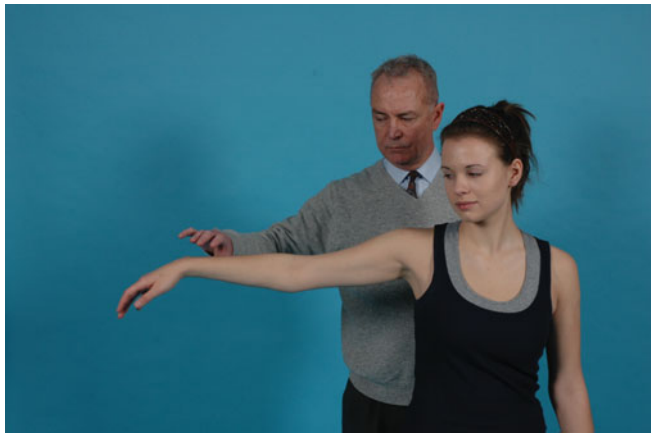

FIGURE 16-67 Drop-arm (Codman) test.

significantly activate the supraspinatus muscle, neither truly isolates this muscle for testing because other muscles are active in both positions. However, dropping of the arm in either position usually indicates a significant supraspinatus muscle tear. More subtle weakness may represent early degeneration of the rotator cuff.

Biceps and Superior Labral Tears

The biceps tendon and superior labrum can be involved in various pathological processes including bicipital tendinitis, biceps rupture, biceps tendon subluxation or dislocation, and tears of the superior labrum (Table 16-28).[190]

Clunk Test. The Clunk test is the traditional test for diagnosing labral tears. The patient lies in the supine position. One hand of the clinician is placed on the posterior aspect of the shoulder over the humeral head, while the other hand grasps the humerus above the elbow (Fig. 16-68). The clinician fully

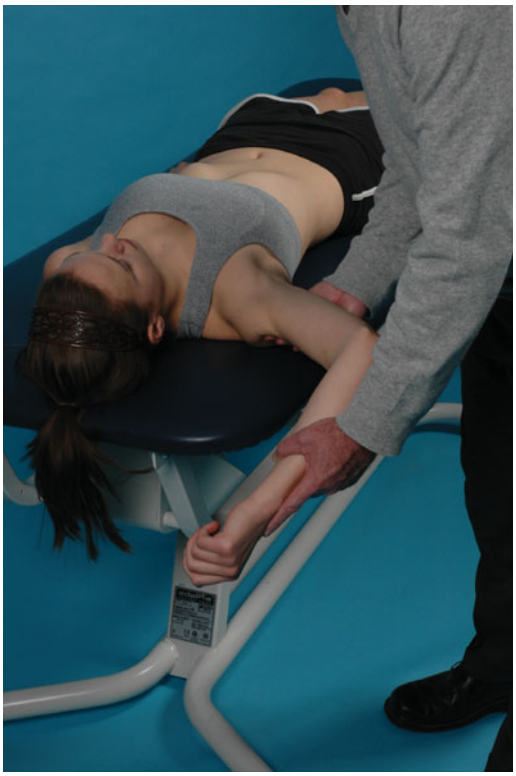

FIGURE 16-68 Clunk test.

FIGURE 16-69 Crank Test.

abducts the arm over the patient's head. By placing the hand posterior to the humeral head, the clinician pushes anteriorly while the other hand externally rotates the humerus. A clunk-like sensation may be felt if a free labral fragment is caught in the joint.[190] Clinical studies have found that a click on manipulation of the G-H joint was a common finding in patients with labral tears, even in the absence of joint instability.[329,330]

The sensitivity of this test was found to be low (15%) in one study[331] when it was used to detect labral tears in a series of 96 arthroscopic surgery patients.

Crank Test. The crank test[332] is performed with the patient in the supine position. Their arm is elevated to 160 degrees in the scapular plane of the body and is positioned in maximal internal or ER. The clinician then applies an axial load along the humerus (Fig. 16-69). A positive test is indicated by the reproduction of a painful click in the shoulder during the maneuver. This test was found to have a high sensitivity (91%) and specificity (93%) for diagnosing labral tears in a series of 62 patients who presented with shoulder pain that was refractory to 3 months of conservative management.[332]

The crank test has been found to have a higher sensitivity (90%) than MRI (59%) and equal specificity (85%) to MRI in diagnosing labral tears (Table 16-28).[330]

Jerk Test. This test is used to detect a posteroinferior labral lesion.[333] The patient sits, with the clinician standing to the side and slightly behind the patient. The clinician grasps the patient's elbow with one hand and the scapula with the other, and then positions the patient's arm at 90 degrees of abduction and IR (Fig. 16-70). The clinician then provides an axial compression-based load to the humerus through the elbow while maintaining the horizontally abducted arm. The axial compression is maintained as the patient's arm is moved into horizontal adduction. A positive test is indicated by sharp shoulder pain with or without a clunk or click (Table 16-28).

Kim Test. This test is used to detect a posteroinferior labral lesion. The patient sits, with the clinician standing on the involved side. The clinician grasps the elbow with one hand and the midhumeral region with the other hand, then elevates the patient's arm to 90 degrees of abduction (Fig. 16-71). Simultaneously, the clinician provides an axial load to the humerus and a 45-degree diagonal elevation to the distal humerus concurrent with a posteroinferior glide to the proximal humerus (Fig. 16-72). A positive test is indicated by a sudden onset of posterior shoulder pain. A study by Kim

FIGURE 16-70 Jerk test.

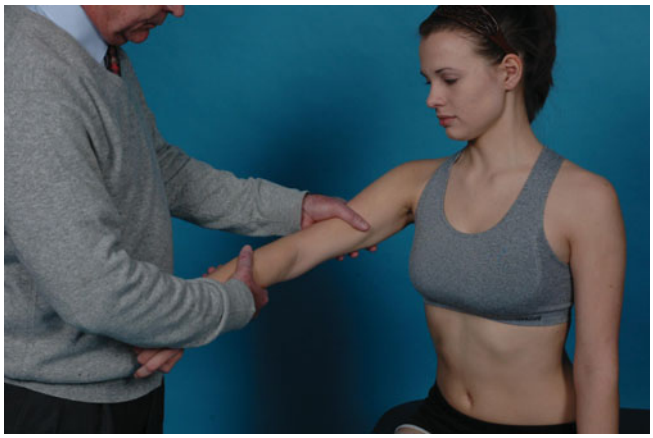

FIGURE 16-71 Kim test—first position.

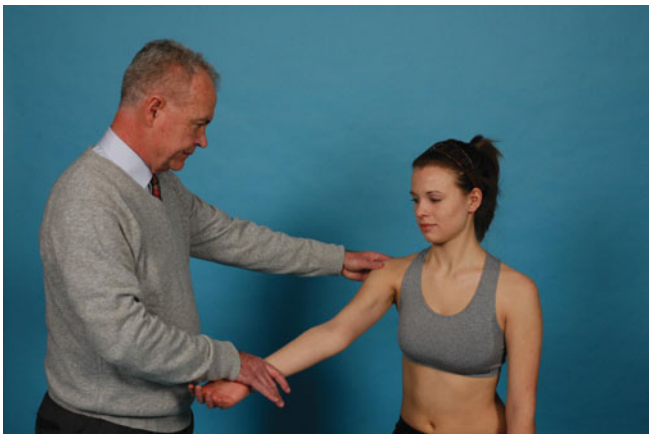

FIGURE 16-73 Speed's test.

et al.[333] found this test to have a sensitivity of 80% and a specificity of 94%, but more strict methodology needs to be followed to corroborate these statistics (Table 16-28).

Speed's Test. The patient's arm is positioned in shoulder flexion, full ER, full elbow extension, and full forearm supination (Fig. 16-73). Manual resistance is applied by the clinician. The test is positive if localized pain at the bicipital groove is reproduced. Wilk et al.[10] have introduced a dynamic version of the Speed's test. During this maneuver, the examiner provides resistance against both shoulder elevation and elbow flexion simultaneously as the patient elevates the arm overhead.

A positive Speed's test suggests a superior labral tear when resisted forward flexion of the shoulder causes bicipital groove pain or deep pain within the shoulder.[1,334] Speed's test is also used to detect bicipital tendinitis (Table 16-28) (see "Yergason's Test" section).[317,335]

Yergason's Test.[336] The patient sits or stands, and the upper arm is positioned with the elbow at 90 degrees of flexion and the forearm pronated. The patient is asked to supinate his or her forearm against the manual resistance of the clinician (Fig. 16-74).

Speed's and Yergason's tests probably discriminate bicipital tendon disorders .[300] However, irritation and edema may also occur in the long head of biceps in any stage of SIS. Biceps tendons may be thickened by fibrinoid degeneration in the SIS.[318,337] This may lead to an inappropriate diagnosis of primary bicipital tendinitis and subsequent tenodesis.[306] In a number of studies, the sensitivity of the Speed's test in biceps tendon disorders was found to be higher than that of the Yergason's test.[306,335,338]

O'Brien (active compression) Test. The O'Brien test (see also "Acromioclavicular Tests" section) is a two-part test. The patient stands with his or her involved shoulder at 90 degrees of flexion, 10 degrees of horizontal adduction, and maximum IR with the elbow in extension. In this position, the patient then resists a downward force applied by the clinician to the distal arm (Fig. 16-75). The patient is asked to report any pain as either "on top of the shoulder" (A-C joint) or "inside the shoulder" (SLAP lesion). The test is then repeated in the same manner except that the arm is positioned in maximum ER. The test is positive for a glenoid labral tear if the patient reports pain for clicking or pain "inside the shoulder" with resisted forward flexion in IR of the shoulder that is relieved by ER of the shoulder (Table 16-28).[1] O'Brien et al.[339] reported a sensitivity of 100% and a specificity of 98.5% for detecting a labral abnormality for this test although the test demonstrated poor study design. For example, the authors provided no data on the amount of force used for the test.

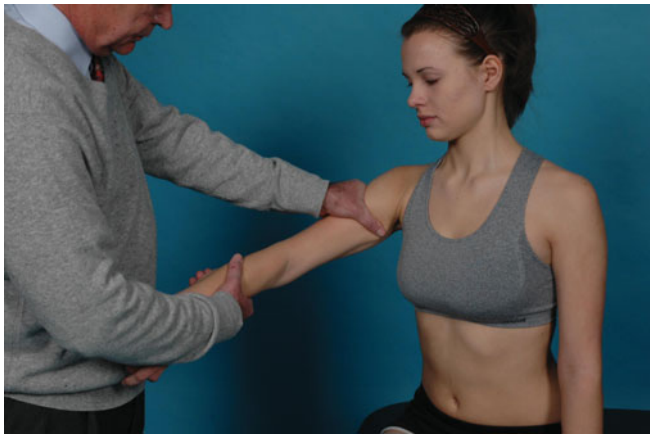

FIGURE 16-72 Kim test—second position.

FIGURE 16-74 Yergason's test.

FIGURE 16-75 O'Brien (active compression) test.

Anterior Slide Test. The "anterior slide test"[340] is another clinical test designed to stress the superior labrum.[190] The patient stands or sits with one hand on the hip such that the thumb is positioned posteriorly. One of the clinicians' hands is placed over the patient's shoulder and the other hand behind the elbow (Fig. 16-76). A force is then applied anteriorly and superiorly at the patient's elbow, and the patient is asked to push back against the force. The test is considered positive if pain is localized to the anterosuperior aspect of the shoulder, if there is a pop or a click in the anterosuperior region, or if the maneuver reproduces the symptoms.[190]

The anterior slide test has demonstrated good sensitivity (78%) and high specificity (92%) when used to detect glenoid labrum tears.[340] However, other research[341–343] found the test to have very low sensitivity, indicating that there is little use for this test in the clinic to detect SLAP lesions.

Compression–Rotation Test. This test is performed with the patient in the supine position and the clinician standing on the involved side of the patient. The clinician passively positions the patient's shoulder at 90 degrees of abduction and the elbow at 90 degrees of flexion. The clinician first applies a compression force to the humerus and rotates the humerus back and forth from IR to ER in an attempt to trap the labrum within the joint (Fig. 16-77). When performing this maneuver, it is recommended that a variety of small and large circles are used, while providing joint compression, in an attempt to grind the labrum between the glenoid and the humeral head. A positive test is indicated by the production of a catching or snapping in the shoulder and McFarland et al.[341] found the test to have a sensitivity of 24% and specificity of 76%. However, another study by Snyder et al. concluded that SLAP [344] lesions can only be diagnosed arthroscopically.

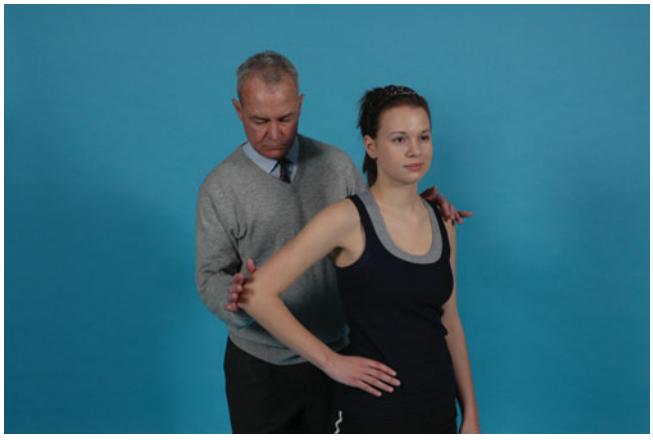

FIGURE 16-76 Anterior slide test.

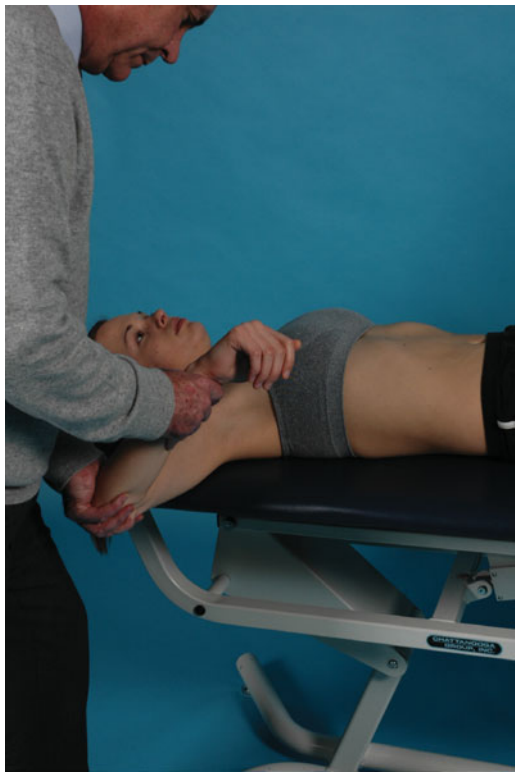

FIGURE 16-77 Compression–rotation test.

Biceps Load Test. The biceps load test was originally described by Kim et al.[345] During this test, the shoulder is placed at 90 degrees of abduction and maximally externally rotated (Fig. 16-78). At maximal ER and with the forearm in a supinated position, the patient is instructed to perform a biceps contraction against resistance.[10] Deep pain within the shoulder during his contraction is indicative of a SLAP lesion. Due to many design faults in the original study, this test has since been refined (biceps load II) with the shoulder being placed in the position of 120 degrees of abduction rather than the originally described 90 degrees, as this position was found to add greater sensitivity to the test (Table 16-28).[346]

Pronated Load Test. The pronated load test[10] is performed with the patient in a supine or seated position with the shoulder abducted to 90 degrees and externally rotated, and the forearm in a fully pronated position (to increase tension on the biceps and subsequently the labral attachment). When maximal ER is achieved, the patient is instructed to perform a resisted isometric contraction of the bicep against the clinician's resistance (Fig. 16-79). This test combines the active bicipital contraction of the biceps load test with the passive ER in the pronated position similar to the pain provocation test (see next).

Pain Provocation Test.[347] The patient is seated and the clinician stands behind the involved shoulder. The clinician

FIGURE 16-78 Biceps load test.

places the patient's shoulder at 90 degrees of abduction and toward end-range ER, the elbow at 90 degrees of flexion and the forearm in maximum supination (Fig. 16-80). The patient is asked to rate his or her pain in this position. The clinician

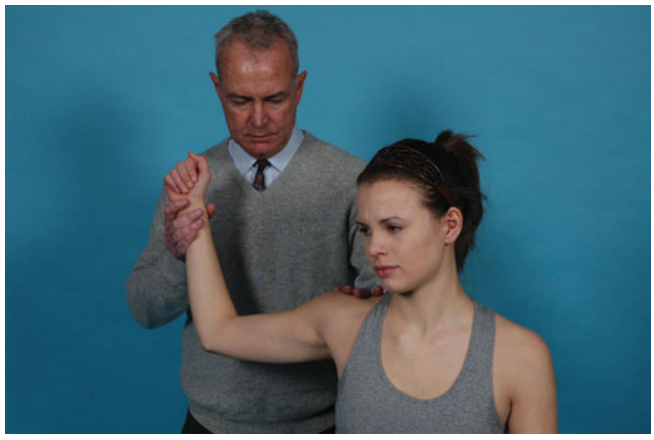

FIGURE 16-80 Pain provocation test.

then fully pronates the patient's forearm and asks the patient to again rate his or her pain. A positive test for a SLAP lesion is indicated if pain is produced with shoulder ER with the forearm in the pronated position or if the severity of the symptoms is greater in the pronated position. A study by Mimori et al.[347] found this test to have high sensitivity (100%) and high specificity (90%), although the study had many design faults.

Resisted Supination External Rotation Test.[348] During this test, the patient lies in the supine position with the clinician standing on the side of the involved shoulder. Supporting the patient's elbow with one hand, the clinician places the patient's shoulder at 90 degrees of shoulder abduction, 80–90 degrees of elbow flexion, and the forearm in neutral pronation/supination (Fig. 16-81). The patient is

FIGURE 16-79 Pronated load test.

FIGURE 16-81 Resisted supination external rotation test.

FIGURE 16-82 Forced shoulder abduction and elbow flexion test.

asked to attempt to supinate his or her arm The clinician resists against a maximal supination effort while gradually passively externally rotating the shoulder. A positive test for a torn labrum/instability is indicated by the production of pain in the anterior or deep shoulder, clicking or catching in the shoulder, or by reproduction of the patient's symptoms. A preliminary study of 40 patients revealed that this test had better sensitivity (82.8%), specificity (81.8%), positive predictive value (92.3%), negative predictive value (64.3%), and diagnostic accuracy (82.5%), compared with the crank test and O'Brien test.[348]

Forced Shoulder Abduction and Elbow Flexion Test. The patient sits, with the clinician standing behind and to the side of the involved shoulder. The clinician positions the patient's shoulder in maximum abduction with full elbow extension and notes any reports of pain in the posterior superior aspect of the shoulder (Fig. 16-82). The clinician then flexes the patient's elbow. A positive test for a superior labral tear is indicated by the production of pain in the posterior superior aspect of the shoulder during shoulder abduction with elbow extension that is diminished or relieved by the elbow flexion. In a study by Nakagawa et al.,[343] this test was found to have a sensitivity of 67% and a specificity of 67%. However, there were some design flaws with this study. For example, all of the subjects were young throwing athletes, and only two of the 54 subjects were female, leading to spectrum bias.

Wilk et al.[10] recommend that the selection of specific SLAP tests to perform should be based on the symptomatic complaints as well as the mechanism of injury described by the patient (Table 16-29).

TABLE 16-29 Selection of SLAP Tests Based on Mechanism of Injury

Mechanism	Test
Compressive injury	Active compression (O'Brien) Compression–rotation Clunk Anterior slide
Traction injury	Speed's Dynamic speed's Active compression
Overhead injury	Pronated load Resisted supination external rotation Biceps load I and II Pain provocation Crank

Data from Wilk KE, Reinold MM, Dugas JR, et al: Current concepts in the recognition and treatment of superior labral (SLAP) lesions. *J Orthop Sports Phys Ther* 35:273–291, 2005.

Acromioclavicular Tests

O'Brien Test. This is the same test described in the section "Biceps and Superior Labral Tears." The test has been found to be both highly sensitive and specific for diagnosing A-C joint abnormalities.[339] The test is considered positive for A-C joint dysfunction if the pain is localized to the AC joint on the first position and relieved or eliminated on the second position.[339,349]

Acromioclavicular Resisted Extension Test. This test is performed with the patient's shoulder positioned at 90 degrees of elevation combined with IR and 90 degrees of elbow flexion. The patient is then asked to horizontally abduct the arm against resistance (Fig. 16-83). This test is considered positive if it causes pain at the A-C joint.[350] Chronopoulos et al.[350] reported sensitivity of 72% and specificity of 85% with this test, but this study had some design flaws such as lack of blinding and not reporting patient inclusion/exclusion criteria.

Crossover Impingement/Horizontal Adduction Test. The patient's arm is positioned at 90 degrees of G-H flexion.

FIGURE 16-83 Acromioclavicular-resisted extension test.

FIGURE 16-84 Cross-over impingement/horizontal adduction test.

The clinician passively moves the patient's arm into horizontal adduction and applies overpressure (Fig. 16-84). Although the crossover impingement/horizontal adduction test provokes compressive forces on the rotator cuff tendons that are localized under the A-C joint, it is a test more likely to be used to investigate A-C joint dysfunction.[318,337] Chronopoulos et al.[350] evaluated the crossover impingement test, the active compression test, and the A-C resisted extension test for the isolated and combined diagnostic utility with regard to chronic isolated A-C joint lesions. The study was a retrospective case–control study that used 35 patients diagnosed with chronic isolated A-C joint lesions and 580 control subjects who had undergone surgical procedures for other shoulder conditions. The authors concluded that the three tests studied had isolated clinical utility. They also analyzed the diagnostic utility of multitest regimens based on these three tests (Table 16-30) and suggested that the clinician should use a criterion of one positive test when high sensitivity is required, whereas a criterion of three positive tests is appropriate when high specificity is necessary.[349,350]

Examination of the Passive Restraint System

If following the ROM, strength, and functional movement tests, the clinician is unable to determine a working hypothesis from which to treat the patient, further examination is required. This more detailed examination involves the assessment of the mobility and stability of the passive restraint systems of the shoulder girdle (Table 16-31).

Stability Testing. It is important to remember that there is no correlation between the amount of joint laxity/mobility and joint instability at the shoulder.[351] Joint stability is more likely a function of connective tissue support and an intact neuromuscular system.[234]

Many provocative maneuvers including the anterior and posterior apprehension tests, the sulcus test,[352–354] and the load and shift test have been described previously. The reproduction of symptoms is important because laxity alone does not indicate instability. Side-to-side translational asymmetry often has been taken as being representative of disease, but healthy shoulders may also have asymmetry up to grade II laxity.[355,356]

Pain and muscle spasm can make the examination challenging. Rarely is examination with the patient under anesthesia useful for anything other than fine-tuning the amount of capsular shift required at surgery.[357]

Glenohumeral: Load and Shift Test. The patient lies in the supine position. The clinician is beside the patient with the inside of the hand over the patient's shoulder and forearm, stabilizing the scapula to the thorax. The clinician places his or her hand across the G-H joint line and humeral head, so that clinician's little finger is positioned across the anterior G-H joint line and humeral head (Fig. 16-85). The clinician then applies a "load and shift" of the humeral head across the stabilized scapula in an anteromedial direction to assess anterior stability, and in a posterolateral direction, to assess posterior instability. The normal motion anteriorly is half of the distance of the humeral head. Although attempts have been made to grade or quantify the degree of instability more specifically, the literature supports no consistency in the grading to date.[168,358–361] This test has been reported to be 100% sensitive for the detection of instability in patients with recurrent dislocation, but not in cases of recurrent subluxation.[359]

Apprehension Test. The patient lies in the supine position with the arm at 90 degrees of abduction and full ER. The

FIGURE 16-85 Load and shift test.

clinician holds the patient's wrist with one hand, while the other hand stabilizes the patient's elbow (Fig. 16-86). The clinician applies overpressure into ER. Patient's apprehension from this maneuver, rather than his/her pain, is considered a positive test for anterior instability. Pain with this maneuver, but without apprehension, may indicate pathology other than instability, such as posterior impingement of the rotator cuff.[75] In a study by Mok et al., [362] this test demonstrated a specificity of 61% and a sensitivity of 63%.

Sulcus Sign for Inferior Instability. The sulcus sign was described by Neer and Foster[353] and is used to detect inferior instability due to a laxity of the superior G-H and coracohumeral ligaments. The patient's arm is positioned at 20–50 degrees of abduction and neutral rotation.[149,363] A positive test results in the presence of a sulcus sign (a depression greater than a fingerbreadth between the lateral acromion and the head of the humerus) (Fig. 16-87) when longitudinal traction is applied to the dependent arm in more than one position.[364]

The sulcus sign can be graded by measuring the distance from the inferior margin of the acromion to the humeral head. A distance of less than 1 cm is graded as 1+ sulcus, 1–2 cm as a 2+ sulcus, and greater than 2 cm as a grade 3+ sulcus.[353] A study by Levy et al.[365] evaluated the inter- and intraobserver reproducibility of the clinical examination of G-H laxity in the unanesthetized shoulder. Forty-three asymptomatic division I collegiate athletes underwent bilateral shoulder laxity examination initially and again after 3 months. Overall intraobserver reproducibility of examination was 46%. When grades 0 and 1 were equalized, overall intraobserver reproducibility improved to 74%. For both the equalized and nonequalized reproducibility values reported by all examiners, the κ values for intraobserver correlation were less than 0.5, which suggests that correlations were not better than those achieved by chance alone. Overall interobserver reproducibility was 47%. When grades 0 and 1 were equalized, interobserver reproducibility improved to 78%.

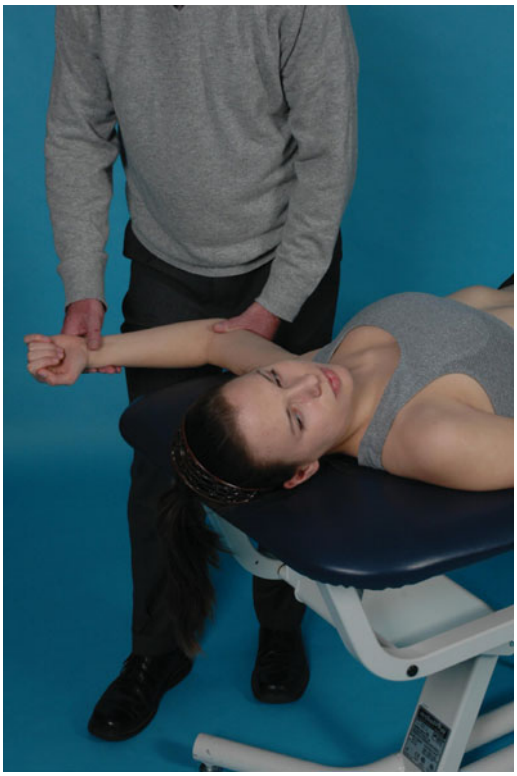

FIGURE 16-86 Apprehension test.

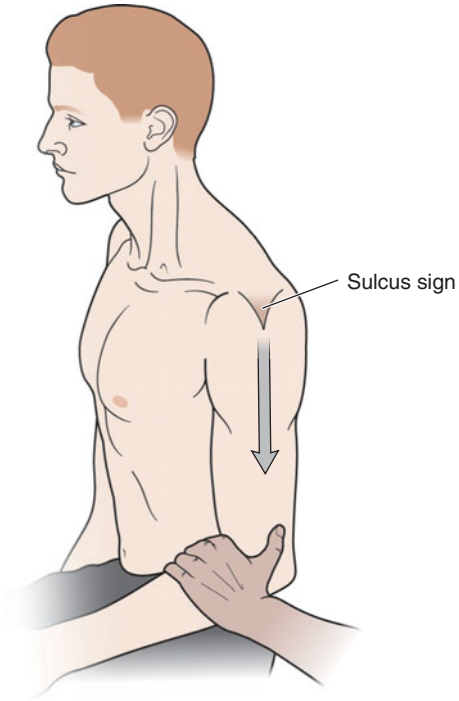

FIGURE 16-87 Sulcus sign.

FIGURE 16-88 Subluxation/relocation test.

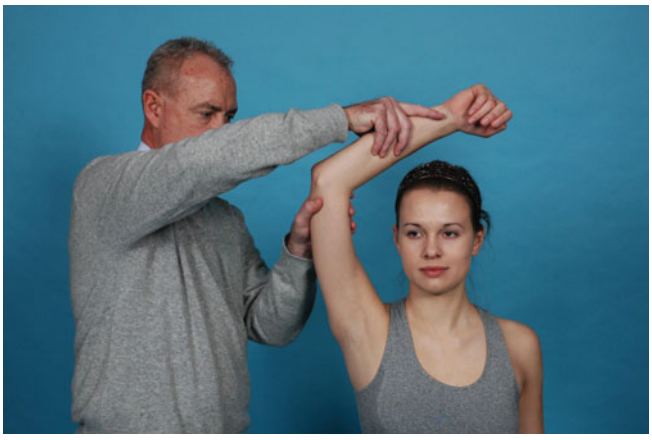

FIGURE 16-89 Rockwood test for anterior instability.

Jobe Subluxation/Relocation Test. This test is similar to the load and shift test, except that manual pressure is applied anteriorly by the clinician in an attempt to provoke a subluxation, before using manual pressure in the opposite direction to relocate the subluxation. The patient lies in the supine position with their arm at 90 degrees of abduction and full ER. The clinician grasps the patient's elbow with one hand to maintain the testing position and grasps the humeral head with the other hand (Fig. 16-88). The clinician gently applies an anterior pull on the humerus. Pain and apprehension from the patient indicate a positive test for a superior labral tear or anterior instability.[1] After pulling the humeral head anteriorly and demonstrating pain and apprehension, the clinician should then push the humeral head posteriorly while maintaining the shoulder in the same position (the relocation part of the test). Reduction of pain and apprehension further substantiates the clinical finding of anterior instability. The sensitivity and specificity of the relocation test is reported to be low when assessing pain response only, but very high when assessing the apprehension response only.[366]

The performance of the relocation part of the test (based on operative findings and manual examination under anesthesia) was compared between two groups of patients: those with anterior instability and with rotator cuff disease.[366] The study found that it is not possible to discriminate between anterior instability and rotator cuff disease by using the relocation test for assessing pain response only.

Modified Jobe Relocation Test. The patient lies in the supine position, and the clinician stands on the involved side of the patient. The clinician prepositions the shoulder at 120 degrees of abduction and then grasps the patient's forearm and maximally externally rotates the humerus. The clinician then applies a posterior to anterior force to the posterior aspect of the humeral head. If the patient reports pain with this maneuver, an anterior-to-posterior force is then applied to the proximal humerus. A positive test for labral pathology is indicated by a report of pain with the anterior-directed force and release of pain with the posterior directed force. In a small study of 14 overhead throwing athletes, aged 21–31 years, Hamner et al.[367] found the test to have high sensitivity (92%) and high specificity (100%). However, there were a number of design faults in the study that led to potential bias and further research is required.

Rockwood Test for Anterior Instability.[368] The patient is seated with the clinician standing. With the arm by the patient's side, the clinician passively externally rotates the shoulder. The patient then abducts the arm to approximately 45 degrees and the test is repeated. The same maneuver is again repeated with the arm abducted to 90 degrees, and then 120 degrees (Fig. 16-89) to assess the different stabilizing structures. A positive test is indicated when apprehension is noted in the latter three positions (45, 90, and 120 degrees).

Anterior Release Test/Surprise Test.[369] The patient lies in the supine position with the shoulder at 90 degrees of abduction and the elbow flexed to 90 degrees. The clinician passively moves the patient's shoulder into ER while applying a posteriorly directed force to the head of the humerus. At the point of end-range ER, the clinician quickly releases the posterior force (Fig. 16-90) and notes whether the patient displays any sign of apprehension. In a study by Lo et al.,[370] which assessed the validity of the apprehension, relocation, and surprise tests as predictors of anterior shoulder instability, for those subjects who had a feeling of apprehension on all three tests, the mean positive and negative predictive values were 93.6% and 71.9%, respectively. The surprise test was the single most accurate test (sensitivity 63.89%; specificity 98.91%). An improvement in the feeling of apprehension or pain with the relocation test added little to the value of the tests. The results of this study would suggest that a positive instability examination on all three tests is highly specific and predictive of traumatic anterior G-H instability.[370]

Anterior Fulcrum Test.[371] The patient lies in the supine position with the shoulder positioned at approximately 90 degrees of abduction and ER. The clinician moves the arm into horizontal abduction while applying an anterior force to the G-H joint in a fulcrum maneuver (Fig. 16-91). The clinician notes the amount of translation and end feel in comparison with the opposite extremity. The test can be repeated at 45 degrees of abduction (to test the middle G-H ligament) and in adduction (to assess the superior G-H ligament).

FIGURE 16-90 Anterior release test.

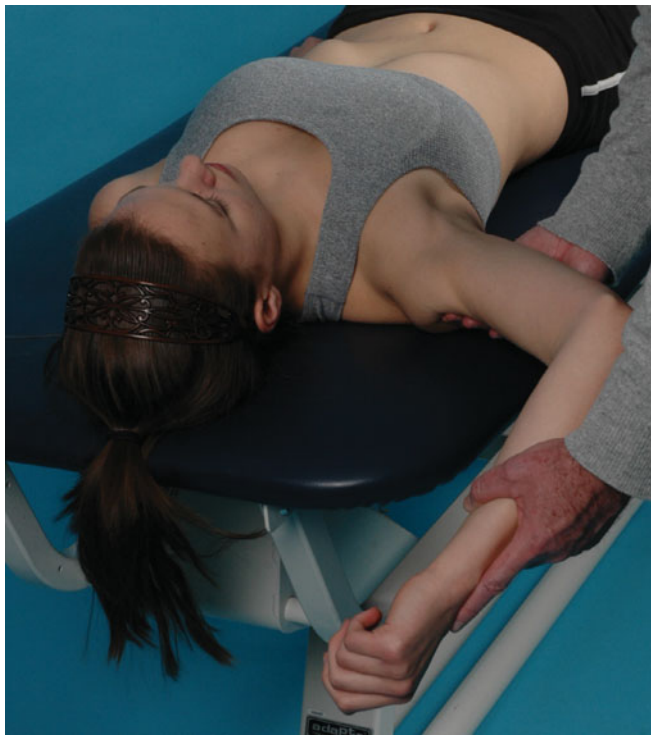

FIGURE 16-92 Lachman test of the shoulder.

Lachman Test of the Shoulder.[372] The patient lies in the supine position and the shoulder is abducted overhead to approximately 120–135 degrees of abduction and full ER (Fig. 16-92). The clinician then translates the G-H joint anteriorly and notes the amount of humeral translation as well as the endpoint of translation, in comparison with the uninvolved shoulder. Theoretically in this position, the integrity of the inferior G-H ligament and the anterior–inferior capsule is tested.

Thoracic Outlet Syndrome Tests

These tests are described in "Special Tests" section in Chapter 25.

FIGURE 16-91 Anterior fulcrum test.

Diagnostic Studies

The conclusions on the radiology reports concerning single-plane views, which include an A-P view with the humerus in IR, and a second A-P view with the humerus in ER (see Chap. 7), should be treated with caution as they have been well documented to result in misdiagnosis.[373]

If A-C separation is suspected, a weighted view is performed with a weight suspended from the wrist on the involved side. Alternative or specialized views are sometimes used in an attempt to better define specific structures. For example, with a suspected shoulder dislocation, the West Point or Lawrence view (inferior–superior axial projection) is used to help display the inferior glenoid fossa and its relationship to the humeral head, in addition to the lateral perspective of the proximal humerus.

Arthrography aids in the diagnosis of full thickness rotator cuff tears.[374] Bone scans are rarely used in the diagnosis of shoulder pain, but a CT scan report can be useful in confirming the clinical findings in some cases.[1] The MRI is very reliable in detecting lesions of the capsule and labrum, as well as associated rotator cuff tears. It can generally indicate the approximate size of a rotator cuff tear and may also indicate whether the critically important subscapularis tendon is torn.[1,375,376]

In a limited number of studies, a comparison has been made as to the accuracy of physical diagnostic tests versus arthroscopic examination. One such study found that the physical therapists were unable to differentiate between a partial and complete tear of the rotator cuff tendons.[377] However, a later study showed that physical therapists were able to discern subacromial disorders and passive restraint disorders with an agreement of 85 and 67%, respectively.[378]

Evaluation

Following the examination, and once the clinical findings have been recorded, the clinician must attempt to determine a specific diagnosis or a working hypothesis, based on a summary of all of the findings. This diagnosis can be structure related (medical diagnosis) (Table 16-32), or a diagnosis based on the preferred practice patterns as described in the *Guide to Physical Therapist Practice*. Further details on the specific conditions listed in Table 16-30 is provided in the following sections.

INTERVENTION STRATEGIES

With the possible exceptions of acute traumatic shoulder dislocation and acute traumatic inability to raise the arm (acute massive rotator cuff tear), a minimum 6-week period of conservative empiric intervention is typically indicated for shoulder injuries. A number of guiding principles can be used in the conservative rehabilitation of the shoulder[379]:

- The shoulder must be rehabilitated according to the stage of healing and degree of irritability. The degree of irritability can be determined by inquiring about the vigor, duration, and intensity of the pain. Greater irritability is associated with very acutely inflamed conditions. The characteristic sign for an acute inflammation of the shoulder is pain at rest, which is diffuse in its distribution and often referred from the site of the primary condition.[324] Pain above the elbow indicates less severity than pain below the elbow. Chronic conditions usually have a low irritability, but can have an associated loss of AROM and PROM. The degree of movement and the speed of progression are both guided by the signs and symptoms.
- Rehabilitate the shoulder using scapular planes rather than the straight planes of flexion, extension, and abduction as the scapular planes are more functional.
- Short lever arms should initially be used with exercises as they decrease the torque at the shoulder. Short levers can be achieved by flexing the elbow or by exercising with the arm closer to the body.
- Obtain a stable scapular platform as early as possible.
- Achieve the closed-pack position of the G-H joint at the earliest opportunity. All ROM exercises for the shoulder have traditionally been initiated in the early ranges of flexion with the goal of achieving full elevation. Given the protection afforded the joint by the passive restraint system, thought should be given to providing ROM exercises initiated at the end ranges of elevation according to patient tolerance. Exceptions to this would be the patient whose condition precluded such exercises, that is, following shoulder surgery, adhesive capsulitis, or instability.
- Reproduce the forces and loading rates that will mimic the patient's functional demands as the rehabilitation progresses.

The manual techniques to increase joint mobility and the techniques to increase soft tissue extensibility are described in "Therapeutic Techniques" section.

ACUTE PHASE

The goals of the acute phase include the following:

- Protection of the healing site.
- Restoration of pain-free ROM throughout the remainder of the kinetic chain.
- Enhance patient comfort by decreasing pain and inflammation.
- Retard muscle atrophy.
- Minimize the detrimental effects of immobilization and activity restriction.[243,244,380–383]
- Maintain general cardiovascular fitness using lower extremity aerobic exercises such as walking.
- Independence with a home exercise program.

The principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication) are applied as appropriate during the early stages of the acute phase,. Icing for 20–30 minutes three to four times a day, concurrent with nonsteroidal anti-inflammatory drugs (NSAIDs) or aspirin, can assist in reducing pain and swelling.

Early active-assisted and passive exercises are performed to nourish the articular cartilage and assist in collagen tissue synthesis and organization.[384–388] These exercises are initiated in pain-free arcs, below 90 degrees of abduction/flexion. Recommended ROM exercises for the acute phase include the following:

- Codman's or other pendulum exercises (Fig. 16-93) **VIDEO**. Codman's pendulum exercise is commonly prescribed after shoulder surgery or injury to provide grade I and grade II distraction and oscillations resulting in decreased pain and early joint mobilization.[389] One study,[389] which measured EMG activity of the shoulder muscles, found that the pendulum exercise did not have a significant effect on shoulder EMG activity. Generally, the supraspinatus/upper trapezius muscle activity was significantly higher than the deltoid and infraspinatus activity—especially in the patients with shoulder pathology. Many shoulder protocols suggest holding a weight while performing the pendulum exercises as rehabilitation progresses. Ellsworth et al.[389] found that performing the pendulum exercise with added weight did not result in significant increased shoulder EMG activity for the deltoid and infraspinatus muscles in subjects with or without shoulder pathology. However, patients with shoulder pathology had more difficulty relaxing their supraspinatus/upper trapezius muscles than did the healthy subjects.[389] Other PROM exercises can also be introduced. These include passive shoulder flexion (Fig. 16-94) **VIDEO**, abduction **VIDEO**, ER **VIDEO**, and IR and elbow flexion and extension **VIDEO**.
- Active assisted ROM (AAROM) exercises. AAROM may include wand or cane exercises that move the arm into functional planes while incorporating combinations of forward flexion (Fig. 16-95) **VIDEO**, extension, abduction, IR, and ER. Over-the-door pulley exercises are performed later in the acute phase as tolerated. However, care must be taken with these exercises in the presence of impingement or

TABLE 16-32 Differential Diagnosis for Common Causes of Shoulder Pain

Condition	Approximate Patient's Age	Mechanism of Injury	Area of Symptoms	Symptoms Aggravated by	Observation	AROM	PROM	End-Feel	Pain with Resisted	Tenderness Palpation
Rotator cuff tendinitis										
Acute	20–40	Microtrauma/ macrotrauma	Anterior and lateral shoulder	Overhead motions	Swelling—anterior shoulder	Limited abduction	Limited abduction	ER	Abduction	Pain below anterior acromial rim
Chronic	30–70	Microtrauma/ macrotrauma	Anterior and lateral shoulder	Overhead motions Atrophy of shoulder area	Atrophy of scapular area	Limited abduction and flexion	Pain on IR and ER at 90-degree abduction	ER IR	Abduction Pain below anterior acromial rim	Anterior shoulder
Bicipital tendinitis	20–45	Microtrauma	Anterior shoulder	Overhead motions May see signs of concomitant rotator cuff pathology	Possible swelling—anterior shoulder Pain on full flexion from full extension	Limited ER when arm at 90-degree abduction Biceps stability test may be abnormal (if tendon unstable)	Pain on combined extension of shoulder and elbow	Speed test painful, Yergason test occasionally painful	Elbow flexion	Of biceps tendon over bicipital groove
Rotator cuff rupture	40+	Macrotrauma	Posterior/ superior shoulder	Arm elevation	Atrophy of scapular area	Limited abduction Pain with or without restriction	Full and pain free	ER	Abduction	Pain below anterolateral acromial rim

(Continued)

TABLE 16-32 Differential Diagnosis for Common Causes of Shoulder Pain *(Continued)*

Condition	Approximate Patient's Age	Mechanism of Injury	Area of Symptoms	Symptoms Aggravated by	Observation	AROM	PROM	End-Feel	Pain with Resisted	Tenderness Palpation
Adhesive capsulitis	35–70	Microtrauma/ macrotrauma	Shoulder and upper arm—poorly localized	All motions	Atrophy of shoulder area	All motions limited especially ER and abduction	All motions limited especially ER and abduction	Capsular	Most/all	Varies
A-C joint sprain	Varies	Macrotrauma	Point of shoulder	Horizontal adduction	Step/bump at point of shoulder	Limited abduction Limited horizontal adduction	Limited abduction Pain with horizontal adduction	Flexion Flexion	ER Soft tissue thickening at point of shoulder	Point of shoulder
Subacromial bursitis	Varies	Microtrauma	Anterior and lateral shoulder	Overhead motions	Often unremarkable	Limited abduction and IR May have full range but pain in midrange of flexion/ abduction	Pain on IR at 90-degree abduction Pain only in midrange abduction and flexion		Most/all	Pain below anterolateral acromial rim
Glenohumeral arthritis	50+	Gradual onset, but can be traumatic	Poorly localized	Arm activity	Possible posterior positioning of humeral head	Capsular pattern (ER> abduction>IR)	Pain	Capsular	Weakness of rotator cuff, rather than pain	Poorly localized

SICK Scapula	20–40	Microtrauma	Anterior/ superior shoulder Posterosuperior scapular Arm, forearm, hand	Overhead activities	Scapular malposition Inferior medial border prominence Dyskinesia of scapular movement	Decreased forward flexion which diminishes when clinician manually repositions the scapula into retraction and posterior tilt	Normal		Weakness rather than pain	Medial coracoid Superomedial angle of scapula
Cervical radiculopathy	Varies	Typically none but can be traumatic	Upper back, below shoulder	Cervical extension, cervical side bending and rotation to ipsilateral side, full arm elevation	May have lateral deviation of head away from painful side	Decreased cervical flexion, cervical side bending and rotation to ipsilateral side; decreased arm elevation on involved side	Painful into restricted active range of motions Positive Spurling's test	Empty	Weakness rather than pain Other neurological changes	Varies; may have numbness over dermatomal area

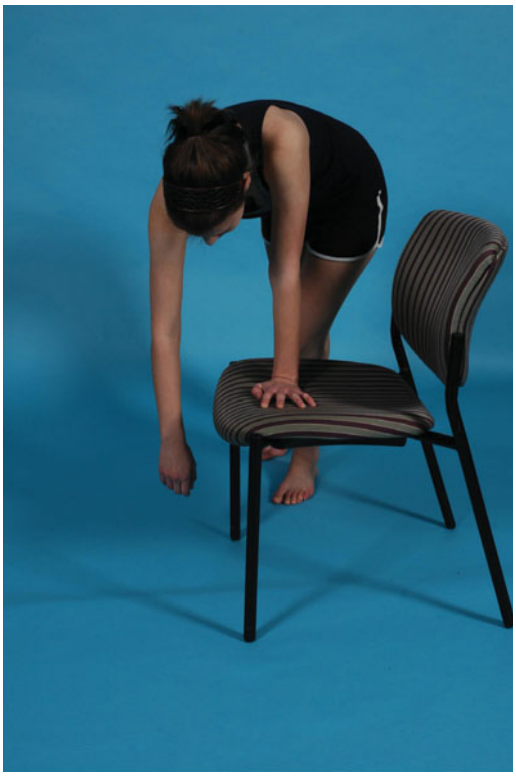

FIGURE 16-93 Codman's pendulum.

adhesive capsulitis as these exercises can reinforce poor scapulohumeral motion.

- Active exercises. These can be performed in a variety of positions including standing, sitting, or lying (Figs. 16-16 and 16-19).

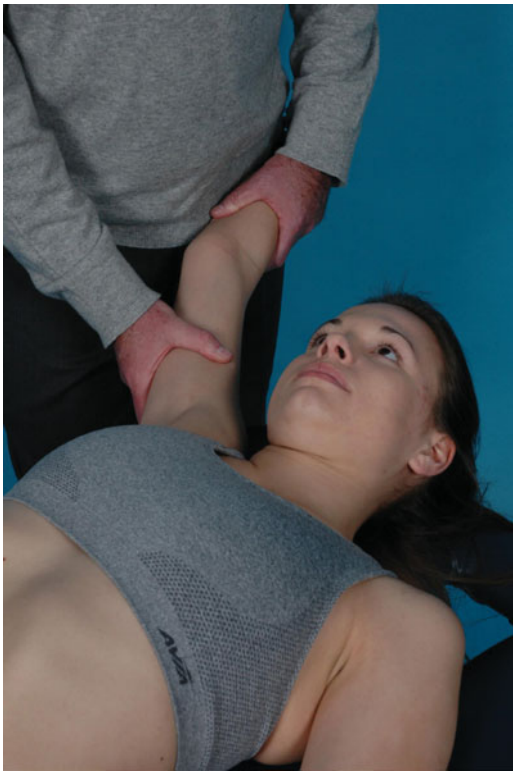

FIGURE 16-94 Passive shoulder flexion.

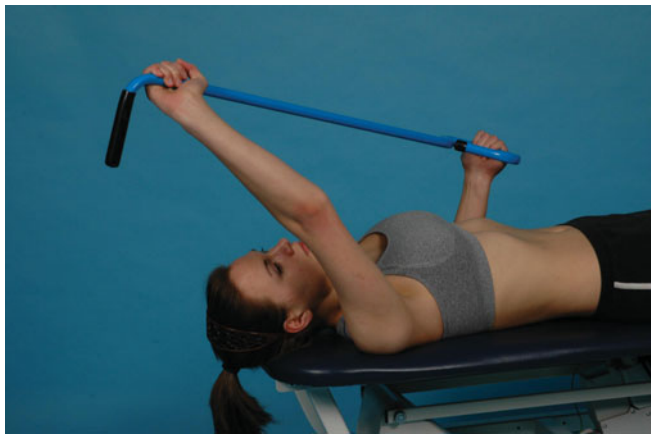

FIGURE 16-95 Active assisted shoulder flexion.

Strengthening exercises for the shoulder are introduced as early as tolerated, initially using isometric exercises, with the arm positioned below 90 degrees of abduction and 90 degrees of flexion. Elbow flexion (Fig. 16-96) and extension progressive-resistive exercises (PREs) are introduced as appropriate **VIDEO**. Specific scapular rehabilitation PREs are typically initiated with the isometric exercises, such as the scapular setting exercise **VIDEO**. Patterns of scapular retraction and protraction are initiated in single planes and then progressed to elevation and depression of the entire scapula. To improve backward reaching, the patient must first learn correct retraction procedures.

Jobe and Pink[98] believe that the order of strengthening in the rehabilitation process should follow a progression based on muscle function. They advocate strengthening the *G-H protectors* (rotator cuff muscles) and scapular *pivoters* (levator scapulae, serratus anterior, middle trapezius, and rhomboids

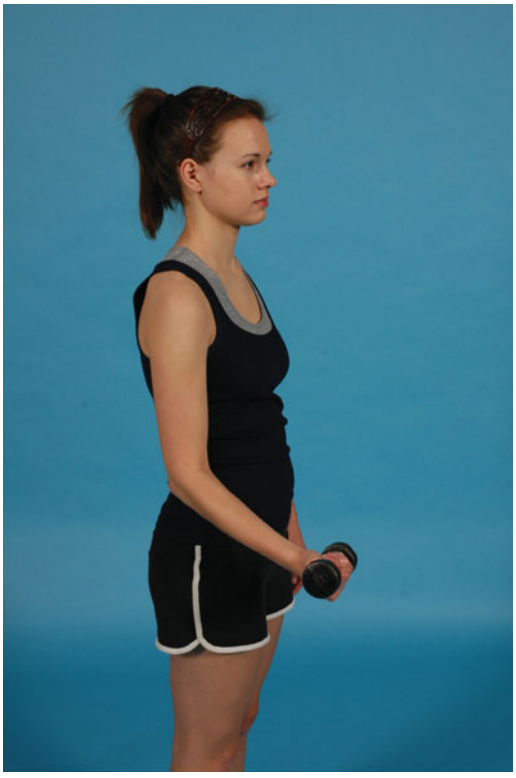

FIGURE 16-96 Elbow flexion PRE.

VIDEO) initially because of the role they play in providing stability. In contrast, exercises for the humeral "positioners" (deltoid) and the humeral "propellers" (latissimus dorsi and pectoralis major) are introduced in the "Functional Phase" section. Exercises for the *G-H protectors* include the AAROM wand exercises, progressing to AROM in the pain-free ranges throughout the functional planes. In addition, the incorporation of scapular retraction and scapular elevation exercises with G-H movements help stimulate a cocontraction of the G-H protectors and allow for a more normal physiologic sequence to redevelop. Scapular *pivoter* exercises include the *scapular pinch*, which is an isometric activity involving scapula retraction toward the midline (Fig. 16-27), and the YTWL exercise (the letters describe the shape the arms adopt) VIDEO.[152,153] Other resisted exercises for the scapular can be introduced at this stage to promote proximal stability. Examples include wall push-ups and isometric chair push-ups at varying degrees of elbow flexion (Fig. 16-97).

Once the arm can be safely elevated and held in the position of 90-degree abduction while standing or sitting, the patient lies in the supine position and the arm is actively raised as high as the pain-free range will allow (from 90 to 180 degrees, depending on tolerance), first without resistance and then with resistance VIDEO. From this position, the patient performs a serratus punch with a "plus." If applicable, the patient is progressed to full push-ups VIDEO. At the end of each push-up as the arm is fully straightened, an extra push is applied. This extra push with the push-up is termed as push-up plus (Fig. 16-98). This exercise strengthens the pectoralis minor, and the lower and middle serratus anterior.[13,122]

The application of joint compression with contraction through the application of closed-chain exercises is important, as closed-chain activities help to balance compression and

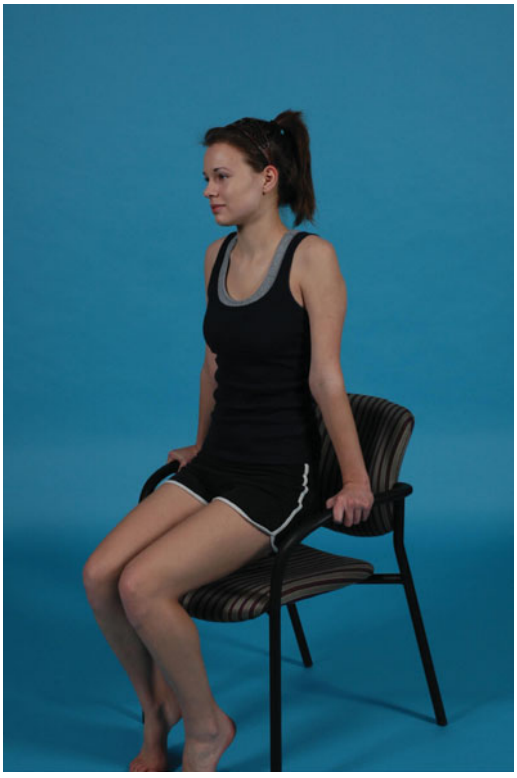

FIGURE 16-97 Isometric chair push-ups.

FIGURE 16-98 Push-up plus.

shear forces at the shoulder. These activities also encourage the correct sequencing of muscle contraction around the shoulder girdle and emphasize the cocontraction of force couples at the scapulothoracic and G-H joints.[87] This results in a correct scapular position and stabilization.[153] Closed-chain exercises may be done early in the rehabilitation phase as they do not put shear on the joint. They also allow the rotator cuff muscles to be activated without being inhibited by pain or deltoid overactivity. The closed-chain exercises can be initiated in the lower ranges using a table (Fig. 16-99), and then progressed to having the hands stabilized in the quadruped position, using a ball (Fig. 16-100). These exercises are started at elevations of 60 degrees or less and are moved up to 90 degrees of flexion, and then abduction, as tolerated to allow for healing of the tissues.[24,144,152,153]

Other closed-chain exercises can be performed by placing both hands on a table and flexing the shoulder to less than 60 degrees and abducting to 45 degrees. Progression is made to weight bearing on a tilt board or a circular board (Fig. 16-101) within tolerance. Other exercises that provide joint compression include the following:

- *Side-lying to sitting transfers* (Fig. 16-102).
- *Elbow rest.* The patient supine in a semireclined position, leaning on the elbows, with the humerus in a neutral or extended position (Fig. 16-103). This exercise can also be performed with the patient in prone (Fig. 16-104). Manual resistance can be applied by the clinician to make the exercise more challenging.
- *Table press-up.* The patient is seated on a chair or bed. The patient then raises and lowers the buttocks off the surface by straightening the elbow (Fig. 16-105). This works the triceps muscles, the pectoralis major and minor, and the latissimus dorsi muscles.[13] This exercise can be progressed to include pushing and pulling exercises and quadruped and tripod balancing (Fig. 16-106).

Flexibility exercises to stretch both the joint capsule and the shoulder girdle muscles are a vital component of the rehabilitation process. These include the sleeper stretch (Fig. 16-107) performed in side-lying VIDEO and then with the arm abducted to 90 degrees VIDEO. Gentle grade I or II oscillations are

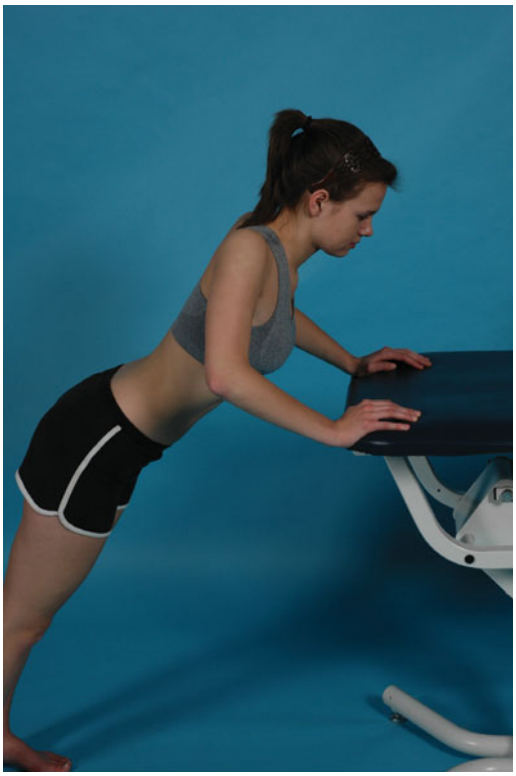

FIGURE 16-99 Closed-chain exercise using upper extremity compression.

FIGURE 16-101 Weight bearing on an unstable surface.

FIGURE 16-102 Side-lying to sitting transfer.

FIGURE 16-100 Joint compression in the quadruped position.

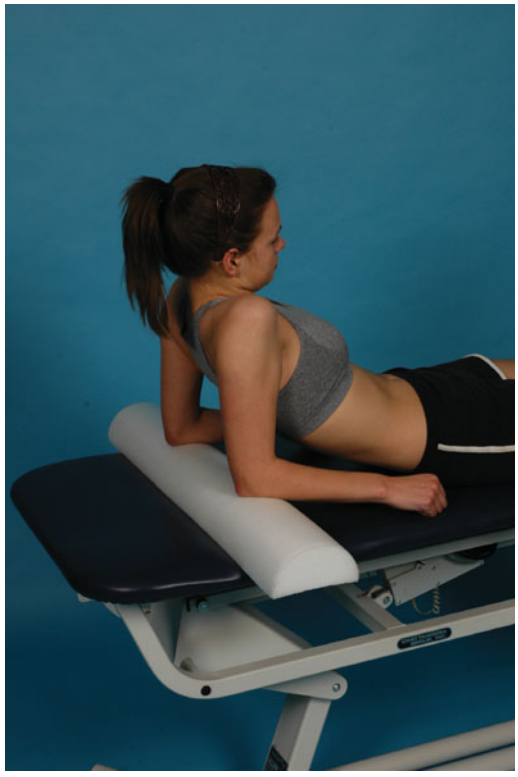

FIGURE 16-103 Elbow recline.

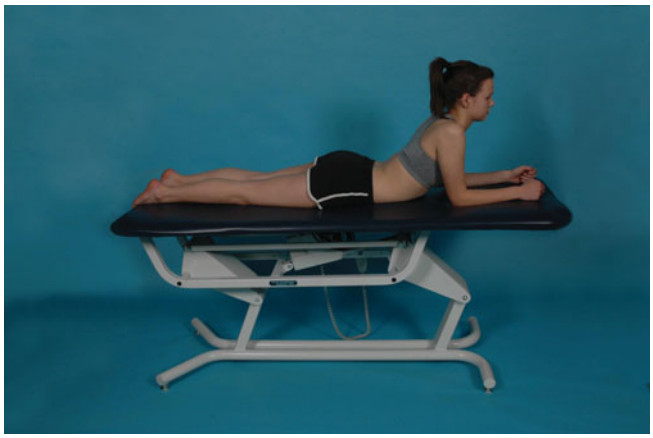

FIGURE 16-104 Prone on elbows with shoulder compression.

performed by the clinician as tolerated by the patient. Another stretch that can be performed is the supine horizontal adduction with IR stretch. To perform the stretch, the patient lies in the supine position with the shoulder flexed to 90 degrees. The clinician applies a stabilizing force to the lateral border of the scapula while the arm is horizontally adducted. At this point, the clinician applies a gentle force into IR. To supplement the stretches applied by the clinician, a number of techniques can be used by the patient to maintain and improve the ROM gains achieved in the clinic (see "Therapeutic Techniques" section).

Kinetic chain preparation can begin in the early stages while the shoulder is recovering from the injury or surgery. The length of the kinetic chain required depends on the needs of the patient and the goals of the rehabilitative process. Longer kinetic chains are associated with the more active patients, and may include the entire lower kinetic chain and the trunk in addition to the upper extremity (see "Biomechanics" section). Kinetic chain preparation will allow for the normal sequencing of velocity and force when the patient returns to their normal activities or athletic pursuits.[152,153]

FIGURE 16-105 Table push-up.

FIGURE 16-106 Quadriceps balancing.

According to Kibler,[153] progression to the functional phase of the rehabilitative process requires that the following criteria be met:

- Progression of tissue healing (healed or sufficiently stabilized for active motion and tissue loading)
- Pain-free ROM of at least 120-degree elevation
- Manual muscle strength in nonpathologic areas 4+/5

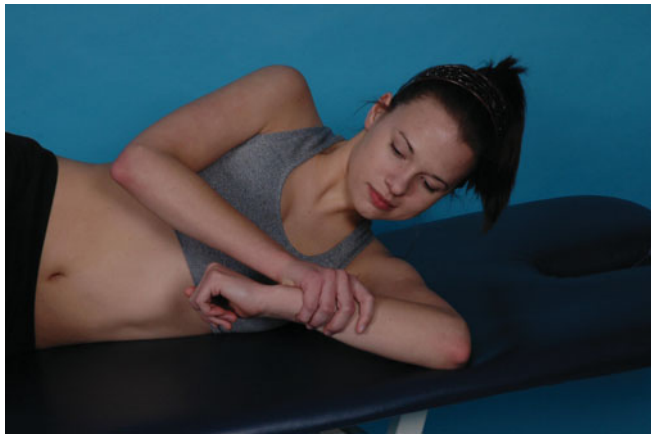

FIGURE 16-107 Sleeper stretch.

- Scapular control, with dominant side/nondominant side scapular asymmetry less than 1.5 cm with lateral slide test

Functional Phase

The functional phase is designed to address any tissue overload problems and/or functional biomechanical deficits. The goals of the functional phase include the following:

- Attain full range of pain-free motion with normal joint kinematics.
- Improve muscle strength to within normal limits.
- Improve neuromuscular control.
- Restore normal muscle force couples.

CLINICAL PEARL

The number of repetitions the patient is asked to perform should be based on the number the patient can do correctly with control, not a predetermined number.

CLINICAL PEARL

Generally speaking, exercise machines are not functional, emphasize the anterior muscle groups rather than posterior muscle groups (often opposite of the desired effect), and use long lever arms, making controlling the motion difficult and increasing the risk of a joint shear.

The exercises during this phase are performed slowly at first and are then progressed to higher functional speeds. Isolated muscle contractions can be achieved by placing the patient in the muscle test position for that muscle. Three sets of the strengthening exercises should be performed daily using weights of 1–10 lb. The number of repetitions is determined by tissue response (pain, fatigue, and compensatory patterns).

Correct activation and functioning of the scapula pivoters is essential. Proper strengthening of the scapular pivoters assures that the scapula follows the humerus, providing dynamic stability and assuring synchrony of the scapulohumeral rhythm. As the scapulothoracic muscles are not required to contract powerfully over short periods, or produce large amounts of force, it could be hypothesized that the scapulothoracic muscles serve a primarily postural function. Thus, in the rehabilitation of the scapulothoracic muscles, their postural function should be addressed and retrained. This can be accomplished in the form of endurance exercises by training the muscles with low weights and high repetitions, or sustained positions.[251]

CLINICAL PEARL

While the patient is performing exercises for the scapulohumeral rhythm, the clinician should note the following[390]:

- In the first phase of arm abduction (0–30 degrees), no or minimal scapula movement should occur.
- In the second phase (30–90 degrees), the scapula should rotate but show minimal protraction or elevation.
- In the third phase (90–180 degrees), ER of the humerus is necessary.

In scaption, the scapulohumeral rhythm is slightly different, with more individual variation in the movement, and more scapular rotation and protraction are common.[390]

Exercises for the scapular pivoters include the following:

- Shoulder shrugs (periscapular—trapezius, levator scapula). Resistance can be added to this exercise by having the patient hold dumbbells in the hands.
- Prone rowing. The patient lies prone on the table with a weight in the hand. With the elbow flexed to approximately 90 degrees, the patient raises the elbow to the ceiling (Fig. 16-108). This exercise strengthens the upper trapezius, levator scapulae, lower trapezius, posterior deltoid, and to a lesser extent, the middle trapezius, rhomboids, and middle deltoid.[13,122,391]
- Modified push-ups (see Fig. 16-109).
- Side-lying abduction exercises **VIDEO** are performed with the subject lying on his or her side and moving into

FIGURE 16-108 Prone rowing.

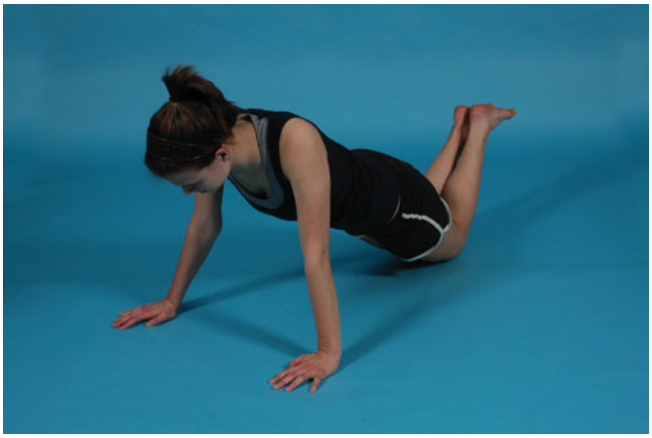

FIGURE 16-109 Modified push-ups.

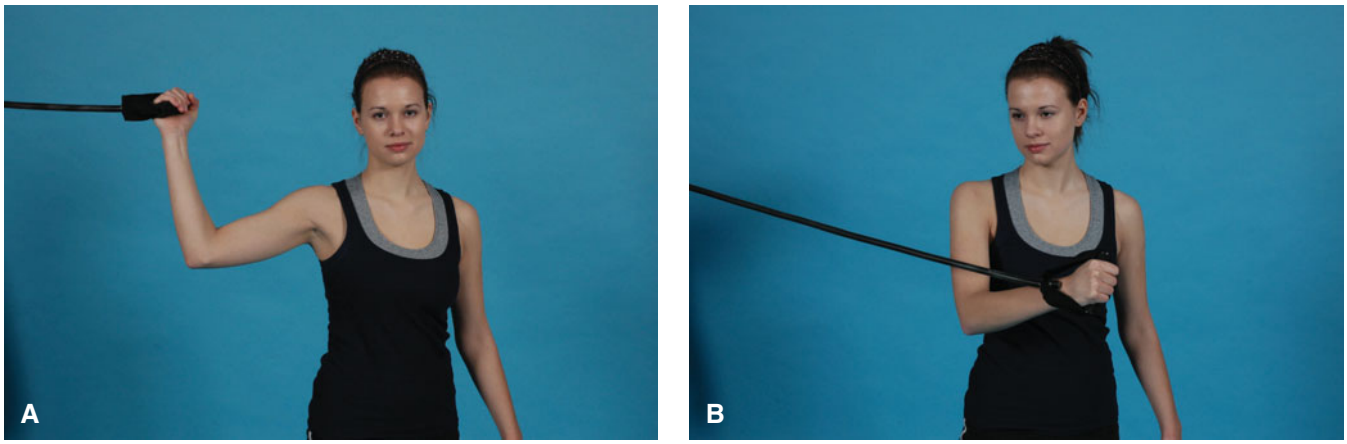

FIGURE 16-110 Diagonal exercise for the upper extremity. **(A)** Start position. **(B)** End position.

45-degree abduction in a neutral rotation position from a neutral or adducted position. Using MRI, side-lying abduction has been shown to produce the greatest signal intensity increase in three muscles of the rotator cuff: supraspinatus, infraspinatus, and subscapularis, as well as the deltoid.[392] A number of other exercises have been reported to demonstrate high subscapularis activity. These include IR at 90 degrees of abduction, the push-up plus, the diagonal exercise (Fig. 16-110A and 110B), and the dynamic hug exercise (Fig. 16-111).

Three exercises that are specific for the middle and lower trapezius include the following:

FIGURE 16-111 Dynamic hug exercise.

- Scapular pinches or squeezes.
- Thumb tubes. These are performed with the elbow extended and the thumb pointing posteriorly while grasping resistive tubing. The patient then performs a series of shoulder extension and/or horizontal abduction motions at various degrees of elevation.
- Power square patterns. These are performed by having the patient elevate the shoulders, pull back (retract) the shoulders while maintaining the elevation, depressing the shoulders while maintaining the retraction, and then moving the shoulders forward (protracting) while maintaining the depression.

Once scapular control has been achieved, exercises for the humeral positioners (the rotator cuff and deltoid) can be initiated to prevent humeral head migration, and to restore voluntary arthrokinematic control of the humeral head through rotator cuff coactivation and stabilization, as well as activation of the biceps and pectoralis major.[390] For example, by strengthening the infraspinatus, teres minor, and subscapularis muscles (relative to the supraspinatus and the deltoid), it may be possible to reestablish the normal balance and force couple during elevation of the G-H joint.[4,39,393]

Open-chain exercises designed to further strengthen the rotator cuff muscles are emphasized. These exercises may include the following:

- Elevation in the plane of the scapula (scaption)—also known as "empty the can," "supraspinatus exercise," "supraspinatus fly," and "Jobe's exercise"—is defined to be abduction in the plane of the scapula (90 degrees combined with 30 degrees of flexion) and IR.[327] Although useful as a special test, this motion does not help to reestablish scapulohumeral rhythm and can be counterproductive as it is often painful early in the rehabilitation process.
- Elevation in the plane of the scapula (scaption) in ER (full-can position). This exercise strengthens the scapula pivoters and may be preferable in the presence of impingement.[13,122,391]
- Military press. This exercise, which is performed by raising both the hands from shoulder height straight up toward the ceiling, strengthens the supraspinatus, subscapularis, upper

TABLE 16-33 Scapular and Humeral Control Exercises

Scapular Control	Humeral Control
Bent-over rowing	Prone horizontal abduction
Push-ups with a plus (maximum shoulder protraction)	Scaption in internal rotation (thumbs down)
Press-ups	Scaption with external rotation (thumbs up)
Forward punch-outs	Prone extension
Scapular squeezes	Side-lying internal and external rotation Prone 90 degrees/90 degrees (90-degree abduction, 90-degree elbow flexion) external rotation

trapezius,[392] anterior deltoid, middle serratus anterior, lower serratus anterior, and middle deltoid.[13,122] As the military press can cause impingement, care must be taken with its use. This exercise is probably better used in a prevention program.

- Scapula retraction with horizontal abduction of the externally rotated shoulder, done in prone. Blackburn et al.[122] demonstrated that externally rotating the humerus during prone exercise increased EMG activity to the highest levels. Horizontal abduction (90 degrees or 100 degrees) in ER strengthens the middle trapezius, infraspinatus and to a lesser extent, the teres minor and posterior deltoid (Table 16-33).[13,122,251,391] The patient lies prone on the table with both arms abducted to 90 degrees (Fig. 16-34) or 100 degrees and thumbs pointing toward the ceiling. With or without a weight in the hand, the patient then raises his/her thumbs toward the ceiling. If the arm is abducted to 100 degrees in the frontal plane, the lower trapezius is exercised.[122]
- Scapular retraction with horizontal abduction of the internally rotated shoulder, performed in prone (Fig. 16-112); this is similar to the previous exercise, but the patient now has the thumbs pointing down toward the ground. He or she is again prone and his or her arms are abducted to approximately 90 degrees. He or she then raises his or her hypothenar eminence toward the ceiling. This exercise strengthens, in order of effectiveness, the posterior deltoid, middle trapezius, rhomboids, middle deltoid, levator scapulae, infraspinatus, teres minor, upper trapezius, and lower trapezius.[13,122,391] This exercise can also be done in standing by using elastic resistance.
- Scapular dump (as though trying to empty things out of a can) exercises that incorporate arm, scapular, and trunk movements.
- Short-arc (pain-free) exercises into scaption, abduction, and forward flexion to 30 degrees initially and then to 90 degrees. These exercises should be performed in ER to facilitate clearance of the greater tuberosity under the coracoacromial ligament.

The open-chain exercises should also include resisted shoulder external **VIDEO** (Fig. 16-113) and internal **VIDEO** (Fig. 16-114) rotation with the arm in increasing amounts of abduction **VIDEO**

FIGURE 16-112 Prone shoulder retraction with glenohumeral joint in internal rotation.

to strengthen the infraspinatus/teres minor and subscapularis muscles, respectively. To avoid concurrent strengthening of the deltoid during the earlier phases of strengthening, the patient is instructed to hold a magazine or towel roll between the extremity and the trunk while strengthening the rotator cuff

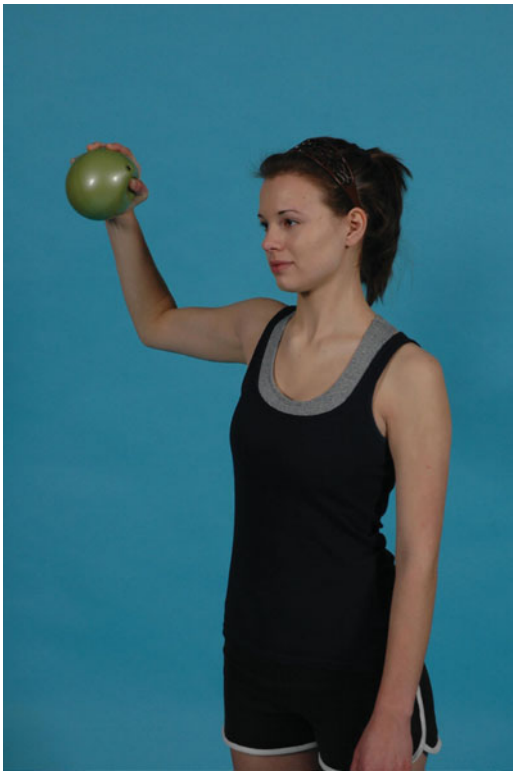

FIGURE 16-113 Resisted external rotation.

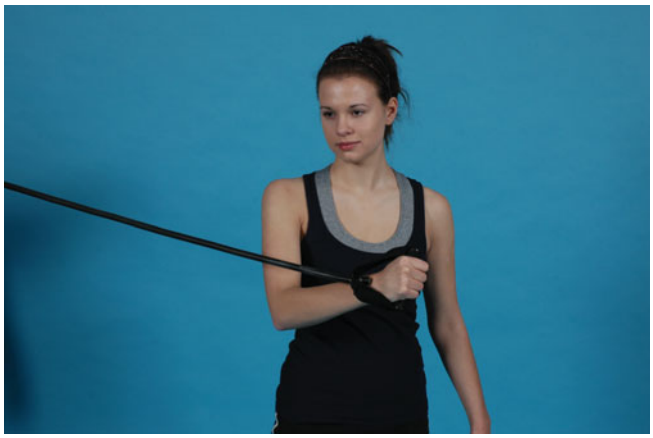

FIGURE 16-114 Resisted internal rotation.

muscles. This forced adduction relaxes the deltoid and isolates the oblique muscles of the rotator cuff.

Once control in most of the range has been achieved, diagonal proprioceptive neuromuscular facilitation (PNF) exercises can be used to teach control and stabilization throughout the whole range. The shoulder D2 pattern (flexion, abduction, and ER) is especially useful for instability.[390]

Once the muscles can contract in the correct sequence, the humeral *propellers* (i.e., the latissimus dorsi, teres major, pectoralis minor and pectoralis major) are trained concentrically, while the humeral *positioners* and *protectors* (i.e., infraspinatus, teres minor, supraspinatus, posterior deltoid, and biceps) and scapula pivoters are trained eccentrically.

In addition to addressing the musculature of the shoulder complex, the clinician must address the whole kinetic chain involved in an activity to which the patient is planning to return. This may include rehabilitation of the legs and hips to focus on the generation of appropriate activity-specific force and velocity from the lower extremity.[152,153] Examples include exercises that develop normal agonist–antagonist force couples in the legs such as squats, plyometric depth jumps, lunges, and hip extensions. Most shoulder activities involve rotation and diagonal patterns.[144,152] Thus the exercises must incorporate trunk rotation exercises (using medicine ball or tubing), which integrate leg and trunk stabilization and incorporate diagonal patterns (Fig. 16-115). These exercises are progressed to incorporate combined patterns of hip and trunk rotation in both directions, and hip and shoulder diagonal patterns from the left hip to the right shoulder and from the right hip to the left shoulder.[144,152]

Endurance activities in the legs should also be emphasized. Both aerobic endurance for recovery from exercise bouts and anaerobic endurance for agility and power work are advocated. These can be done using mini-trampoline exercises, agility drills with running and jumping, jumping jacks, and slider or Fitter boards.[153]

The arthrokinematic movements of the joints in the entire kinetic chain must be addressed for hypomobility and hypermobility, as appropriate. These joints include the A-C joint, the S-C joint, the scapulothoracic joint, the cervical and upper thoracic spine, and the upper ribs. For example, the clinician should check for GIRD, restriction of the inferior G-H ligament, and any loss of range in the pectoralis major and pectoralis minor.

FIGURE 16-115 Trunk rotation exercises with medicine ball.

CLINICAL PEARL

The *circle concept of instability*[36,142] relates to the fact that injury to structures on one side of the joint sufficient to result in instability can, simultaneously, cause injury to structures on the other side or other parts of the joint, particularly in the presence of trauma. For example, a traumatic anterior instability of the shoulder can lead to injury of the posterior structures. Thus, the clinician must always be aware of potential injuries on the opposite side of the joint even if symptoms are predominantly on one side. In addition, if a joint is hypermobile in one direction, it may be hypomobile in the opposite direction. For example, with anterior instability, the posteroinferior capsule tends to be tight and therefore requires mobilization, whereas the anterior capsule is hypermobile and requires protection.[390]

Proprioception exercises can be introduced as soon as the patient has gained scapular control. These exercises can include the aforementioned closed-chain activities for the upper extremity. Open kinetic chain activities may also be used, but they are not as effective, and they do not require the same level of stability.[390]

Activity-specific progressions must be completed before full return to function is allowed. This is done to test all of the working components involved in the activity. Very few deviations from the normal parameters of arm motion, arm position, force generation, smoothness of all of the kinetic chain, and from preinjury form should be allowed as most of these adaptations will be biomechanically inefficient.[144,152,153,394,395]

FIGURE 16-116 Regular push-up.

Advanced stabilization exercises are designed to test the ability of the patient to stabilize the scapula statically in positions above 30 degrees, most commonly in an open kinetic chain. The patient is asked to perform isometric hold or eccentric break activities of the internal and external rotators in various positions of G-H abduction, scaption, and forward flexion. Closed-chain exercises include wall falls, table falls, and balancing on different balance devices. Closed-chain exercises in this phase may also include the following:

- Regular push-ups (Fig. 16-116) are progressed as tolerated.
- Medicine ball catch-and-throw (Fig. 16-117) **VIDEO**.

Dynamic weight-shifting exercises are introduced during this phase. With the patient weight bearing on all fours in the quadruped position, and while keeping their hands stationary in the same position, the patient can rock the body forward and backward, and side to side. A similar exercise can be performed on an unsteady surface by using equipment such as the BOSU trainer **VIDEO**. Alternatively, the patient can slide their hands, or one hand, forward, backwards, and side to side while maintaining their trunk still. Resistance can be added using a Fitter board (Fig. 16-118).

Finally, dynamic stabilization exercises that involve controlled eccentric movement of the scapula while the arm moves are introduced.[153] Eccentric exercises are particularly important for those patients where tensile overloading is suspected to be the cause, and for the overhead athlete population.[379,396] Exercises such as bent over rows, and lunges with dumbbells are good examples.

The criteria for return to activity include the following[153]:

- Little or no pain
- Functional ROM with involvement of the whole kinetic chain
- Normal movement patterns and functional ability
- Appropriate levels of fitness
- Near-normal strength
- Ability to perform the necessary skills

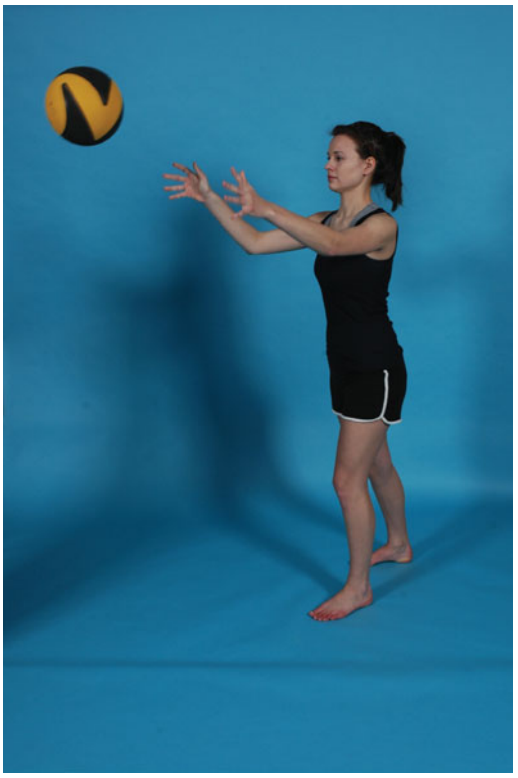

FIGURE 16-117 Medicine ball throw and catch.

Table 16-34 may be referred to for a typical program given for a pitcher returning to full function. This program can and should be modified as needed by the clinician. Each phase may take a longer or shorter time than that listed, and the program should be monitored closely.

PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION WITH CONNECTIVE TISSUE DYSFUNCTION

The primary impairment in pattern 4D, when applied to the shoulder, is hypomobility due to capsular restriction. In addition to limited joint movement and decreased ROM associated with pain, the impairments in this pattern include decreased motor control and muscle performance.

The clinical findings in this pattern include, but are not limited to, pain, limited ROM in a capsular pattern of restriction, an alteration in the scapulohumeral rhythm, crepitus, and a positive impingement sign.

Arthritis

Traumatic Arthritis of the G-H Joint

Traumatic or primary G-H arthritis is an entity that has been well described and documented by Neer et al.,[326,397] who highlighted the presence of significant posterior glenoid erosion causing static posterior subluxation of the humeral head. Traumatic arthritis of the G-H joint rarely occurs in individuals under the age of 45. The condition is characterized by pain, progressive functional impairment, and reports of instability.[398] Passive horizontal adduction is usually the most limited and painful motion.

Conservative intervention consists of rest, modification of activity, and NSAIDs. Electrotherapeutic modalities and physical agents may be used to control pain and the active inflammation. Joint mobilizations of grade I or grade II may also be used to decrease pain. Once pain and inflammation is under control, the rehabilitation progresses to strengthening of the shoulder protectors and scapular pivoters, as described in the "Intervention Strategies" section.

Immobilization

Postsurgical immobilization occurs at any age, although it is more common in the elderly. The clinical progression is similar to that of traumatic arthritis. This condition should ideally be treated by prophylaxis.

Rheumatoid Arthritis

Rheumatoid arthritis is described in Chapter 5. Conservative intervention for this population includes patient education on how they can influence their disease process by alleviating the impairments, functional limitations, and disability. Electrotherapeutic modalities and cryotherapy can be used to help control pain and inflammation. Thermal modalities may also be used in the nonacute phases. Therapeutic exercise can be beneficial for the patients who are weak and stiff prior to the onset of end-stage arthritis, where the ROM and strength can be regained, or at least maintained.[399] However, caution must be used with those patients with end-stage arthritis who have stiffness secondary to joint incongruity, as they may actually have their symptoms exacerbated with aggressive stretching exercises.[399]

When pain becomes too severe and conservative intervention is unable to relieve this pain and restore function, surgical measures are considered. These measures may include synovectomy, G-H arthrodesis, or total joint arthroplasty.

Septic Arthritis

See Chapter 5.

Avascular Necrosis of the Humeral Head

Avascular necrosis of the humeral head is described in Chapter 5.

Hemorrhagic Shoulder (Milwaukee Shoulder)

L'épaule sénile hémorragique (the hemorrhagic shoulder of the elderly) was first described in 1968. It consisted of recurrent, blood-streaked effusions of the shoulder along with radiographic findings of severe degenerative G-H arthritis and a chronic tear of the rotator cuff.[400] The term *Milwaukee shoulder* was not introduced until 1981.[401–403]

The condition generally affects a subset of the elderly population who have G-H arthritis in conjunction with a complete rotator cuff tear.

One theory to explain the Milwaukee shoulder describes a hydroxyapatite-mineral phase that develops in the altered capsule, synovial tissue, or degenerative articular cartilage. This releases basic calcium phosphate crystals into the synovial fluid.[401–403] These crystals are phagocytized by synovial cells and form calcium phosphate crystal microspheroids. These induce the release of activated enzymes from these cells, causing destruction of the periarticular tissues and articular surfaces.[404]

Another theory is the cuff tear theory. In 1983, Neer et al.[405] postulated that untreated chronic, massive tears would lead to a degenerated G-H joint. The mechanism of destruction of the articular cartilage was said to include mechanical and nutritional alterations in the shoulder.[405] The mechanical factors include A-P instability of the humeral head resulting from a

massive tear of the rotator cuff, and rupture or dislocation of the LHB that leads to proximal migration of the humeral head and acromial impingement.[404] G-H articular wear was thought to occur as a result of repetitive trauma from the altered biomechanics associated with the loss of the primary and secondary stabilizers of the G-H joint.[404] Changes in the composition of the articular cartilage follows because of inadequate diffusion of nutrients and the diminished quantity of synovial fluid.[404] Degenerative arthritis and subchondral collapse eventually develops.[404]

If the resultant rotator cuff tear arthropathy causes relatively mild symptoms, intervention should consist of mild anti-inflammatory medication and gentle stretching exercises to maintain or regain a functional ROM.[404] A strengthening program should follow to improve the active use of the arm for ADL. If conservative management fails, a humeral hemiarthroplasty is the procedure of choice to provide reliable relief of pain and functional improvement.[404]

Frozen Shoulder/Adhesive Capsulitis

Since this condition also involves an inflammation of the capsule, a patient with this condition could also be classified under preferred practice pattern 4E.

The frozen shoulder syndrome was first described by Duplay in 1872,[406] who used the term *periarthritis scapulohumerale*. It was not until 1934 that Codman[61] used the term *frozen shoulder* to describe this condition. In 1945, Neviaser introduced the term *adhesive capsulitis* to reflect his findings of a chronic inflammatory process at surgery and autopsy.[407]

Although the etiology of frozen shoulder remains elusive, the understanding of the pathophysiology has recently improved. Factors associated with adhesive capsulitis include female gender,[408] age older than 40 years,[409] trauma,[409] diabetes,[222,242,410–413] prolonged immobilization,[414] thyroid disease,[415–417] stroke or myocardial infarction,[411,418] certain psychiatric conditions,[419,420] and the presence of autoimmune diseases.[421,422]

The prevalence of frozen shoulder in the general population is slightly greater than 2%,[408,423] and 11% of the adult diabetic population.[410] Approximately 70% of patients with adhesive capsulitis are women, and 20–30% of those affected subsequently will have adhesive capsulitis develop in the opposite shoulder.[424] Complicating the diagnosis is the fact that there are many conditions that can cause shoulder stiffness (Tables 16-35 and 16-36).

Nash and Hazelman[425] have described the concept of primary and secondary frozen shoulders, with the former idiopathic in origin, and the latter either traumatic in origin or related to a disease process, neurologic, or cardiac condition.

TABLE 16-35 Intrinsic Causes of Shoulder Stiffness

Cause	Example
Bursitis	Subacromial Calcific tendinitis Snapping scapula
Biceps tendon	Tenosynovitis Partial or complete tears SLAP lesions
Rotator cuff	Impingement syndrome Partial rotator cuff tears Complete rotator cuff tears
Trauma	Fractures Glenoid Proximal humerus Surgery Postoperative shoulder, breast, head, neck, chest Gastrointestinal disorders Esophagitis Ulcer Cholecystitis
Instability—glenohumeral	Recurrent dislocation anterior and posterior Chronic dislocation
Arthritides	Glenohumeral and acromioclavicular Osteoarthritis Rheumatoid Psoriatic Infectious Neuropathic
Miscellaneous	Avascular necrosis Hemarthrasis Osteochondromatosis Suprascapular nerve palsy

Primary Adhesive Capsulitis

Primary adhesive capsulitis is characterized by an idiopathic, progressive, and painful loss of active and passive shoulder motion, particularly ER, which causes the individual to gradually limit the use of the arm. Difficulty is reported with putting on a jacket or coat, putting objects into back pockets, or hooking garments in the back.[195,426–428] Inflammation and pain can cause muscle guarding of the shoulder muscles, without true fixed contracture of the joint capsule. Disuse of the arm results in a loss of shoulder mobility, whereas continued use of the arm through pain can result in development of subacromial impingement.[424] Over a period of weeks, compensatory movements of the shoulder girdle develop to minimize pain.[424] With time, there is resolution of pain and the individual is left with a stiff shoulder and with severe limitation of function.

Secondary or Idiopathic Adhesive Capsulitis

Zuckerman and Cuomo[429] defined idiopathic adhesive capsulitis as a condition characterized by substantial restriction of both active and passive shoulder motion that occurs in the absence of a known intrinsic shoulder disorder. Two clinical forms are recognized:

TABLE 16-36 Extrinsic Causes of Shoulder Stiffness	
Cause	**Example**
Neurologic	Parkinson's disease Automatic dystrophy (CRPS) Intradural lesions Neural compression Cervical disk disease Neurofibromata Foraminal stenosis Neurologic amyotrophy Hemiplegia Head trauma
Muscular	Poliomyositis
Cardiovascular	Myocardial infarction Thoracic outlet syndrome Cerebral hemorrhage
Infections	Chronic bronchitis Pulmonary tuberculosis
Metabolic	Diabetes mellitus Progressive systemic sclerosis (scleroderma) Paget's disease Thyroid disease
Inflammatory	Rheumatologic disorders Polymyalgia rheumatica
Trauma	Surgery Axillary node dissection, sternotomy, thoracotomy Fractures Cervical spine, ribs, elbow, hand, etc.
Medications	Isoniazid, phenobarbitone
Congenital	Klippel–Feil Sprengel's deformity Glenoid dysplasia Atresia Contractures Pectoralis major Axillary fold
Behavioral	Depression Hysterical paralysis
Referred pain	Diaphragmatic irritation
Neoplastic	Pancoast tumor Lung carcinoma Metastatic disease

Data from Cohen BS, Romeo AA, Bach BR: Shoulder injuries. In: Brotzman SB, Wilk KE, eds. *Clinical Orthopaedic Rehabilitation*. Philadelphia, PA: Mosby, 2003:125–250.

1. One form is defined as when the pain is more noticeable than the motion restriction. This condition is self-limiting, and the patient spontaneously recovers within 6 months to a year. Two studies[430,431] of patients with idiopathic adhesive capsulitis found that the vast majority of patients with this condition were successfully treated with a specific shoulder-stretching exercise program.
2. The other form is defined as when the pain, which can radiate below the elbow, is as noticeable as the restriction. The patient complains of pain at rest and is unable to sleep on the involved side. ER of the G-H joint is usually affected more than abduction or flexion.[195] The initial phase of this condition is characterized by pain and progressive loss of motion lasting 2–6 months. This form responds well to a series of corticosteroid injections or local anesthetic (distension therapy).

To formulate a logical approach to the intervention of patients with adhesive capsulitis, the clinician needs to determine the degree of inflammation and irritability. To help in this determination, it is necessary to have a better understanding of the underlying cellular and biochemical pathophysiology of this disease.

There is disagreement as to whether the underlying pathologic process is an inflammatory condition,[432–434] or a fibrosing condition.[435] Significant evidence exists[421,422,434,436] in support of the hypothesis that the underlying pathologic changes in adhesive capsulitis are synovial inflammation with subsequent reactive capsular fibrosis, making adhesive capsulitis an inflammatory and a fibrosing condition, depending on the stage of the disease. The initial biologic trigger in this cascade of inflammation and subsequent fibrosis is unknown, although it is likely to involve multiple factors. In some areas, there seems to be a seasonal variation in patients presenting with adhesive capsulitis, suggesting that a virus is responsible.[424]

Stages of Progression

Adhesive capsulitis is suggested by Neviaser[407] to pass through four stages based on pathologic changes in the synovium and the subsynovium, with each stage having an individual intervention strategy, although there is controversy about this idea.[75]

Stage I. In stage I, patients present with mild signs and symptoms of less than 3 months' duration, which are often described as achy at rest and sharp at extremes of ROM. The symptoms often mimic those of an impingement syndrome, where restriction of motion is minimal and pain that appears to be due to a rotator cuff tendinitis has been present for less than 3 months. However, the patient reports a progressive loss of motion and intervention protocols for rotator cuff tendinitis fail. A capsular pattern of motion (loss of ER and abduction) is present, and a more subtle loss of IR in adduction. In adhesive capsulitis due to type 1 diabetes mellitus, the capsular pattern is typically equal to the limitation of ER and IR, which is greater than the limitation of abduction.

In this early stage, the majority of motion loss is secondary to the painful synovitis, rather than a true capsular contraction.

Stage II. Patients presenting with stage I and stage II adhesive capsulitis have pain on palpation of the anterior and posterior capsules and describe pain radiating to the deltoid insertion. An intra-articular injection of steroid and local analgesic given by a physician can be extremely useful in the diagnosis and intervention of adhesive capsulitis.[424] After the injection, passive G-H ROM is reevaluated. If the patient has significant improvement in pain and normalization of motion, the diagnosis of stage I adhesive capsulitis is confirmed.[424] If the patient has a significant improvement in pain but no significant improvement in ROM, then by definition he or she has stage II adhesive capsulitis, although it must be emphasized that these stages represent a continuum of the inflammatory and scarring processes.[432]

In stage II, symptoms have been present for 3–9 months with progressive loss of ROM and persistence of the pain pattern described above. The motion loss in stage II adhesive capsulitis reflects a loss of capsular volume and a response to the painful synovitis. The patient demonstrates a loss of motion in all planes, as well as pain in all parts of the range. Evaluation of AROM and PROM should be performed because documenting the initial ROM, especially passive motion, is critical in determining the efficacy of the intervention plan. The causes of the restricted PROM need to be assessed and a differentiation must be made between protective muscle guarding, adaptive changes in musculotendinous structures, or capsular adhesions and contracture.

CLINICAL PEARL

It is important to note that the restricted ROM seen in patients with adhesive capsulitis occurs both actively and passively, which is in contrast to a number of other shoulder conditions in which a loss of AROM of the G-H joint occurs, but reasonably good, if not full, PROM is maintained.[73]

Stage III. In stage III, patients present with a history of painful stiffening of the shoulder and a significant loss of ROM. Symptoms have been present for 9–14 months and have been observed to change with time. Patients often report a history of an extremely painful phase that has resolved, resulting in a relatively pain-free but stiff shoulder.

Poor scapulohumeral rhythm is observed during elevation of the arm. There is a dominance of the upper trapezius resulting in hiking of the shoulder girdle. This is attributed to a decreased inferior glide of the G-H joint, which prevents G-H abduction.[437]

Stage IV. Stage IV, also known as the "thawing stage" for adhesive capsulitis, is characterized by the slow, steady recovery of some of the lost ROM resulting from capsular remodeling in response to use of the arm and shoulder. Although many people feel less restricted in this phase, objective measurements show only minor improvement.[438] No arthroscopic or histologic data are available for patients with stage IV adhesive capsulitis because these patients rarely undergo surgery. Patients who present with stages III and IV adhesive capsulitis often report a history of long-standing pain at rest and pain at night that have resolved spontaneously.[439] The objective findings typically include a stiff shoulder, with striking alteration of scapulohumeral mechanics and limited use of the arm during ADL. A capsular pattern of motion is a characteristic finding. Resistance in the form of a capsular end-feel is felt before pain is reached as the G-H joint is taken through PROM.

Other pathologic conditions that can create a painful restriction of G-H motion should be ruled out. Typically, the physician uses a routine radiographic evaluation to rule out other causes for a stiff, painful shoulder including G-H arthritis, calcific tendinitis, or long-standing rotator cuff disease.[424] Radiographs usually are negative in patients with frozen shoulder, although there may be evidence of disuse osteopenia.[424] MRI has been used for investigative purposes in patients with adhesive capsulitis and has shown an increased blood flow to the synovium in frozen shoulder.[440]

Intervention

The conventional management for adhesive capsulitis incorporates patient advice, analgesics, NSAIDs, steroid injection, and a wide array of physical therapy methods.[441] The primary goal of conservative intervention is the restoration of the ROM and focuses on the application of controlled tensile stresses to produce elongation of the restricting tissues.[242,243,424,442–444] Once this has been established, strengthening of the rotator cuff and the three parts of the deltoid muscle is important. Systematic reviews concerning physical therapy interventions with adhesive capsulitis have traditionally compared the efficacy of one component of physical therapy. For example, comparing the effect of ultrasound alone or mobilization alone. The outcomes from these studies have been, perhaps not surprisingly, poor. However, when combined physical therapy methods are analyzed, the results have been more encouraging. Pajareya et al.[441] performed a randomized control trial of 122 patients to study the effectiveness of ibuprofen and a combination of physical therapy (PT) techniques versus ibuprofen alone. The PT intervention (three times a week for 3 weeks) included short-wave diathermy, joint mobilizations, and passive G-H stretching exercises up to the patient's tolerance. At 3 weeks it was concluded that the PT group demonstrated more beneficial effects than the group using ibuprofen alone.[441]

These results must be taken in the context of earlier studies that have indicated that a gradual return of full mobility occurs within 18 months to 3 years in most patients, even without specific intervention.[445–447] In a study by Diercks et al.,[448] 77 patients with idiopathic frozen shoulder syndrome were included in a prospective study to compare the effect of intensive physical rehabilitation treatment, including passive stretching and manual mobilization (stretching group) versus supportive therapy and exercises within pain limits (supervised neglect group). All patients were followed up within 24 months after the start of treatment. The study concluded that supervised neglect yields better outcomes than intensive physical therapy and passive stretching in patients with frozen shoulder with regard to the functional end result and the speed of recovery.

These conflicting findings may be the result of an incorrect treatment approach. As a general guideline, the patient with capsular restriction and low irritability may require aggressive soft tissue and joint mobilization, whereas patients with high irritability may require pain-easing manual therapy techniques.[449] In contrast, the emphasis on intervention for limited ROM due to nonstructural changes is aimed at addressing

the cause of the pain.[247,423,429,436,446,450–452] The trust and confidence of the patient is essential, and it is important to ensure that no harm is caused, or that the clinician does not indicate any frustration. During the acute phase, pendulum exercises and low-grade joint mobilization techniques are recommended to relieve pain and apply a gentle stretch to the capsule. In addition, passive stretching of the upper trapezius and levator scapulae muscles can be performed by the clinician and then taught to the patient as part of a home exercise program. During the subacute phase, more aggressive ROM exercises can be incorporated using PNF techniques, wall climbing, and wall/corner stretches. As ROM returns, strengthening becomes the focus, initiating with isometrics, and then progressive strengthening of the shoulder complex during the chronic phase.

A number of questions are often raised by the patient with regard to corticosteroid injections. Although these questions are best answered by the appropriate physician, there is extensive information regarding the efficacy of intra-articular corticosteroid in the intervention of patients with adhesive capsulitis.[453–457] Hazelman[458] summarized numerous studies on the use of intra-articular corticosteroid and reported that the success of intervention is dependent on the duration of symptoms.

- Patients treated within 1 month of onset of symptoms recovered in an average of 1.5 months.
- Patients treated within 3 months of the onset of symptoms reported a significant improvement in symptoms.
- Patients treated within 2–5 months of onset of symptoms recovered within 8.1 months of onset of symptoms.
- Patients treated after 5 or more months of onset of symptoms had a more delayed recovery, with the time necessary for full recovery reported to be dependent on the duration of symptoms.
- Patients treated 6–12 months after onset of symptoms required an average of 14 months for full recovery.

These data, along with others, support the hypothesis that adhesive capsulitis is an inflammatory and fibrotic condition.[432,434,435,453,459] Early intervention with intra-articular corticosteroid may provide a chemical ablation of the synovitis, thus limiting the subsequent development of fibrosis and shortening the natural history of the disease.[432] With resolution of the synovitis and loss of the cytokine stimulus to the capsular fibroblasts, capsular remodeling and recovery of ROM take place.[432]

Surgical intervention is reserved for those patients who do not respond to conservative intervention. Historically, arthroscopy has been of little diagnostic and therapeutic value in patients with adhesive capsulitis of the shoulder,[409] and closed manipulation appears to be the operation of choice if conservative methods fail. However, closed manipulation is contraindicated in patients with significant osteopenia, recent surgical repair of soft tissues about the shoulder, or in the presence of fractures, neurologic injury and instability.[424]

Selective Hypomobility

A generalized decrease in shoulder ROM may be due to a number of reasons such as arthritis or adhesive capsulitis. Selective hypomobility is usually the result of a restriction of the joint capsule. An asymmetrical restriction of the capsule causes an obligate translation away from the side of the joint where the tightness is located. For example, a posterior capsule restriction causes an increase in anterior translation of the humeral head during cross-arm adduction and with flexion of the G-H joint.[46] The posterior capsule restriction also results in a superior translation of the humeral head with flexion of the G-H joint.

Passive movement testing may be used to detect the direction of the hypomobility by examining the end-feel, and the amount of translation that occurs. Such tests include the load and shift test, the anterior release test, and the sulcus sign test. ROM tests are used to determine the amount of internal and ER. There is a close association between the amount of IR at the G-H joint and the posterior shoulder capsule tightness.[460]

The intervention for this impairment includes a warm-up phase using a moist heating pad or upper-body ergometer. The patient is then taught the position to adopt to stretch the restricted portion of the capsule. The maximum stretch position is then maintained for approximately 20 minutes, or as long as the patient can tolerate, whichever occurs first. The patient is instructed to perform the warm-up and stretch at home. The duration of the stretch is gradually increased until the patient is able to tolerate the stretch position for 60 minutes per day.

The patient performs multiple angle isometrics or short-arc exercises in the newly acquired range to improve neuromuscular dynamic control. When full ROM has been restored, the patient performs full range resistive exercises and combinations of arm and trunk exercises, such as PNF.

According to Sahrmann, correction of resting scapular malalignment is always indicated in this patient population, particularly when the PROM is not restricted by more than 20 degrees. [206]

Downwardly Rotated Scapula[206]

The G-H joint becomes the site of compensation because the scapula does not fully rotate upwardly. The scapula should be constantly supported in its correct position by providing support for the arm. Exercise intervention should include strengthening for the serratus anterior and the trapezius. Stretching exercises are prescribed for those muscles found to be adaptively shortened in the examination. Those muscles usually include the rhomboid and levator scapulae.

Scapular Depression[206]

This syndrome is characterized by weakness and lengthening of the upper trapezius. It is often accompanied by adaptive shortness of the latissimus dorsi, pectoralis major, and pectoralis minor. When the scapula fails to elevate sufficiently during G-H flexion or abduction, the lower trapezius becomes more dominant than its upper counterpart. The intervention should focus on providing support for the shoulder so that it does not become depressed. The patient is instructed to perform shoulder shrugs with the G-H joint in its anatomic position and also with the shoulder flexed above 120 degrees. A mirror can be used to teach the patient to correct the depression of the shoulder girdle during arm elevation.

Stretching exercises are prescribed for those muscles found to be shortened in the examination.

Scapular Abduction Syndrome[206]

This syndrome is characterized by excessive scapular abduction during G-H flexion or abduction. It is also associated with a lengthening of the trapezius and possible lengthening of the rhomboid muscles and adaptive shortening of the serratus anterior, resulting in poor control of the scapula. Adaptive shortness of the deltoid or supraspinatus muscles can also indirectly hold the scapula in an abducted position. Intervention should focus on stretching the short G-H and thoracohumeral muscles and improving the performance of the adductor components of the lower and middle trapezius muscles.

Scapular Winging Syndrome

This syndrome is characterized by an inability to elevate and/or lower the arm without the scapula winging or its inferior angle tilting. This syndrome results from a weakness and adaptive shortness of the serratus anterior, with accompanying shortness of the pectoralis minor and scapulohumeral muscles.

Intervention should focus on stretching the pectoralis minor to correct the tilting and serratus anterior for strengthening and retraining.

Humeral Anterior Glide Syndrome[206]

This syndrome is characterized by a humeral head that is positioned more than one-third anteriorly to the acromion, and which moves anteriorly during G-H abduction. Other findings typically include relative tightness of the posterior capsule when compared with the anterior, weak or lengthened subscapularis, adaptive shortness of the scapulohumeral external rotators, and the pectoralis major.

Intervention should shorten and strengthen the subscapularis, and stretch the humeral external rotators and the pectoralis major.

Humeral Superior Glide Syndrome[206]

This syndrome is characterized by an excessive movement of the humeral head in a superior direction during G-H flexion, abduction, or elevation. Clinical findings usually include adaptive shortness of the deltoid, weakness of the rotator cuff muscles, and adaptive shortness of the humeral internal and/or external rotators. Intervention focuses on the deltoid; increasing its length if shortened, and diminishing its activity if dominant. The patient should be instructed to avoid performing activities that involve ER in adduction as well as abduction exercises and resisted shoulder flexion with the elbow extended, as these can exacerbate the condition.

Glenohumeral Instability

The structures involved in the maintenance of the static and dynamic stability of the shoulder, also provide neurologic feedback that mediates reflex stabilization around the joint.[461,462] Laxity is the physiologic motion and a necessary attribute of the G-H joint that allows normal ROM, which is normally asymptomatic.[357] Laxity is not always synonymous with instability.[463] In contrast, instability is the abnormal symptomatic motion of the G-H joint that affects normal joint kinematics and results in pain, subluxation, or dislocation of the shoulder.[143,461,464,465]

In the early years of life, the G-H joint is fairly stable due to the active mechanisms stabilizing the joint. However, if an individual becomes deconditioned, the dynamic mechanisms become unable to provide support and the joint becomes involved in a self-perpetuating cycle of instability, less use, more shoulder dysfunction, and further instability. In addition to redundance of the shoulder capsule, underlying causes of G-H instability can include genetic, collagen, and biomechanical factors.[357]

There is considerable variation in the amount of translation normally elicited in an asymptomatic shoulder.[355,356,360,466] Shoulder laxity tests show that translations in the asymptomatic shoulder as compared with the contralateral symptomatic shoulder can be as large as 11 mm in one direction.[356,467] Although it has been shown that healthy shoulders can have asymmetric translation in at least one direction, no healthy shoulder is asymmetric in all three directions.[356]

Characteristic of G-H instability is the complaint of the shoulder "slipping" or "popping out" during overhead activities. Instability of the shoulder can be classified by frequency (acute or chronic), magnitude, direction, and origin.[75] Acute traumatic instability with dislocation of the shoulder is the most dramatic variety, and often requires manipulative reduction. Shoulder instability may also be classified according to the direction of the subluxation as either unidirectional (anterior, posterior, or inferior), bidirectional, or multidirectional. Posterior instability, which results either from avulsion of the posterior glenoid labrum from the posterior glenoid, or stretching of the posterior capsuloligamentous structures, is often difficult to diagnose with no single test having high sensitivity and specificity. Recently, both multidirectional instability and its hallmark, inferior G-H instability, have been scrutinized much more closely.[134,156,468]

Most patients presenting with hypermobility or instability of the anterior G-H joint are athletic adolescents or young adults with joint laxity.[357,469] Anterior instability occurs when the abducted shoulder is repetitively placed in the anterior apprehension position of ER and horizontal abduction. Such individuals may have pain with overhead movements due to an inability to control the laxity through muscle support. They may develop enough instability directed superiorly that they present with impingement-like symptoms (instability–impingement overlap), especially in positions of abduction and ER.[470] In general, the patients have had normal asymptomatic shoulder function until some event precipitates symptoms. The event usually involves only relatively minor trauma when compared with the traumatic causes of unidirectional instability, or repetitive microtrauma as occurs in patients who participate in swimming and gymnastics.[278] The most common presenting complaint is pain.[471,472]

Unilateral dislocations occurring from acute traumatic events include the Bankart lesion or Hill-Sachs lesion. The Bankart lesion is an avulsion of the anterior inferior labrum from the glenoid rim and requires surgical stabilization (*t*raumatic, *u*nidirectional instability with *B*ankart lesion requiring *s*urgery or TUBS), using the Bankart procedure, which

addresses the lesion without significant loss of ER,[473] or a capsular reconstruction procedure.

CLINICAL PEARL

Multidirectional instability (see later) is often described using the abbreviation AMBRII (*a*traumatic onset of *m*ultidirectional instability that is accompanied by *b*ilateral laxity or hypermobility. *R*ehabilitation is the primary course of intervention to restore G-H stability. However, if an operation is necessary, a procedure such as a capsulorrhaphy is performed to tighten the *i*nferior capsule and the rotator *i*nterval).[474]

The Hill-Sachs lesion is a compression fracture of the posterior humeral head at the site where the humeral head impacted the inferior glenoid rim. Dislocation of the G-H joint is not uncommon in older people, although the incidence is less after 50 years of age.[195] Chronic recurrent dislocations of the shoulder can lead to degenerative arthritis. An older person who dislocates a shoulder is likely to have concurrently torn the rotator cuff and should be examined with this idea in mind.[475–477] Lesser traumatic injuries can cause subluxation of the shoulder to such a degree that recurrent subluxation rather than dislocation becomes the source of dysfunction.[143]

The predominant pattern of instability is best determined from the patient's medical history and provocative maneuvers on physical examination.[357] The mechanism for a subluxation or recurrent dislocation usually involves a FOOSH injury, whereby the arm is forced into abduction, extension, and ER. Due to the potential for nerve injury with these dislocations, a thorough neurovascular examination is essential.[75]

Anterior Instability

Anterior instability of the G-H joint is the most common direction of instability. Repetitive overhead activities such as throwing can lead to microtrauma at the shoulder, leading to eventual breakdown of both the static and dynamic stabilizers of the joint, or G-H instability. Once the stability of the G-H joint has been compromised, the structures of the rotator cuff can become injured, resulting in a tear of one or more of the muscles. Patients who describe symptoms occurring in the abducted and externally rotated position have chronic anteroinferior instability.

The mechanism for an anterior dislocation is abduction, ER, and extension and is common in throwing and racquet sports, gymnastics, and swimming. Following an acute trauma, the patient typically complains of severe pain and a sense that the shoulder is "out." Radiographs confirm the dislocation, and reduction is often necessary. Frank anterior subluxation and dislocation of the G-H joint is rare in children but common in adolescents.[478] Severe pain causes the patient to immobilize the involved arm, in a slightly abducted and externally rotated position with the other hand. Spasm will typically occur to stabilize the joint. The humeral head will be palpable anteriorly and the posterior shoulder will exhibit a hollow beneath the acromion (see "Special Tests" section). In younger age groups (approximately 25 years and younger), the chance of recurrent anterior dislocation after the initial event is greater than 95%.[479] Recurrences are rare in patients older than 50 years of age.[465]

When anterior instability is suspected, the clinician should assess for tightness of the posterior capsule. Posterior capsule tightness has been shown to accentuate anterior translation and superior migration.[361] Loss of IR in young patients may be an important finding suggestive of posterior capsular contracture that is often associated with subtle instability.[197] The posterior joint glide is also restricted. Symptoms also include varying degrees of instability, transient neurologic symptoms, and easy fatigability.[472] Warner et al.[480] reported a lower IR-to-ER ratio for peak torque and total work in the dominant shoulder of patients with instability as compared with healthy controls. This suggests that an association exists between relative IR weakness and anterior instability.[357]

SLAP Lesions

Athletes performing overhead movements, particularly baseball pitchers, may develop a "dead arm" syndrome[481] in which they have a painful shoulder with throwing and can no longer throw a baseball with their preinjury velocity. The main problem is usually a tear of the superior labrum, the so-called SLAP lesion.[1] SLAP lesions are described as *s*uperior *l*abral lesions that are both *a*nterior and *p*osterior.[482] There are several injury mechanisms that are speculated to be responsible for creating SLAP lesions ranging from single traumatic events to repetitive microtraumatic injuries.[10] During a dislocation, tears to the glenoid labrum occur in isolation or in combination. The superior aspect of the labrum is more mobile and prone to injury due to its close attachment to the LHB tendon.[75] The lesion typically results from a FOOSH injury, sudden deceleration or traction forces such as catching a falling heavy object, or chronic anterior and posterior instability.[482,483]

Traumatic SLAP lesions can also develop in the nonathletic population.[483] This occurs as the result of a fall or motor vehicle accident (e.g., drivers who have their hands on the wheel and sustain a rear-end impact).

SLAP lesions have traditionally been classified into four main types[483] by signs and symptoms:

- ***Type I.*** This type involves a fraying and degeneration of the edge of the superior labrum. The patient loses the ability to horizontally abduct or externally rotate with the forearm pronated without pain.[484]
- ***Type II.*** This type involves a pathologic detachment of the labrum and biceps tendon anchor, resulting in a loss of the stabilizing effect of the labrum and the biceps.[485]
- ***Type III.*** This type involves a vertical tear of the labrum, similar to the bucket-handle tear of the knee meniscus, although the remaining portions of the labrum and biceps are intact.[75]
- ***Type IV.*** This type involves an extension of the bucket-handle tear into the biceps tendon, with portions of the labral flap and biceps tendon displaceable into the G-H joint.[75]

Maffet et al.[486] have suggested expanding the classification scale to a total of seven categories, adding descriptions for types V through VII.

- ***Type V.*** This type is characterized by the presence of a Bankart lesion of the anterior capsule that extends into the anterior superior labrum.
- ***Type VI.*** This type involves a disruption of the biceps tendon anchor with an anterior or posterior superior labral flap tear.
- ***Type VII.*** This is described as the extension of a SLAP lesion anteriorly to involve the area inferior to the middle G-H ligament.

Diagnosis of a SLAP lesion can often be difficult as the symptoms are very similar to those of instability and rotator cuff disease. No findings on physical examination have been found to be specific for identifying patients with a SLAP lesion. The patient typically complains of pain with overhead activities and symptoms of catching or locking.[487]

Several special tests can be used to help identify the presence of a SLAP lesion (see "Special Tests" section), including the O' Brien (active-compression) test, the clunk test,[329,330] the crank test,[332] the Speed's test,[483] the Jobe relocation test, the biceps load test,[345] and the anterior slide test.[340]

Conservative intervention should address the underlying hypermobility or instability of the shoulder using dynamic stabilization exercises of the G-H joint to effectively return function and symptomatic relief to the patient (see "Intervention Strategies" section).

Arthroscopic labral debridement is not an effective long-term solution for labral pathology.[488]

Studies of surgical labral repairs are generally good to excellent in terms of returning patients to their prior level of activity, whether sports or work.[75,487,489,490]

Posterior Instability

Posterior instabilities, which are rare and only comprise approximately 2% of all shoulder dislocations,[159] are often associated with seizure, electric shock, diving into a shallow pool, or motor vehicle accidents. Patients who have a posterior instability pattern typically report symptoms with the arm in a forward flexed, adducted position, such as when pushing open heavy doors. Posterior dislocations are classified as subacromial (posterior and inferior to the acromion process—the most common), subglenoid (posterior and inferior to the glenoid rim), and subspinous (medial to the acromion and inferior to the scapular spine).[75]

The most characteristic sign for a posterior dislocation is a loud clunk as the shoulder is moved from a forward flexed position into abduction and external rotation, a positive finding that is often misdiagnosed as an anterior dislocation. The findings for a posterior dislocation are usually severe pain, limited ER, often to less than 0 degree, and limited elevation to less than 90 degrees. There is usually a posterior prominence and rounding of the shoulder as compared to the opposite side, and a flattening of the anterior aspects of the shoulder. Looking down at the patient's shoulders from behind can best assess these asymmetries.

Inferior Instability

Inferior dislocations are very uncommon and are typically elicited by carrying heavy objects at one's side (i.e., grocery bags or a suitcase), or by hyperabduction forces that cause a levering of the humeral neck against the acromion.[464,488]

The diagnosis for this type of dislocation is relatively straightforward, as the patient's arm is typically locked in abduction.[75] The sulcus sign can be used to assess inferior stability.

Multidirectional Instability

Multidirectional instability is a symptomatic G-H instability that is present in more than one direction.[464] It is commonly believed that females have more joint laxity than males, a fact propagated by the medical literature and medical training.[357] In describing multidirectional instability of the shoulder, a typical patient is presented, as "an adolescent female who can habitually and reproducibly sublux one or both shoulders."[468] However, with the exception of a few articles, there is inadequate evidence to confirm this view. One of the exceptions was a recent study by Borsa et al., [491] which demonstrated that healthy women have significantly more anterior joint laxity and less anterior joint stiffness than do men. Another study by Huston and Wojtys[492] used an instrumented arthrometer to assess knee joint laxity in athletic and nonathletic men and women. Overall, they found women to have significantly more knee joint laxity than men. Interestingly, they found that athletic women had significantly less knee joint laxity than nonathletic women did, and athletic men had significantly less knee joint laxity than nonathletic men. These findings imply that physical training and conditioning may decrease joint laxity.[491]

The patient with a multidirectional instability is difficult to diagnose as there is usually no associated traumatic event or mechanism of injury. Rotator cuff pain is often the first presenting symptom. Patients with multidirectional instability typically have scapulothoracic dyskinesia that contributes to the instability.[283]

Lephart et al.[493] showed that patients with multidirectional instability also have deficits in shoulder proprioception. Therefore the intervention for patients with instability should begin with a rehabilitation program aimed at improving the dynamic stabilizers, neuromuscular coordination, and proprioception of the G-H and scapulothoracic joints.[24,357,494]

Intervention

Intervention goals for G-H instability or hypermobility are similar regardless of the instability classification. The goal is to restore dynamic stability and control to the shoulder using the dynamic stabilizers to contain the humeral head within the glenoid.[19,119,159,470,494]

A brief period of sling immobilization is usually necessary for comfort. Prolonged immobilization should be avoided because of the tendency of the shoulder to stiffen quickly, especially in the elderly population.[195] For patients with an anterior instability, ROM exercises for the G-H joint should emphasize posterior capsule stretching to decrease the accentuation of the anterior translation and superior migration. The positions and exercises to modify or avoid based on the direction of instability are illustrated in Table 16-37.[495]

The general approach for all forms of G-H instability includes the following:

TABLE 16-37 Exercise Modification According to the Direction of Glenohumeral Instability		
Direction of Instability	**Position to Avoid**	**Exercises to Modify or Avoid**
Anterior	Combined position of external rotation, extension, and abduction	Chest press, pull-down, push-up, bench press, military press, flyes
Posterior	Combined position of horizontal adduction, internal rotation, and flexion	Chest press, push-up, bench press, flyes, weight-bearing exercises
Inferior	Full elevation, dependent arm	Shrugs, elbow curls, incline press, military press

- ***Scapular stability exercises.*** These can be started early and include the scapular pinch (see Fig. 16-27) and shoulder shrug exercises.[24] In this early stage, the control of the scapula position can be aided by taping the scapular in a retracted or elevated position, or by the use of a figure-8 collar, both of which help to normalize the scapular muscle firing pattern.[24]
- ***Closed-chain exercises.*** These are normally performed with the hand stabilized on a wall or object, simulate normal functional patterns, and reorganize and reestablish normal motor firing patterns.[24,144,145,281] All of the movements of the scapula and shoulder are coupled and are predictable based on arm position.[170,496] Similar to the lower extremity, closed-chain exercises should involve integration of all the joints in the appropriate kinetic chain with the specific scapular maneuvers of elevation, depression, retraction, and protraction.[24]
- ***Early exercises to rehabilitate scapular dyskinesis.*** These include modified push-ups, and progress to facilitation patterns that include hip extension, trunk extension, and scapular retraction.[395] Clock exercises, in which the hand is placed on a wall and the scapula is rotated in elevation/depression and retraction/protraction, also develop coordinated patterns for scapular control.[395]

Open-chain exercises follow the isometric and closed-chain activities as these exercises are more strenuous.[24] Open-chain exercises include PNF patterns, diagonals, upright rows, and ER and scapular retraction activities, as well as machine exercises consisting of lat pull-downs.[24]

Progression of the scapular rehabilitation can be evaluated using the scapular slide measurements, and once the lateral slide asymmetry is less than 1 cm, specific strengthening for the rotator cuff can commence.[24]

Besides rehabilitation, activity modifications to avoid any arm positions that provoke symptoms can be helpful.[357]

Sprained Conoid and Trapezoid Ligaments

A sprain of these ligaments can result from a clavicular fracture, but it can also occur in sports that require the arm to be pulled into the extremes of extension or ER. Pain is felt at the extremes of all passive arm and scapula movements. Forced ER with the arm in horizontal abduction will usually be the most painful test, and differentiation between the two structures is made by palpation of the coracoid process. No limitation of active shoulder range is usually found and resistive movements are painless.

Interventions for these ligament sprains include electrotherapeutic modalities and physical agents, transverse friction massage (TFM), and progression of ROM of the shoulder complex and strengthening of the G-H muscles and scapular pivoters.

Acromioclavicular Joint Sprain

An injury to the A-C joint, which is one of the most frequently injured joints in the body, can be categorized as either acute traumatic or chronic.[71] The majority of acute traumatic injuries occur from a fall onto the shoulder with the arm adducted at the side. The ground reaction force produces displacement of the scapula in relation to the distal clavicle.[71] The chronic disorder may be atraumatic or posttraumatic, with the former being attributed to generalized osteoarthritis, inflammatory arthritis, or mechanical problems of the meniscus of this joint.[195] Injuries to the A-C joint were originally classified by Tossy et al.[497] and Allman[89] as incomplete (grades I and II) and complete (grade III). This classification has been expanded to include six types of injuries based on the direction and amount of displacement (Table 16-38).[80,498–500] As with the S-C joint, A-C joint injuries are classified according to ligamentous injury rather than injury to the joint itself:

- ***Type I.*** Tenderness and mild pain at the A-C joint. Sometimes there is a high, painful arc (160–180 degrees), and resisted adduction is painful. Passive A-P joint gliding is painful, especially in patients over 50 years of age.[501]
- ***Type II.*** Moderate to severe local pain with tenderness in the coracoclavicular space. The clavicle may appear to be slightly higher than the acromion, although in reality the opposite is true. All passive motions are painful at the end of ROM, and usually both resisted adduction and abduction are painful. Passive posteroanterior translation at the A-C joint is greater than that of the opposite joint.
- ***Type III.*** The patient usually holds the arm against the body in a slightly adducted position and exerts an upward axial pressure through the humerus. An obvious gap is visible between the acromion and the clavicle. All active motions are painful, especially abduction. The piano key phenomenon is present; after pushing the clavicle inferiorly, it springs back to its original position.
- ***Type IV.*** Similar findings as those of type III, except the pain is severe and the clavicle is displaced posteriorly.
- ***Type V.*** There is a large distance between the clavicle and coracoid process and there is tenderness to palpation over the entire lateral half of the clavicle.

TABLE 16-38	Classification of A-C Injuries and Clinical Findings
Type I	Isolated sprain of acromioclavicular ligaments Coracoclavicular ligaments intact Deltoid and trapezoid muscles intact Tenderness and mild pain at A-C joint High (160–180 degrees) painful arc Resisted adduction is often painful Intervention is with TFM, ice, and pain-free AROM
Type II	A-C ligament is disrupted Sprain of coracoclavicular ligament A-C joint is wider; may be a slight vertical separation when compared to the normal shoulder Coracoclavicular interspace may be slightly increased Deltoid and trapezoid muscles intact Moderate-to-severe local pain Tenderness in coracoclavicular space PROM all painful at end range with horizontal adduction being the most painful Resisted abduction and abduction are often painful Intervention initiated with ice and pain-free AROM/PROM; TFM introduced on day 4
Type III	A-C ligament is disrupted A-C joint dislocated and the shoulder complex displaced inferiorly Coracoclavicular interspace 25–100% greater than normal shoulder Coracoclavicular ligament is disrupted Deltoid and trapezoid muscles are usually detached from the distal end of the clavicle A fracture of the clavicle is usually present in patients under 13 yr of age Arm held by patient in adducted position Obvious gap visible between acromion and clavicle AROM all painful; PROM painless if done carefully Piano key phenomenon (clavicle springs back after being pushed inferiorly) present
Type IV	A-C ligament is disrupted A-C joint dislocated and the clavicle anatomically displaced posteriorly into or through the trapezius muscle Coracoclavicular ligaments completely disrupted Coracoclavicular interspace may be displaced but may appear normal Deltoid and trapezoid muscles are detached from the distal end of the clavicle Clavicle displaced posteriorly; Surgery indicated for types IV–VI
Type V	A-C ligaments disrupted Coracoclavicular ligaments completely disrupted A-C joint dislocated and gross disparity between the clavicle and the scapula (300–500% greater than normal) Deltoid and trapezoid muscles are detached from the distal end of the clavicle Tenderness over entire lateral half of the clavicle
Type VI	A-C ligaments disrupted Coracoclavicular ligaments completely disrupted A-C joint dislocated and the clavicle anatomically displaced inferiorly to the clavicle or the coracoid process Coracoclavicular interspace reversed with the clavicle being inferior to the acromion or the coracoid process Deltoid and trapezoid muscles are detached from the distal end of the clavicle Cranial aspect of shoulder is flatter than opposite side; Often accompanied with clavicle or upper rib fracture and/or brachial plexus injury

AROM, active range of motion; PROM, passive range of motion; TFM, transverse friction massage.
Data from Allman FL. Fractures and ligamentous injuries of the clavicle and its articulation. *J Bone Joint Surg Am* 1967;49:774–784; Rockwood CA Jr, Young DC. Disorders of the acromioclavicular joint. In: Rockwood CA Jr, Matsen FA III, eds. *The Shoulder*. Philadelphia, PA: WB Saunders, 1990:413–468.

- ***Type VI.*** The superior aspect of the affected shoulder is flatter than the noninvolved side. Often there are associated fractures of the clavicle and upper ribs, as well as injury to the brachial plexus.

Types I–III and V all involve inferior displacement of the acromion with respect to the clavicle. They differ according to the severity of ligamentous injury and the amount of resultant displacement.[173]

Types I and II typically result from a fall or a blow to the point on the lateral aspect of the shoulder, or a FOOSH injury.

Types III and IV usually involve a dislocation (commonly referred to as an A-C separation) and a distal clavicle fracture, both of which commonly disrupt the coracoclavicular ligaments.[71] In addition, damage to the deltoid and trapezius fascia, and rarely the skin, can occur.[71] Type IV injuries are characterized by posterior displacement of the clavicle.

Type VI injuries have a clavicle inferiorly displaced into either a subacromial or subcoracoid position. These types (IV, V, VI) also have complete rupture of all the ligament complexes and are much rarer injuries than types I through III.[71]

In the pediatric patient, A-C sprains are usually grade I or II and may occur without clavicular fracture.[478] Grade III sprains in this population commonly rupture the posterior (dorsal) clavicular periosteum. However, the coracoclavicular ligaments and A-C ligaments remain intact.[478]

The clinical findings are based on injury severity (Table 16-38). Patients who have suffered an injury to the joint typically present with a history of either a distinctive, traumatic mechanism of injury or a more insidious type of onset that began with pain and dysfunction.[73] The joint is quite superficial and direct palpation is accomplished easily. The patient may report that the arm feels better with a superiorly directed support on the arm, such as a sling. Pain is typically reproduced at the end range of passive elevation, passive ER and IR, and especially with passive horizontal adduction, across the chest. This cross-arm test compresses the A-C joint and is highly sensitive for A-C joint pathology.[71,74,80,502] The ROM available depends on the stage of healing and severity. In the very acute stage, range may be limited by pain, whereas the less acute stage will be painful at the end of range in full elevation or horizontal adduction. Pain, crepitus, or hypermobility may be encountered with mobility testing. Resistive movements are usually painless. It is important to assess for secondary injury to the surrounding soft tissues and to the other three articulations of the shoulder complex when there is a history of trauma to the A-C joint.

A complete radiographic examination including a 15-degree-superior A-P view, a lateral Y view, and an axillary film should confirm the diagnosis.[71]

The intervention for A-C joint sprains depends on the severity of the injury and the physical requirements of the patient.

- ***Types I and II.*** These patients will usually recover full and painless function with conservative intervention.[74] Although adhesive taping devices and orthotics have been used in the early phase after injury to attempt reduction of the clavicle in the type II injury, they have not demonstrated efficacy in any good experimental trials.[71] Ice, nonsteroidal anti-inflammatories, and analgesics should be used judiciously. Most physicians prescribe a sling for 1–2 weeks. Gentle ROM exercises and functional rehabilitation are started immediately following immobilization, and then isometric exercises are prescribed for those muscles with clavicular attachments. The exercises are progressed to PREs for the muscles that attach to the clavicle and the scapular pivoters. A graduated return to full activity is very important. Most patients will be back to full sport/occupation participation within 12 weeks, although they may have a slight cosmetic deformity.[71]
- ***Type III.*** The intervention for type III injuries is controversial.[71] A survey of orthopaedic residency programs in 1992 revealed that 86.4% preferred conservative intervention.[503] The natural history of this injury with conservative intervention suggests that patients have no long-term difficulty with pain or loss of function.[504–508] A more recent study[509] found no strength deficits at follow-up, although discomfort at higher levels of activity was more pronounced. There is a reported high complication rate with attempts at surgical stabilization.[510,511] Citing the concern regarding greater displacement, some authors have proposed surgical intervention, but there have been several controlled comparative studies[502,510,511] that suggest that conservative intervention gave results comparable to those of surgically treated patients, but without surgical complications.[71]

A reasonable approach would be to initially treat all types conservatively with sling immobilization, followed by supervised rehabilitation.[71] Once the sling is removed, pendulum exercises can be initiated. PROM in the extremes of motion are avoided for the first 7 days, but the goal should be for full PROM after 2–3 weeks. A graduated resistance exercise program is initiated once pain is improved and AROM is full. These exercises should emphasize strengthening of the deltoid and upper trapezius muscles and promote dynamic stabilization of the shoulder complex.[198] Full return to sport is expected by 6–12 weeks.[71] If patients are still functionally limited after more than 3 months, a secondary reconstructive procedure may be necessary.[71]

- ***Types IV, V, and VI.*** These types of displacement all require surgical intervention.[74] Care should be taken to accurately identify these injuries and refer them early to a surgical specialist.[71] The greater displacement and injury includes damage to the deltoid and trapezius muscle and fascia. Failure to reduce these and repair them may lead to chronic pain and dysfunction.[71] The postsurgical progression involves gaining pain-free ROM prior to advancing to exercises to regain strength, manual techniques to normalize arthrokinematics, and functional training to improve neuromuscular control of the shoulder complex.

Late complications, including degenerative changes of the distal clavicle, can develop with a subluxed clavicle.[71] Symptoms may be treated with the selective use of modalities and steroid injections. If this conservative approach fails, then the patient should be considered as a surgical candidate.[71]

Acromioclavicular Joint Arthrosis

A-C joint arthrosis may be degenerative or posttraumatic. It is most commonly seen in middle-aged patients, either as an

isolated entity or in combination with rotator cuff tendinitis and impingement syndrome.[71,74]

A-C joint arthrosis is diagnosed by the history and physical examination. Patients typically complain of pain locally or distributed to the anterolateral neck, the trapezius–supraspinatus region, and the anterolateral deltoid.[512] This pain is usually exacerbated with overhead and/or flexed and adducted positions of the arm.[71] Direct palpation to the A-C joint will sometimes reproduce the patient's pain. Impingement of the rotator cuff must be ruled out. The selective use of cortisone injections into the A-C joint or the subacromial space can be applied to help differentiate A-C pain from rotator cuff tendinitis and treat both of these conditions.[71,74]

Conservative intervention consists of rest, modification of activity, and NSAIDs. Electrotherapeutic modalities and cryotherapy may be used to control pain and the active inflammation. Joint mobilizations of grade I or II may also be used to decrease pain. Once pain and inflammation are under control, the rehabilitation progresses to strengthening of the dynamic restraints of the A-C joint (primarily the deltoid, trapezius, and pectorals).[74,198] Any activities involving raising the arm above the level of the shoulder or reaching across the chest should be avoided as these will tend to aggravate the A-C joint.[195]

Sternoclavicular Joint Sprain

The S-C joint can sustain sprains, dislocations, or other injuries, but is less involved than the A-C joint with osteoarthritis or mechanical conditions.[195] Posterior S-C dislocations, although rare, are frequently delayed in their diagnosis, and can even be life-threatening due to the pressure placed on many vital structures lying between the sternum and the cervical spine such as the trachea, esophagus, and major blood vessels. However, most of these dislocations occur anteriorly and are more obvious.[190]

Any trauma to the shoulder girdle may cause an S-C dislocation, although the joint is most commonly injured through motor vehicle accidents, followed by sports.[91] In sports, the mechanism of injury is usually secondary to a FOOSH with the arm in either a flexed and adducted position, or extended and adducted position.[470] The well-developed interarticular meniscus can be torn and can lead secondarily to degenerative changes. Irritation of this joint may also occur in inflammatory conditions, such as rheumatoid arthritis or repetitive microtrauma.[192] Infection of this joint usually indicates a systemic source, such as bacterial endocarditis.[195]

An injury to the S-C joint can be significant because the joint plays an integral role in scapular motion through the clavicle's articulation with the scapula. Subjectively, the patient reports discomfort with end-range movement of the shoulder. S-C injuries are graded according to severity of injury to the ligament supporting the joints rather than injury to the joint itself.[66]

- ***Type I.*** Sprain of S-C ligament.
- ***Type II.*** Subluxation, partial tear of capsular ligaments, disk, or costoclavicular ligaments.
- ***Type IIA.*** Anterior subluxation; this is the most common grade.
- ***Type IIB.*** Posterior subluxation.[192]
- ***Type IIIA.*** Anterior dislocation.
- ***Type IIIB.*** Posterior dislocation.
- ***Type IV.*** Habitual dislocation (rare).

The clinical presentation for S-C sprains are characterized by deformity, local pain or tenderness, and subsequent ecchymosis. With a posterior dislocation or subluxation, some shortness of breath or even venous congestion in the neck may be seen, with decreased circulation sometimes evident in the arm.[73]

Chronic subluxation or damage to the intra-articular disk can produce long-term discomfort with repetitive strong movements of the upper limb and therefore may require surgical stabilization of the S-C joint.[73]

The conservative intervention for first- or second-degree sprains (providing that the joint is deemed stable) is aimed at addressing the function of the shoulder complex, particularly the end ranges, and is dependent on the cause. Typically the shoulder is immobilized for 3–4 days, as pain dictates. In more severe sprains (second- or third-degree sprain with instability following reduction), a shoulder sling or figure-8 strap is worn for 2–3 weeks to minimize stress on the joint, and then the arm may be protected for a further 2 weeks.

- Appropriate modalities are used to control pain and the inflammatory process.
- ROM exercises are initiated early, and care is taken to avoid excessive movement at the S-C joint. Initially, until the pain and inflammation is under control, activities should be limited to midrange. ROM is increased based on patient tolerance.
- Any hypomobilities of the neighboring joints are addressed using specific mobilizations of an appropriate grade.
- In cases with residual ligamentous laxity, stabilization exercises should focus on strengthening those muscles that attach to the clavicle (pectoralis minor, sternal fibers of the pectoralis major and upper trapezius), performed within ranges that do not stress the joint. Exercises include incline bench, shoulder shrugs, and the seated push-up.[513] The scapular pivoters should also be strengthened. For example, exercises such as Superman, bent over row, rhomboids, and push-ups with a plus should be included.[513]
- Return to normal activity is permitted when the patient no longer has associated pain with movements of the shoulder complex, and the rehabilitation program has been progressed to the appropriate level of stress for the specific demands of the patient's activity.

Complications of anterior S-C dislocation include cosmetic deformity, recurrent instability, and late osteoarthrosis.[73] Complications of posterior dislocation include all of these plus pressure or rupture of the trachea, pneumothorax, rupture of the esophagus, pressure on the subclavian artery of brachial plexus, voice changes, and dysphagia.[73]

Total Shoulder Arthroplasty

A total shoulder arthroplasty (TSA) is a surgical option typically reserved for elderly patients with cuff-deficient

arthritic shoulders.[514] Other patients who may require a TSA include those with bone tumors, rheumatoid arthritis, Paget's disease, osteonecrosis of the humeral head, fracture dislocations, and those who incur recurrent dislocations.[515,516]

The primary indication for surgical intervention is complaints of unremitting pain, rather than decreased motion, and a failure of conservative measures. Additional considerations include patient age, activity level, job requirements, and general health.[514]

A course of preoperative intervention is recommended. This should include an assessment of ROM, scapular mobility, muscle imbalances, and pain. The key muscles to examine preoperatively for strength include the rotator cuff, deltoid, trapezius, rhomboids, serratus anterior, latissimus dorsi, teres major, and pectoralis major and minor.[254] The patient should be provided with exercise instruction and patient education on postsurgical precautions. A course of shoulder stretching before a prosthetic arthroplasty may improve postsurgical function.[517]

The TSA is a very difficult procedure, and the outcome depends on the skill of the reconstruction, the soft tissue repair, the orientation of the implants, and the success of the rehabilitation.[405,515,518,519] The total shoulder replacement provides significantly greater pain relief than hemiarthroplasty, with approximately 80% of patients reporting pain relief after hemiarthroplasty versus more than 90% after shoulder replacement.[519]

Four types of replacement components have traditionally been used:

1. ***Unconstrained.*** This is the most widely used component and consists of a humeral component that exists with a scapular component.
2. ***Constrained.*** This type, in which the glenoid and humeral components are coupled and fixed to bone, was designed for patients who had severe deterioration of the rotator cuff but with a functioning deltoid. However, due to the high rate of associated complications, it is rarely used nowadays.
3. ***Reversed ball and socket.*** This design consists of a small humeral socket that slides on a larger ball-shaped glenoid component.
4. ***Semiconstrained.*** This type involves the use of a smaller and spherical humeral head with a head–neck angle of 60 degrees, which reportedly permits increased ROM.

The unconstrained technique and the postsurgical rehabilitation that follows this procedure are described in this section.

Although surgical techniques vary, most involve the dissection of the subscapularis or a rotator cuff repair, or a combination of both. The patient is usually placed in a sling or an elastic shoulder immobilizer following the operation that positions the humerus in adduction, IR, and slight forward flexion. An abduction splint may be issued if a rotator cuff repair is performed and is worn for 4–6 weeks, according to the surgeon's instructions.

The long-term outcome following shoulder arthroplasty depends on many factors including the quality of the soft tissue (especially the integrity of the rotator cuff), the quality of the bone, the type of implant and fixation used, the patient's expectations, and the quality of the rehabilitation program.[254] Most surgeons have their own postsurgical rehabilitation protocols—only the surgeon knows the extent of soft tissue damage and repair, and any guidelines communicated to the clinician must be strongly adhered to. Typically, the only motions not allowed in the early weeks are active IR and active and passive ER beyond 35–40 degrees.

PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION WITH LOCALIZED INFLAMMATION

In addition to those conditions producing impaired ROM, motor function, and muscle performance attributed to inflammation, this pattern includes conditions that cause pain and muscle guarding without the presence of structural changes. Such conditions include rotator cuff tears, tendinitis, bursitis, capsulitis, and tenosynovitis.

Rotator Cuff Pathology

Fifty to seventy percent of shoulder issues seen by clinicians are related to conditions of the rotator cuff (RC).[520,521] The frequency of RC problems is not surprising as these structures play an essential role in supporting the shoulder capsule and holding the humeral head in proper alignment in the glenoid cavity. Problems can occur from a number of sources including trauma, attrition, and the anatomical structure of the subacromial space. The supraspinatus is the tendon most often affected because of its location beneath the anterior acromion, and its extensions into the infraspinatus tendon that may also become involved.[522,523] Significant tears of the RC rarely involve the subscapularis tendon.[522,523]

A number of mechanisms are recognized and include compression, tensile overload, and macrotrauma.

- ***Compression.*** Compression of the RC can either be primary or secondary. Primary compression is due to a reduction in the size of the subacromial space (e.g., a type III hooked acromion process or a congenitally thick coracoacromial ligament in younger patients, or an osteophyte on the undersurface of the acromion process in the older patient). Secondary compression occurs as a result of a decrease in G-H joint stability that allows the humeral head to compress the RC.
- ***Tensile overload.*** Tension overload can also be either primary or secondary. Primary tensile overload occurs when the RC attempts to resist horizontal adduction, IR, anterior translation, and distraction forces during such activities as throwing (the deceleration phase) and hammering. Secondary tensile overload occurs as a result of G-H instability that places greater distractive and tensile forces on the RC, and eventual failure of the tendon.
- ***Macrotrauma.*** Macrotrauma and subsequent tearing of the tendon results when the forces generated by the trauma

exceed the tensile strength of the tendon. RC tears are not as common in the skeletally immature athlete as in the older athlete. Indeed, the incidences of RC tear increases with age. Approximately 50% of individuals older than 55 years demonstrated an arthrographically detectable RC tear.[524] Although cadaver studies of individuals older than 40 years have generally shown a prevalence of full-thickness RC tears between 5% and 20%,[525] the prevalence of partial-thickness RC tears has been shown to be in the 30–40% range in adult cadavers.[525]

A detailed history is important to diagnose a RC injury and the cause, and it can help to determine whether the patient's symptoms are related to a specific injury or event, or to a repetitive motion, or are of a more insidious onset (e.g., referred pain from the cervical spine, more serious referred symptoms of cardiac origin). Activities and arm positions that increase or decrease symptoms are also helpful in diagnosing and guiding treatment. Prior episodes of similar symptoms may give a useful clue to the patient's present condition. A social history should include the patient's occupation and sport (including position), and level of athletic participation. Repetitive motion can be associated with the symptoms. The presence of associated symptoms (e.g., instability, weakness, swelling, numbness, loss of motion, catching or popping of the shoulder) also provides helpful information.

Pain, weakness, and loss of shoulder motion are common symptoms reported with RC pathology. The patient complains initially of a dull ache radiating into the upper and lower arm. This ache is worse after activity, at night when the patient lies on the affected shoulder, and with actions such as reaching above the head or putting on a coat. The characteristic physical finding is the painful arc. The pain may begin around 50–60 degrees of abduction in patients with shoulder immobility. The symptoms may be relatively acute, either following an injury or associated with a known repetitive overuse activity.

In elderly patients, symptoms are often insidious and with no specific injury.

The clinician can often determine the involved tendon by resisting the AROM of each tendon.

Palpable anterior tenderness over the coracoacromial ligament is common with impingement.[28,526] Tenderness of the biceps tendon and at the supraspinatus insertion is also commonly found.

Patients with a painful arc and the above history, but no pain to resisted shoulder movements, are likely to have subacromial–subdeltoid bursitis.[195]

A study by Park et al.[527] evaluated eight physical examination tests for RC pathology (the Neer impingement sign, Hawkins–Kennedy impingement sign, painful arc sign, supraspinatus muscle strength test, Speed test, cross-body adduction test, drop-arm sign, and infraspinatus muscle strength test) to determine their diagnostic values, including likelihood ratios and posttest probabilities, for three degrees of severity in RC disease: bursitis, partial-thickness RC tears, and full-thickness RC tears. The sensitivity, specificity, positive predictive value, negative predictive value, and overall accuracy of the eight tests varied considerably—the combination of the Hawkins–Kennedy impingement sign, the painful arc sign, and the infraspinatus muscle test yielded the best posttest probability (95%) for any degree of impingement syndrome. The combination of the painful arc sign, drop-arm sign, and infraspinatus muscle test produced the best posttest probability (91%) for full-thickness RC tears.[527] The study concluded that the severity of the impingement syndrome affects the diagnostic values of the commonly used clinical tests and that the variable accuracy of these tests should be taken into consideration when evaluating patients with symptoms of RC disease.[527]

RC tears are described by size, location, direction, and depth.

Weakness to some extent always accompanies RC tears. The amount of weakness is directly related to the size of the tear.[1] For example, with small tears, the weakness may not be detected and the patient may have full ROM, although there may be a painful arc. Massive tears of the RC present with sudden profound weakness with an inability to raise the arm overhead, and exhibit a positive "drop-arm" sign (see "Special Tests" section).[528] In this situation, infiltration of the subacromial space with a local anesthetic may eliminate the pain and allow more accurate testing of the muscle–tendon unit. The use of corticosteroid injections for RC tears to promote healing is controversial because of their association with weakening the integrity of tendons with repeated use. Some studies have supported this belief,[39,529–531] although only one case of RC rupture following steroid injection has been reported in the literature.[529] Two recent studies have demonstrated that corticosteroid injections are more effective than anti-inflammatory drugs in the management of RC problems.[532,533] However, if the patient has not responded to 1–2 well-placed injections, either other intervention modalities should be considered or the diagnosis questioned.

Acute massive tears require prompt evaluation for surgical repair because little is known about the efficacy of conservative intervention.[1,295,534–541] However, the patient may decide against surgery for various reasons, including concerns about a successful repair, surgical risks, or lack of functional improvement.[542] The conservative program for full-thickness RC tears is directed toward stretching and strengthening the remaining RC, deltoid, pectoralis major, and trapezius muscles.[521,543] The postsurgical approach is initiated with some form of immobilization that restricts positions based on the surgical repair, and promotes pain control. For example in open repairs, flexion, and abduction might be restricted for as long as 4 weeks, or if the capsulolabral complex has been repaired the patient might spend up to 2 weeks in an airplane or ablation splint.[513] Exercises in the early phase include shoulder shrugs, isometrics, and then AAROM exercises. Once the subacute stage of healing has been achieved, the focus of the rehabilitation program is to regain full ROM and to gradually increase the stress to healing tissue. At this stage, AROM exercises are initiated before progressing to gradual resistance using surgical tubing with a focus on the restoration of normal arthrokinematics and a normal scapulothoracic rhythm.[513] The rehabilitation during the final stage of healing mirrors that of conservative management.

The conservative intervention for patients with a partial tear varies. If the symptomatic tear is partial, then a period of conservative intervention should be attempted.[501,521,544,545]

TABLE 16-39 Specific Strengthening Exercises for the Shoulder Girdle

Muscle	Exercise
Middle trapezius	Prone row Prone horizontal abduction with the arm and 90-degree abduction with ER
Lower trapezius	Prone horizontal at 90-degree abduction with ER Prone full can Prone ER at 90-degree abduction Bilateral ER
Upper trapezius	Shoulder shrugs Prone row Prone horizontal abduction at 90-degree abduction with ER
Supraspinatus	Full can Prone full can
Infraspinatus and teres minor	Sitting, external rotation of the arm with a towel roll Side-lying external rotation Prone ER at 90-degree abduction
Rhomboids and levator scapulae	Prone row Prone horizontal abduction at 90-degree abduction hip ER Prone extension with ER
Serratus anterior	Dynamic hug Push-up with plus Serratus punch 120°
Subscapularis	Lift-off (Gerber) IR at 0-degree abduction IR at 90-degree abduction IR diagonal exercise Shoulder dumps
Deltoid	Side-lying, 45-degree abduction

Data from Reinold MM, Escamilla RF, Wilk KE: Current concepts in the scientific and clinical rationale behind exercises for glenohumeral and scapulothoracic musculature. *J Orthop Sports Phys Ther* 39:105–117, 2009.

- Stage I. The focus of early rehabilitation is the reduction of pain and inflammation through modalities, activity modifications, and NSAIDs prescribed by the physician. Jobe and Nuber[184] describe a program of kinesiologic repair that strengthens the RC (to increase the depressor effect on the humeral head) and the scapular pivoters, but avoids any increase in the elevating effect of the deltoid. The mainstays of this strengthening program are the IR and ER exercises (Table 16-39).[251] These are initially performed as isometric exercises at various parts of the range. Once these are tolerated well, concentric exercises of the scapular pivoters are introduced beginning with manual resistance and progressing to free weights (see "Intervention Strategies" section). Care should be taken with exercises that involve the use of weights with the arm flexed or abducted away, or overhead, as these may exacerbate supraspinatus impingement and tendinitis symptoms if performed in the early stages of rehabilitation. The exercises prescribed should be as specific as possible, and tailored to the patient's functional and athletic goals. The lower extremity and trunk muscles that provide core stability should also be strengthened. Deficits in strength, strength imbalances, and flexibility in the legs, hips, and trunk should be addressed. This is particularly so in throwing athletes, where restrictions of the hip and back motion are common.[35,48,144,151]

Manual techniques can be used to address any tightness in the capsule (usually the posterior and inferior aspects) or motion restrictions of the S-C or A-C joints (see "Therapeutic Techniques" section). The patient should be instructed on how to perform an isolated posterior capsule stretch.

- Stage II. Restoration of ROM using exercises, stretching techniques, and self-mobilization. During this stage, the patient should be exercising with free weights, with an emphasis on eccentric exercises of the RC. Concentric exercises for the upper trapezius and deltoid are added. These include shoulder flexion, and reverse flys. The serratus anterior is strengthened using push-ups and the push-up plus. Neuromuscular retraining exercises for the shoulder complex include rocking on all fours, and the Fitter board, as appropriate. Plyometric exercises using small medicine balls and push-ups with a hand clap are also included during this stage as appropriate. Neuromuscular techniques can also be applied manually and include quick reversals during PNF patterns. Other manual techniques include stretching of the capsule and any other pericapsular structures that appear tight.
- Stage III. PNF diagonal patterns are initiated in this stage in addition to eccentric exercises of the RC. Typical exercises performed in this stage include the military press, reverse flies, and push-ups.
- Stage IV. Plyometric strengthening and sport/activity specific training with a gradual return to normal activity.

Subacromial Impingement Syndrome

SIS is a recurrent and troublesome condition closely related to RC disease.[546] In the presence of a normal RC, normal scapular pivoters, and no capsular contractures, the humeral head translates less than 3 mm superiorly during the midranges of active elevation, whereas at the end ranges, A-P and superoinferior translations of 4–10 mm do occur, all of which are coupled with specific motions of IR or ER.[19,48,153,252,280,547–550] An increase in superior translation with active elevation may result in encroachment of the coracoacromial arch.[40,547] This encroachment produces a compression of the suprahumeral structures against the anteroinferior aspect of the acromion and coracoacromial ligament. Repetitive compression of these structures, coupled with other predisposing factors, results in a condition called SIS. SIS was first recognized by Jarjavay[551] in 1867, and the term *impingement syndrome* was popularized by Neer[40] in the 1970s.

Both intrinsic and extrinsic factors have been implicated as etiologies of the impingement process, and a number of

impingement types have evolved. Two of those types include the outlet (intrinsic/internal) impingement and the nonoutlet (extrinsic/external) impingement (Fig. 16-64).

Outlet (Intrinsic or Internal) Impingement

This type of impingement occurs as a result of abnormal contact between the RC undersurface and the posterosuperior glenoid rim (Fig. 16-64). The etiology of posterosuperior glenoid impingement has been a source of much debate. Neer[40] proposed that a tight or crowded subacromial space (e.g., one in which the space is compromised by an anterior acromial osteophyte) could cause a mechanical abrasion of the RC against the acromion with abduction above 80–90 degrees without concomitant ER. Others have attributed internal impingement secondary to anterior microinstability and tightness of the capsule posteriorly.

Whatever the underlying cause, the abrasion of the soft tissue structures located between the head of the humerus and the roof of the shoulder during elevation of the arm produces an irritation, inflammation, and tearing of the RC muscles, an irritation of the LHB, and subacromial bursitis.[58,552,553]

This type of impingement is known as an *outlet impingement*, because it occurs at the supraspinatus outlet formed by the coracoid process, the anterior acromion, the A-C joint, and the coracoacromial ligament. It clinically manifests as a "painful arc." A painful arc describes a region of pain in a particular motion, which has pain-free areas on either side of it.[317] For example, during abduction the patient may feel an onset of pain at 80 degrees, which then disappears at 100 degrees. The general cause of a painful arc is impingement of a tender subacromial structure during motion, although loose bodies and instabilities may also cause a painful arc.

Although Neer and Poppen[554] reported that 90–95% of RC tears were the result of the outlet subacromial impingement, the role of age-related or senescent degeneration and tensile overload has been emphasized more recently (see later).[552,553,555–559]

Nonoutlet (Extrinsic/External) Impingement

Nonoutlet impingement, sometimes referred to as posterior internal impingement, in which the subacromial space appears to be normal, occurs in the younger patient performing repetitive overhead motions. The mechanism in this condition appears to be an impingement of the RC against the posterior superior glenoid labrum and the humeral head during forced humeral elevation and IR. This can eventually result in posterior superior tears in the glenoid labrum, and lesions in the posterior humeral head (Bankart lesion).

Primary and Secondary Impingement

Two other types of impingement, which relate to chronic disorders of the RC, have been proposed with four subclassifications (Table 16-40):[98,560]

- Primary (anterior) impingement refers to an intrinsic degenerative process in the structures occupying the subacromial space, which occurs when the superior aspect of the RC is compressed and abraded by the surrounding bony and soft tissues due to anatomical crowding, posterior capsular tightness, and/or excessive superior migration of the humeral head.[561] Patients with primary impingement are typically over the age of 40 and present with limited horizontal abduction (as compared with the uninvolved side), and limited IR (<50 degrees). This condition, commonly treated operatively, often is the result of cyclical repetitive abduction, forward flexion, and IR motion at the G-H joint.
- Secondary (coracoid) impingement occurs when the lesser tuberosity of the humerus encroaches on the coracoid process. The primary cause is G-H instability and/or tensile overload of the RC resulting in poor control of the humeral head during overhead activities involving forward flexion, IR, and abduction.[98,560,562] Secondary impingement is a condition found in both older and younger individuals with varying levels of activity, although patients in this group are usually younger than 35 years, have a history of traumatic anterior instability, a posterior defect of the humeral head, and damage to the posterior glenoid labrum. These individuals typically present with limited IR, excessive ER, and anterosuperior humeral head migration.[166]

TABLE 16-40 Jobe and Kvnite Classification of Shoulder Dysfunction in the Overhead Athlete[511]

- *Group IA*. This group, typically found in the older population, encompasses those patients with pure and isolated impingement and no instability
- *Group IB*. This group, typically found in the older population, encompasses those patients with instability secondary to mechanical trauma
- *Group II*. Patients in this group, who are usually young (<35 yr old) overhead athletes, demonstrate instability with impingement secondary to microtrauma that comes from overuse
- *Group III*. Patients in this group, who are also typically young overhead athletes, demonstrate atraumatic, generalized ligamentous laxity
- *Group IV*. Patients in this group are young (<35 yr old) who have experienced a traumatic event, resulting in instability in the absence of impingement

CLINICAL PEARL

It is recognized that primary impingement syndrome conditions can lead to secondary impingement if not managed appropriately.[563,564]

Thus the pathophysiology of SIS and RC disorders may have both intrinsic and extrinsic factors. In addition to the shape and form of the acromion, the amount of vascularization to the RC, the correct functioning of the dynamic stabilizers, and the condition of the A-C joint, a number of other intrinsic and extrinsic factors have been found to predispose an individual to SIS, including the following[39,41,56,63,565]:

1. ***Age.*** The age of the patient appears to be an important etiologic factor in the development of subacromial impingement in association with repetitive motion.[566–570] In the absence of repetitive motion as a causative factor, SIS is more common after the third decade of life and is

uncommon in individuals younger than 30 years.[39,40] In addition, there is a normal age-related increase in asymptomatic RC defects.[566–568,570,571] Constant and Murley[572] have also shown that there is an age-related decrease in shoulder function in healthy volunteers.

2. ***Position of the arm during activities.*** The arm position adopted during activities may contribute to the development of subacromial impingement significantly.[201] Because of the tangential vector of deltoid contraction, the tendency for superior translation of the humeral head is greatest between 60 and 90 degrees of elevation[44,547,573] Thus repetitive activities in this range of elevation place a high demand on the RC to counteract this tendency. In addition, repetitive activities that occur during higher levels of elevation of the arm bring the greater tuberosity and supraspinatus insertion into close proximity to the coracoacromial arch.[44,547,573]
3. ***Muscle imbalances.*** Sustained or repetitive overhead activity requires the scapular pivoters to constantly maintain appropriate scapular rotation.[39,112,125] Fatigue of the scapular pivoters may lead or contribute to relative subacromial impingement because of poor or asymmetric scapular rotation.[39,112,125] Secondary impingement can occur because of serratus anterior dysfunction, resulting in the anterior and inferior movement of the coracoacromial arch, which reduces available clearance for the RC and greater tuberosity as the shoulder is flexed forward.[4,112] Scapular lag from dysrhythmic scapulothoracic motion can also contribute to subacromial impingement because the acromion fails to rotate with the humerus, thereby producing a relative decrease in the acromiohumeral interval.[4,112] Defects in proprioception and motor coordination of the RC and the deltoid muscle were recently discussed as playing a major role in the development of SIS.[574,575]
4. ***Capsular tightness.***[576] Capsular tightness is a common mechanical problem related to primary impingement syndrome and has been reported to occur at the posterior,[112] anterior,[44] and inferior[437,535] portions of the capsule. Individuals who avoid painful overhead activity, or who are predisposed to motion imbalances because of their work or sport, can develop capsular tightness.[577] During the period of pain avoidance or unbalanced movement, the capsular connective tissue may lose the ability to lengthen due to decreased critical fiber distance and abnormal collagen fiber cross-linking. This in turn can lead to capsular tightness, joint stiffness, painful or limited function, and to an earlier onset or greater degree of subacromial compression, particularly in elevated planes of movement.[39,243,393,578] This is particularly true with a posterior capsular contracture, which commonly coexists with SIS and RC disease. Posterior capsular contracture may add to the abnormal subacromial contact by producing an anterosuperior translation during active elevation.[38,39] Tightness of the posterior capsule can also cause a decrease in IR of the G-H joint, which leads to an increase in the anterior and superior migration of the humeral head. In contrast, tightness of the anteroinferior capsule results in limited ER, preventing the greater tuberosity from sufficient ER to "clear" the coracoacromial arch.[121] Thus, the restoration of capsular mobility is an important component in the rehabilitation process.
5. ***Postural imbalance.*** Postural imbalance, particularly scapulothoracic dysfunction in relation to the FHP, has been implicated as an etiologic factor in secondary impingement syndrome.[39,282] The FHP, which is associated with an increase in the thoracic kyphosis angle, a forward shoulder posture, and a scapula that is positioned in relatively more elevation, protraction, downward rotation, and anterior tilt has been cited as a potential etiologic factor in the pathogenesis of SIS.[579] The effect of these changes leads to a loss of G-H flexion and abduction range, compression and irritation of the uppermost (bursal) surface of the supraspinatus tendon, resultant changes in the activation patterns of the length-dependent force couples, and a reduction in the range of G-H elevation.[579] However, the evidence for this is limited, with research studies reporting equivocal findings.[250,580–583] Postural imbalance can also occur as a secondary development in primary SIS.[576]
6. ***Repetitive overhead activities.*** Repetitive activities that involve humeral flexion have been reported to predispose individuals to RC disorders.[41,252] In fact, any repetitive elevation beyond 90 degrees has the potential to provoke RC disorders.[44]
7. ***Structural asymmetry.*** Scapular asymmetry and its role in impingement have been widely reported by investigators of upper extremity pathology.[112,223,480,584] Warner et al.[480] determined that 57% of their subjects with impingement syndrome demonstrated static scapular postural asymmetry, and all demonstrated weakness of the scapular pivoters (rhomboids, serratus anterior, lower trapezius, deltoid, and RC).
8. ***The position of the humerus at rest.*** This can affect the healing process of patients with primary shoulder impingement syndrome. The work of Rathburn and Macnab[57] illustrated the deleterious "wringing out" effect on RC tendon vascularity with an adducted dependent posture of the humerus.
9. ***Impaired scapular kinematics.*** Many researchers have studied the scapular kinematics in patients with SIS, but results of these studies to date have been largely variable, because often control subjects were included who were not matched to the subjects with SIS, or because the studies compared shoulder motion of the affected shoulder with the asymptomatic side only.[585]

A study by McClure et al.[586] included a matched control group as well as measurements of several physical characteristics of patients with SIS, including kinematics of the scapula, shoulder ROM, shoulder muscle force, and both upper thoracic spine and shoulder resting posture. All subjects were examined with the following tests and measures: (1) goniometric measurement of shoulder ROM, (2) assessment of upper thoracic spine and scapular resting posture, (3) measurement of shoulder isometric muscle force with a handheld dynamometer, and (4) assessment of shoulder kinematics with an electromagnetic motion analysis system during three active shoulder motions (shoulder flexion, scapular plane elevation,

and ER at 90 degrees of abduction). The study had the following findings[585,586]:

- There were no differences in resting posture between the subjects with and without SIS.
- The SIS group demonstrated less ROM of the shoulder in all directions assessed, and less isometric muscle force for shoulder ER and scapular plane elevation.
- The subjects with SIS demonstrated slightly greater upward rotation of the scapula and elevation of the clavicle with shoulder flexion and slightly more posterior tilt and retraction of the clavicle with scapular plane elevation compared with those who did not have SIS.

Given the limited mobility and decreased shoulder muscle force identified in the SIS group and the kinematic differences identified between the two groups, it is tempting to conclude that the weakness of the shoulder musculature, or loss of mobility of the shoulder, or both, cause compensatory scapulothoracic movement strategies. However, further research is needed to determine whether a management strategy that specifically addresses the identified impairments of reduced muscle force, ROM, and altered kinematics results in greater improvements in pain, activity, and participation than competing noninvasive management strategies.[585,586]

If SIS is allowed to progress, the patient moves the shoulder less frequently due to the pain. The lack of movement increases the potential of developing adhesive capsulitis (frozen shoulder), particularly in the older patient. Neer[41] divided the impingement process into three stages, although the condition is a continuum of symptoms with overlap at the margins of each stage.[75] Each impingement stage is managed based on the specific findings and the intrinsic or extrinsic factors contributing to the problem, whether they result from compression, tensile overload, or macrotrauma.

Stage I. This stage consists of localized inflammation, slight bleeding, and edema of the RC. This stage is typically observed in patients under 25 years of age, although it can also be seen in older populations due to overuse. The patient reports pain in the shoulder and a history of acute trauma or repetitive microtrauma.

The physical examination during this stage reveals tenderness at the supraspinatus insertion and anterior acromion, a painful arc, and weakness of the RC secondary to pain, particularly when tested at 90-degree abduction or flexion. Acromial elevation and scapular stabilization are often jeopardized early in the injury process due to pain-based inhibition of the serratus anterior and lower trapezius, and due to subclinical adaptations altering the position of the scapula to accommodate injury patterns in subluxation or impingement.[152,153] Stage I is a reversible condition.

The subacromial space can be identified as a source of impingement by using the Neer impingement test supplemented with the Hawkins–Kennedy impingement test (see "Special Tests" sections).

The emphasis during the intervention of this phase is to control the pain and inflammation. The pain from subacromial impingement usually resolves with a period of rest and activity modification. Rest is advocated to prevent further trauma to the area and reduce excessive scar formation.[587] In addition to the rest and modification of activities, pain and inflammation may be controlled with the use of electrotherapeutic modalities, cryotherapy, and NSAIDs prescribed by the physician.

Stage II. Stage II represents a progressive process in the deterioration of the tissues of the RC. This stage is generally seen in the 26–40-year-old age group. Irritation of the subacromial structures continues as a result of the abnormal contact with the acromion. The subacromial bursa loses its ability to lubricate and protect the underlying RC, and tendinitis of the cuff develops. The patient often reports that a specific activity brings on their symptoms, especially an overhead activity. Pain is generally located on the top of the shoulder and will radiate to the midbrachium in the region of the deltoid insertion. The physical examination reveals crepitus or catching at approximately 100 degrees and restriction of PROM (due to fibrosis). This stage is no longer reversible with just rest. Although this stage often responds to long-term conservative care, it can progress to a partial thickness tear. If the level of symptoms is severe enough, surgery is often required. Conservative intervention during this stage involves a progressive strengthening program as described in the "Intervention Strategies" section.[588,589]

CLINICAL PEARL

A study by Bang and Deyle[590] determined that a combination of manual therapy applied by experienced clinicians and supervised exercise was better than exercise alone to increase strength, decrease pain, and improve function in patients with SIS.

Fifteen to twenty-eight percent of those patients diagnosed with SIS may eventually require surgery.[393,538] Surgical intervention is usually reserved for those who have failed to make satisfactory improvement over a period of 6 months. However, at least two randomized controlled clinical trials that examined the efficacy of conservative intervention with SIS have found that exercise supervised by a physical therapist was superior to placebo and was as effective as surgical subacromial decompression combined with postoperative rehabilitation in the intervention of patients with stage II primary impingement.[590,591] Another randomized controlled study[592] reported improved ROM, decreased pain, and increased function in patients with shoulder pain who underwent a program of individualized muscle stretching, strengthening, and retraining versus surgery.[590]

Stage III. Stage III is the end stage, common in the over-40 age group, where destruction of the soft tissue and rupture, or macrotrauma of the RC, is seen (see "Rotator Cuff Pathology" section). Localized atrophy can occur with this stage. Osteophytes of the acromion and A-C joint develop. The wear of the anterior aspect of the acromion on the greater tuberosity and the supraspinatus tendon eventually results in a full-thickness tear of the RC. The physical examination reveals atrophy of the infraspinatus and supraspinatus, and more limitation in AROM and PROM than the other stages.

Many protocols exist for patients with SIS. A progression from isometric exercises to close chain, and finally to

open-chain activities beginning with scapulothoracic strengthening and scaption retraining, and then proceeding to RC strengthening, is generally recommended (see "-Intervention Strategies" section).

- Scapulothoracic strengthening and scaption retraining exercises include isometric scapular pinches and shrug exercises, rowing, press ups, and the push-up plus. Exercises to improve the scapulohumeral rhythm include the PNF D2 pattern, alternating serratus punches with tubing, and latissimus dorsi pull downs.
- Rotator cuff strengthening exercises include the empty can, biceps curl, IR and ER of the shoulder against resistive tubing, elbow extension, prone ER of the shoulder, and shoulder flexion and abduction (performed below 90 degrees).

Posterior Superior Glenoid Impingement

Posterior superior glenoid impingement is newly recognized as a source of RC pathology in athletes. This type of impingement is thought to result from an impingement of the RC between the greater tuberosity and the posterior superior glenoid labrum, although the actual cause has yet to be determined.[593,594]

Periarticular Syndromes

The historical features of all these syndromes are similar. Pain is increased after exercise and is usually worse at night, often waking the patient from sleep. Certain movements, such as reaching above the head or putting on a coat, will produce pain. ER and IR motions are usually within normal limits when compared with the uninvolved side, but abduction and flexion are painful between 70 and 110 degrees. Disorders of the periarticular inert structures, such as the bursae, are characterized by a noncapsular pattern. These can be divided into two subgroups. One group has a restricted range of passive movement, and the other has an unrestricted range. Two common periarticular syndromes that affect the shoulder in older patients are subacromial–subdeltoid bursitis and bicipital tendinitis.

According to Nevasier,[595] primary shoulder bursitis is seen only in gout, rheumatoid arthritis, pyogenic infections, and tuberculosis.[596] Secondary bursitis, due to the proximity of the bursae to an inflamed tendon, is far more common.

Calcified Bursitis

Etiology of this condition is a result of decreased vascularization, cuff degeneration, and/or increased levels of the HLA-1 antigen. There are three recognized stages:

- ***Precalcific***—calcium deposits in the matrix of vesicles
- ***Calcific***—continued calcium deposition and increased pressure
- ***Postcalcific***—the body decreases its blood supply to the area in an attempt to get rid of the calcium, producing severe pain (comparable to kidney stones)

The condition produces a limitation of ROM in all directions, and the area is very tender to touch or compression.

Conservative intervention consists of an intramuscular steroid injection to decrease pain and inflammation, ice applications, and Codman's exercises to relieve pressure. Typically, the pain decreases with an increase in ROM in 48–72 hours. After 72 hours, the bursitis is treated as a traumatic bursitis (see next).

Traumatic Bursitis and Hemorrhagic Bursitis

Traumatic bursitis is the result of direct trauma. But it can also be secondary to a degenerative rotator cuff. The patient often complains of pain at night. Pain is typically felt over the deltoid and its insertion, with the arm in extension. The patient demonstrates limited AROM and PROM in a noncapsular pattern, and an empty end-feel at approximately 70–80 degrees with G-H abduction.

The condition responds well to a conservative regimen of pain and inflammation control, capsular stretching (especially posteriorly), Codman's exercises, manual techniques to increase the acromiohumeral interval (scapula down and back, inferior glide), postural reeducation, restoration of normal synergy patterns for the G-H depressors, and functional restoration.

Calcific Tendinitis

Calcific tendinitis or, more accurately termed calcific tendinopathy, is characterized by a reactive calcification that affects the rotator cuff tendons. It is a common cause of shoulder pain.[597] Frequently, such calcifications are incidental radiographic findings in asymptomatic patients.[598] Approximately 50% of patients with calcific tendinitis have shoulder pain,[599,600] with associated acute or chronic painful restrictions of shoulder ROM, impacting ADLs.

The cause and pathogenesis of calcifications of the rotator cuff are unclear.[57,601] Ischemia as a result of hypovascularization in the so-called critical zone of the rotator cuff,[57] degeneration of the tendons,[601] and metabolic disturbances[602] have all been suggested as possible causes. According to Uhthoff et al.,[603,604] fibrocartilaginous transformation of the tendon tissue leads to calcium deposits. The course of the disease may be cyclic, with spontaneous resorption and reconstitution of the tendon.[603,604] The factor that triggers metaplasia has not yet been determined, although tissue hypoxia is thought to be the primary factor.[602] Clearly, degeneration of the rotator cuff tendons is a precursor for calcification.[195] Both shoulders are involved at 20–30% of patients with calcific tendinitis of the shoulder.[599,600] Calcific tendinitis is observed infrequently in people under age 40.[195] The prevalence of calcific tendinitis has been reported to be between 3% [599] and 7%.[605] Calcific tendinitis can be acute or chronic.[604] In general, the condition is found more frequently in women than men.[599] A relationship to occupation must be considered because there is a high incidence among clerical workers.[604]

The course of calcific tendinopathy is variable. In most cases, the deposits are located 1–2 cm from the insertion of the supraspinatus tendon on the greater tuberosity.[598] In some patients, the deposits are absorbed spontaneously with limited pain. Chronic calcific tendinitis generally presents with impingement symptoms of pain with overhead motion. Other patients have persistent and recurring episodes of severe pain.

Uhthoff[604] suggests dividing calcific tendinitis into a formative phase and a resorptive phase. In the formative phase,

calcium deposits crystallize with minimal inflammation. Pain is usually mild and self-limiting during this phase. In the later, resorptive phase, the calcific material changes consistency from a solid to a paste or liquid. Shoulder pain is seen more often in this phase. This pain can be severe and develop abruptly. During these acute episodes of shoulder pain, the physical examination is often difficult due to pain limiting AROM and PROM.

Management of calcific tendinitis is often conservative, consisting of ice applications and pendulum exercises (prescribed in the acute phase) to prevent the development of adhesive capsulitis.[75]

Promising results have been reported for shock-wave therapy.[606,607] Ultrasound therapy, using a wide intensity range is commonly used as an intervention for painful musculoskeletal disorders.[608] The way in which ultrasound stimulates resorption of calcium deposits has not been established.[598] It may stimulate the accumulation of peripheral-blood mononuclear cells by activating endothelial cells. It may also act indirectly by increasing the intracellular calcium levels.[609] At higher intensities, ultrasound may trigger or accelerate the disruption of apatite-like microcrystals. The appearance of these smaller calcium crystals may then stimulate macrophages to remove calcifications by phagocytosis.[610,611] Finally, the increases in the temperature of tissue exposed to ultrasound may increase blood flow (i.e., induce hyperemia) and metabolism, thus facilitating the disintegration of calcium deposits.[598]

Invasive interventions directed at the calcium deposits, such as open surgical removal of the deposits, percutaneous needle aspiration and closed lavage of the deposits with lidocaine reduce pain and restore shoulder function in some patients, but not in all.[195,600,612–614]

Acute Subacromial–Subdeltoid Bursitis

This is an extremely uncomfortable condition. Active elevation is very painful and greatly restricted, and can be accompanied by a painful arc. While most patients with subacromial–subdeltoid bursitis describe a mechanical mechanism, bilateral bursitis is often seen in patients with inflammatory arthritis.[195] A differential diagnosis should be made between gouty arthritis, septic arthritis, a pathologic fracture, or a dislocation of the shoulder, and these can be differentiated from one another by their accompanying symptoms. Regardless of the severity of the pain, other conditions need to be ruled out. These include subscapular tendinitis, a pectoralis major lesion, a sprain of the conoid–trapezoid ligament, or early G-H arthritis. The pain of bursitis is usually reproduced with passive abduction at 180 degrees, passive IR, and passive horizontal adduction. Resistive testing may also produce pain. Associated and predisposing findings may also be noted. These include winging of the scapula, and forward head and rounded shoulder posture.

With the shoulder positioned in extension to expose more of the bursa, palpation of the shoulder region can elicit tenderness of the rotator cuff tendons and tenderness of the subacromial–subdeltoid bursa over the anterior humeral head.

Conservative intervention for this condition involves the use of modalities to help control the pain and inflammation, and patient education to avoid exacerbation.

Primary Chronic Subacromial–Subdeltoid Bursitis

Two types of primary chronic bursitis are defined:

1. The type caused by degenerative changes, especially of the supraspinatus and A-C joint. This can produce a reduced space for the bursa and cause an inflammatory reaction of the bursa.
2. The type caused by a systemic disease such as rheumatoid arthritis.

With primary chronic bursitis, pain develops gradually. The pain is usually localized to the shoulder and lateral deltoid area, but it can spread into the upper arm. Findings from the objective examination include a positive painful arc into abduction or forward flexion, but full movement in other directions. One or more resisted tests are often painful, but may be negative if repeated with an inferior pull on the arm.

The intervention of choice is a course of local anesthetic injections.

Secondary Chronic Subacromial–Subdeltoid Bursitis

Secondary chronic bursitis is more common than the primary type and results from other shoulder pathologies, including a rupture of the medial coracohumeral ligament. Similar to primary chronic bursitis, the pain develops gradually in the shoulder and lateral deltoid region, but can radiate into the upper arm.

The objective findings are the same as those for the primary chronic bursitis. However, the exception is that other pathologies are present and make a specific diagnosis more difficult.

The intervention of choice is similar to primary chronic bursitis, although the primary lesion should be sought and treated.

Bicipital Tendinitis

Tendinitis of the LHB occurs more often as a secondary condition related to an impingement syndrome.[427,595] Slatis and Aalto[615] described a three-part classification for biceps lesions:

- Type A: Impingement tendinitis, which occurs secondary to impingement syndrome and rotator cuff disease. Since the tendon passes beneath the anterior edge of the acromion, impingement can cause biceps tendinopathy as well as rotator cuff problems.
- Type B: A subluxation of the biceps tendon.
- Type C: Attrition tendinitis, commonly associated with spurring and fraying.

In addition, the biceps tendon sheath is a direct extension of the G-H joint, and inflammatory conditions such as rheumatoid arthritis can involve the biceps tendon.

Other researchers[616] have proposed two main categories related to age with younger patients developing problems due to repetitive trauma and anomalies of the bicipital groove, and the older age group developing problems associated with degenerative changes in the tendon.

The pain associated with inflammation of the LHB is typically felt along the anterior lateral aspect of the shoulder with radiation into the biceps muscle, and tenderness is noted directly over the bicipital groove.

Objective findings for this condition include the following:

- Full AROM and PROM, although pain is often reported at the end range of flexion and abduction.
- Normal accessory glides at the G-H joint (negating the need to use joint mobilizations).[427,595]
- Pain on palpation of the bicipital groove while the arm is positioned at 10 degrees of IR.
- Pain with resisted elbow flexion or resisted forward flexion of the shoulder.
- Pain on passive stretch of the biceps tendon.
- Positive Speed's test.

Every attempt must be made to identify associated lesions (e.g., those affecting the glenoid labrum and rotator cuff) or to note any contributing factors (e.g., a poorly stabilized scapular, the hypomobile cervical and/or thoracic spine, or altered muscle recruitment patterns).[73]

The conservative intervention for biceps tendinitis secondary to chronic impingement is similar to that described for rotator cuff tendinitis. These include electrotherapeutic modalities, physical agents, NSAIDs, TFM, and gentle stretching of the contractile tissues. Care must be taken with the TFM so as to not exacerbate the acutely or chronically inflamed tissue. Once the pain and inflammation are under control, the patient is progressed through ROM exercises within the pain-free ranges. Intensive strengthening is initiated when full pain-free AROM has been restored.

Subluxing Biceps Tendon

The LHB tendon, with its proximal point of exit at a 30–40-degree angle from the straight line of the tendon and the tunnel, swings from one side of the groove to the other during the motions of IR and ER of the humerus.[30] If the groove is shallow, the tendon may force its way over the lesser or greater tuberosity, tearing the transverse humeral ligament in the process. Repeated subluxation wears down the tuberosity and increases the frequency of the subluxation.

If the groove is narrow and tight, the constant pressure of the tendon has the potential to cause tendinitis or even rupture of the tendon.[30]

The pain, not often severe, has the same referral pattern as that of bicipital tendinitis. A click is typically felt during abduction and ER motions, with reduction of the tendon occurring with adduction and IR. There is tenderness over the bicipital groove, which follows the groove as the arm is rotated. On IR, the groove is under the coracoid, and during ER it is at the anteromedial line.[30]

The intervention depends largely on how important athletics is to the participant. Conservative intervention involves the temporary avoidance of the pain and click-provoking movements, and the application of TFM. In severe cases, surgical intervention may be indicated, which offers excellent results.[30]

Rupture of the Long Head of Biceps

A total rupture of the LHB is usually seen in middle-aged patients, resulting from repeated injections of steroid into the bicipital groove or in cases of chronic impingement.[195] The tendon is avascular, and as it weakens, it tears with a minimal amount of force.

Patients usually report hearing or feeling a "snap" at the time of the injury. Typically, rupture is followed by a few weeks of mild-to-moderate pain, followed by resolution of the pain and restoration of normal function.[195] When attempts are made to contract the biceps, the muscle belly rolls down over the distal humerus, producing a swelling close to the elbow instead of in the middle of the arm: the so-called "Popeye" sign. Functional limitations are unusual after this rupture, especially in the older population, because the short head of the biceps remains intact.[617] Typically, there is a negligible loss of elbow flexion and supination strength.

Surgical repair is rarely indicated except in the younger, active population (<50 years). With or without surgery, a rupture of the LHB increases the risk of developing an SIS. This results from the short head of the biceps pulling the humeral head upward, without the presence of the long head to hold the humeral head downward.

PATTERN 4G: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION WITH FRACTURES

Atraumatic Osteolysis of the Distal Clavicle

Atraumatic osteolysis of the distal clavicle[71] (AODC) was first described in 1959 by Ehricht.[618]

The etiology is thought to be a stress failure of the distal clavicle due to an initial stress fracture, followed by cystic and erosive changes secondary to bone resorption. Subsequent bone formation and remodeling cannot occur because of continued stress on the joint.

It is most common in athletes involved in prolonged weight training and appears to be on the increase. The recent increase in incidence may be due to the emphasis on strength training regimens in sport. In a group of Danish weightlifters, the prevalence was found to be 27% compared with a normal (non–weight-lifting) control group.[619]

The symptoms usually begin insidiously. They are usually described as a painful, dull ache localized to the A-C joint. The ache, which tends to be worse at the beginning of exercise, may radiate into the deltoid and trapezius. Bench presses, dips, and push-ups are usually the most painful exercises. Abduction of the arm beyond 90 degrees causes pain. Throwing is also painful. On examination, there is point tenderness at the A-C joint and forced arm adduction across the chest increases the symptoms. Symptoms are bilateral in 20% of cases.

The most common differential diagnoses to be considered are cervical spondylosis and rotator cuff disease. AODC can be distinguished from rotator cuff tendinitis by selective injection of anesthetic into the A-C joint. An abolishment of the pain

with the provocative maneuvers subsequent to the injection helps confirm the diagnosis.

The majority of patients with this condition respond to conservative management and activity modification, with most improving by reducing or eliminating their strength training activities.[619] However, even after several years' layoff, if strength training is reinstituted at the same level, the symptoms will commonly recur.[620,621] Other aspects of conservative intervention involve heat, NSAIDs, ROM, and stretching and strengthening exercises. The exercises should be performed below 90 degrees of abduction. Ultrasound has also been advocated.[619] Although a consideration, intra-articular injection of steroid does not provide long-lasting success. It is more helpful to aid in the diagnosis and predicting surgical success.

Conservative intervention failure is an indication for surgical management. This consists of resection of the distal clavicle, either open or arthroscopic.

Clavicle Fractures

Fractures of the clavicle account for 5 to 10% of all fractures and 35 to 40% of shoulder girdle injuries in adults. The clavicle is the most commonly fractured bone in childhood.[89] Fractures of the clavicle usually result from a FOOSH, a fall or blow to the point of the shoulder, or less commonly from a direct blow.

The classic presentation following a clavicular fracture is guarded shoulder motions and difficulty elevating the arm beyond 60 degrees. A clavicular deformity may also be observable. There is also exquisite tenderness to palpation or percussion (bony tap) over the fracture site. Horizontal adduction is painful. The diagnosis is confirmed by radiograph.

The conservative intervention for clavicle fractures includes approximation of the fracture ends followed by immobilization with a sling and figure-8 strap for 3–6 weeks. AAROM and then AROM exercises for the shoulder can be initiated once clinical union has been established (in 2–3 weeks). Due to the importance of the clavicle in shoulder function, joint mobilizations are started immediately after the period of immobilization, and strengthening exercises for the deltoid, pectoralis major, and upper trapezius muscles are prescribed when appropriate. As with all shoulder injuries, the clinician should ensure that the scapulohumeral rhythm is normal and symmetrical and that the essential stabilizing musculature of the G-H joint is intact. Normal healing times for clavicular fracture are 6 weeks in young children in 8 weeks in adults.[622] Surgical intervention is reserved for those cases involving neurovascular compression, an open fracture, associated fractures, and marked displacement.

Proximal Humeral Fractures

A proximal humeral fracture, involving the proximal third of the humerus, is the most common fracture of the humerus in the young and the elderly. In the skeletally immature patient, the fracture frequently presents as an epiphyseal fracture of the proximal humeral growth plate as the result from a direct blow to the anterior, lateral, or posterolateral aspect of the humerus, or a FOOSH injury.[623] In the elderly, the fractures usually occur through osteopenic bone following minimal trauma.

The majority of proximal humeral fractures are stable with no significant displacement of the fracture. This type is typically treated conservatively, with an emphasis on controlling distal edema and stiffness, and early motion at the shoulder to prevent the development of arthrofibrosis secondary to prolonged immobilization.[624]

The arm is usually immobilized in a sling until pain and discomfort subsides, often after 2 weeks if the fracture is classified as nondisplaced and stable. If the fracture is classified as nondisplaced it is considered unstable and the immobilization period is typically approximately 4 weeks. AROM exercises for the wrist and hand are initiated immediately following immobilization. Typically, passive and active assisted exercises for the shoulder can be initiated approximately 1 week after injury. Clinical unity of the fracture usually occurs after 1–4 weeks. This can be tested by having the patient stand with the involved arm at their side with the elbow flexed. The clinician places one hand on the humeral head, and then gently rotates the humerus with the other. Clinical unity is established when the fracture fragments move in unison and the movement is free of crepitation. At this point, gentle AROM exercises are initiated for the shoulder and elbow. Once clinical union is confirmed by radiograph (usually at around 6 weeks), full PROM exercises to the shoulder and elbow are performed, with progressive resistive exercises typically initiated at 6–8 weeks.

Scapular Fractures

Scapular fractures are not common, accounting for only 1% of all fractures, 3% of all shoulder injuries and 5% of fractures involving the entire shoulder.[625] The anatomic features of the scapula provide insight into the mechanisms of injury and offer a convenient classification system (Table 16-41):

- Injuries to the body or the spine of the scapula typically result from a direct blow with significant force, such as from a motor vehicle accident or a fall.
- Acromion injuries usually result from a direct downward force to the shoulder.
- Scapular neck fractures most frequently result from an anterior or posterior force applied to the shoulder.

TABLE 16-41 Classification of Glenoid Cavity Fractures

Type	Description
IA	Anterior rim fracture
IB	Posterior rim fracture
II	Fracture line through the glenoid fossa exiting at the lateral border of the scapula
III	Fracture line through the glenoid fossa exiting at the superior border of the scapula
IV	Fracture line through the glenoid fossa exiting at the medial border of the scapula
VA	Combination of types II and IV
VB	Combination of types III and IV
VC	Combination of types II, III, and IV
VI	Comminuted fracture

- Glenoid rim fractures most often result from force transmitted along the humerus after a fall onto a flexed elbow.
- Stellate glenoid fractures usually follow a direct blow to the lateral shoulder.
- Coracoid process fractures may result from either a direct blow to the superior aspect of the shoulder or a forceful muscular contraction that causes an avulsion fracture.

In addition to a history of trauma, the most common findings are tenderness, edema, and ecchymosis over the affected area. In addition, the upper extremity is held in adduction and any attempt to abduct the extremity increases pain.

Most scapular fractures, depending on location and classification, can be treated successfully without surgical intervention. Conservative intervention consists of approximately 7–10 days of sling immobilization, followed by a progressing regimen of pendular and gentle PROM exercises as comfort and control allow.[73] Once sufficient healing has been demonstrated radiographically, the patient is encouraged to discontinue immobilization and proceed with AAROM and AROM exercises. Exercises that strengthen the muscles that attach to the scapula and those that arise from the scapula must be introduced at the earliest opportunity.

INTEGRATION OF PATTERNS 4B AND 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION SECONDARY TO IMPAIRED POSTURE, AND CONNECTIVE TISSUE DYSFUNCTION

Scapular Dyskinesis

Strengthening and stretching exercises for scapular muscles are a common part of rehabilitation programs designed for people with shoulder dysfunctions. Scapular dyskinesis is an alteration in the normal position or motion of the scapula that occurs during coupled scapulohumeral movements as a response to shoulder dysfunction.[626] The causes are many (Table 16-42). It should be suspected in patients with shoulder injury and can be identified and classified by specific physical examination. There are three types of scapular dyskinesis:

- Type I is characterized by prominence of the inferior medial scapular border. In throwers, this type may be referred to as a SICK scapula (malposition of the Scapula, prominence of the Inferior medial border of the scapula, Coracoid pain and malposition, and scapular dysKinesia).[262] A thrower with this syndrome presents with an apparent "dropped" scapula in the symptomatic shoulder compared with the contralateral shoulder's scapular position. Viewed from behind, the inferior medial scapular border appears very prominent, with the superior medial border and acromion less prominent. When viewed from the front, this tilting (protraction) of the scapula makes the shoulder appear to be lower than the opposite side. The pectoralis minor tightens as the coracoid tilts inferiorly and shifts laterally away from the midline, and its insertion at the coracoid becomes very tender.[262]
- Type II is characterized by protrusion of the entire medial border.
- Type III involves superior translation of the entire scapula and prominence of the superior medial border.

TABLE 16-42 Potential Causes of Scapular Dyskinesis

Potential Causes	Examples
Abnormality in bony posture or injury	Excessive scapular protraction and acromial depression in all stages of motion which increases the risk for impingement Excessive resting kyphosis Forward head posture creates tightness to the anterior neck musculature, which again in turn facilitates the abnormal scapula position
AC joint injuries or instabilities	Can alter the center of rotation of the scapula, leading to faulty mechanics
Muscle function alterations	Alterations involving the serratus anterior and lower trapezius are a common source of dysfunction, especially in cases of secondary impingement Microtrauma due to excessive strain in the muscles, fatigue, and inhibition due to pain
Nerve damage	A rare cause
Contractures	Especially of the anterior musculature that attaches to the coracoid process (pectoralis minor and short biceps head) can create an anterior tilt and forward lean to the scapula, as can tightness to the posterior capsule and latissimus

Data from Kibler WB, McMullen J: Scapular dyskinesis and its relation to shoulder pain. *J Am Acad Orthop Surg* 11:142–151, 2003.

Evaluation of the patient should include the trunk segments, hip and lower extremity function, and scapular position and movement analysis. There may be pain at the coracoid process, and the entire medial border may be tender with trigger points found in the upper trapezius. There may even be painful scar tissue found in the musculature due to long-standing dyskinesis. Motion about the scapulothoracic joint should be smooth with no catching or rapid movements, which are more often seen during the lowering phase of the arm. Strength testing can include the isometric scapular pinch, the SAT, the scapular retraction test, and the lateral slide test (LST). Once all the factors involved in the dysfunction of the shoulder are identified, treatment can begin on restoring normal scapular position and movement. More extensive therapy, including strengthening, should not occur until this step is accomplished; otherwise the shoulder is being worked in a faulty position.

The intervention of scapular dyskinesis is directed at managing underlying causes and restoring normal scapular muscle activation patterns by kinetic chain-based rehabilitation protocols. Leg, back, and trunk flexibility and strength should be

normalized, and exercises that emphasize kinetic chain activation of the leg, trunk, and scapula should be instituted. Useful combinations of movements to allow activation include trunk extension and scapular retraction, trunk rotation and scapular retraction, and one-legged stance and diagonal trunk rotation and scapular retraction. All of these exercises facilitate lower trapezius muscle activation.

Snapping Scapular

The term *snapping scapula* has been used to describe the clinical scenario of tenderness at the superomedial angle of the scapula, painful scapulothoracic motion, and scapulothoracic crepitus.[96,627–630] Infrequently, an underlying cause for the scapulothoracic dyskinesia is identified. The uncommon etiologies of snapping scapula include scapular exostoses, malunited scapular or rib fractures, and Sprengel's deformity.[628,631–633] Pain is usually reported at the superomedial angle of the scapula, with or without scapulothoracic crepitus.

The intervention for this condition is based on the cause. Common causes for this condition are an inflammation of the bursa between the scapula and thorax (scapulothoracic bursitis), prominence of the superomedial angle of the scapula, and muscular imbalance of the scapular pivoters.[96,628–630,634–637]

INTEGRATION OF PATTERNS 4B, 4C, 4F, AND 5F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION SECONDARY TO IMPAIRED POSTURE, SPINAL DISORDERS, MYOFASCIAL PAIN DYSFUNCTION, THORACIC OUTLET SYNDROME, COMPLEX REGIONAL PAIN SYNDROME, PERIPHERAL NERVE ENTRAPMENT

Impaired Posture

Patients with impaired posture have functional limitations associated with muscle imbalances, repetitive altered joint mobility, and pain. Impaired posture is commonly associated with referred pain to the shoulder. The most common posture referring pain to the shoulder is a forward head posture (FHP) with rounded shoulders. This posture is characterized by hypertrophy of the anterior chest and cervical musculature (including the pectoralis minor muscle and the anterior and medial scalene muscles). The position adopted in the FHP can compromise the space in the scalene triangle and cause compression of the neurovascular structures, resulting in a condition called TOS (see Chap. 23).[449]

This posture can also lead to soft tissue restrictions of the anterior shoulder muscles, suboccipital muscles, and shoulder rotators.[449]

The intervention includes a conservative regime of postural reeducation and exercises to restore the normal synergy patterns for G-H depressors, to increase shoulder stability, and facilitate functional restoration (see Chap. 25). Cervical and thoracic stabilization exercises may be introduced in addition to the correction of any muscle imbalances.

Referred Pain

See Chapter 5.

Scapulocostal Syndrome

Although this syndrome has been documented,[638–640] it is poorly understood. Scapulocostal syndrome (SCS) is an enthesopathy (a disorder of the attachment of a ligament, tendon, joint capsule, or muscle to bone) of the origin of the serratus posterior superior muscle. Clinically, it appears that SCS is a distinct variety of fibromyalgia.[640]

SCS has been postulated to have many causes including[640]

- ischemia[641]
- trigger point[638]
- postural degeneration[642,643]
- physical sloth[644]

Clinical findings for this syndrome include the following[640]:

- Pain of a cervicobrachial nature, described as burning and aching, is the most common presenting symptom.
- Active and passive motions of the shoulder girdle are usually full and pain free.
- Poor overall physical conditioning.

Conservative intervention, which includes intralesional injections and physical rehabilitation involving ROM, strengthening, and conditioning exercises, was shown in one study[640] to be successful in 95.9% of 201 patients.

Subclavian Steal Syndrome

See Chapter 5.

Myofascial Pain Syndrome

Shoulder pain can often be caused by myofascial dysfunction. The following muscles are most commonly involved. The intervention strategies for myofascial trigger points are described in Chapter 10.

Infraspinatus

The infraspinatus is a frequent cause of myofascial shoulder pain, with the trigger points in this muscle commonly referring pain deep into the shoulder joint. Due to the severity of the referred pain from this muscle's trigger points, it is often misdiagnosed as subdeltoid bursitis or supraspinatus tendinitis.

Pain can also be felt in the anterior shoulder and anterior upper arm. In extreme cases, the pain may refer to the extensor area of the forearm and into the hand.

Clinical findings can include the following[645]:

- A history of sleeping difficulty on the involved side because of pressure on trigger points. Sleeping on the uninvolved

side can also produce pain because of stretching of the muscle. Supporting the involved arm on a pillow while sleeping on the uninvolved side is a significant help.

- Limited IR and adduction of the shoulder, including horizontal adduction in severe cases.
- Shoulder girdle muscle fatigue rather than weakness. Pain is elicited on resisted testing of the infraspinatus and middle and posterior deltoid muscles.
- Decreased grip strength.
- Positive signs of subacromial impingement due to dysfunction of the infraspinatus.

Anterior Deltoid

Anterior deltoid trigger points typically refer pain and tenderness in the area of the muscle itself. Clinical findings include decreased ER and extension of the shoulder.

Posterior Deltoid

Trigger points in this muscle (located posterior to the humeral head) and in the levator scapulae are the most frequent cause of myogenic posterior shoulder pain.[645] Pain is elicited on resisted testing, reaching across to the opposite shoulder anteriorly and toward the end of ER while the arm is abducted at 90 degrees because of the shortening action in the muscle.[645]

Levator Scapulae

This muscle is one of the most frequent myofascial sources of shoulder and neck pain. Pain reference is to the base of the neck, the posterior shoulder joint over the area of the humeral head, and along the medial scapular border.

Clinical findings include the following:

- painful ipsilateral rotation of the neck,
- a limitation of full shoulder abduction accompanied by reproduction of posterior shoulder pain.[645]

These trigger points are activated by holding a telephone receiver between the shoulder and ear; sleeping on a sofa with the head on the armrest, which causes prolonged stretching deformation of the muscle; postural stress due to shoulder girdle asymmetry; and psychologic distress.[645]

Scalenes

The pain pattern is similar for all three scalenes and can include the anterior chest, the upper arm both anterolaterally and posteriorly, the thumb and index finger, and the medial scapular area.[645] Tenderness is referred to the infraclavicular fossa and disappears immediately after inactivation of the trigger points.

Supraspinatus

Rarely occurring in isolation, supraspinatus trigger points refer pain around the shoulder area, particularly to the mid-deltoid region, and the lateral epicondyle of the humerus. When the muscle is less severely involved, the patient will have difficulty fully abducting the shoulder.

As described previously, supraspinatus dysfunction can have wide-ranging consequences in shoulder biomechanics.

Subscapularis

Pain from subscapularis trigger points is felt at rest or on motion over the posterior shoulder. The pain may also extend over the scapula and posteromedial arm as far as the wrist.

Clinical findings include the following:

- painful and limited shoulder abduction, especially if ER of the arm is added to the movement,
- painful resisted shoulder adduction and IR,
- decreased posterior glide of the G-H joint,
- positive subacromial impingement signs.

Trapezius

The trigger points of the trapezius are usually found in the upper trapezius near the distal clavicle and in the lower border of the lower trapezius near the medial scapular border. Both areas refer pain and tenderness to the top of the shoulder over the acromion.[645] These trigger points may cause tenderness of the A-C joint ligaments. Trigger points in the lower trapezius can refer pain into the ipsilateral posterior neck and suboccipital region.[645]

Thoracic Outlet Syndrome

The chief complaint of TOS is one of diffuse arm and shoulder pain, especially when the arm is elevated beyond 90 degrees. Potential symptoms include pain localized in the neck, face, head, upper extremity, chest, shoulder, or axilla; and upper extremity paresthesias, numbness, weakness, heaviness, fatigability, swelling, discoloration, ulceration, or Raynaud's phenomenon. TOS is described in Chapter 25.

Crutch Palsy

Brachial plexus compressive neuropathy following the use of axillary crutches is rare but well recognized. There are a number of documented reports of compressive neuropathies stemming from the incorrect use of axillary crutches, the so-called "crutch palsy."[646–648] The diagnosis of crutch palsy is usually made clinically by taking a careful history and performing a physical examination. This includes observation of the patient during ambulation using crutches and looking at the axilla for such signs of chronic irritation as hyperpigmentation and skin hypertrophy. A detailed neurologic examination is usually sufficient to determine the cord or terminal branch(es) involved and the level of the involvement.[646]

The incorrect use of axillary crutches, with excessive weight bearing on the axillary bar, leads to a sevenfold increase in force on the axilla.[649]

Complex Regional Pain (Shoulder/Hand) Syndrome

This condition is described in detail in Chapter 18.

Cervical Radiculitis

The onset of cervical radiculitis (see Chap. 25) can be insidious or traumatic, or secondary to shoulder disease such as adhesive capsulitis.[207,650]

The patient reports a wide range of symptoms. These range from mild discomfort to severe pain that is associated with neck motion restrictions, particularly hyperextension and rotation.[72,651]

Objectively, there may be a loss of cervical lordosis with associated paravertebral muscle spasm. Palpation may reveal tenderness over the posterior aspect of the neck, which can exacerbate the radicular symptoms in the arm.[652] The testing of muscle strength, sensation, and muscle stretch reflexes should help confirm the diagnosis.

Conservative intervention consists of the control of pain and inflammation through rest and activity modification. The patient is educated on positions to avoid, including rotation toward the involved side and neck extension. Once the pain is controlled, the program is progressed to cervical ROM and strengthening exercises, postural education, and general strengthening and conditioning of the upper extremities.

Peripheral Nerve Entrapment

There are a number of common peripheral nerve neuropathies in the shoulder region (see Chap. 3), which are being recognized with increasing frequency. The nerves that can be injured in the region include the suprascapular, accessory, long thoracic, axillary, posterior (dorsal) scapular, and musculocutaneous.

Quadrilateral Space Syndrome

Idiopathic quadrilateral space syndrome, a compression of the axillary nerve as it passes with the posterior circumflex artery through the quadrilateral space, is rare.

The typical clinical presentation includes[640]

- vague, poorly localized shoulder discomfort,
- pain with fatigue when the patient attempts to maintain the arm above shoulder level,
- paresthesias in a nondermatomal pattern,
- tenderness to palpation in the quadrilateral space can occur.[653]

The initial intervention is conservative and includes rest, muscle relaxants, and NSAIDs. Surgery may be required if there is no improvement in 3–6 months.[653]

Adverse Neural Tension

An abnormal response to mechanical stimuli of neural tissue is termed *adverse neural tension* (see Chap. 11).[654,655] The G-H joint can be the source of neurologic tension due to multidirectional instability, direct trauma, or poor posture and resultant tension on the brachial plexus.[207,656] The movements of shoulder ER and depression stretch the brachial plexus. Side flexion of the cervical spine away from the tested side also stretches the brachial plexus. Often the patient adopts postures to compensate for tight neurologic structures and relieve the tension on the brachial plexus. One of the most common of these adaptive postures is elevation of the shoulder girdle.

Adhesions of the brachial plexus can be detected using the upper limb tension tests 1 and 2 (refer to Chap. 11).[655]

THERAPEUTIC TECHNIQUES

Techniques to Increase Joint Mobility

With some slight variations, the same techniques that are used to examine the joint glides of the shoulder complex (see "Passive Accessory Motion Tests" section) can be used to mobilize the joints, with the clinician varying the intensity of the mobilizations based on the intent of the treatment, patient response, and the stage of tissue healing. Unlike the testing positions, where the joint is placed in the resting position, the joint position for mobilization techniques varies:

- The resting position is used if gentle techniques are to be used.
- The restricted ROM is approximated if more aggressive techniques are to be used.

The purposes of joint mobilization include the following:

- to increase accessory motion;
- to increase ROM;
- to decrease pain;
- to improve periarticular muscle performance.

Joint mobilization may be preferable to stretching at the shoulder because it provides a precise stretch to a specific part of the capsule. It also can be performed with less pain, reduced load on other periarticular structures, and less compressive force on articular structures[423,657] as compared with physiologic stretching.[1] A number of studies[282,658,659] have examined the efficacy of passive joint mobilization and/or PROM. They found this mode of intervention to be effective for enhancing ROM in the patient with SIS. Investigators have suggested that joint mobilization, especially posterior gliding, may have an important role in restoring capsular extensibility in primary SIS[437,480] by preventing or stretching abnormal collagen cross-linkage,[244] rupturing adhesions,[660] reducing edema,[661] or reducing pain.[662] In addition to the G-H joint, the clinician should also ensure that the mobility at the A-C, S-C, and scapulothoracic joints are normal.

Kaltenborn[286] stressed the importance of promoting joint glides for increasing capsular mobility and prevention of joint compression and periarticular soft tissue injury that may occur with long lever angular mobilizations.[432] Sustained manual capsule stretches are particularly effective in regaining motion.[1,663,664] Low load, prolonged stretching produces plastic elongation of tissues as opposed to the high tensile resistance seen in high load, brief stretching.[444,665] (i.e., the arm is brought to end range, pushed slightly beyond that range, and held in that position for 10–20 seconds).

Glenohumeral Joint

Distraction of the G-H Joint

This is a general technique to stretch G-H capsule.

Inferior Glide of the G-H Joint

This technique can be used to increase G-H abduction

Posterior Glide of the G-H Joint

This technique can be used to increase G-H IR, flexion, and horizontal adduction.

Anterior Glide of the G-H Joint

This technique can be used to increase G-H ER, extension, and horizontal abduction. Caution must be used when using this technique in patients with a history of G-H subluxation/dislocation.

Scapulothoracic Joint

Distraction

This technique is a general technique to apply a stretch to the serratus anterior and to break up adhesions at the scapulothoracic joint.

Superior Glide

This technique is applied to increase ROM into scapulothoracic joint elevation and ER.

Inferior Glide

This technique is applied to increase ROM into scapulothoracic joint depression and IR.

Medial Glide

This technique can be used for increasing ROM into scapulothoracic joint retraction, depression, and IR.

Lateral Glide

Although this technique can be used for increasing ROM into scapulothoracic joint protraction, elevation, and ER, it should be used with caution in patients with posture impairments involving shoulder as this motion might already be hypermobile.

Sternoclavicular Joint

The S-C joint rarely needs mobilizing as it is often hypermobile.

Acromioclavicular Joint

Anterior and Posterior Rotation of the Clavicle

This technique can be used to help with the overall motion of the clavicle, although these motions may already be hypermobile.

Superior Glide of the Acromion on the Clavicle

This technique can be used as a general mobilization technique and is particularly useful if the patient's A-C joint is tender to palpation.

SPECIFIC PASSIVE PHYSIOLOGIC MOBILIZATION: HUMERUS AND SCAPULA

Quadrant Technique

The quadrant technique previously described as the Lock test (special tests of the shoulder) can also be used as a mobilization technique. This is done by adjusting the intensity according to the irritability of the condition. If the pain is severe, grade IV (small oscillatory techniques just into the tissue resistance) are used. If this technique decreases the pain, the technique is reapplied and reassessed. If the intervention produces no change in the symptoms, the clinician increases the grade slightly or increases the vigor and reassesses. If the intervention produces an increase in pain, the clinician continues with the same intervention but at a lesser grade.

Scapular Assist

The clinician stands behind the patient. The scapula is stabilized with one hand and, as the patient raises the arm, the scapula motion is assisted by applying a compressive force over the scapula with one hand while stabilizing the A-C joint with the other hand (Fig. 16-18). A similar technique may be used for increasing motion at the end range of arm elevation. This is a good technique to gain ROM during the period when the scapular controllers are being strengthened but have not reached the point when they are able to work independently.

Posterior Capsule (Sleeper) Stretch

The patient is in side-lying with the affected shoulder toward the table and the arm at 90 degrees of forward flexion.[166] The patient is asked to roll forward to approximately 45-degree angle. At this point scapular winging should be noticeable. The clinician stands behind the patient and applies pressure with the palm of the hand onto the medial border of the scapular. The scapula is then depressed down toward the posterior thorax reversing the scapular winging, with the amount of scapula pressure gauged by the clinician's position in relation to the patient. The amount of forward roll and the degree of forward flexion of the involved extremity are important variables in adjusting the technique.

SPECIFIC PASSIVE/ACTIVE PHYSIOLOGIC MOBILIZATION OF THE SHOULDER

Elevation through Abduction

The patient lies in the supine position with his or her head supported. The patient's upper extremity is adducted across his or her abdomen. The clinician palpates the posterior aspect of the patient's wrist with one hand and the proximal forearm with the other. The motion barrier is localized by instructing the patient to elevate the arm in the scaption plane to the limit of the physiologic ROM. [666] From this position, the patient is instructed to hold still while the clinician applies a gentle

resistance into further elevation. The contraction is held for 3–5 seconds, after which the patient is instructed to relax completely. The new barrier of elevation/abduction is located and the mobilization is repeated.

Elevation through Adduction

The technique is identical to the one already described with the exception that the abduction component is replaced by one of adduction so that the patient performs a combination of elevation and adduction.

MOBILIZATIONS WITH MOVEMENT

Decreased Elevation

The patient is seated and the clinician stands on his or her uninvolved side. The clinician places one hand over the scapula of the involved side. Using the other hand, the clinician reaches around the front of the patient to place the thenar eminence or a belt (Fig. 16-119) on the anterior aspect of the head of the humerus of the involved shoulder. The patient is asked to elevate his or her arm while the clinician applies a posterior glide to the humeral head (avoiding pressure over the sensitive coracoid process).[667] If this technique is successful, the patient is asked to hold a weight while elevating the arm (Fig. 16-119).

Decreased Internal Rotation

The patient is seated with his or her hands as far behind the back as possible. The clinician stands facing the patient on the involved side. The clinician places one hand in the crease of the patient's elbow and the web space of other hand in the patient's axilla to stabilize the scapula by using a lumbrical grip (Fig. 16-120). While maintaining the stabilization of the scapula, the clinician glides the humerus inferiorly in the glenoid fossa using the hand at the elbow and applies an adduction force by pressing their abdomen against the patient (see Fig. 16-120) as the patient internally rotates the shoulder (using their other hand to help if necessary). The technique can also be performed using a belt (Fig. 16-121).

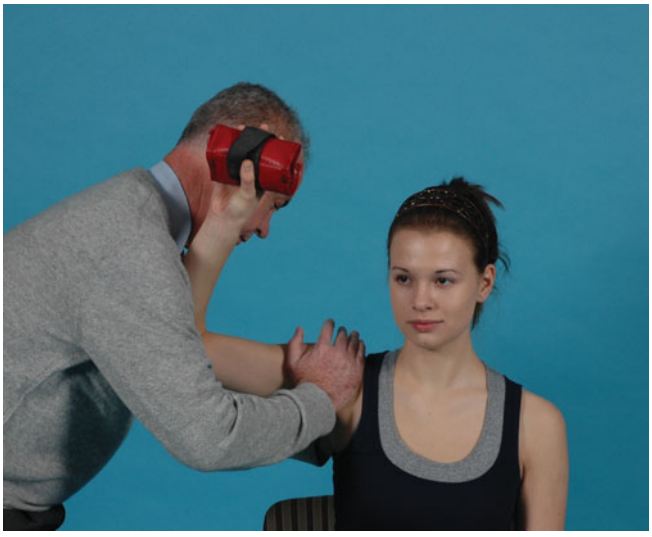

FIGURE 16-119 Mobilization with movement to increase elevation.

FIGURE 16-120 Mobilization with movement to increase internal rotation.

FIGURE 16-121 Mobilization with movement to increase internal rotation using belt.

Transverse Friction Massage

Deep TFM is a good treatment adjunct for tendon and ligament injuries of the shoulder. Since the procedure needs to be performed at a specific area, the examination must accurately determine which structure is involved.

Biceps

The patient is positioned with the shoulder abducted to 30 degrees and the elbow flexed. The clinician stands at the patient's side and supports the arm (Fig. 16-122). The clinician places his or her fingers on the biceps tendon and alternately applies a medial and lateral glide motion to the tendon to create gentle friction.

Supraspinatus

The supraspinatus tendon is located just distal to the anterolateral corner of the acromion. It can become more discernible by positioning the patient's arm in slight extension

FIGURE 16-122 Transverse friction massage of biceps tendon.

behind the back (Fig. 16-123). The massage is applied perpendicular to the tendon at the point of relative hypovascularity, which is located approximately 1 cm proximal to its insertion into the greater tuberosity of the humerus.[61]

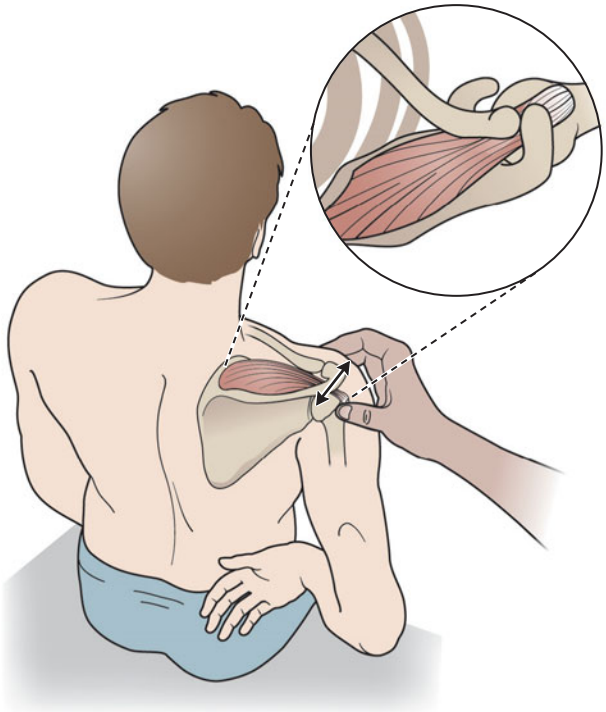

FIGURE 16-123 Transverse friction massage of the supraspinatus tendon.

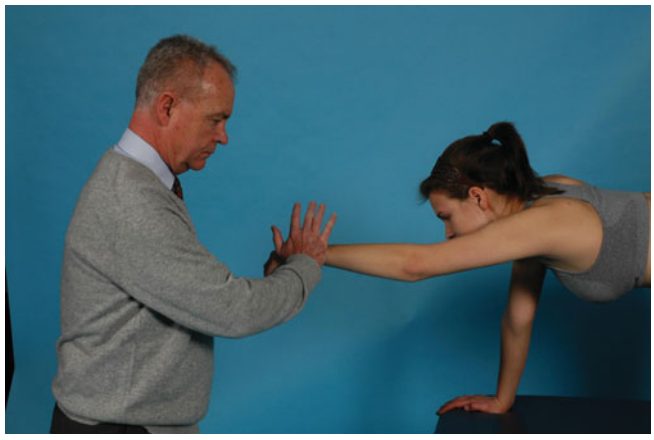

FIGURE 16-124 Rhythmic stabilization in quadruped.

Rhythmic Stabilization

The patient is positioned on all four limbs. The patient raises the involved arm to approximately 90 degrees of flexion and is asked to hold this position (Fig. 16-124) while the clinician applies a series of controlled alternating isometric contractions of the agonist and antagonist muscles to stimulate movement of the agonist, and develop stability, while monitoring scapular muscle activity.

The same exercise can be performed in a variety of positions.

Self-Stretches

The "Saw"

This exercise can be used to stretch the anterior capsule when motion above 90 degrees is restricted. The patient can be in the standing or sitting position. Maintaining his or her arm in approximately 90 degrees of elbow flexion, the patient is asked to perform a sawing motion as though cutting through wood.

Wall Walking

Wall walking can be used when attempting to regain full-range elevation. Clock exercises are a variation of wall walking. The hand is moved to the various positions on an imaginary clock face on the wall, ranging from 8 o'clock, through 12 o'clock, to 4 o'clock. This allows for rotation of the humerus throughout varying degrees of flexion or abduction to replicate rotator cuff activity. This exercise is first performed against a fixed resistance such as a wall or a countertop, and then can be moved to moveable resistance such as a ball or some other moveable implement.

Pulleys

Pulley exercises are commonly used as an active assisted exercise to help regain full overhead motion. However, it is recommended that pulley exercises not be used until the patient has at least 120 degrees of elevation, and then only used in a pain-free arc to decrease the potential for impingement.

FIGURE 16-125 Horizontal adduction stretch.

Wall Corner Stretch

This stretch is used to increase the flexibility of the anterior joint capsule, pectoralis major and minor, anterior deltoid, and coracobrachialis. The patient stands in a corner and places both hands and forearms on the wall, so that the upper arms are level with the shoulders. The stretch is applied by moving the trunk toward the wall, while keeping it perpendicular to the floor. The exercise can be modified to stretch one shoulder by performing the exercise in a doorway.

Horizontal Abductors and Posterior Capsule

The horizontal abductors (posterior deltoid, infraspinatus, teres minor, rhomboids, and middle trapezius) and the posterior joint capsule are stretched by having the patient pull the arm across the front of their body (Fig. 16-125). This exercise should be used with caution for those patients with an impingement syndrome or A-C dysfunction.

Inferior Capsule

The inferior capsule stretch is performed by placing the arm in the fully elevated overhead position (Fig. 16-126).

Pectoralis Minor

The pectoralis minor can be stretched by asking the patient to clasp his or her hands behind the head (Fig. 16-127). From this position, the patient attempts to move the elbows in a posterior direction. Initially, the clinician can monitor the exercise to ensure that the stretch is occurring in the correct region.

Shoulder Flexors

A T-bar or L-bar is used for this exercise. Two positions are used depending on the intent of the stretch.

To stretch the latissimus dorsi, teres major and minor, the posterior deltoid, triceps, and inferior joint capsule, the patient lies in supine position with the arm overhead (Fig. 16-128). Overpressure can be applied with the bar.

To stretch the anterior deltoid, coracobrachialis, pectoralis major, biceps, and anterior joint capsule, the patient's arm is positioned out to the side in approximately 90 degrees of abduction. The patient extends the arm as far as is comfortable (Fig. 16-129). The bar can be used to apply overpressure into further shoulder extension.

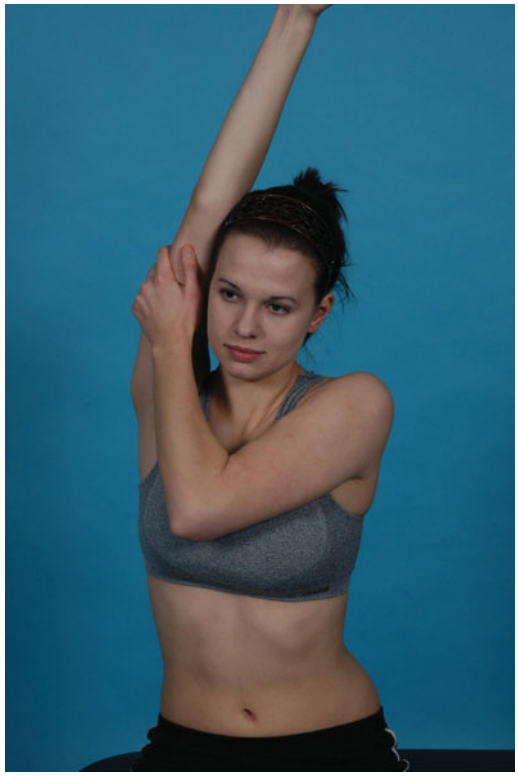

FIGURE 16-126 Inferior capsule stretch.

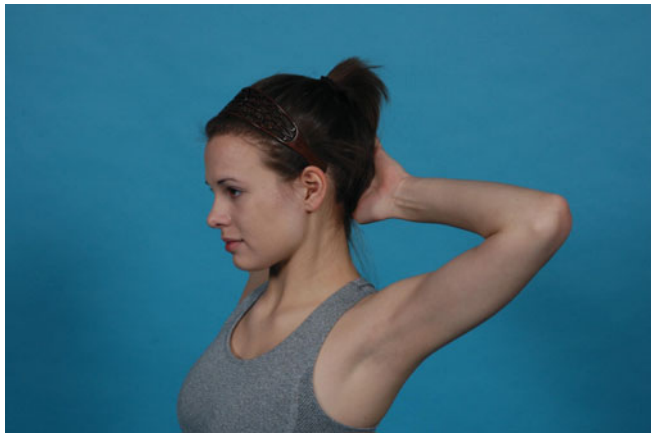

FIGURE 16-127 Pectoralis minor stretch.

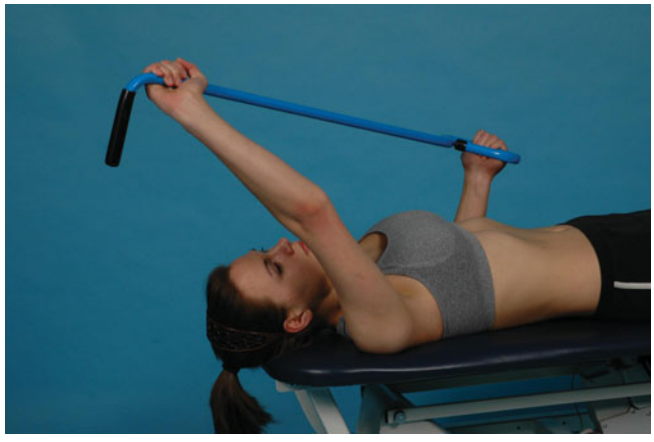

FIGURE 16-128 T-bar exercise for flexion.

FIGURE 16-129 T-bar exercise for extension.

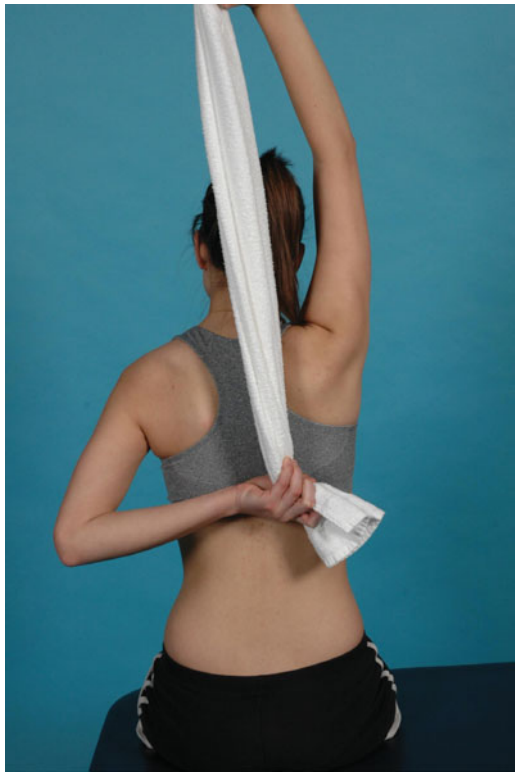

FIGURE 16-131 Towel stretch.

Shoulder Internal Rotators

A T-bar or L-bar is used for this exercise. The patient lies in supine position. The arm is flexed at the elbow and in one of the three positions of abduction at the shoulder: 0 degrees, 90 degrees (see Fig. 16-130), and 130 degrees. For each of the three positions, the shoulder is externally rotated as far as is comfortable. Overpressure is then applied by the bar to stretch the subscapularis, pectoralis major, anterior deltoid, latissimus dorsi, and the anterior joint capsule.

FIGURE 16-130 T-bar exercise into external rotation.

Shoulder External Rotators

A T-bar or L-bar is used for this exercise. The patient lies in supine position. The elbow is flexed and the arm is abducted into one of the three positions at the shoulder: 0 degrees, 90 degrees, and 130 degrees. For each of the three positions, the shoulder is internally rotated as far as is comfortable. Overpressure can then be applied using the bar to stretch the infraspinatus, teres minor, posterior deltoid, and posterior joint capsule.

Alternatively, the patient can sit sideways to a table. The entire upper arm is placed on the table top, bending the trunk as necessary. The elbow is flexed to approximately 90 degrees. Using the other arm, the patient grasps the forearm of the involved arm and moves it into IR as far as is comfortable. Rhythmic oscillations, or hold–relax techniques, can be applied at the end of range.

Towel Stretch

The towel-stretch exercise (Fig. 16-131) combines the motions of ER and IR and stretches the capsule accordingly.

AUTOMOBILIZATION TECHNIQUES

Inferior Distraction

The patient sits with a towel draped over his or her arm (Fig. 16-132). Using the opposite hand, the patient grasps the

FIGURE 16-132 Self-inferior distraction.

involved arm either just proximal to the humeral epicondyles or by the forearm. From this position, the patient applies an inferior glide to the G-H joint as he or she pulls the involved arm downward toward the floor and uses rhythmic oscillations (see Fig. 16-132). For a sustained inferior distraction, a weight or bag can be placed in the hand.

Inferior Distraction with Adduction

The patient stands or sits on a stool. A towel roll is placed under the axilla, and the arm to be mobilized is positioned across the chest. Using the uninvolved hand, the patient grasps the involved forearm just above the styloid processes and pulls the arm rhythmically across the chest into G-H adduction, and downward toward the floor (Fig. 16-133).

Inferior Glide

This is a good technique if the patient's shoulder abduction range is limited to below 90 degrees. The patient sits sideways next to a table. The involved arm is comfortably positioned using a towel roll or pillow in as much abduction as can be tolerated painlessly. The elbow is in full extension (Fig. 16-134). Using the uninvolved hand, or a towel wrapped around the humerus, the patient grasps the superoanterior aspect of the proximal humerus of the involved arm (see Fig. 16-134). From this position, an inferior glide is produced by pushing the humerus directly downward, or pulling the towel toward the floor. Rhythmic oscillations can be used.

If the patient has more than 90 degrees of abduction, another technique is preferable. The patient stands against a wall with the involved shoulder positioned comfortably into abduction. The elbow is flexed to approximately 90 degrees and the fleshy part of the forearm rests against a wall. The other hand grasps the superoanterior aspect of the proximal humerus of the involved arm and applies an inferior glide by pushing the humerus downward toward the floor.

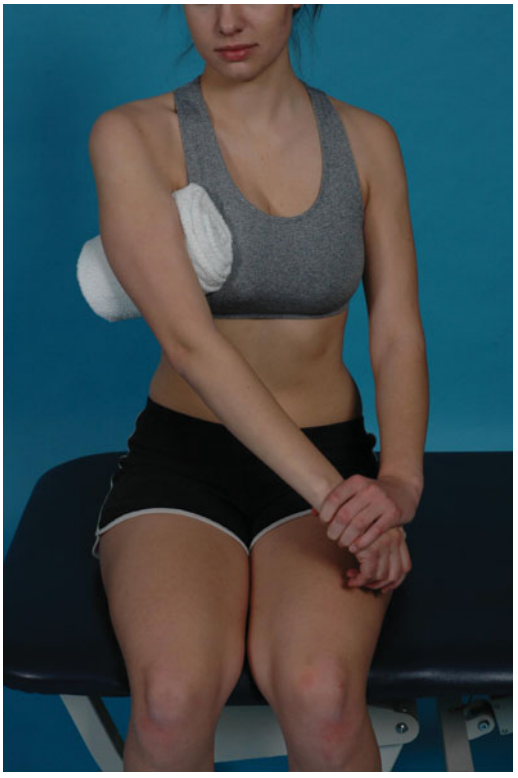

FIGURE 16-133 Inferior distraction with adduction.

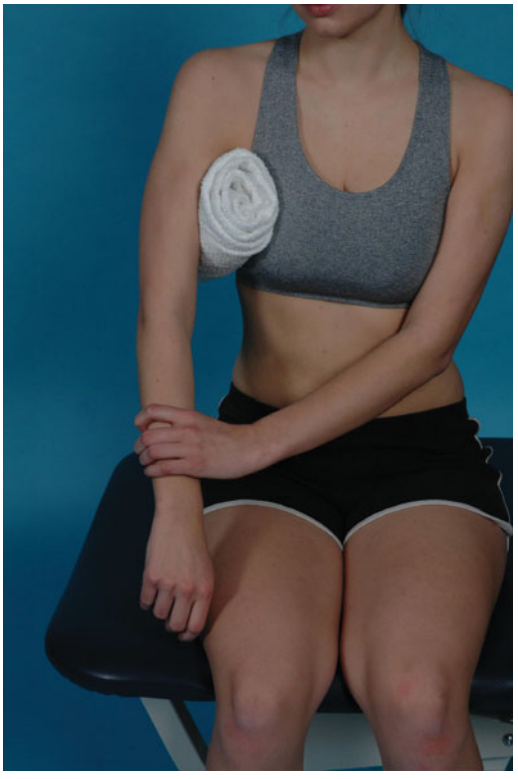

FIGURE 16-134 Inferior glide.

CASE STUDY

SHOULDER PAIN WITH CERTAIN MOTIONS

HISTORY AND SYSTEMS REVIEW

General Demographics

The patient is a 22-year-old male who lives at home with his parents.

History of Current Condition

Insidious onset of intermittent left shoulder pain began 2 weeks ago, with a report of occasional referral of pain into the upper left arm. The patient denies numbness or tingling into the left upper extremity. Pain increased sufficiently the past week to prompt the patient to see a physician, who diagnosed the condition as rotator cuff impingement and prescribed physical therapy and NSAIDs. The patient was also placed on work restrictions; maximum lift limited to 10 lb.

History of Current Condition

No history of left shoulder pain.

Medical and Surgical History

Unremarkable.

Medications

Ibuprofen, 800 mg daily.

Functional Status and Activity Level

The patient reported stiffness and soreness of the left shoulder on arising in the morning and again at the end of the day after working. Difficulty was also reported with putting on a jacket, driving to work which takes 45 minutes, and the use of a hedge trimmer. The patient reported that the shoulder pain interrupts his sleep two to three times every night and that he was having difficulty combing his hair, brushing his teeth, or lifting his arm without pain. He also reported that he enjoyed swimming but cannot swim the crawl or backstroke because of the pain. The patient described "cracking" and "popping" of the shoulder with activity.

Health Status (Self-Report)

Generally in good health but pain interferes with tasks at home and at work.

Questions

1. What structure(s) do you suspect to be involved in this patient?
2. What could the history of pain with certain overhead movements indicate?
3. Why do you think the patient's symptoms are worsened with certain functional and recreational activities?
4. What additional questions would you ask to help rule out cervical involvement or pain referred from a visceral structure?
5. What is your working hypothesis at this stage? List the various diagnoses that could present with these signs and symptoms, and the tests you would use to rule out each one.
6. Does this presentation/history warrant a Cyriax upper quarter/quadrant scanning examination? Why or why not?

CASE STUDY

STIFF AND PAINFUL SHOULDER

History and Systems Review

General Demographics

The patient is a 55-year-old female who lives alone.

History of Current Condition

The patient reports a 7-month history of unilateral shoulder girdle stiffness, pain, and weakness with a diagnosis from the physician of "right frozen shoulder." There was no history of trauma, but the patient reported an abrupt onset of very severe pain 7 months prior. Within several days, she also had right forearm and thumb pain of lesser severity, and weakness of the right shoulder.

The forearm and thumb pain had since resolved, and although there was some restricted motion of the shoulder, the more marked painful stiffness of the shoulder did not occur until 2 or 3 months after the onset of symptoms. After 3 months, she was having difficulties performing her job functions and sought medical attention. Thus far, she had been treated with a series of two corticosteroid injections, both of which had given her short-term relief.

History of Current Condition

Non–work-related right shoulder injury 5 years ago, which resolved in 2 months with a course of physical therapy, including ROM and strengthening exercises, which she followed for 1 month after discharge from physical therapy.

Medical and Surgical History

Unremarkable. Gall bladder surgery 2 years ago.

Medications

Daily 800 mg ibuprofen and high blood pressure medication.

Other Tests and Measures

None.

Occupational, Employment, and School

Patient was a mail reception clerk for the postal service, and her job involved monitoring incoming mail, which required repeated opening and lifting of mail packages.

Functional Status and Activity Level

Stiffness/soreness occurs at the first hour in the morning, and again at the end of the day after working. Pain interferes with sleep two times per night, especially with rolling in bed or driving to work, which takes 30 minutes. The patient discontinued her normal three-times-a-week aerobic workout and upper and lower body resistance exercises approximately 3 months ago.

Health Status (Self-Report)

In general, the patient is in good health, except for a minor heart problem (congestive heart failure) and high blood pressure.

Questions

1. At this point in the examination, is it possible to determine the patient's diagnosis? Why or why not?
2. What does the history of pain with sleeping on the shoulder and pain/stiffness in the morning tell the clinician?
3. Why do you think the patient's symptoms are related to time of day?
4. What additional questions would you ask to help rule out pain referred from a visceral structure given the patient's medical history?
5. Do you have a working hypothesis at this stage? List the various diagnoses that could present with these signs and symptoms, and the tests you would use to rule out each one.
6. Does this presentation/history warrant a scan? Why or why not?
7. Do you think the patient's age is a factor?

REVIEW QUESTIONS*

1. What is the capsular pattern of the G-H joint?
2. The shoulder joint is capable of much motion, but sacrifices some stability to achieve this degree of motion. The weakest portion of the shoulder joint capsule is located:
   A. anteriorly
   B. posteriorly
   C. laterally
   D. inferiorly
   E. superiorly
3. Name four muscles that internally rotate the shoulder.
4. Name three muscles that externally rotate the shoulder.
5. Name four muscles that attach to the greater tuberosity of the humerus.

*Additional questions to test your understanding of this chapter can be found in the Online Learning Center for *Orthopaedic Assessment, Evaluation, and Intervention* at www.duttononline.net.

CHAPTER 17 Elbow

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joints, ligaments, muscles, and blood and nerve supply comprising the elbow complex.
2. Describe the biomechanics of the elbow complex, including open- and close-packed positions, normal and abnormal joint barriers, force couples, and stabilizers.
3. Describe the purpose and components of the tests and measures for the elbow complex.
4. Perform a comprehensive examination of the elbow complex, including palpation of the articular and soft-tissue structures, specific passive mobility and passive articular mobility tests, and stability tests.
5. Evaluate the total examination data to establish a prognosis.
6. Describe the relationship between muscle imbalance and functional performance of the elbow.
7. Outline the significance of the key findings from the tests and measures and establish a diagnosis or working hypothesis.
8. Summarize the various causes of elbow dysfunction.
9. Develop self-reliant intervention strategies based on clinical findings and established goals.
10. Describe and demonstrate intervention strategies and techniques based on clinical findings and established goals.
11. Evaluate the intervention effectiveness in order to progress or modify an intervention.
12. Plan an effective home program and instruct the patient in same.

OVERVIEW

The elbow serves an important linkage function that enables proper positioning of the hand and the transmission of power from the shoulder to the hand, thus augmenting the versatility and agility of the upper extremity. Unlike the shoulder, the elbow complex is an inherently strong and stable joint, because of the interrelationship of its articular surfaces and ligamentous constraints. However, the stability of the elbow complex allows little in the way of compensatory adjustments, making it particularly vulnerable to overuse injury from repetitious muscle activity and sudden movements of acceleration and deceleration. Appropriate diagnosis and treatment require a detailed understanding of the normal anatomy of the elbow.

ANATOMY

The elbow complex, enclosed within the capsule of the cubital articulation, is composed of three distinct articulations: the humeroulnar joint, the humeroradial joint, and the proximal radioulnar joint. The anterior joint capsule of the elbow originates from the distal humerus proximal to the radial and coronoid fossa, from where it then inserts distally into the rim of the coronoid and the annular ligament (AL).[1] Posteriorly, the capsule incorporates the area proximal to the olecranon process; it attaches distally along the articular margin of the sigmoid notch and the proximal aspect of the olecranon fossa.[2]

CLINICAL PEARL

The joint capsule of the elbow complex is thin but strong, and is reinforced medially and laterally by ligaments. Anteriorly, the capsule contributes 38% of the resistance to valgus force and 32% of the resistance to varus force in full extension.[3] The capsule of the joint does not respond well to injury or prolonged immobilization, and often forms thick scar tissue, which may result in flexion contractures of the elbow.[4–6]

HUMEROULNAR JOINT

The humeroulnar (trochlear) joint is a uniaxial hinge joint formed between the incongruent saddle-shaped joint surfaces of the spool-shaped trochlea of the humerus and the trochlear notch of the proximal ulna (Fig. 17-1). Anteriorly, the humeral

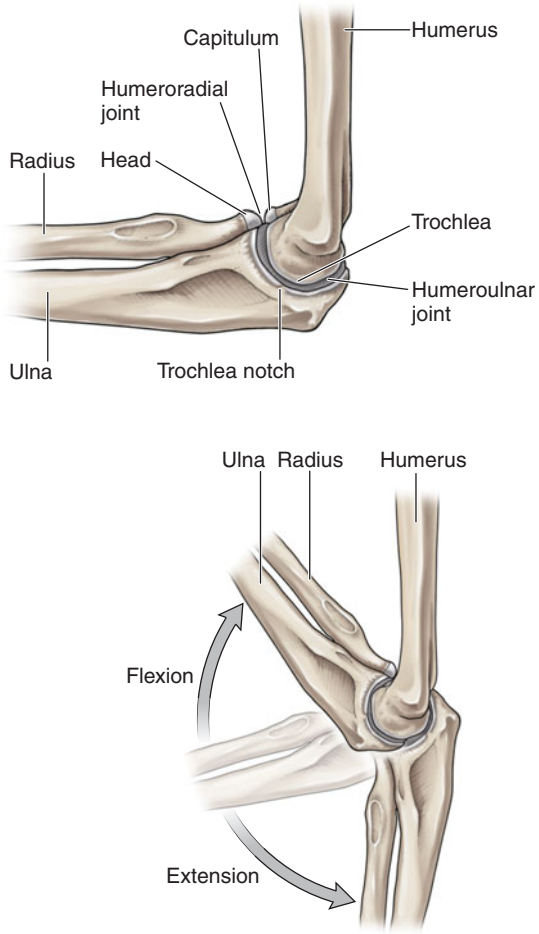

FIGURE 17-1 The bony structures of the elbow complex. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *Gross Anatomy: The Big Picture*. McGraw-Hill, 2011)

trochlear groove is vertical and parallel to the longitudinal groove, while, posteriorly, the groove runs obliquely lateral and distal, forming an acute angle of about 15 degrees with the longitudinal axis of the humerus.[7] This valgus angulation is referred to as the "carrying angle" of the elbow. Three hundred degrees of the articular surface of the trochlea is covered with hyaline cartilage, compared with only 180 degrees on the trochlear notch.[8]

CLINICAL PEARL

The carrying angle serves to direct the ulna laterally during extension and increase the potential for elbow flexion motion, as the offset allows room anteriorly for approximation of the muscles of the arm and the forearm. The carrying angle is approximately 11–14 degrees in males and 13–16 degrees in females.[9–11]

The resting, or open-packed position for the humeroulnar joint is 70 degrees of flexion with 10 degrees of forearm supination. The close-packed position is full extension and maximum forearm supination. For the part of the joint between the coronoid process and the humerus, the close-packed position is maximum flexion. The capsular pattern is much more limitation of flexion than extension.[12]

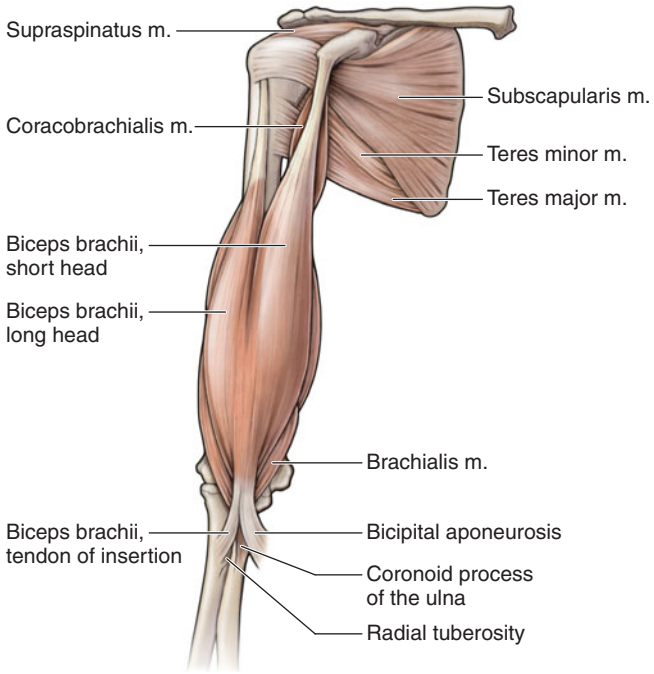

FIGURE 17-2 The biceps. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *Gross Anatomy: The Big Picture*. McGraw-Hill, 2011)

HUMERORADIAL JOINT

The humeroradial (radiocapitellar) joint is a uniaxial hinge joint formed between the spherical capitellum of the humerus and the concave fovea of the radial head (see Fig. 17-1). The design of this joint allows the elbow to flex and extend and for the radius to rotate. The superior surface of the proximal end of the radius is biconcave, while the head of the radius is slightly oval. The radial tuberosity (see Fig. 17-2) serves as a site of attachment for the biceps brachii (see Fig. 17-2). The humerus widens at the elbow and forms the medial and lateral epicondyles.

CLINICAL PEARL

The resting, or open-packed position of the humeroradial joint is extension and forearm supination. The close-packed position is approximately 90 degrees of elbow flexion and 5 degrees of supination. There is no true capsular pattern at this joint, although clinically an equal limitation of pronation and supination is observed.

PROXIMAL RADIOULNAR JOINT

The radius and the ulna lie side by side, with the radius being the shorter and more lateral of the two forearm bones. The proximal or superior radioulnar joint is a uniaxial pivot joint. It is formed between the periphery of the convex radial head, and the fibrous osseous ring formed by the concave radial notch of the ulna (see Fig. 17-3), which lies distal to the trochlear notch, and the AL. The AL (Fig. 17-4) forms 80% of the articular surface of the proximal radioulnar joint (see Annular Ligament later).

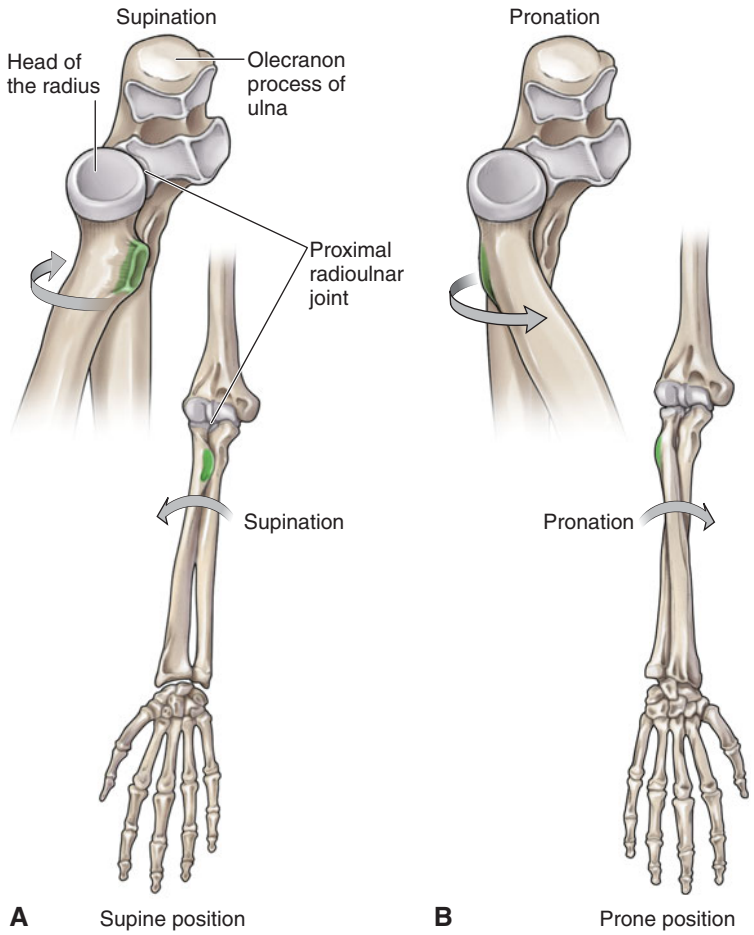

FIGURE 17-3 The proximal radioulnar joint. (Reproduced with permission, from Morton DA, Foreman KB, Albertine KH: *Gross Anatomy: The Big Picture*. McGraw-Hill, 2011)

CLINICAL PEARL

The resting, or open-packed position for the proximal radioulnar joint is 70 degrees of flexion and 35 degrees of forearm supination. The close-packed position is 5 degrees of forearm supination. The capsular pattern is minimal loss of motion, with pain at the end ranges of pronation and supination.[12]

The proximal and distal radioulnar joints together form a bicondylar joint. An interosseous membrane, sometimes

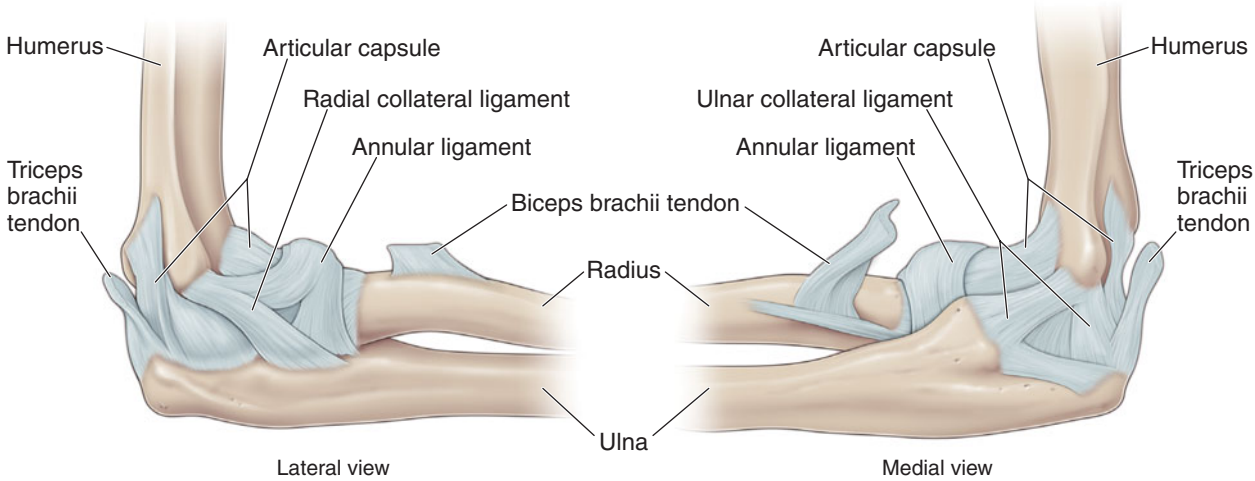

FIGURE 17-4 Elbow joint with ligaments detailed. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *Gross Anatomy: The Big Picture*. McGraw-Hill, 2011)

referred to as the middle radioulnar articulation and located between the radius and the ulna, serves to help distribute forces throughout the forearm, and provide muscle attachment. Most of the fibers of the interosseous membrane of the forearm are directed away from the radius in an oblique medial and distal direction.[8] Approximately 8% of the compression force due to bearing weight to the forearm crosses the wrist between the lateral side of the carpus and the radius.[8] The remaining 20% of the compression force passes across the medial side of the carpal bones and the ulna.[8] Because of the fiber orientation of the interosseous membrane, some of the proximal directed force through the radius is transferred across the membrane to the ulna.[13]

LIGAMENTS

Support for the elbow complex is provided through strong ligaments (Fig. 17-4).

Medial Ligament Complex

The ulna collateral ligament (UCL) or medial collateral ligament (MCL) extends from the central two-thirds of the anteroinferior surface of the medial epicondyle to the proximal medial ulna, from just posterior to the axis of the elbow medial epicondyle,[14–16] to just distal to the tip of the coronoid (see Fig. 17-4).[17,18]

The fan-shaped MCL is the most important ligament in the elbow for providing stability against valgus stress, particularly in the range of 20–130 degrees of flexion and extension,[19] with the humeroradial joint functioning as a secondary stabilizer to valgus loads.[20,21] The MCL achieves this stability through almost the total range of flexion and extension due to its eccentric location with respect to the axis of elbow motion.[22–25] In full elbow extension, valgus stability of the elbow is provided equally by the MCL, the joint capsule, and the joint interactions.[5]

There are three distinct components of the MCL[14,17,26,27]: the anterior bundle, the transverse bundle, and the posterior bundle (Fig. 17-4).

Anterior Bundle

The anterior bundle of the MCL is the strongest and stiffest of the elbow collateral ligaments, with an average load to failure of 260 newtons (N).[19] The anterior bundle of the MCL inserts an average of 18 mm distal to the coronoid tip, and is composed of two other components, the anterior band and the posterior band, which perform reciprocal functions[17,22,26]:

- The anterior band of the anterior bundle is the most important component of the ligamentous complex, because it primarily stabilizes the elbow against valgus stress in the ranges of 0–60 degrees of flexion, and becomes a secondary restraint with further flexion.[3,14,17,20–22,24,26,28] The anterior band is primarily responsible for stability against valgus stresses at 30, 60, and 90 degrees of flexion, making it the most important component in resisting the valgus forces associated with overhead sports activities.[1] Recently, Ochi and colleagues[15] determined that the deep middle portion of the anterior band, previously described as the "guiding bundle,"[27] is a prime limiting factor in humeroulnar motion.[22,29]
- The posterior band is taut from 60 degrees to 120 degrees of elbow flexion, and is a secondary restraint to valgus stress at 30 degrees and 90 degrees of flexion, but a primary restraint to valgus at 120 degrees of elbow flexion.[26] The posterior band functions as an equal co-restraint with the anterior band at terminal elbow flexion,[3,19,22,26,28] and also acts as a primary restraint to passive elbow extension. In the higher degrees of flexion, the posterior band is nearly isometric and is thus functionally important in the overhead athlete in counteracting valgus stresses.[30]

Oblique (Transverse) Bundle

The oblique bundle, also known as Cooper's ligament, is variably present.[14,17,31] It does not cross the elbow joint and comprises fibers running along the medial joint capsule from the tip of the olecranon to the medial ulna, just distal to the coronoid.[14,32] The transverse fibers have little role in elbow stability due to the fact that they both originate and insert on the ulna.

Posterior Oblique Bundle

The posterior bundle of the MCL originates from the medial epicondyle and inserts onto the medial margin of the semilunar notch, forming the floor of the cubital tunnel and a thickening of the posterior elbow capsule.[32,33] Being thinner and weaker than the anterior bundle, the posterior bundle becomes taut at 60 degrees of elbow flexion, but provides only secondary restraint to valgus stress at flexion beyond 90 degrees.[22,23]

Lateral Ligament Complex

Unlike the medial ligament complex, the lateral ligamentous complex (see Fig. 17-4) is less discrete and individual variation is common. The lateral complex consists of the AL, the lateral-radial collateral ligament (LCL), and the lateral ulnar collateral ligament (LUCL).[19] The LCL courses distally and forms a broad conjoint insertion onto the proximal ulna.[34,35] The proximal margin of this conjoined insertion begins at the proximal aspect of the radial head, just inferior to the radial notch. From here, it progresses along a rough ridge in line with the supinator crest of the ulna.[19] The LCL is closely associated with the insertions of the extensor carpi radialis brevis (ECRB) and the supinator, with the latter muscle crossing this ligament complex obliquely from distal to proximal at its ulnar attachment and becoming confluent with the underlying AL and LCL more proximally at its humeral origin.[19] The LUCL originates from the lateral epicondyle from where it passes over the AL and then begins to blend with it distally where it inserts onto the supinator crest of the ulna.[14] It is unclear as to how much stability is provided by the LUCL, but it may help prevent posterolateral rotary instability.[36]

As a unit, the lateral ligament complex functions to maintain the ulnohumeral and radiohumeral joints in a reduced position when the elbow is loaded in supination. More specifically, the anterior portion of the LCL stabilizes the proximal radioulnar joint during full supination; the posterior portion

stabilizes the joint during pronation. As the axis of rotation passes through the origin of the LCL, the various fibers of this ligament maintain consistent patterns of tension whether varus, valgus, or no force is applied to the elbow throughout the arc of flexion.[14,28] The LCL contributes only 9% of the restraint to varus stress at 90 degrees of flexion. In extension the LCL contributes 14% of this restraint.[28]

Insufficient lateral support of the elbow complex results in lateral gapping at the ulnohumeral joint and posterior translation of the radial head in relation to the capitellum.[19] However, the proximal radioulnar relationship remains undisturbed.

CLINICAL PEARL

As much as 50% of elbow stability is the result of the joint capsule, MCL and the lateral ligament complex. The remaining 50% is associated with the bony structure of the joint. Other structures also provide passive support to the elbow complex. Secondary restraints of the lateral elbow consist of the bony articulations, and the extensor muscles with their fascial bands and intermuscular septa (see "Force Couples of the Elbow"). Secondary restraints of the lateral elbow consist of the bony articulations, the joint capsule (see Fig. 17-4), and the extensor muscles with their fascial bands and intermuscular septa. These independently support the forearm unit from laterally rotating away from the humerus by virtue of their anatomic arrangement, and provide a secondary static and dynamic vector supporting the lateral joint.[35]

Annular Ligament

The AL (Fig. 17-4), which is wider proximally and distally, runs around the radial head from the anterior and the posterior margin of the radial notch, to approximate the radial head to the radial notch and enclose the radial circumference. The AL forms a band that encircles 80% of the radial head and functions to maintain the relationship between the head of the radius and the humerus and ulna. The internal circumference of the AL is lined with cartilage to reduce the friction against the radial head during pronation and supination.[8] The external surface of the ligament receives attachments from the elbow capsule, the radial collateral ligament, and the supinator muscle.

Quadrate Ligament

The quadrate ligament is a short, stout ligament that arises just below the radial notch of the ulna and attaches to the medial surface of the neck of the radius.[8] This ligament lends structural support to the capsule of the proximal radioulnar joint.[8]

BURSAE

There are numerous bursae in the elbow region.[23] The olecranon bursa is the main bursa of the elbow complex and lies posteriorly between the skin and the olecranon process. Under normal conditions, the bursa does not communicate with the elbow joint, although its superficial location puts it at high risk of injury from direct trauma to the elbow.

Other bursae in the posterior elbow region include the deep intratendinous bursa and a deep subtendinous bursa, which are present between the triceps tendon and olecranon. Anteriorly, the bicipitoradial bursa separates the biceps tendon from the radial tuberosity. Along the medial and lateral aspects of the elbow are the subcutaneous medial epicondylar bursa and the subcutaneous lateral epicondylar bursa.[37]

MUSCLES

A summary of the muscles of the elbow is outlined in Table 17-1. The muscles of the forearm are contained within three major fascial compartments, the anterior forearm, the posterior forearm, and the compartment referred to as the mobile wad (Table 17-2).

Elbow Flexors

Anatomic, biomechanic, and electromyographic (EMG) analyses have demonstrated that the prime movers of elbow flexion are the biceps, brachialis, and brachioradialis (see Table 17-1).[38] The pronator teres, flexor carpi radialis (FCR), flexor carpi ulnaris (FCU) (Fig. 17-5), and the extensor carpi radialis longus (ECRL) muscles are considered to be weak flexors of the elbow.[37] Most elbow flexors, and essentially all the major supinator and pronator muscles, have their distal attachments on the radius.[8] Contraction of these muscles, therefore, pulls the radius proximally against the humeroradial joint.[39,40] The combined efforts of all the elbow flexors can create large amounts of elbow flexion torque. The interosseous membrane transfers and dissipates a portion of this muscle force to the radius and to the ulna.[8] The reverse action of the elbow flexors can be used in a closed chain activity by bringing the upper arm closer to the forearm such as when performing a pull-up.[41]

Biceps Brachii

The biceps is a two-headed muscle that spans two joints. The short head of the biceps arises from the tip of the coracoid process of the scapula, whereas the long head arises from the supraglenoid tuberosity of the scapula (Fig. 17-2). The biceps has two insertions: the radial tuberosity and by the lacertus fibrosus (see Fig. 17-2).

At the elbow, the biceps is a dominant flexor, but its secondary function is supination of the forearm.[42] The supination action of the biceps increases the more the elbow is flexed and is maximal at 90 degrees. It diminishes again when the elbow is fully flexed. No,[43] or limited,[44] biceps muscle activity has been demonstrated during elbow flexion, with the forearm pronated.[37] The biceps, via its long head, also functions as a shoulder flexor (see Chap. 16).

Brachialis

The brachialis (Fig. 17-6) originates from the lower two-thirds of the anterior surface of the humerus and inserts on the ulnar tuberosity and the coronoid process. The brachialis is the workhorse of the elbow and functions to flex the elbow regardless of the degree of pronation and supination of the forearm.[44] It is the most powerful flexor of the elbow when the forearm is pronated.[45]

TABLE 17-1 Muscles of the Elbow, Forearm, Wrist, and Hand: Their Actions, Nerve Supply, and Nerve Root Derivation

Muscles	Nerve Supply	Nerve Root Derivation	Action
Triceps	Radial	C7–C8	Elbow extension
Anconeus	Radial	C7–C8, (T1)	
Brachialis	Musculocutaneous	C5–C6, (C7)	Elbow Flexion
Biceps brachii	Musculocutaneous radial	C5–C6	
Brachioradialis		C5–C6, (C7)	
Biceps brachii	Musculocutaneous	C5–C6	Supination of the forearm
Supinator	Posterior interosseous (radial)	C5–C6	
Pronator quadratus	Anterior interosseous (median)	C8, T1	Pronation of the forearm
Pronator teres	Median	C6–C7	
Flexor carpi radialis	Median	C6–C7	
Extensor carpi radialis longus	Radial	C6–C7	Extension of the wrist
Extensor carpi radialis brevis	Posterior interosseous (radial)	C7–C8	
Extensor carpi ulnaris	Posterior interosseous (radial)	C7–C8	
Flexor carpi radialis	Median	C6–C7	Flexion of the wrist
Flexor carpi ulnaris	Ulnar	C7–C8	
Flexor carpi ulnaris	Ulnar	C7–C8	Ulnar deviation of the wrist
Extensor carpi ulnaris	Posterior interosseous (radial)	C7–C8	
Flexor carpi radialis	Median	C6–C7	Radial deviation of the wrist
Extensor carpi radialis longus	Radial	C6–C7	
Abductor pollicis longus	Posterior interosseous (radial)	C7–C8	
Extensor pollicis brevis	Posterior interosseous (radial)	C7–C8	
Extensor digitorum communis	Posterior interosseous (radial)	C7–C8	Extension of the fingers
Extensor indicis	Posterior interosseous (radial)	C7–C8	
Extensor digiti minimi	Posterior interosseous (radial)	C7–C8	
Flexor digitorum profundus	Lateral: Anterior interosseous (median) Medial: Ulnar	C8, T1 C8, T1	Flexion of the fingers (lateral aspect flexes the second and third digits; medial aspect flexes the fourth and fifth digits
Flexor digitorum superficialis	Median	C7–C8, T1	Flexion of the fingers

Brachioradialis

The brachioradialis (Fig. 17-5) arises from the proximal two-thirds of the lateral supracondylar ridge of the humerus and the lateral intermuscular septum. It travels down the forearm and inserts on the lateral border of the styloid process on the distal aspect of the radius.

The brachioradialis appears to have a number of functions, two of which occur with rapid movements of elbow flexion. Initially it functions as a shunt muscle, overcoming centrifugal forces acting on the elbow, and then by adding power to increase the speed of flexion.[42]

The brachioradialis also functions to bring a pronated or supinated forearm back into the neutral position of pronation and supination. In the neutral or pronated position, the muscle acts as a flexor of the elbow, an action that diminishes when the forearm is held in supination.[44,46]

Pronator Teres

The pronator teres (see Fig. 17-5) has two heads of origin: a humeral head and an ulnar head. The humeral head arises from the medial epicondylar ridge of the humerus and common flexor tendon, whereas the ulnar head arises from the medial aspect of the coronoid process of the ulna. The pronator teres inserts on the anterolateral surface of the midpoint of the radius. The muscle functions predominantly to pronate the forearm, but can also assist with elbow flexion.[5,45,46]

TABLE 17-2 Muscle Compartments of the Forearm

Compartment	Principal Muscles
Anterior	Pronator teres
	Flexor carpi radialis
	Palmaris longus
	Flexor digitorum superficialis
	Flexor digitorum profundus
	Flexor pollicis longus
	Flexor carpi ulnaris
	Pronator quadratus
Posterior	Abductor pollicis longus
	Extensor pollicis brevis
	Extensor pollicis longus
	Extensor digitorum communis
	Extensor digitorum proprius
	Extensor digiti quinti
	Extensor carpi ulnaris
Mobile wad	Brachioradialis
	Extensor carpi radialis longus
	Extensor carpi radialis brevis

Extensor Carpi Radialis Longus

The ECRL arises from a point superior to the lateral epicondyle of the humerus on the lower third of the supracondylar ridge, just distal to the brachioradialis. It travels down the forearm to insert on the posterior surface of the base of the second metacarpal. The muscle functions as a weak flexor of the elbow, as well as assisting with wrist extension and radial deviation.

Flexor Carpi Radialis

The FCR (see Fig. 17-5) arises from the common flexor tendon on the medial epicondyle of the humerus and inserts on the base of the second and third metacarpal bones. The FCR functions to flex the elbow and wrist but also assists in pronation and radial deviation of the wrist.

Flexor Carpi Ulnaris

The FCU (see Fig. 17-5) has two heads of origin. The humeral head arises from the common flexor tendon on the medial epicondyle of the humerus. It inserts on the pisiform, hamate, and fifth metacarpal bones. The FCU functions to assist with elbow flexion in addition to flexion and ulnar deviation of the wrist.

Forearm Pronators

Pronator Teres

See above.

Pronator Quadratus

The fibers of the pronator quadratus run perpendicular to the direction of the arm, running from the most distal quarter of the anterior ulna to the distal quarter of the anterior radius (see Fig. 17-5). It is the only muscle that attaches only to the ulna at one end and the radius at the other end.

The pronator quadratus is the main pronator of the hand.

Forearm Supinators

Biceps

The effectiveness of the biceps as a supinator is greatest when the elbow is flexed to 90 degrees, placing the biceps tendon at a 90-degree angle to the radius. In contrast, with the elbow flexed only 30 degrees, much of the rotational efficiency of the biceps is lost.[41]

Supinator

The supinator originates from the lateral epicondyle of the humerus, LCL, the AL, the supinator crest, and the ulnar fossa. It inserts on the superior third of the anterior and lateral surface of the radius. The supinator muscle is a relentless

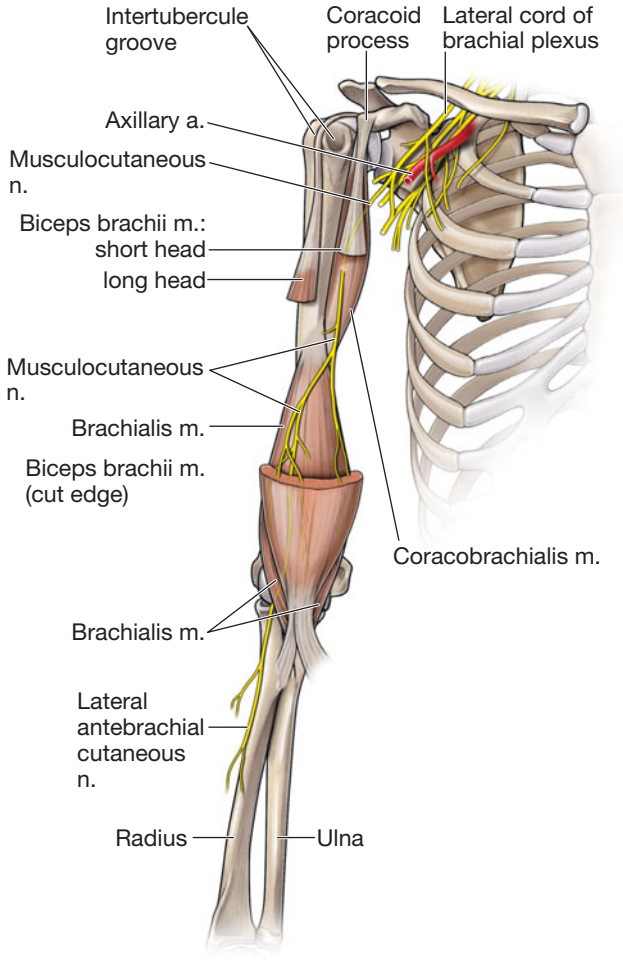

FIGURE 17-6 The brachialis muscle. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *Gross Anatomy: The Big Picture.* McGraw-Hill, 2011)

forearm supinator, similar to the brachialis during elbow flexion. The supinator functions to supinate the forearm in any elbow position, while the previously mentioned ECRL and brevis work as supinators during fast movements, and against resistance.

The nervous system usually recruits the supinator muscle for low-power tasks that require a supination motion only, while the biceps remains relatively inactive—a fine example of the law of parsimony (see Chap. 3).[8]

CLINICAL PEARL

The muscles about the elbow help provide stability by compressing the joint surfaces through muscular contraction.[47] The flexor and pronator muscles, which originate at the medial epicondyle, provide additional static and dynamic support to the medial elbow,[5] with the FCU and flexor digitorum superficialis (FDS) being the most effective in this regard.[48]

Elbow Extensors

There are two muscles that extend the elbow: the triceps and the anconeus (see Table 17-1).

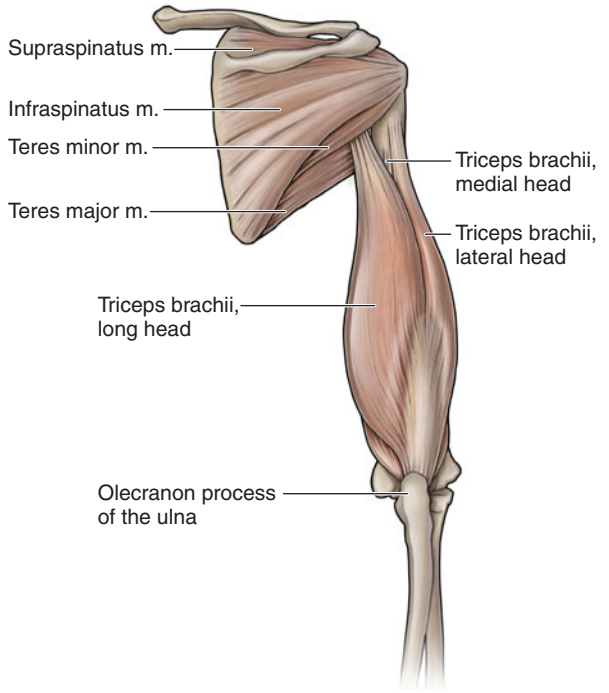

FIGURE 17-7 The triceps. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *Gross Anatomy: The Big Picture.* McGraw-Hill, 2011)

Triceps Brachii

The triceps brachii (Fig. 17-7) has three heads of origin. The long head arises from the infraglenoid tuberosity of the scapula, the lateral head from the posterior and lateral surface of the humerus, and the medial head from the lower posterior surface of the humerus. The muscle inserts on the superoposterior surface of the olecranon and deep fascia of the forearm. The triceps has its maximal force in movements that combine both elbow extension and shoulder extension. Like the biceps, it is a two-joint muscle. The medial head of the triceps is the workhorse of elbow extension, with the lateral and long heads recruited during heavier loads.[49] During strong contractions of the triceps, for example a push-up, which involves a combination of elbow extension and shoulder flexion, as the triceps strongly contracts to extend the elbow, the shoulder simultaneously flexes by the action of the anterior deltoid, which overpowers the shoulder extension torque of the long head of the triceps.[41]

Anconeus

The anconeus arises from the lateral epicondyle of the humerus and inserts on the lateral aspect of the olecranon and posterior surface of the ulna. The exact function of the anconeus in humans has yet to be determined, although it appears to be a fourth head of the elbow extension mechanism, similar to the quadriceps of the knee.[8] It has been suggested that in addition to assisting with elbow extension, forearm pronation and supination, the anconeus functions to stabilize the ulnar head in all positions (except radial deviation) and to pull the subanconeus bursa and the joint capsule out of the way during extension, thus avoiding impingement.[5,44,50]

CLINICAL PEARL

Tendinitis of the anconeus can mimic tennis elbow, while hypertrophy of the anconeus muscle can compress the ulnar nerve.[51]

CUBITAL TUNNEL

The cubital tunnel, a fibro-osseous canal, was originally described by Feindel and Stratford.[52] The ulnar nerve passes through this tunnel. The floor of the tunnel is formed by the MCL, whereas the roof is formed by an aponeurosis, the arcuate ligament, or Osborne's band, which extends from the medial epicondyle to the olecranon and arises from the origin of the two heads of the FCU.[53–56] The medial head of the triceps constitutes the posterior border of the tunnel, and its anterior and lateral borders are formed by the medial epicondyle and olecranon, respectively.[30]

The volume of the cubital tunnel is greatest with the elbow held in extension.[57] As the elbow is brought into full flexion, there is a 55% decrease in canal volume.[53] Vanderpool and colleagues[58] reported that with each 45 degrees of flexion of the elbow, there was a concomitant 5-mm increase in distance between the ulnar and humeral attachments of the arcuate ligament. At full elbow flexion, there was a 40% elongation of the ligament and a decrease in canal height of approximately 2.5 mm.

A few other factors have been associated with a decrease in the size of the cubital tunnel. These include space-occupying lesions, osteoarthritis, rheumatoid arthritis, heterotopic bone formation, or trauma to the nerve.[57] Patients with systemic conditions such as diabetes mellitus, hypothyroidism, alcoholism, and renal failure also may have a predisposition.[59]

Bulging of the MCL has also been described as a factor.[58] More than 40% of athletes with valgus instability develop ulnar neuritis secondary to irritation from inflammation of the MCL.[60,61]

O'Driscoll and coworkers[56] reported that the groove on the inferior aspect of the medial epicondyle was not as deep as the groove posteriorly, and the floor of the canal seems to rise with elbow flexion.[56] These changes lead to an alteration of the cross-sectional area of the cubital tunnel from a rounded surface to a triangular or elliptic surface with elbow flexion.[53,57]

CLINICAL PEARL

The volume of the cubital tunnel is greatest with the elbow held in extension.

CUBITAL FOSSA

The cubital fossa (Fig. 17-8) represents a triangular space, or depression that is located over the anterior surface of the elbow joint, and which serves as an "entry way" to the forearm, or antebrachium. The boundaries of the fossa are

- ***lateral.*** Brachioradialis and ECRL muscles;
- ***medial.*** Pronator teres muscle;
- ***proximal.*** An imaginary line that passes through the humeral condyles;

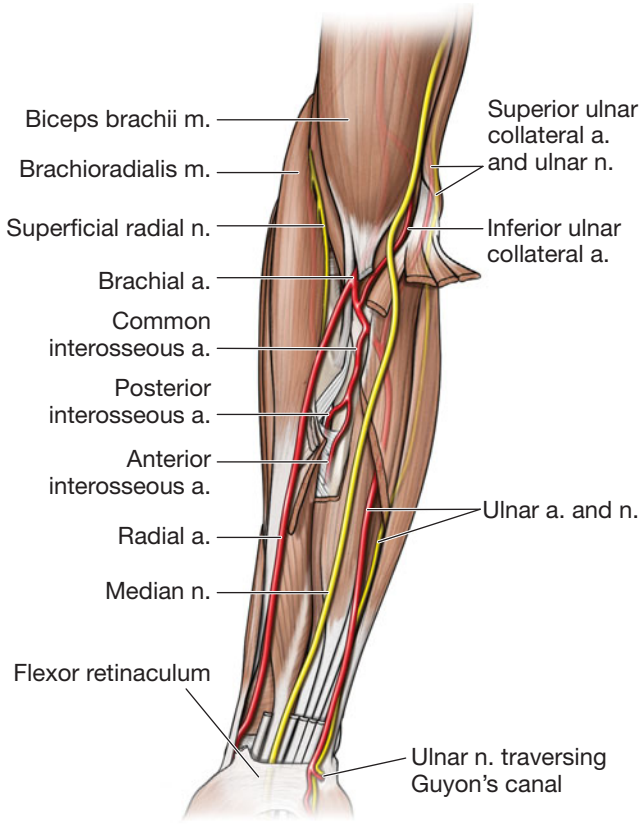

FIGURE 17-8 The cubital fossa. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *Gross Anatomy: The Big Picture.* McGraw-Hill, 2011)

- ***floor.*** Brachialis muscle.

The contents of the fossa include (see Fig. 17-8)

- the tendon of the biceps brachii, which lies as the central structure in the fossa;
- the median nerve, which runs along the lateral edge of the pronator teres muscle;
- the brachial artery, which enters the fossa just lateral to the median nerve and just medial to the biceps brachii tendon;
- the radial nerve (not shown), which runs along the medial edge of the brachioradialis and ECRL muscles and is vulnerable to injury here;
- the median cubital or intermediate cubital cutaneous vein, which crosses the surface of the fossa.

NERVES

The neurologic supply of the bones, joints, muscles, and skin of the elbow and forearm is derived from the C5 through C8 nerve roots, which exit from the intervertebral foramina of C4–5 through C7–T1 (Fig. 17-6 and Fig. 17-9).[62]

Ulnar Nerve (C8–T1)

From its origin as the largest branch of the medial cord of the brachial plexus, the ulnar nerve continues along the anterior compartment of the arm, before passing through the medial intermuscular septum at the level of the coracobrachialis insertion.

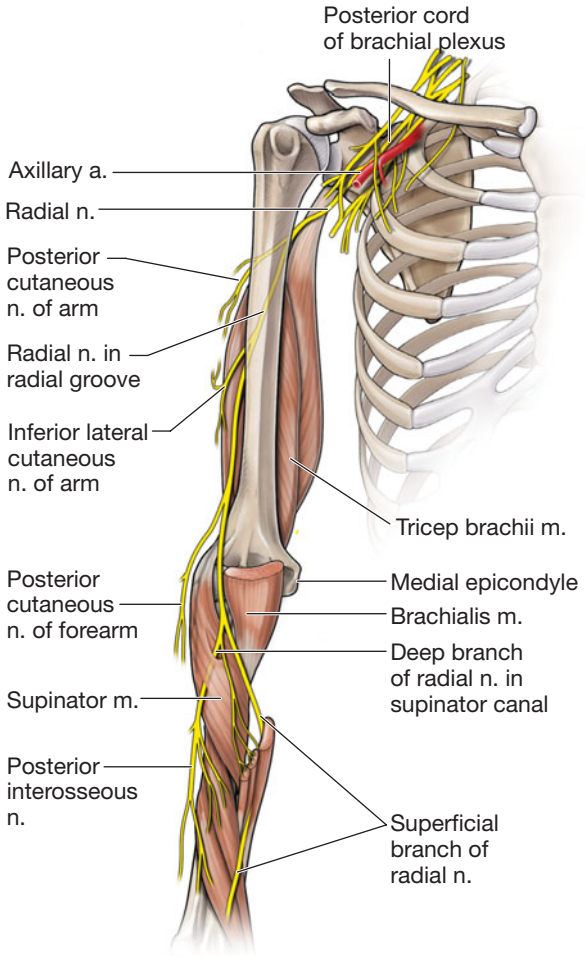

FIGURE 17-9 Nerve supply of the elbow and forearm. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *Gross Anatomy: The Big Picture*. McGraw-Hill, 2011)

At the level of the elbow, the ulnar nerve passes posterior to the medial epicondyle, where it enters the cubital tunnel. Ulnar nerve compression in the cubital tunnel is a common entrapment neuropathy of the upper extremity, second only to carpal tunnel syndrome (CTS).[63] After leaving the cubital tunnel, the ulnar nerve passes between the two heads of the FCU origin and traverses the deep flexor–pronator aponeurosis.[64,65]

Median Nerve (C5–T1)

The median nerve extends medially down the upper arm across the anterior aspect of elbow joint. The ligament of Struthers arises from an abnormal spur on the shaft of the humerus and runs to the medial supracondylar process.[55] The supracondylar process with its ligamentous extension encloses a foramen, bounded medially by the medial intermuscular septum, and the distal anterior surface of the medial epicondyle, through which the brachial artery and median nerve pass.[66]

As the median nerve passes through the cubital fossa, the anterior interosseous nerve (AIN) branches off it, as it passes through the two heads of the pronator teres muscle. The AIN supplies the motor innervation to the index and middle flexor digitorum profundus (FDP), the flexor pollicis longus (FPL), and the pronator quadratus.

Radial Nerve (C5–T1)

The radial nerve sits superiorly and medially in the upper arm, and winds around humeral shaft. At a point approximately 10–12 cm proximal to the elbow joint, the radial nerve passes from the posterior compartment of the arm by piercing the lateral intermuscular septum.[67] The nerve travels in the anterior forearm between the brachialis muscle and the biceps tendon medially, and the brachioradialis, ECRL, and ECRB muscles laterally.[67] Within an area approximately 3 cm proximal or distal to the elbow joint, the radial nerve branches into a deep mixed nerve, the posterior interosseous nerve (PIN), and a superficial sensory branch.[68,69] After dividing, the two terminal divisions usually follow the same course, sharing a single epineurium for several centimeters, before the superficial radial nerve moves anteriorly to lie on the undersurface of the brachioradialis, and the deep branch travels posteriorly to enter the radial tunnel/supinator canal, distal to the origin of the ECRB, at the level of the radiohumeral joint.[67] Entering the canal, the deep branch supplies the ECRB then passes deep to the superficial head of the supinator, where the arcade of Fröhse* can impinge on the nerve.[70,71]

The nerve continues between the two heads of the supinator and innervates this muscle during its passage to the posterolateral aspect of the radius. On emerging from the supinator, a motor division (supplying the abductor pollicis longus, extensor pollicis brevis, extensor indicis proprius, and extensor pollicis longus muscles) and a mixed lateral branch (supplying the extensor carpi ulnaris, extensor digitorum communis, and extensor digiti minimi muscles) are recognized. The lateral branch continues along the posterior-radial border of the radius to the wrist as the sensory branch of the PIN, which innervates the posterior (dorsal) capsule of the wrist and intercarpal joints (see Chap. 18).[67,71]

The Radial Tunnel/Supinator Canal

The radial tunnel lies on the anterior aspect of the radius and is approximately three to four fingerbreadths long, beginning just proximal to the radiohumeral joint and ending at the site where the PIN passes deep to the superficial part of the supinator muscle.[72] The lateral wall of the tunnel is formed by the brachioradialis, ECRL, and ECRB. These muscles cross over the nerve to form the anterior wall of the radial tunnel as well, while the floor of the tunnel is formed by the capsule of the humeroradial joint, and the medial wall is composed of the brachialis and biceps tendon.[67]

VASCULAR SUPPLY

The vascular supply to the elbow (Fig. 17-10) includes the brachial artery, the radial and ulnar arteries, the middle and radial collateral artery laterally, and the superior and inferior ulnar collateral arteries.[37]

*The arcade of Fröhse is an inverted arched structure that lies within 1 cm distal of the fibrous edge of the ECRB and approximately 2–4 cm distal to the radiohumeral joint. It represents the proximal border of the superficial head of the supinator, through which the radial nerve passes.

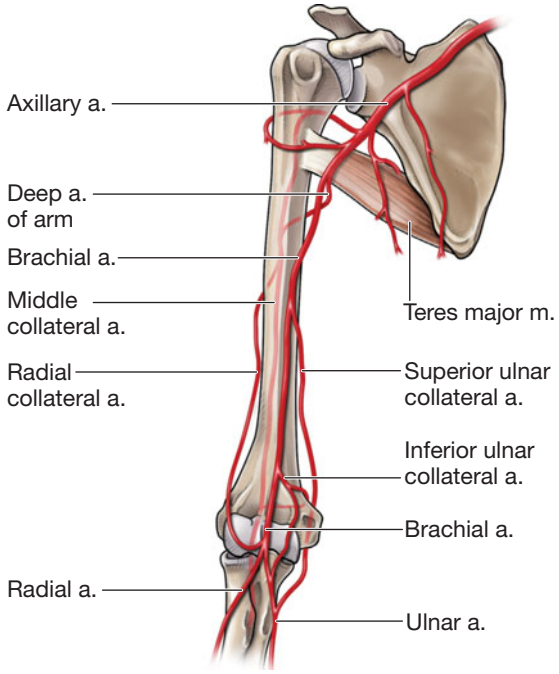

FIGURE 17-10 Vascular supply of the elbow and forearm. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *Gross Anatomy: The Big Picture*. McGraw-Hill, 2011)

BIOMECHANICS

There is still controversy in the literature as to the precise biomechanics of the elbow,[73] and how the axes of motion relate to the anatomy of the joint. Biomechanically, the elbow predominantly functions as an important central link in the upper extremity kinetic chain, allowing for the generation and transfer of forces that occur in the upper extremity. The common stresses that occur at the elbow include valgus stress, which results in medial tension and lateral compression loading; varus stress, which results in lateral tension loading; extension stress; and multiple combinations of these stresses. These forces produce repetitive tensile loads on the ligamentous and muscular support systems around the elbow, and compressive and shear loads on the bony constraints.[74] Truly impressive loads can be placed through the elbow during activities such as throwing or pitching.

It is important that the elbow is able to move freely and painlessly throughout its available motion. These motions include elbow flexion and extension, and forearm pronation and supination.

Flexion–Extension

Flexion–extension of the elbow complex occurs about a relatively fixed axis of rotation passing through the center of arcs formed by the trochlea and the capitellum (Fig. 17-1). The maximal range of passive motion generally available to the elbow is from 5 degrees of hyperextension to 145 degrees of flexion. Full active extension in the normal elbow is some 5–10 degrees short of that obtainable by forced extension, due to passive muscular restraints (biceps, brachialis, and supinator).[75,76] Passive extension is limited by the impact of the olecranon process on the olecranon fossa, tension in the dermis, the fibers of the MCL, and the anterior capsule.[77] Excessive ectopic bone formation around the olecranon fossa can also limit full passive extension. Passive flexion is limited by bony structures (the head of the radius against the radial fossa and the coronoid process against the coronoid fossa), tension of the posterior capsular ligament, soft-tissue approximation, and passive tension in the triceps.[77]

TABLE 17-3 Structures that can Restrict Supination and Pronation

Data from Bert JM, Linscheid RL, McElfresh EC: Rotatory contracture of the forearm. *J Bone Joint Surg Am* 62:1163–1168, 1980.

Supination–Pronation

Pronation and supination require simultaneous joint movement at the proximal and distal radioulnar joints (Fig. 17-3).[8] The longitudinal axis of rotation about which supination and pronation occur is considered to pass from the center of the head of the radius to the convex articular surface of the ulnar at the distal radioulnar joint. Supination at the proximal radioulnar joint occurs as a spinning of the radial head within the fibro-osseous ring formed by the AL and radial notch of the ulna.[8] The arthrokinematics of pronation at the proximal radioulnar joint occurs by similar mechanisms.

Restrictions in the passive range of pronation and supination motions can occur from tightness in muscle and/or connective tissues (Table 17-3).[78,79]

HUMEROULNAR JOINT

The motions that occur at the humeroulnar joint involve impure flexion and extension, which are primarily the result of rotation of the concave trochlear notch of the ulna about the convex trochlea of the humerus. From a sagittal section, the firm mechanical link between the trochlear and the trochlear notch, however, limits the motion to essentially a sagittal plane.[8]

HUMERORADIAL JOINT

Any motion at the elbow and forearm complex involves motion at the humeroradial joint. Thus, any limitation of motion at the humeroradial joint can disrupt both flexion and extension, and pronation and supination.[8]

During flexion and extension of the elbow, the humeroradial joint follows the pathway dictated by the anatomy of the ulnohumeral joint to which it is firmly attached by the annular and interosseous ligaments.[62] At rest in full extension, little if any physical contact exists at the humeroradial joint.[8,80] During active flexion, however, muscle contraction pulls the radial fovea against the capitulum.[81,82]

Some supination and pronation also occur at this joint due to a spinning of the radial head.

Although the humeroradial joint provides minimal structural stability to the elbow complex, it does provide an important bony resistance against a valgus force.[8,21]

PROXIMAL RADIOULNAR JOINT

At the proximal radioulnar joint, one degree of freedom exists, permitting pronation and supination (Fig. 17-3). Both the fascia and the musculature of the forearm depend on the integrity of the interosseous radioulnar relationship for their mechanical efficiency.[62]

The proximal radioulnar joint is structurally an ovoid, with very little swing available to it due to its ligamentous constraints. As a consequence, its movement is confined to accommodating the osteokinematic spin of the radius. As the radial head forms the convex partner, there is a tendency for the radial head to move posterolaterally during pronation and anteromedially during supination, but these movements are strongly curtailed by the annular and interosseous ligaments.

COUPLED MOTIONS

Conjunct rotations occur at the elbow complex with all motions. In addition, the elbow motions of flexion and extension are associated with adduction and abduction motions. The ability to abduct and adduct can easily be observed during pronation and supination. In the fully supinated position, the ulna is much nearer the midline of the body than it is in full pronation. Therefore, abduction occurs with pronation, and adduction occurs with supination.

The abduction that occurs with extension occurs at the humeroulnar joint and is more apparent than real. An increase in the carrying angle of the forearm during extension must not be confused with the abduction of the ulna, which occurs because of the unequal ranges of extension between the ulna and the humerus, and the radius and the humerus (the capitellum being oriented more anteriorly than the trochlear). This inequity produces a conjunct humeral adduction with flexion and a conjunct humeroulnar abduction with extension, both of which are controlled by the lateral and medial collateral ligaments.[62]

Thus, it is apparent that pronation–supination and flexion–extension are interdependent, and each is a conjunct motion of the other, at least at the extremes of range. Since pronation and supination involve the proximal and distal radioulnar joints and the humeroulnar, humeroradial, and radiocarpal joints, mechanical dysfunction of any of these joints may become apparent, especially in the extremes of elbow flexion or extension.[62]

FORCE COUPLES OF THE ELBOW

The role of the elbow musculature as dynamic joint stabilizers is still somewhat unclear. Both varus and valgus forces are produced by muscles during elbow motions. The valgus forces are produced by the extensor carpi ulnaris (ECU), EDC, ECRL, and brachioradialis, while varus forces are produced by the FCR, FDS, pronator teres, and FCU. Forces transmitted across the articulating surfaces include the forces created by muscles working together to produce the desired activity. The important force couples of the elbow include[83]:

- the triceps/biceps during elbow extension and flexion;
- pronator teres and pronator quadratus/supinator during forearm pronation and supination;
- FCR, FCU, flexor digitorum communis/ECRL, ECRB, and extensor communis during wrist flexion and extension;
- triceps/biceps and brachioradialis; pronator teres/supinator; and FCR, FCU/ECRB, and ECRL during activities requiring elbow stabilization.

EXAMINATION

Since the elbow is one of the multiple links of the upper extremity kinetic chain, a thorough static and dynamic examination of the entire upper extremity and cervical spine as well as the trunk should be performed in addition to examination of the elbow proper. The physical examination must include at least inspection, range-of-motion testing, palpation, provocative testing, and neuromuscular testing. The interventions for the common pathologies of the elbow complex and their interventions are detailed after the examination is described. An understanding of both is obviously necessary. As mention of the various pathologies occurs with reference to the tests and measures and vice versa, the reader is encouraged to switch between the two.

HISTORY

During the history, the clinician must determine the chief complaint and location of symptoms. In addition to the questions listed under history in Chapter 4, answers to the following questions must be obtained:

- What is the patient's chief complaint? The patient's chief complaint can often afford clues as to the underlying pathology. For example, a chief complaint of pain upon leaning on the point of the elbow is usually associated with olecranon bursitis.
- How old is the patient? There are a number of age-related elbow conditions. For example, pain in a young child would be suggestive of nursemaid's elbow (dislocation of the head of the radius), elbow pain between the ages of 15 and 20 could be osteochondritis dissecans, and tennis elbow (lateral epicondylitis) typically occurs in individuals 35 years of age or older.
- Was there a mechanism of injury or any antecedent trauma? Traumatic elbow injuries often occur with a fall on the

outstretched hand (FOOSH) injury. This type of fall can result in a number of upper extremity and neck injuries. At the elbow, the FOOSH injury can result in a hyperextension injury of the joint. If the fall was on the tip of the elbow, or there was blunt trauma to the olecranon process, this may indicate an olecranon bursitis, ulnar nerve lesion, or olecranon fracture.[84] If the patient reports an insidious onset of symptoms, especially if the patient has complained of weakness and pain, the clinician should consider performing an examination of the cervical spine, and an upper quarter screening examination as part of the overall examination.

- Is the patient right- or left-hand dominant? This may have an impact on the ability of the elbow to rest or on the functional status of the patient.
- Is there a history of pain following overuse or repetitive activities? Elbow injuries are common in sports as well as from cumulative overuse in the athlete and nonathlete. For example, repetitive hyperextension, accompanied by pronation of the elbow, can stress the distal biceps and lacertus fibrosus in the cubital fossa.[85]
- Are the symptoms related to the patient's occupation? The improper use or unaccustomed use of tools such as hammers, saws, and screwdrivers can cause lateral or medial elbow pain.
- Is there any history of locking or catching of the elbow with movement? Twinges of pain, or locking of the elbow, could indicate a loose body within the joint. An inability to fully extend the elbow may indicate a number of conditions including synovitis of the elbow,[84] especially if it is accompanied by pain and fullness of the paraolecranon grooves.[86]
- Is the patient an athlete? A history of a "pop" followed by pain and swelling on the medial aspect of the elbow in a throwing athlete may indicate an MCL sprain.[87] Individuals involved in racquet sports commonly develop lateral elbow pain suggesting lateral epicondylitis (tennis elbow). In these situations, it is well worth investigating recent changes in equipment (e.g., tennis racquet head size, string tension, grip size). In a throwing athlete, the clinician should seek out details, including[88]
  - acute versus progressive injury;
  - intensity of symptoms;
  - duration of symptoms;
  - throwing schedule;
    - frequency of throwing;
    - intensity;
    - duration;
    - types and proportion of pitches delivered;
    - delivery style (sidearm versus overhead—the former is more injurious to the elbow);
    - types and proportions of throws delivered (e.g., curve balls are more deleterious than fastballs);
    - rest periods employed;
    - warm-up and cool-down regimens employed;
    - phase the pain manifests in (e.g., early cocking, acceleration, and follow-through);
  - restriction of motion;
  - locking or checkrein-type symptoms.
- How long has the patient had the symptoms and are the symptoms improving or worsening? Such information can give clues as to the stage of healing or seriousness of the condition.
- Where are the symptoms located? Determining the details can help the clinician determine whether the symptoms are from a local source, or whether they are referred, or the result of compromise to a peripheral nerve, or cervical spine nerve root (radiculopathy). With few exceptions, pain in a particular area of the elbow is caused by the surrounding or underlying physical structures (Table 17-4).

TABLE 17-4 Differential Diagnosis of Elbow Pain According to Symptom Location

Location	Possible Disorders
Anterior	Anterior capsular strain Distal biceps tendon rupture/tendinitis Dislocation of the elbow Pronator syndrome (throwers)
Medial	Medial epicondylitis Ulnar collateral ligament injury (MCL) Ulna neuritis or ulnar nerve subluxation Flexor–pronator muscle strain Fracture Little league elbow in skeletally immature throwers Valgus extension overload overuse symptoms
Posteromedial	Olecranon tip stress fracture Posterior impingement in throwers Trochlear chondromalacia
Posterior	Olecranon bursitis Olecranon process stress fracture Triceps tendinitis
Lateral	Capitellum fracture Cervical radiculopathy—referred pain Lateral epicondylitis Lateral collateral injury Osteochondral degenerative changes Osteochondritis dissecans (Panner's disease) Posterior interosseous nerve syndrome Radial head fracture Radial tunnel syndrome Synovitis

MCL, medial collateral ligament.

Data from Conway JE: Clinical evaluation of elbow injuries in the athlete. *J Musculoskeletal Med* 10:20–28, 1988; Wilk KE, Andrews JR: Elbow injuries. In: Brotzman SB, Wilk KE, eds. *Clinical Orthopaedic Rehabilitation*. Philadelphia, PA: Mosby, 2003:85–123.

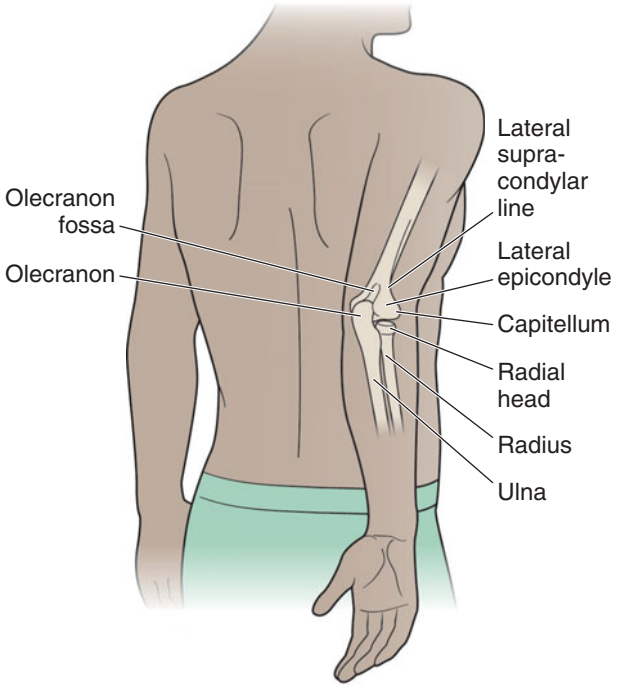

FIGURE 17-11 Lateral view of the elbow.

- ***Lateral elbow pain.*** Epicondylitis should be suspected if there is tenderness over a bony prominence (Fig. 17-11).
- ***Medial elbow pain.*** This is usually due to a tendinopathy at the site of the attachment of the superficial forearm flexors and the pronator teres muscle to the medial epicondyle (Fig. 17-12).[87] However, it may also indicate an MCL sprain, or an ulnar nerve compression.

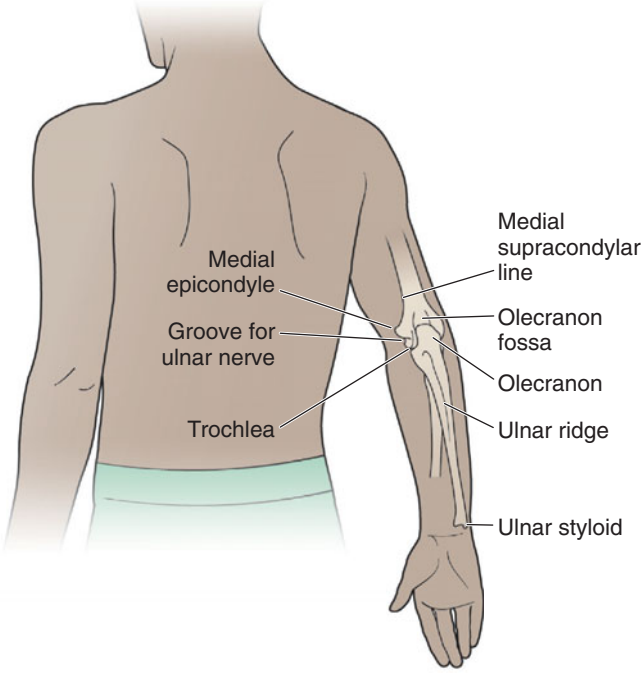

FIGURE 17-12 Medial view of the elbow.

- ***Posterior elbow pain.*** This suggests olecranon bursitis, triceps tendinosis, or a valgus extension overload.[89]
- ***Cubital fossa pain.*** This is most likely to result from a tear of the brachialis muscle at the musculotendinous junction and is a common injury in rock climbers,[90] or a biceps brachii lesion. Cubital fossa pain may also be associated with a compression of the PIN or a capsular injury.[91]
- ***Left-arm and elbow pain.*** This, when precipitated by physical exertion and relieved by rest, should suggest angina.[87]

- Are there any associated joint noises or crepitus? A snapping elbow is synonymous with the relatively common recurrent dislocation of the ulnar nerve. However, the medial head of the triceps muscle or tendon may also dislocate over the medial epicondyle and result in snapping either as the elbow is flexed or as it is extended from a flexed position.[84] Dislocation of the medial head of the triceps can occur in combination with dislocation of the ulnar nerve, producing the clinical finding of at least two snaps at the elbow, with or without discomfort on the medial side of the elbow and with or without ulnar neuropathy. Joint crepitus may also indicate the presence of a loose body or synovitis. Catching or locking sensations are suggestive of joint instability or a loose joint body.
- Which activities or arm positions appear to aggravate the condition? Grasping and twisting activities tend to stress the elbow structures.
- Is the pain constant or intermittent? A visual analog scale can be used to record the patient's pain level.
- Is there any associated pain in the neck or shoulder? Intrinsic pain of the elbow structures is exacerbated by movement of the elbow joint, whereas referred pain is usually independent of elbow activity (see "Systems Review," later).[84,92]
- Are there any other joints that appear to be painful? This finding may suggest a systemic or infectious component.
- Are the symptoms better or worse at particular times of day or night?
- Are there any sensory changes, paresthesia, and muscle weakness in the ipsilateral limb? Such neurological findings are suggestive of a spinal nerve root or peripheral nerve lesion.
- Is there any underlying joint disease? Several types of arthritides or osteochondrosis dissecans develop in the elbow region without a known cause.[89]
- How is the condition affecting the patient's function in activities of daily living and recreational pursuits?
- Has the patient had this condition before and, if so, how was it treated and what was the outcome?
- Is the patient taking any medications? What conditions in addition to the present condition are the medications for?
- How is the patient's general health?

SYSTEMS REVIEW

Signs or symptoms of a visceral, vascular, neurogenic, psychogenic, spondylogenic, or systemic disorder that may be local or referred are described in Chapter 5. Conditions that are out of the scope of physical therapy require that the patient be referred to an appropriate health-care provider. Scenarios related to the elbow that warrant further investigation include an insidious onset of symptoms and complaints of numbness or paresthesia in the upper extremity. The Cyriax scanning examination (see Chap. 4) can help highlight the presence or absence of neurological complications including spinal nerve root and peripheral nerve palsies. The scanning examination includes strength testing of the key muscles (see "Resistive Testing"), sensation testing, and reflex testing (see "Neurologic Examination").

Reproduction of the patient's elbow or other symptoms with cervical motion, rather than elbow movement, is a strong indicator of a cervical and upper thoracic source (ligaments, muscles, zygapophysial joints, and disks) for the symptoms, with either the segmental roots or the brachial plexus being involved.[19]

In addition to the cervical and upper thoracic spine, the related joints referring symptoms to the elbow require clearing, especially the shoulder.

Systemic causes of insidious elbow pain include gout, infective arthritis, polyarthritis, and vascular disorders, such as Volkmann's ischemia (see Chap. 5). Morning stiffness lasting for more than 1 hour, constitutional signs, and physical signs of joint inflammation are all indicative of an inflammatory disease. Systemic conditions are typically associated with other signs and symptoms that are not related to movement and that are systemic in nature (fever, chills, etc.). Respiratory and cardiovascular conditions must also come into consideration when examining the elbow.[84] The upper arm is very close to the chest and its viscera, so reference of pain to the elbow from these structures can occur.

CLINICAL PEARL

Severe progressive pain not affected by movement, persistent throughout the day and night, and associated with systemic signs may indicate referred pain from a malignancy.

Following the history and systems review, the clinician should be able to determine the suitability of the patient for physical therapy.

TESTS AND MEASURES

Observation

For an accurate and thorough examination of the elbow, the clinician must be able to visualize both arms. The involved elbow should be inspected for scars, deformities, and swelling. Any asymmetry in size or positioning between the extremities should be noted. The earliest sign of elbow effusion is a loss of the elbow dimples. Most swelling appears beneath the lateral epicondyle. Even minor swelling or effusion prevents full extension of the elbow. Anterior joint effusion is evidence of significant swelling. Gradual swelling over the posterior tip of the elbow, which can be golf ball sized and is often not tender to palpation, is usually olecranon bursitis. The clinician should observe for normal soft-tissue and bony contours. Hypertrophy of the dominant forearm is common in tennis players and pitchers.

CLINICAL PEARL

Sudden swelling in the absence of trauma suggests infection, inflammation, or gout.

The clinician should observe the "carrying angle" of the involved elbow (the angle formed between the arm and the forearm) and compare it to the other side. The carrying angle varies from 13 to 16 degrees for females, and 11 to 14 degrees for males.[5,11] Any difference in the carrying angle of the elbow is obvious when the elbow is in extension. An increased carrying angle (>15 degrees) is called *cubitus valgus*. Cubitus varus, or "gunstock deformity," is the term used to describe a decreased carrying angle (<10 degrees). The most common causes of an altered carrying angle are past trauma or epiphyseal growth disturbances. For example, a cubitus valgus can be caused by a lateral epicondylar fracture, whereas a cubitus varus is frequently the result of a supracondylar fracture.

The triangular relationship of the epicondyles and the olecranon at 90 degrees of elbow flexion and at full extension is often disrupted in the presence of a fracture, dislocation, or degeneration. At 90 degrees of flexion, the three bony landmarks form an isosceles triangle, and when the arm is extended they form a straight line.[89,93]

Excessive tension at the elbow can be produced in occupations that place the elbows in sustained positions of flexion and adduction (e.g., keyboard operators). The tension increases resistance to movement and joint play at the elbow.[94,95] Elbow flexion also increases tension at the fibrous arch that connects the two heads of the FCU, which can lead to compression of the ulnar nerve.[96]

A combination of sustained flexion and a restriction in joint play decreases the overall volume within the cubital tunnel, which can further increase the potential of ulnar nerve compression.[96,97]

CLINICAL PEARL

The pronated forearm position, combined with elbow flexion, wrist extension, and cyclic finger flexion and extension, creates shearing and compressive forces at several soft-tissue interfaces in the forearm.[98,99] The pronators and EDC adaptively shorten over time because of prolonged contractions in their most shortened positions.[94,98]

Palpation

Since they are superficial, most of the elbow structures are easily palpable (Figs. 17-11 and 17-12), making it easier for the clinician to pinpoint the specific area of pain. However, in

cases in which the pain is more diffuse, the diagnosis becomes somewhat more difficult.

Palpation of the elbow complex is best performed with the patient seated or supine, so they are able to relax. A logical sequence based on surface anatomy is outlined below.

Bony Structures

Bony structures feel hard, whereas ligamentous structures feel firm. Bony palpation of the elbow should start with assessment for crepitus during flexion and extension of the elbow. The presence of pain, swelling, or temperature elevation should also be appreciated.

- ***Medial epicondyle (Fig 17-12).*** The medial epicondyle can be palpated on the medial aspect of the distal humerus. Just anterior and distal to the medial epicondyle one can palpate from proximal to distal the muscle origins of the pronator teres, FCR, palmaris longus, FDS, and FCU.[100] Just posterior to the medial epicondyle, the ulnar groove can be palpated, as can the ulnar nerve traveling within.
- ***Olecranon process.*** The olecranon (see Fig. 17-11) should be easy to locate on the posterior aspect of the elbow. The olecranon bursa will not be palpable unless inflamed or thickened. The olecranon ends distally in a point. Just distal to this point, the posterior border of the ulna can be palpated along its entire length (see Fig. 17-11). The clinician should assess for crepitus in the olecranon fossa as well as for any subtle extension blockage suggestive of synovitis, or the presence of intra-articular loose bodies.
- ***Lateral epicondyle (Fig. 17-11).*** Midway between the olecranon and the lateral epicondyle is the anconeus muscle. The lateral epicondyle is more difficult to palpate than the medial epicondyle as the former is covered by a large mass of extensor muscle, called the extensor bundle or wad.
- ***Supracondylar ridge (see Fig. 17-11).*** The supracondylar ridge is just superior to the lateral epicondyle. A number of tendons/muscles are located in the region between the lateral supracondylar ridge and the lateral epicondyle. The muscles from proximal to distal are the brachioradialis, ECRL, ECRB, and the EDC. By asking the patient to make a fist with the wrist in slight extension, the ECRL can be felt on the supracondylar ridge.[89]
- ***The joint line.*** The joint line is located at a point approximately 2 cm down from an imaginary line joining the two epicondyles, which passes medially and inferiorly. The joint lines are firm on palpation, and lie between two structures that are harder.[89]
- ***Head of the radius.*** The radial head is located in the skin depression immediately distal to the lateral epicondyle. To palpate the radial head (see Fig. 17-11) at the humeroradial joint, the clinician places the index finger on the lateral humeral epicondyle. From here, the index finger slides posteriorly and distally between the humerus and the radial head (see Fig. 17-11). Rotation of the radial head will be noted with pronation and supination.[89] A traumatically dislocated radius will appear out of position and tender to palpation.

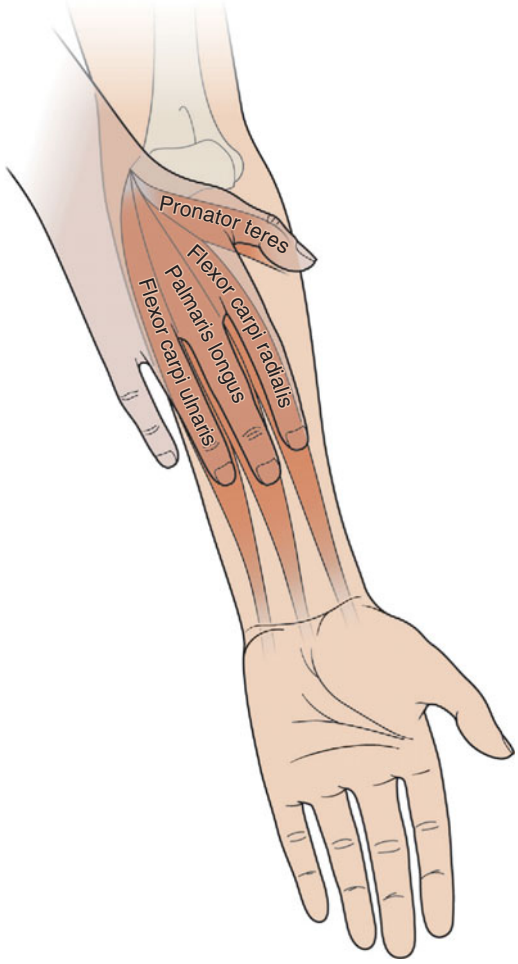

FIGURE 17-13 The wrist flexor–pronator muscle group

After examining the elbow's bony components, attention should be turned to the elbow's soft-tissue structures, which may be divided into four clinical zones: medial, posterior, lateral, and anterior.[89] The elbow's soft-tissue structures are best appreciated in 90 degrees of flexion. Swelling of the elbow can be localized as in a swollen olecranon bursa or diffuse as in a supracondylar fracture.

The medial aspect of the elbow contains the ulnar nerve, the wrist flexor–pronator muscle group (Fig. 17-13), and the MCL. The ulnar nerve can be felt as a soft tubule coursing through the groove between the medial epicondyle and the olecranon process. Secondary damage to the ulnar nerve can occur in supracondylar or epicondylar injuries.[89] The four muscles of the wrist flexor–pronator muscle group, pronator teres, FCR, palmaris longus, and FCU (see Fig. 17-13), originate from the medial epicondyle before diverging into separate paths down the forearm (see "Muscles," later). Overuse of the flexor mass results in pain and palpable tenderness at the medial epicondyle, extending approximately 1–3 cm distal to the epicondyle. Pain due to medial elbow tendinosis will be intensified with provocative testing, such as resistive wrist flexion and forearm pronation with the elbow extended and, in advanced cases, with the elbow flexed as well. The fan-shaped MCL connects the medial epicondyle to the medial margin of

the ulna's trochlear notch. The anterior bundle of the MCL ligament is usually palpable with the elbow flexed from 30 to 60 degrees. Tenderness in this area can be due to MCL sprain. The valgus stress test is performed to assess MCL stability (see later).

Within the lateral aspect of the elbow are the wrist extensors, the LCL, and the AL. The three muscles of the wrist extensor group, brachioradialis, ECRL, and ECRB, are palpated as a unit, with the forearm in a neutral position and the wrist at rest (see "Muscles," later). These three muscles are commonly involved in lateral epicondylitis or "tennis elbow." Palpable tenderness over the ECRB is common in this condition. Pain due to lateral elbow tendinosis is intensified with resisted wrist and finger extension with the elbow extended and, in advanced cases, with the elbow flexed as well.[89] The LCL extends from the lateral epicondyle to the side of the AL, a ring-shaped band located deep to the extensor aponeurosis, cupping the radial head and neck. Although the LCL is difficult to directly palpate because of the overlying musculature, disruption of either the LCL or the AL can be assessed by palpation of the area and by the varus stress test (see later).

Muscles

- ***Biceps.*** The short head of the biceps is located at the coracoid process (together with the coracobrachialis muscle).[89] The long head of the biceps cannot be palpated at its origin, but it is palpable in the intertubercular groove of the proximal humerus. The muscle belly of the biceps is easily identifiable, especially with resisted elbow flexion and forearm supination.
- ***Brachialis.*** The origin of the brachialis can be palpated posterior to the deltoid tuberosity. Its insertion can be palpated at a point medial to the musculotendinous junction of the biceps, at the proximal border of the bicipital aponeurosis.[89]
- ***Brachioradialis.*** The brachioradialis can be palpated from the radial border of the cubital fossa distally to the radial styloid process.
- ***Common flexor origin at the medial epicondyle.***
- ***Common extensor origin at the lateral epicondyle.***
- ***Supinator.*** The borders of the supinator within the cubital fossa are formed by the brachioradialis (radially), pronator teres (ulnarly), and tendon of the biceps (proximally).[89]
- ***Triceps.*** Palpation of the triceps can be simplified by having the patient abduct the arm to 90 degrees. The lateral head of the triceps borders directly on the brachial muscle, whereas the medial head runs underneath both the long and lateral heads of the triceps. These two heads of the triceps can be palpated until their common insertion at the olecranon (Fig. 17-14).[89]
- ***Anconeus.*** This small muscular triangle can be palpated between the olecranon, the posterior border of the ulna, and the lateral epicondyle. If crepitus is felt at full elbow extension, the clinician can manually push the subanconeus bursa superiorly during elbow extension. If the crepitus decreases, a dysfunction of the anconeus should be suspected, which can be treated with electrical stimulation and mobilization of the olecranon in a medial or lateral direction.

FIGURE 17-14 Palpation of the triceps at the elbow.

Active Range of Motion with Passive Overpressure

The patient with elbow pain should have a detailed assessment of his or her motion (Figs. 17-15 and 17-16). Range of motion can be assessed with the patient seated, although elbow extension is better evaluated with the patient standing. The patient is asked to perform active flexion and extension of the elbow, pronation and supination of the forearm, and wrist flexion and extension, with the ranges being recorded using a goniometer VIDEO:

- Flexion: active elbow flexion (Fig. 17-17) is 140–150 degrees.
- Extension: active elbow extension is 0 degree, although up to a 10-degree hyperextension is not uncommon, especially in women. This hyperextension is considered normal if it is equal on both sides and there is no history of trauma.
- Supination: active supination (Fig. 17-18) should be 90 degrees with no substitute motions (adduction) occurring at the shoulder.
- Pronation: active pronation is approximately 8–90 degrees with no substitute motions (abduction) occurring at shoulder.

Wrist flexion and extension, and forearm supination and pronation should be tested with the elbow flexed to 90 degrees and then fully extended.

In a study by Armstrong et al.,[101] the intratester, intertester, and interdevice (universal standard goniometers, a computerized goniometer, and a mechanical rotation measuring device) reliability of range-of-motion measurements of the elbow and forearm was assessed. Intratester reliability was high for all three measuring devices.[101] Intertester reliability was high for flexion and extension measurements with the computerized goniometer and moderate for flexion and extension measurements with the universal goniometer.[101] Intertester reliability was high for pronation and supination with all three devices.[101] The authors concluded that reliable measurements of elbow and forearm movement are obtainable,

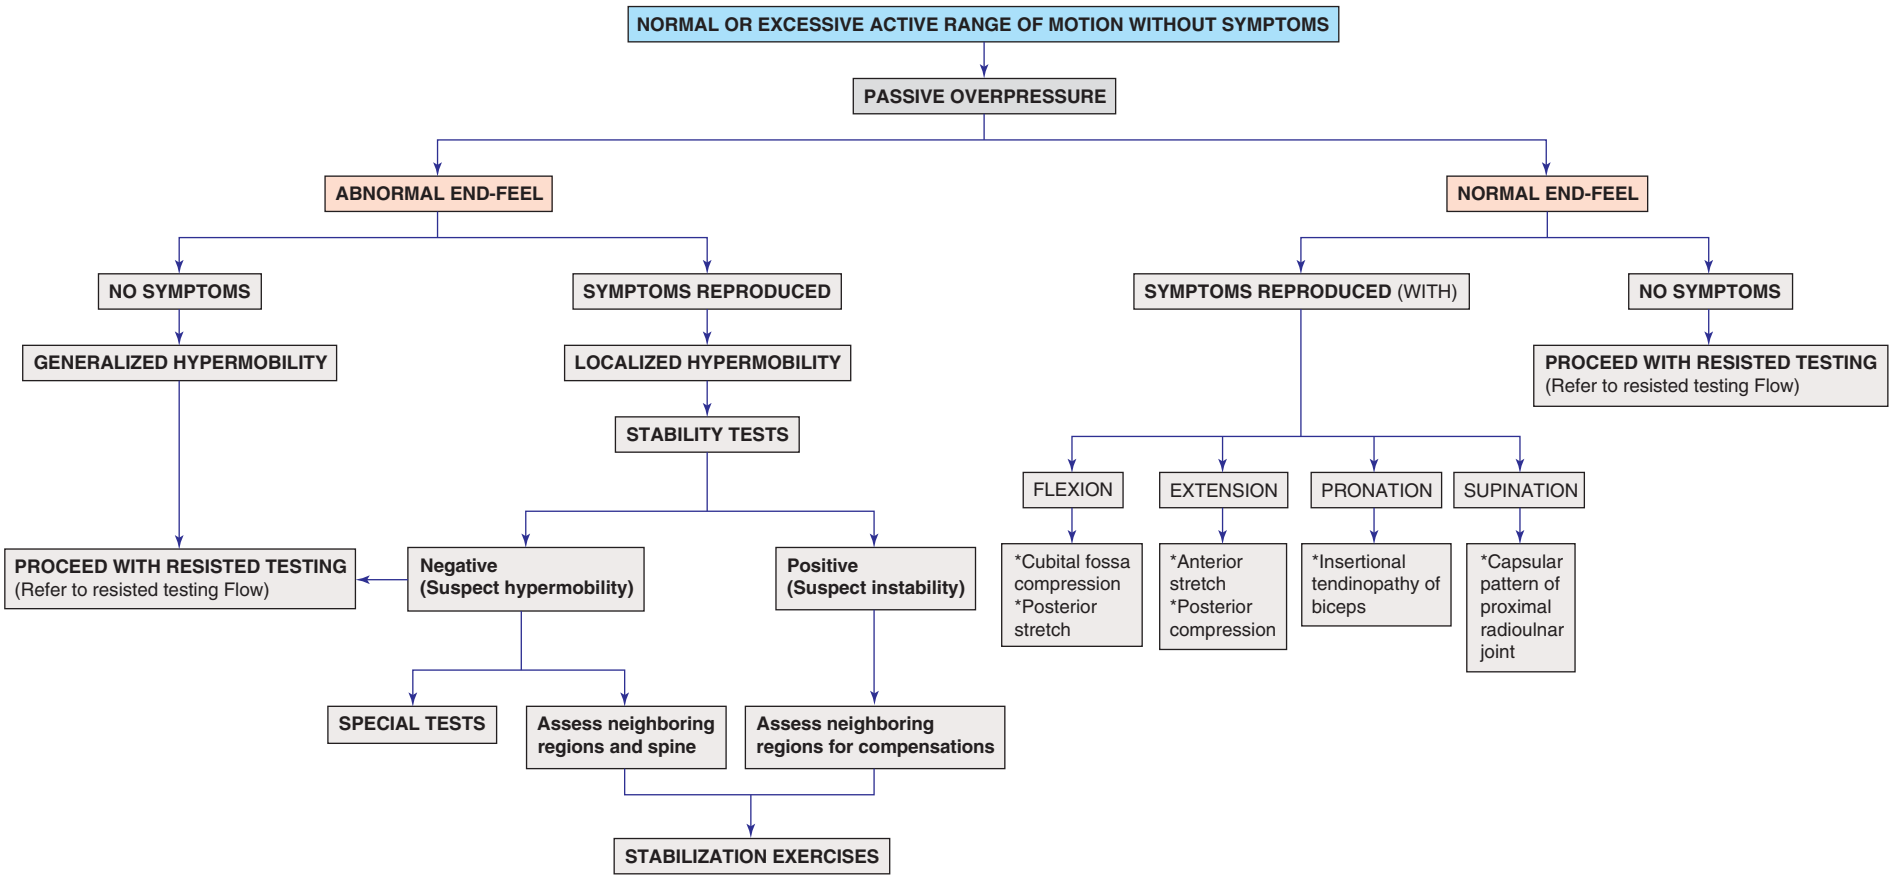

FIGURE 17-15 Examination sequence in the presence of symptoms with normal or excessive active range of motion in the elbow.

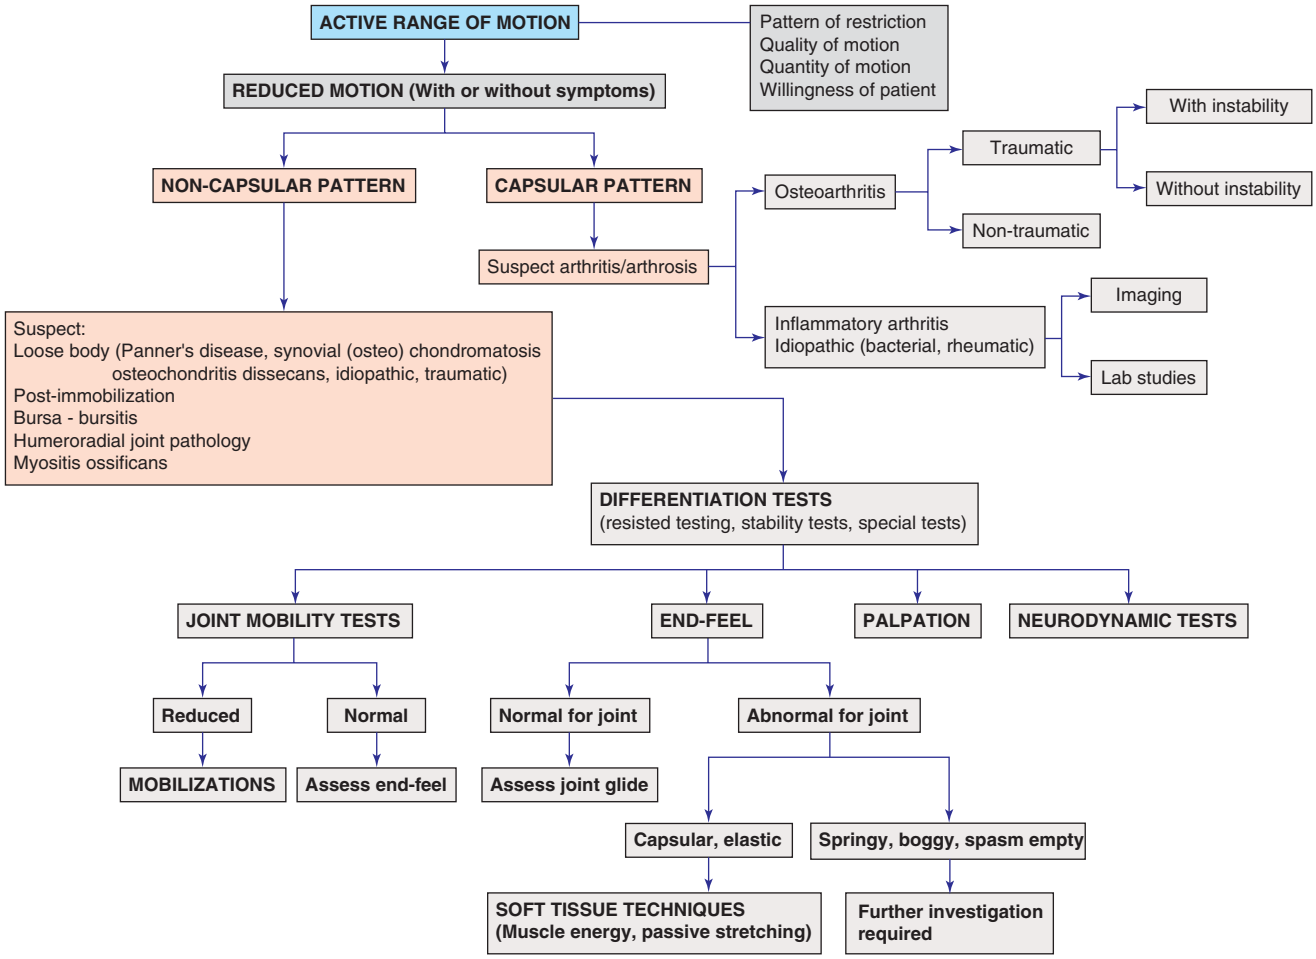

FIGURE 17-16 Examination sequence in the presence of painful flexion and/or extension at the elbow.

regardless of the level of experience, when standardized methods are used.[101]

Capsular or noncapsular patterns should be determined. The capsular pattern at the elbow is characterized by limitation of more flexion than extension. If motion restrictions are present, the nature and location of the motion barrier, and the relationship of pain to the motion barrier should be noted.[102]

The end-feels of elbow motion should be classified as either compliant, suggesting soft-tissue restriction, or rigid, suggesting a mechanical bony limit. Passive limitation warrants further investigation for the source of mechanical blockage. Pain that occurs at the limit(s) of motion suggests bony impingement. The clinician should also note the degree of ulnar adduction or abduction that occurs with the elbow motions.

Passive pronation and supination are applied by grasping the proximal aspect of the forearm. Passive overpressure is superimposed at the end of the available ranges of flexion and extension, using the appropriate conjunct rotations. Internal rotation of the forearm (pronation) is the conjunct rotation

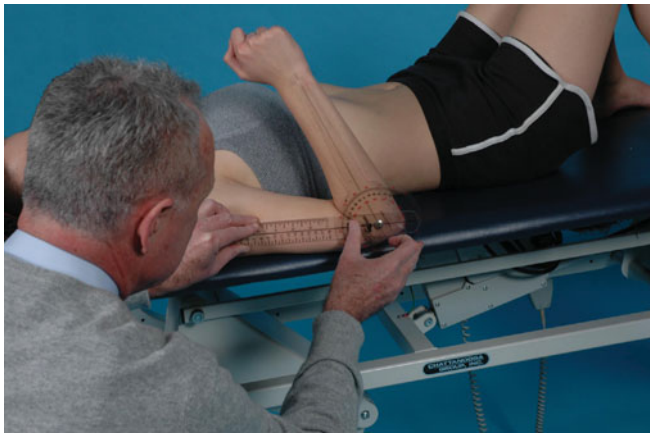

FIGURE 17-17 Elbow flexion.

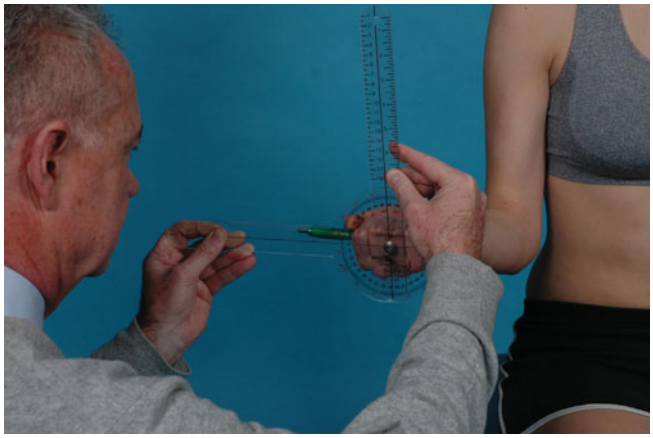

FIGURE 17-18 Forearm supination.

associated with elbow extension; external rotation of the forearm (supination) is the conjunct rotation associated with elbow flexion.[77,85] Normal values for elbow pronation and supination are approximately 75-degree pronation and 85-degree supination.[5]

CLINICAL PEARL

Decreased supination and pronation are frequent sequelae of a Colles' fracture, advanced degenerative changes, dislocations, and fractures of the forearm and elbow.

If there is a gross loss of pronation and supination posttrauma, a fractured radial head is a possibility. Of particular interest is the acute limitation of supination and extension in children, which likely results from a "pulled elbow" (also referred to as "nursemaid's elbow," see "Intervention Strategies" section).

Passive elbow flexion (Fig. 17-19) should have an end-feel of soft-tissue approximation. Elbow flexion combined with supination should have a capsular end-feel, whereas elbow flexion combined with pronation should have a bony end-feel. Passive flexion may aggravate an ulnar nerve neuropathy.[77] Loss of normal elbow flexion (~140 degrees) may be caused by osteophytic arthritis, intra-articular loose bodies, posterior capsule tightness, or possibly triceps tendinosis.

Passive elbow extension (Fig. 17-20) should have a bony end-feel. A springy end-feel may indicate a loose body. Elbow extension is usually the first motion to be limited and the last to be restored with intrinsic joint problems.[77,85] The clinician should be particularly careful of an elbow that has lost a gross amount of extension posttrauma, especially if accompanied by a painful weakness of elbow extension, as this may indicate an olecranon fracture. A significant loss of motion, with no accompanying weakness, could indicate myositis ossificans.

CLINICAL PEARL

Pain throughout the central arc of flexion and extension, or pronation and supination, implies degeneration of the humeroulnar or proximal radioulnar joints, respectively.

FIGURE 17-20 Passive elbow extension.

Combined Motions

Combined movement testing is used to assess the patient who has full range of motion but still has complaints of pain. The following combinations are assessed:

- Elbow flexion, adduction, and forearm pronation (Fig. 17-21)
- Elbow flexion, abduction, and forearm supination (see Fig. 17-22)
- Elbow extension, abduction, and forearm pronation (Fig. 17-23)
- Elbow extension, adduction, and forearm supination (see Fig. 17-24)

FIGURE 17-19 Passive elbow flexion.

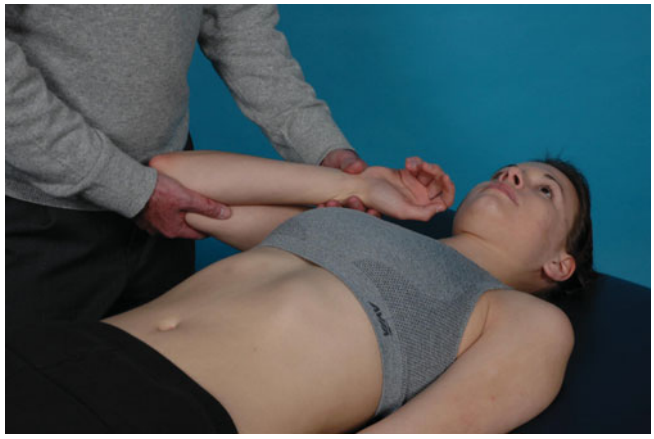

FIGURE 17-21 Combined motion of elbow flexion and pronation.

FIGURE 17-22 Combined motion of elbow flexion and pronation.

FIGURE 17-24 Combined motion of elbow extension and supination.

FIGURE 17-23 Combined motion of elbow extension and pronation.

Resistive Testing

In addition to all of the shoulder muscles that insert at or near the elbow (biceps, brachialis, and triceps), the clinician must also test the other muscles responsible for elbow flexion (Fig. 17-25) and extension and the muscles involved with forearm supination, pronation, and wrist flexion and extension. Elbow flexion strength is normally 70% greater than extension strength.[103] Muscle flexion power is greatest in the range of 90–110 degrees of flexion with the forearm supinated. In contrast, the flexion power is only 75% of maximum when the elbow is positioned in 45–135 degrees of flexion.[104] Supination strength is normally 15% greater than pronation strength.[103] The use of a dynamometer for testing upper extremity muscle groups has been found to be reliable.[105] Using make or break tests produce reliable results.[106] The most painful movement or movements should be tested last.

Elbow Flexion (C5–6)

Resisted elbow flexion is tested with the elbow flexed to 90 degrees, with the forearm in pronation **VIDEO**, then in supination **VIDEO**, and then in neutral rotation (Fig. 17-26) **VIDEO**. Pain with resisted elbow flexion most frequently implicates the biceps, especially if resisted supination is also painful. The brachialis is implicated if resisted elbow flexion with the forearm in full pronation is painful. The brachioradialis is rarely involved. Both sides are tested for comparison.

Elbow Extension (C7)

Resisted elbow extension is tested with forearm pronation, supination, and neutral. Both sides are tested for comparison. Pain with resisted elbow extension implicates the triceps muscle, although the anconeus muscle could also be involved.

Forearm Pronation/Supination (C5–7)

The clinician should test the strength of the forearm muscles by grasping the patient's hand in a handshake. The patient

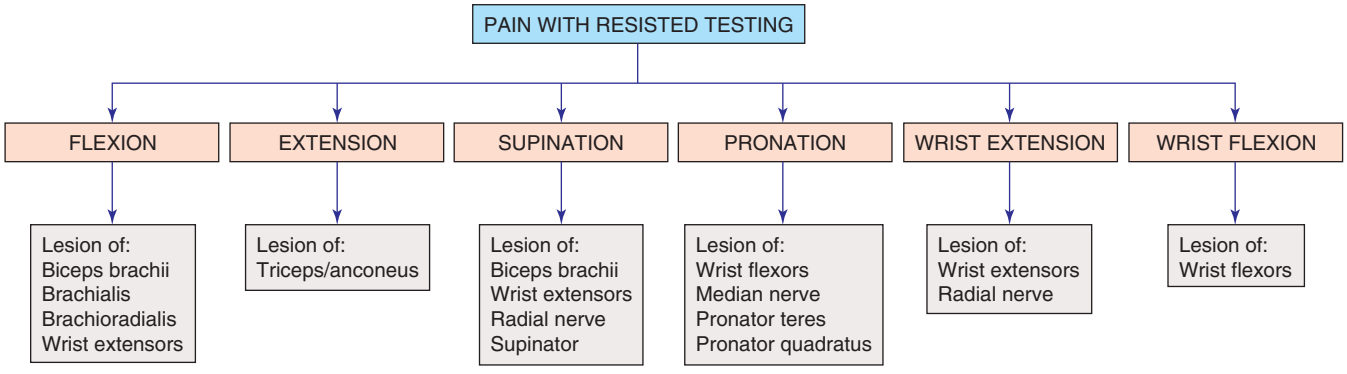

FIGURE 17-25 Symptoms reproduced with resisted testing at the elbow.

FIGURE 17-26 Resisted elbow flexion.

FIGURE 17-27 Resisted wrist flexion.

should be asked to exert maximum pressure to turn the palm first up (using supinators) and then down (using pronators). Supination is primarily the function of the supinator muscle, with augmentation from the biceps brachii for quickness or to overcome resistance. Supinator function can be effectively isolated during clinical assessment, by placing the elbow in extension VIDEO or near terminal elbow flexion VIDEO. Both these positions decrease the mechanical advantage of the biceps brachii. Weakness with supination may indicate a rupture, or a subluxation of the biceps tendon at the shoulder. It may also indicate a C5–6 nerve root lesion, radial nerve lesion (supinator), or musculocutaneous nerve lesion (biceps). The supinator muscle is rarely injured.

Pronator weakness is associated with rupture of the pronator teres from the medial epicondyle, fracture of the medial elbow, and lesions of the C6–7 or median nerve roots. Pronator quadratus weakness, which is tested with the elbow held in a flexed position VIDEO to neutralize the humeral head of the pronator teres muscle could indicate a lesion of the AIN. The pronator teres or quadratus muscles, which can be tested together VIDEO are rarely injured. Individuals with medial or lateral epicondylitis will also find the aforementioned maneuvers painful, and resisted wrist flexion and extension can be used to help differentiate the former and the latter, respectively.

Wrist Flexion

The FCU is the strongest wrist flexor. To test the flexors, the clinician stabilizes the patient's mid-forearm with one hand while placing the fingers of the other hand in the patient's palm, with the palm facing the patient (Fig. 17-27). The patient attempts to flex the wrist, with the elbow flexed and then extended. Weakness is evident in rupture of the muscle origin, lesions involving the ulnar (C8, T1) or median nerve (C6, C7), or tendinitis at the medial elbow if there is pain.

Wrist Extension

The most powerful wrist extensor is the ECU. To test the wrist extensors, the clinician's hands are placed in the same position as in the preceding test, with the patient's palm facing the clinician. The patient is asked to extend the wrist, with the elbow flexed and then extended (Fig. 17-28). Rupture of the extensor origin, lesions of the C6–8 nerve root, or lateral epicondylitis can cause weakness.

Radial Deviation

Resisted radial deviation is tested with the elbow at 90 degrees of elbow flexion, and at full elbow extension (see Chap. 18). Pain with resisted radial deviation is usually the result of lateral epicondylitis.

Ulnar Deviation

Resisted ulnar deviation, although rarely affected, is tested with the fingers in full flexion, and then in full extension (see Chap. 18).

Extension of Fingers 2–5

For resisted extension of fingers 2–5, the elbow is positioned in full extension, the wrist in neutral, and the metacarpophalangeal (MCP) joints at 90 degrees of flexion. Pain here is usually the result of extensor digitorum tendinitis, or lateral epicondylitis.

Extension of Fingers 2–3

For resisted extension of fingers 2–3, the patient is positioned as above. Pain with resistance implicates lateral epicondylitis.

If the above testing procedures are negative, or if the patient has complained that the combined movements cause the symptoms, resisted testing can be performed using combined movements. For example, testing elbow flexion in supination/pronation in varying degrees of elbow flexion.

FIGURE 17-28 Resisted wrist extension.

FIGURE 17-29 Biceps DTR.

FIGURE 17-31 Triceps DTR.

Neurologic Examination

Sensation about the elbow is supplied by four different nerves and is evaluated as follows: lateral arm (axillary nerve, C5), lateral forearm (musculocutaneous nerve, C6), medial forearm (antebrachial cutaneous nerve, C8), and the medial arm (brachial cutaneous nerve, T1). Sensory testing may include Semmes–Weinstein sensibility and two-point discrimination (see Chaps. 3 and 18). An EMG evaluation can supplement the neuromuscular physical examination as needed. The three major muscle stretch reflexes of the elbow are the biceps (musculocutaneous nerve, C5), brachioradialis (radial nerve, C6), and the triceps (radial nerve, C7). The biceps reflex is elicited by placing a thumb over the biceps tendon in the cubital fossa and striking it with a reflex hammer while the patient's arm is relaxed and partially flexed (Fig. 17-29). The biceps muscle should be felt or seen to jerk slightly. The brachioradialis reflex is a radial jerk elicited by tapping the brachioradialis tendon at the distal end of the radius (Fig. 17-30). The triceps reflex can be elicited with the arm in the same position of partial, relaxed flexion (Fig. 17-31). The triceps muscle should jerk when the triceps tendon is tapped where it crosses the olecranon fossa. Depressed, exaggerated, or absent upper extremity reflexes are noted and compared with reflex testing at the other elbow.

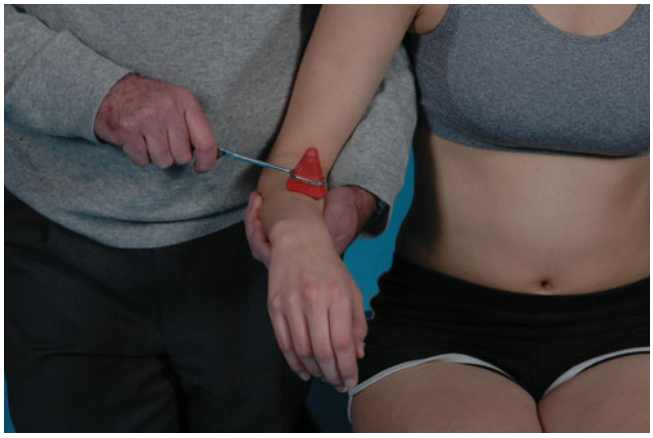

FIGURE 17-30 Brachioradialis DTR.

Functional Assessment

The functional strength of the elbow complex can be assessed using the tests outlined in Table 17-5. Like the shoulder, the elbow serves to position the hand for functional activities. A number of studies have reported the range-of-motion requirements for everyday activities. A total range of motion of 60–100 degrees of elbow flexion and 100 degrees of supination–pronation are required for tasks such as eating, dressing, and daily hygiene. The range of motion required for athletic activities, such as throwing a baseball, requires at least 10–20% greater range of motion.

Passive Articular Motion Testing

The passive articular mobility tests are used to examine the arthrokinematic motions of a joint or the accessory joint glides (see Chap. 4).

Ulnohumeral Joint

The patient is positioned in supine, with their head supported. The clinician sits or stands facing the patient.

Distraction/Compression. The clinician wraps the fingers around the proximal third of the forearm (Fig. 17-32). The clinician applies a longitudinal force through the proximal forearm, at an angle that is in 45 degrees less flexion than the position of the ulnar shaft, to either distract or compress the ulnohumeral joint. The quality and quantity of motion is noted. The test is repeated on the opposite extremity and the findings compared. An alternative method involves positioning the patient in prone, with the humerus being supported on the table and the arm hanging over the edge of the table (Fig. 17-33). Using one hand to stabilize the humerus, the clinician uses the other hand to apply a distraction force at the ulnohumeral joint. This position can also be used to assess the medial and lateral glides of this joint (Fig. 17-34).

Medial Glide. The clinician glides the ulna medially on the fixed humerus along the mediolateral plane of the joint line. The quality and quantity of motion is noted. The test is repeated on the opposite extremity and the findings compared.

Lateral Glide. The clinician glides the ulna laterally on the fixed humerus along the mediolateral plane of the joint line. The quality and quantity of motion is noted. The test

TABLE 17-5 Functional Testing of the Elbow

Starting Position	Action	Functional Test
Sitting, cuff weight attached to wrist	Elbow flexion	5-lb weight: functional 3–4-lb weight: functionally fair Active flexion (0 lb): functionally poor Cannot flex elbow: nonfunctional
Standing	Elbow extension with wall push-up	5 reps: functional 3–4 reps: functionally fair 1–2 reps: functionally poor 0 reps: nonfunctional
Standing facing door	Turning door knob into supination	5 reps: functional 3–4 reps: functionally fair 1–2 reps: functionally poor 0 reps: nonfunctional
Standing facing door	Turning door knob into pronation	5 reps: functional 3–4 reps: functionally fair 1–2 reps: functionally poor 0 reps: nonfunctional

Data from Palmer ML, Epler M: *Clinical Assessment Procedures in Physical Therapy*. Philadelphia, PA: JB Lippincott, 1990.

is repeated on the opposite extremity and the findings compared.

Radiohumeral Joint

The patient is positioned in sitting or supine, with their arm resting on the table. The following tests are performed[107,108]:

Anterior Glide. The clinician stabilizes the humerus and applies an anterior glide of the radius (Fig. 17-35), to assess the accessory glide that accompanies flexion.

Posterior Glide. The clinician stabilizes the humerus and applies a posterior glide of the radius (see Fig. 17-35) to assess the accessory glide that accompanies extension.

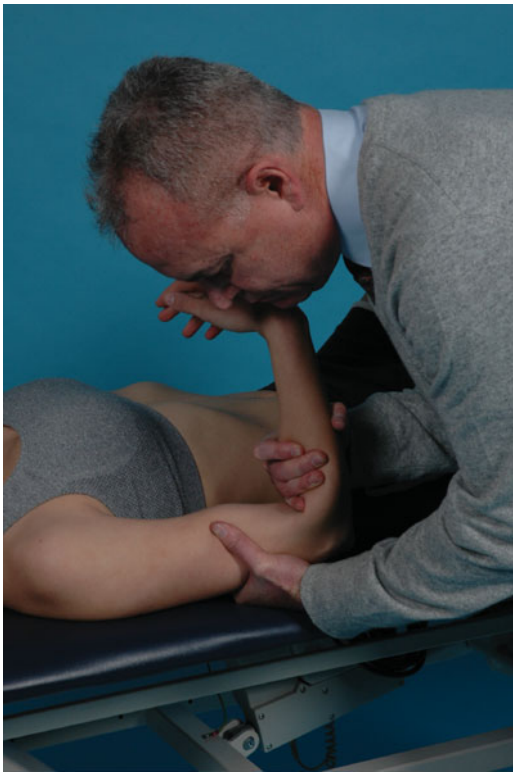

FIGURE 17-32 Ulnohumeral distraction/compression.

FIGURE 17-33 Ulnohumeral distraction.

FIGURE 17-34 Medial and lateral glides of the ulnohumeral joint.

Distraction. The clinician stabilizes the radial head and the lateral epicondyle with one hand. With the other hand, the clinician grasps the radius and applies a longitudinal distraction force along the length of the radius (Fig. 17-36). A longitudinal compression force can be applied using the same patient–clinician position.

FIGURE 17-35 Radiohumeral joint glides.

FIGURE 17-36 Distraction of radius.

Motion Testing of the Radial Head. The patient is positioned in sitting or supine, with the clinician facing the patient. The radial head is located by flexing and extending the elbow. Once located, the radial head is grasped by the clinician between the thumb and the index finger (see Fig. 17-36). The radial head is moved in an anterior and posterior direction, and any restriction of motion is noted. The posterior glide of the radius is coupled with pronation/extension, and anterior glide is coupled with supination/flexion. The most common dysfunction of the radial head is a posterior-radial head, which is accompanied by a loss of the anterior glide.

Stress Tests

Medial (Ulnar) Collateral Ligament (Valgus Test)

The patient is positioned in supine, with their head supported. The clinician stabilizes the distal humerus with one hand and palpates the distal forearm with the other. The anterior band of the MCL tightens in the range of 20–120 degrees of flexion, becoming lax in full extension, before tightening again in hyperextension. The posterior bundle is taut in flexion beyond 55 degrees.[3,14,23,85]

The anterior band is tested by flexing the elbow to between 20 and 30 degrees to unlock the olecranon from its fossa, as a valgus stress is applied continuously (Fig. 17-37).[25,60]

The posterior band is best tested using a "milking" maneuver. The patient is seated and the arm is positioned in shoulder flexion, elbow flexion beyond 55 degrees, and forearm supination. The clinician pulls downward on the patient's thumb (Fig. 17-38).[25] This maneuver generates a valgus stress on the flexed elbow. A positive sign is indicated by the reproduction of pain.

The tests are repeated on the opposite extremity and the findings compared. No diagnostic accuracy studies have been performed to determine the sensitivity or specificity of this test.

Lateral Pivot Shift Apprehension Test

The lateral pivot shift test is used in the diagnosis of posterolateral rotatory instability.[36] The patient is positioned in supine, with the involved extremity overhead. The clinician grasps the patient's wrist and elbow. The elbow is supinated with a mild force at the wrist, and a valgus moment and

FIGURE 17-37 Ulnar collateral ligament stress test.

compressive force is applied to the elbow during flexion (Fig. 17-39).[109] This results in a typical apprehension response with reproduction of the patient's symptoms and a sense that the elbow is about to dislocate. Reproducing the actual subluxation, and the clunk that occurs with reduction, usually can only be accomplished with the patient under general anesthesia or occasionally after injecting local anesthetic into the elbow.

Lateral (Radial) Collateral Ligament (Varus Test)

The LCL is tested with the elbow positioned in 5–30 degrees short of full extension. The clinician stabilizes the humerus and adducts the ulna, producing a varus force at the elbow (Fig. 17-40). The end-feel is noted. No diagnostic accuracy studies have been performed to determine the sensitivity or specificity of this test.

FIGURE 17-38 Milking maneuver.

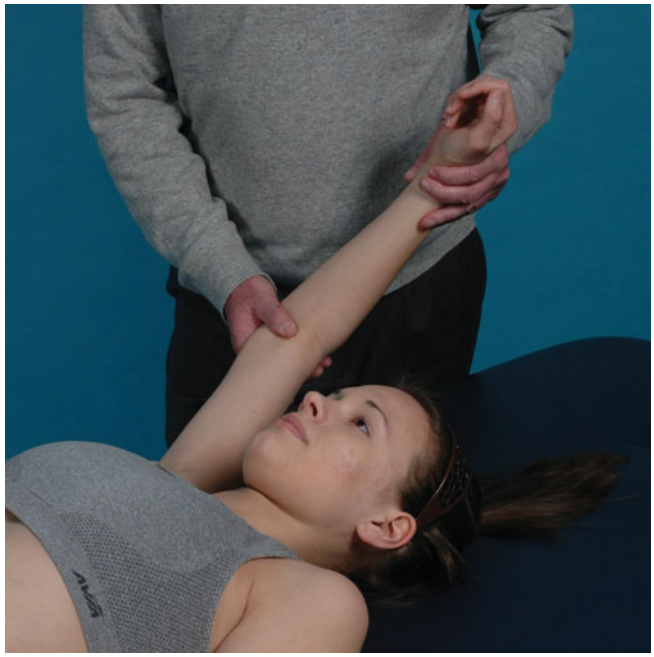

FIGURE 17-39 Lateral pivot shift apprehension test.

Special Tests

A number of special tests for the elbow exist. The diagnostic usefulness for some of these tests is outlined in Table 17-6.

Tennis Elbow

A number of tests exist for tennis elbow (lateral epicondylitis). Three are described here.

FIGURE 17-40 Radial collateral ligament stress test.

TABLE 17-6 Diagnostic Usefulness of Some Special Tests for the Elbow

Test and Related Diagnosis	Study Description	Reliability	Sensitivity	Specificity	LR+	LR−	DOR	QUADAS Score
Elbow flexion (cubital tunnel syndrome)	Evaluated the clinical usefulness of provocative testing in 32 subjects with electrodiagnostically proven cubital tunnel syndrome using Tinel's sign, elbow flexion (without wrist extension and with forearm supination held for 60 seconds), pressure provocation, and combined elbow flexion and pressure provocation.[a]	NT	75	99	75	0.25	297	7
Pressure provocation (cubital tunnel syndrome)		NT	89	98	45	0.11	396	7
Percussion test/Tinel's sign (cubital tunnel syndrome		NT	70	98	35	0.31	114	7
Elbow extension (elbow fracture)	110 of 114 patients with acute elbow injury underwent radiographic evaluation. Inability to extend the elbow was found in 37 of 38 patients with bone injury.[b]	NT	97	69	3.1	0.04	72	10
Moving valgus stress (chronic medial collateral ligament tear of the elbow)	21 patients, who underwent surgical intervention for medial elbow pain due to medial collateral ligament insufficiency or other abnormality of chronic valgus overload, were assessed preoperatively with this test.[c]	NT	100	75	4	0	NA	10
Biceps squeeze test (distal biceps tendon rupture)	25 consecutive patients with presumptive distal biceps tendon ruptures were evaluated using this test. The test was positive in 24 patients. 21 of 22 patients had operative confirmation of a complete distal biceps tendon rupture.[d]	NT	96	100	N/A	0.04	N/A	9

FIGURE 17-41 Cozen's test.

Cozen's Test. The clinician stabilizes the patient's elbow with one hand, and the patient is asked to pronate the forearm and extend and radially deviate the wrist against the manual resistance of the clinician (Fig. 17-41). A reproduction of pain in the area of the lateral epicondyle indicates a positive test. No diagnostic accuracy studies have been performed to determine the sensitivity or specificity of this test.

Mills' Test. The clinician palpates the patient's lateral epicondyle with one hand, while pronating the patient's forearm, fully flexing the wrist, and extending the elbow (Fig. 17-42). A reproduction of pain in the area of the lateral epicondyle indicates a positive test. No diagnostic accuracy studies have been performed to determine the sensitivity or specificity of this test.

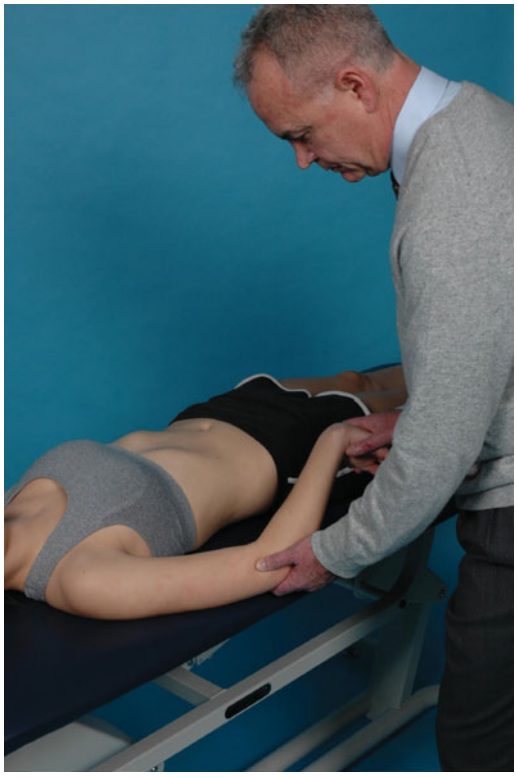

FIGURE 17-42 Mills' test.

FIGURE 17-43 Maudsley test.

Maudsley Test. The patient is seated facing the clinician. Using one hand, the clinician grasps the patient's wrist, and using the other hand, resists third digit extension, stressing the extensor digitorum muscle (Fig. 17-43). A positive test is reproduction of pain along the lateral epicondyle. No diagnostic accuracy studies have been performed to determine the sensitivity or specificity of this test.

Golfer's Elbow (Medial Epicondylitis)

The clinician palpates the medial epicondyle with one hand, while supinating the forearm and extending the wrist and elbow with the other hand. A reproduction of pain in the area of the medial epicondyle indicates a positive test.

Elbow Flexion Test for Cubital Tunnel Syndrome

The patient is positioned in sitting or standing with both arms and shoulders in the anatomic position. The patient is asked to depress both shoulders, flex both elbows maximally, and supinate the forearms (Fig. 17-44). The patient is then asked to extend the wrists.[110] This position is maintained for 3–5 minutes and then the patient is asked to describe any symptoms. Tingling or paresthesia in the ulnar distribution of the forearm and hand indicates a positive test.

Pressure-Provocative Test for Cubital Tunnel Syndrome

Pressure is applied by the clinician, proximal to the cubital tunnel, with the elbow held in 20 degrees of flexion and the forearm in supination (Fig. 17-45).[111]

Percussion Test/Tinel's Sign (at the Elbow) for Cubital Tunnel Syndrome

The clinician locates the groove between the olecranon process and the medial epicondyle through which the ulnar nerve passes. This groove is tapped 4 to 6 times by the index finger of the clinician (Fig. 17-46). A positive sign is indicated by a tingling sensation in the ulnar distribution of the forearm and hand distal to the tapping point.

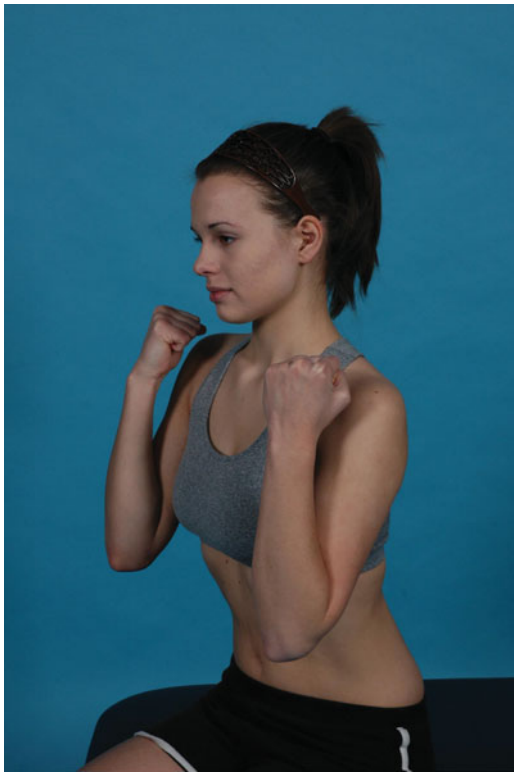

FIGURE 17-44 Elbow flexion test.

FIGURE 17-46 Percussion test/Tinel's sign (at the Elbow).

Elbow Extension Test

The patient is positioned in supine and is asked to fully extend the elbow. A positive test for elbow fracture is indicated by the patient's inability to fully extend the elbow.

FIGURE 17-45 Pressure-provocative test for cubital tunnel syndrome.

Moving Valgus Stress Test

The patient is positioned in sitting and the clinician stands behind the patient. The clinician positions the patient's shoulder in 90 degrees of abduction and 120 degrees of elbow flexion. The clinician applies a modest valgus torque to the elbow until the shoulder reaches full external rotation. While applying a constant valgus torque, the elbow is quickly extended to 30 degrees (Fig. 17-47). A positive test for a chronic MCL tear of the elbow is the reproduction of medial elbow pain when forcibly extending the elbow from a flexed position between 120–70 degrees.

Biceps Squeeze Test

The patient is seated with the forearm resting comfortably in the patient's lap with the elbow flexed to approximately 60–80 degrees and the forearm in slight pronation. Standing on the

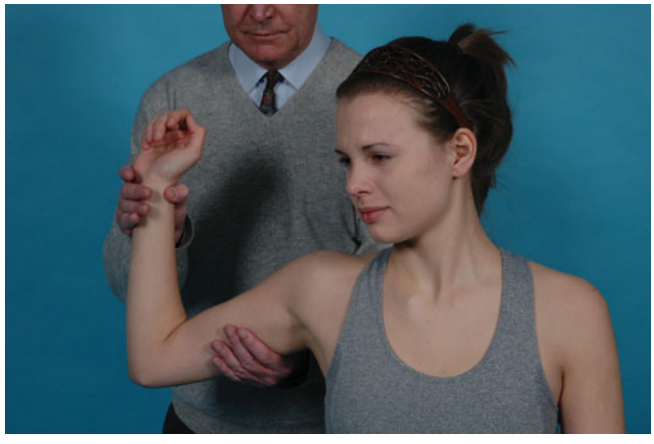

FIGURE 17-47 Moving valgus stress test.

involved side, the clinician squeezes the biceps firmly with one hand stablizing the upper extremity and the other hand around the belly of the biceps brachii (Fig. 17-48). A positive test for a distal biceps tendon rupture is a loss of forearm supination as the biceps brachii is squeezed.

Radiographic Evaluation

The standard X-ray series of the elbow includes anteroposterior (A-P) and lateral views (see Chap. 7).

THE EVALUATION

Following the examination, and once the clinical findings have been recorded, the clinician must determine a specific diagnosis or a working hypothesis, based on a summary of all of the findings. This diagnosis can be structure related (medical diagnosis) (Tables 17-7 and 17-8), or a diagnosis based on the preferred practice patterns as described in the Guide to Physical Therapist Practice.

INTERVENTION STRATEGIES

The intervention following elbow injury or elbow surgery follows a sequential and progressive multiphase approach. However, due to the unique orientation of the elbow complex,

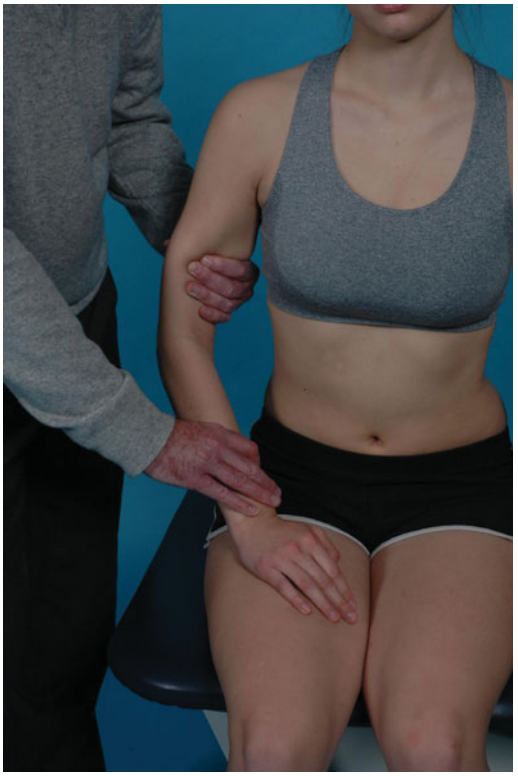

FIGURE 17-48 Biceps squeeze test.

TABLE 17-7 Differential Diagnosis for Common Causes of Elbow Pain

Condition	Patient Age (y)	Mechanism of Injury	Area of Symptoms	Symptoms Aggravated by	Observation
Bicipital tendinitis	20–50	Repetitive hyperextension of the elbow with pronation or repetitive stressful pronation–supination	Anterior aspect of the distal part of the arm	Elbow extension and shoulder extension	Unremarkable
Triceps tendinitis	20–50	Overuse of the upper arm and elbow, especially in activities like throwing and hammering	Posterior aspect of elbow	Activities involving elbow extension or full elbow flexion	Possible swelling near the point of the elbow
Lateral epicondylitis	35–55	Gradual overuse	Lateral aspect of elbow	Activities involving wrist extension/grasping	Possible swelling (over lateral elbow)
Medial epicondylitis	35–55	Gradual overuse	Anteromedial aspect of elbow	Activities involving wrist flexion	Possible swelling (over medial elbow)
Olecranon bursitis	20–50	Trauma	Posterior aspect of elbow	Contact with posterior elbow	Swelling over posterior elbow
Ulnar collateral ligament injury	20–45	Excessive valgus force to medial compartment of the elbow	Ulnar aspect of the elbow	Valgus stress of the elbow, throwing, and pitching	May have ecchymosis over ulnar aspect
Ulnar nerve entrapment	20–40	Gradual overuse Trauma	Medial elbow, forearm, and hand Medial 11/2 fingers	Activities involving elbow and wrist extension	Atrophy of hand muscles if chronic
Radial nerve entrapment	Varies	Can be overuse, direct trauma	Lateral elbow	Varies	Usually unremarkable
Median nerve entrapment	20–40	Gradual overuse	Anterior forearm Lateral 31/2 fingers	Activities involving full elbow extension or pronation of the forearm	Atrophy of anterior forearm and hand muscles if chronic

AROM, active range of motion; PROM, passive range of motion; ECRB, extensor carpi radialis brevis; ECRL, extensor carpi radialis longus.

AROM	PROM	End-Feel	Resisted	Special Tests	Tenderness with Palpation
Possible pain with elbow flexion	Pain with passive shoulder and elbow extension		Pain on elbow flexion and supination		Distal biceps belly The musculotendinous portion of the biceps Bicipital insertion of the radial tuberosity
Elbow extension Possible pain with extreme elbow flexion	Pain with passive shoulder and elbow flexion		Pain on elbow extension		Posterior aspect of elbow
Possible pain on wrist flexion with elbow extension	Pain on wrist flexion with the forearm pronated and the elbow extended		Pain on resisted wrist extension and radial deviation, with the elbow extended Pain on finger extension	Cozen Mills'	Lateral elbow (over the ECRB and ECRL)
Pain on wrist extension	Pain on combined wrist extension and forearm supination		Pain on pronation with wrist flexion	Passive supination of the forearm and extension of the wrist and elbow	Anteromedial elbow
Possible pain with extreme elbow flexion	Pain on full elbow flexion		Strong and pain free	Valgus stress with elbow flexed at ~25 degrees and humerus in external rotation	Posterior elbow
Pain with full extension possible	Passive extension of the elbow, valgus stress	Depends on severity	Usually unremarkable		Ulnar aspect of elbow
Inability to fully close hand	Full and pain free		Weakness of grip	Elbow flexion and pressure-provocative test Tinel's at elbow Wartenberg's sign Froment's sign	Anteromedial elbow
Usually unremarkable	Usually unremarkable		Pain with resisted forearm supination, resisted extension of middle finger		Maximal tenderness is usually elicited over the radial tunnel if radial tunnel syndrome
Pain on forearm pronation	Full and pain free		Weakness on pronation, wrist flexion, and thumb opposition	Benediction sign Inability to perform "OK" sign (anterior interosseous syndrome) Resisted supination (compression of the lacertus fibrosus)	Over the pronator teres 4 cm distal to the cubital crease, with concurrent resistance against pronation, elbow flexion, and wrist flexion—pronator syndrome

TABLE 17-8 Findings in Common Conditions of the Elbow and Forearm

Condition	Findings
Valgus extension overload syndrome	Tenderness around the tip of the olecranon Pain with forced passive elbow extension Increased valgus laxity (variable)
Cubital tunnel syndrome	Tenderness over the course of the ulnar nerve Abnormal Tinel's sign over the ulnar nerve, as it passes through the cubital tunnel (medial elbow) Ulnar nerve compression test abnormal Elbow flexion test abnormal (variable) Abnormal sensation (two-point discrimination or light touch), in the ulnar distribution: little finger; ulnar aspect of ring finger; ulnar aspect of hand Possible weakness and atrophy of the ulnar-innervated intrinsic muscles of the hand Possible weakness of flexor digitorum profundus to the little finger Possible signs of concomitant ulnar nerve instability, elbow instability, or elbow deformity
Radial tunnel syndrome	Tenderness in the extensor muscle mass of the forearm (distal to lateral epicondyle) at the arcade of Fröhse Long finger extension test reproduces pain Weakness of finger and thumb extensors and extensor carpi ulnaris
Pronator teres syndrome	Tenderness over the pronator teres in the proximal forearm Possible abnormal sensation (two-point discrimination or light touch) in the median nerve distribution: thumb, index finger, long finger, and radial side of ring finger On occasion, prolonged resisted pronation reproduces symptoms of weakness of median-innervated muscle Rare, but often incorrectly diagnosed as carpal tunnel Resisted elbow flexion and forearm supination reproduce symptoms due to compression at the lacertus fibrosus Resisted long finger proximal interphalangeal joint flexion reproduces symptoms due to compression by the flexor digitorum superficialis Possible weakness of median-innervated muscles
Anterior interosseous nerve syndrome	Weakness of flexor pollicis longus and flexor digitorum profundus to index finger Weakness of pronator quadratus
Distal biceps tendon rupture	Swelling Ecchymosis Palpable gap in the biceps tendon Weak or absent elbow flexion and supination
UCL strain or tear	Medial elbow joint pain in a thrower Complete tears open on valgus stress testing with the elbow flexed at 25 degrees compared to the uninvolved side, whereas incomplete tears are tender on palpation of the UCL but do not open on valgus stressing
Nursemaid's elbow (pulled elbow syndrome)	Mean age is 2–3 years History is critical to making diagnosis: reports of longitudinal traction on an extended elbow, resulting in a partial slippage of the annular ligament over the head of the radius and into the radiocapitellar joint Child typically holds the arm at the side, with the hand pronated (palm down) Closed reduction with manipulation is highly successful
Little league elbow	Covers a spectrum of pathologies about the elbow joint in young developing (pediatric) throwers Four distinct vulnerable areas to throwing stress: (1) medial elbow tension overload; (2) lateral articular surface compression overload; (3) posterior-medial shear forces; and (4) extension overload of the lateral restraints May present as Panner's disease (necrosis of the capitellum), OCD, medial epicondylar fracture, medial apophysitis, medial ligament rupture, and posterior osteophyte formation at the tip of the olecranon

UCL, ulnar collateral ligament.

Data from Birnie R, Reider B: Elbow and forearm. In: Reider B, ed. *Orthopaedic Physical Examination*. Philadelphia, PA: WB Saunders, 1999:67–98. With permission from WB Saunders.

the clinician is faced with multiple clinical challenges to successfully rehabilitate the injured elbow and should always consider the functional expectations of the individual patient when determining the most appropriate intervention.[7]

The techniques to increase joint mobility and the techniques to increase soft-tissue extensibility are described in the "Therapeutic Techniques" section.

ACUTE PHASE

The goals of the acute phase of elbow rehabilitation include:

- protection of the injury site;
- restoration of pain-free range of motion in the entire kinetic chain;
- improvement of patient comfort by decreasing pain and inflammation;
- retardation of muscle atrophy;
- minimization of the detrimental effects of immobilization and activity restriction;[112–117]
- maintenance of general cardiovascular fitness;
- ensuring that the patient is independent with a home exercise program.

During the early stages of the acute phase, the principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication) are applied as appropriate. Icing for 20–30 minutes, three to four times a day, concurrent with nonsteroidal anti-inflammatory drugs (NSAIDs) or aspirin, can aid in reducing pain and swelling.

CLINICAL PEARL

Corticosteroid injections have been advocated for elbow injuries to promote and progress healing. Although the use of local injections increases the risks of disrupting tissue planes, fenestration of the area of tendinosis may be beneficial because of the bleeding that occurs in the new channels, which has the potential for transforming a failed intrinsic healing process into an extrinsic response.[118,119]

Early active-assisted and passive exercises are performed in all planes of the shoulder, elbow (Fig. 17-49) **VIDEO**, and wrist motions **VIDEO**, to nourish the articular cartilage and assist in collagen tissue synthesis and organization.[7,120–123] As the available range at the elbow occurs at the humeroulnar, humeroradial, and proximal and distal radioulnar joints, restrictions or laxities at any of these joints can affect the eventual outcome of the rehabilitative process.

The formation of an elbow flexion contracture must be avoided, as this contracture can place abnormal stresses on the elbow complex, especially during athletic activities.[124] One of the most common causes of joint contracture at the elbow is scarring of the anterior capsule, and at the insertion site of the brachialis.[7] This scarring can be minimized by performing joint mobilizations to the humeroulnar and humeroradial joints. A posterior glide of the ulna on the humerus is used to help restore elbow extension. The anterior capsule can be

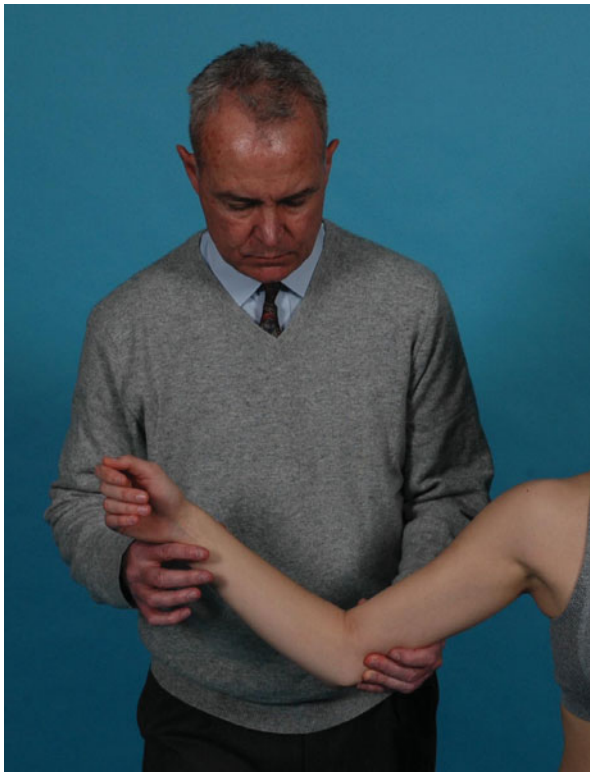

FIGURE 17-49 PROM/AAROM of elbow flexion.

stretched using long-duration, low-intensity stretching to produce a plastic response from the collagen tissue.[7,125,126] Such a stretch can be accomplished by positioning the patient in supine, with a towel roll placed under the elbow joint, and the forearm hanging over the edge of the bed (Fig. 17-50). A

FIGURE 17-50 Passive elbow extension using weight in hand.

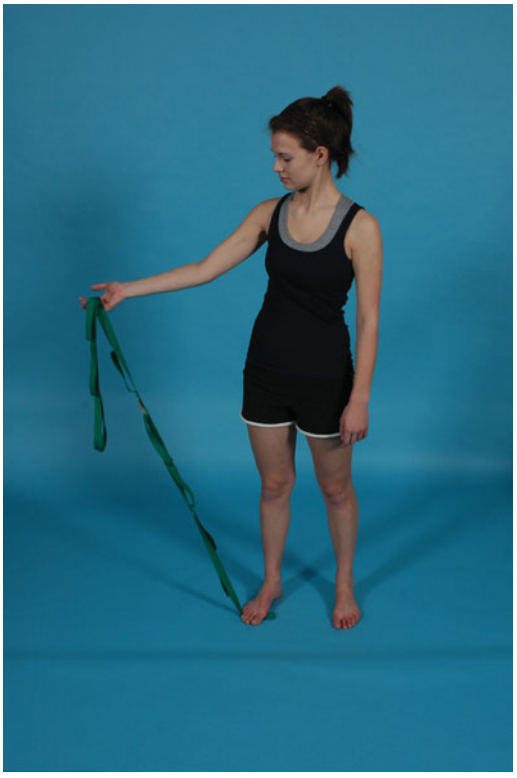

FIGURE 17-51 Elbow and wrist flexor stretch.

light weight (2–4 lb) is placed in the hand, and the elbow is extended as far as is comfortable. The passive stretch is maintained for 5–7 minutes, avoiding excessive pain manifested by a protective muscle response. This exercise becomes an important component of the patient's home exercise program. The elbow flexors (Fig. 17-51) and wrist flexors (Fig. 17-52) can also be stretched manually by the patient as part of the home exercise program.

Initially, the patient is advised to decrease the level of activity with the level of pain as the limiting factor, but without immobilizing the injured part completely.

Patients are initially instructed to perform submaximal isometric exercises at multiple angles for the elbow flexors and extensors, the forearm supinators and pronators, and the wrist flexors and extensors. Once full pain-free range

FIGURE 17-53 Wrist flexor PREs.

of motion has been achieved, the patient's strengthening program is progressed from the multiple angle isometrics to concentric progressive resistance exercises (PREs) using dumbbells or surgical tubing. Low resistance is used initially with one to two sets of 10 repetitions, progressing as tolerated to five sets of 10 repetitions. Once five sets of 10 repetitions can be performed without pain and in a slow and controlled manner, additional resistance is added in 1–3-lb increments.[7] The resistance-based exercise program is the mainstay of nonoperative intervention for the elbow and serves to retard muscle atrophy of the elbow and wrist musculature. Patients are advanced in concordance with their ability to participate in the program. Patients should be taught how to perform these exercises independently at the earliest opportunity.

Specific exercises to increase strength should include the following:

- Concentric exercises to the wrist flexors **VIDEO** and extensors **VIDEO**, elbow flexors **VIDEO** and extensors **VIDEO**, and radial **VIDEO** and ulnar deviators **VIDEO**, performed at varying speeds and resistance. These include wrist curls (Fig. 17-53), reverse wrist curls (Fig. 17-54) **VIDEO**, neutral wrist curls **VIDEO**, biceps curl (Fig. 17-55), and triceps strengthening (Fig. 17-56) resisted pronation (Fig. 17-57), resisted supination (Fig. 17-58) **VIDEO**. The exercises are initially performed using low speeds and resistance; the speed and the intensity of resistance are then gradually increased.

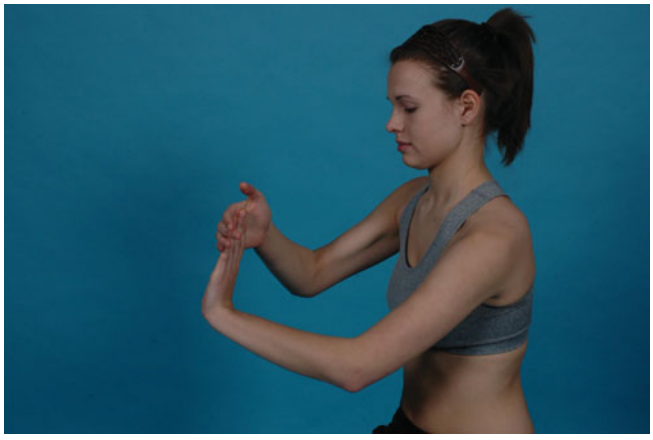

FIGURE 17-52 Wrist flexor and elbow flexor stretch.

FIGURE 17-54 Wrist extensor PREs.

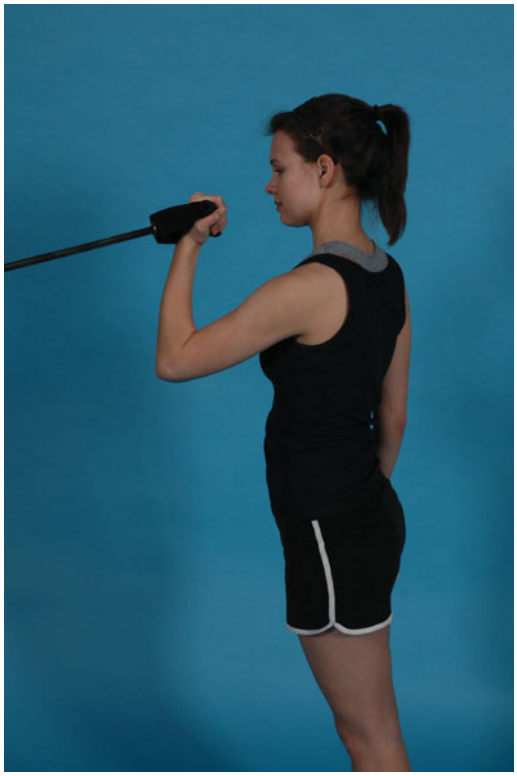

FIGURE 17-55 Elbow flexion PREs.

- The broom-handle exercise, which is a recommended exercise for the wrist flexors and extensors. A weight is tied to a rope or piece of string approximately 3 ft in length, which is then tied to a broom handle or dowel. The broom handle is held out in front of the patient with the palms down (for wrist extensors, see Fig. 17-59) or palms up

FIGURE 17-57 Strengthening exercise for pronators.

FIGURE 17-58 Strengthening exercise for supinators.

FIGURE 17-56 Triceps strengthening.

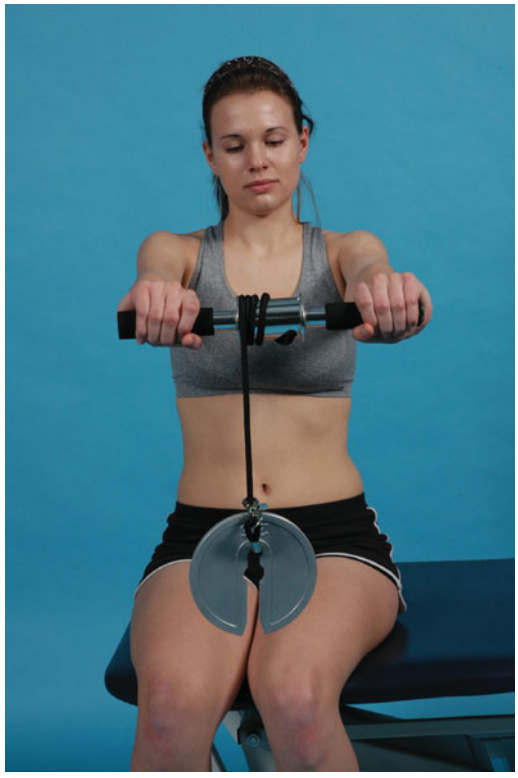

FIGURE 17-59 Broom-handle exercise.

FIGURE 17-60 Tennis ball squeezes.

(for wrist flexors). The patient then rolls the string onto the handle/dowel to raise and then lower the weight.

- Tennis ball squeezes (Fig. 17-60) to improve grip strength (once symptoms have subsided).
- Exercises to increase the strength in opposing muscles, such as the flexors of the wrist and digits, in order to balance the force couple.

Shoulder exercises should also be introduced as early as possible, although caution should be used with shoulder external rotation exercises because of the potential for valgus stress to the elbow.[7,119,127,128] In the earlier phases of pain, modification of activity may involve alternating between low- and high-intensity workouts.[129,130] Endurance is developed over time, as the patient becomes able to tolerate more repetitions and sustained activities. If endurance is not developed and the muscle–tendon unit becomes fatigued, the muscular portion can no longer absorb the stresses and greater stresses are absorbed by the tendon.[131] Throughout all phases of rehabilitation and exercise, training should be within physiologic limits for cellular response and homeostasis.[132] Therefore, relative rest is sometimes advised during painful periods.

Stability at the shoulder and the elbow is extremely important for those patients returning to overhead sports and can be addressed using proprioceptive neuromuscular facilitation (PNF) patterns with increasing resistance.

In the presence of joint laxity that is not controllable with adequate exercise or ergonomic modifications, bracing can be effective.

Progression to the next phase occurs when the patient has full, pain-free range of motion, and strength at least 70% of the contralateral limb.

FUNCTIONAL PHASE

The functional phase addresses any tissue overload problems and functional biomechanical deficits. The goals of the functional phase include:

- restoring normal joint kinematics;
- improving muscle strength to within normal limits (WNL);
- improving neuromuscular control;
- restoring the normal strength and relationships of the muscle force couples.

If the feet and trunk are stabilized during an activity, the upper quarter kinetic chain involves the cervical spine, thoracic outlet, thoracic spine, shoulder, elbow, wrist, and hand. The upper quarter operates as a mechanical unit whose links are functionally interdependent on one another.

The clinician must be aware of any substitutions as individuals will instinctively modify their exercises to avoid motions involving painful, injured tissues, and to prevent further abuse of the overused tissues.[130,132] In such cases, the exercises must be corrected or discontinued.

Cocontraction of the muscles around the elbow can be produced with closed chain exercises such as the push-up, quadruped exercises, and dips, incorporating a wide range of equipment such as gymnastic balls, BAPS boards, mini-tramp, and slide board (see Chap. 16).

Training can also involve dynamic muscle cocontractions in an open kinetic chain by using ballistic movement patterns, with elastic tubing incorporating PNF diagonals. These ballistic movements, which can be increased in terms of speed based on tolerance, result in synchronous activation of agonists and antagonists.[133–135]

The function of the biceps is integral to the stability of the elbow complex and must be exercised, emphasizing slow and fast muscular contractions in both concentric and eccentric modes.[7] Wilk and colleagues[7] advocate the following drill to enhance the dynamic stability of the elbow:

- The patient flexes the elbow against resistance provided by elastic tubing.
- The patient holds a position isometrically, while the clinician employs rhythmic stabilization resistance anteriorly and posteriorly.
- The procedure is repeated for the wrist flexors–extensors and the forearm pronators–supinators.

Plyometric exercises are introduced as tolerated and as appropriate[136]:

- The patient grasps a length of elastic tubing and fully flexes the elbow, with the shoulder flexed to about 60 degrees (Fig. 17-61). This position is maintained briefly. The patient then releases the isometric hold, allowing the elbow to extend rapidly. As full extension is reached, the movement is quickly reversed back into full elbow flexion.[136] The forearm pronators–supinators can all be exercised in a similar fashion.
- For overhead athletes, ER exercises can be performed with elastic tubing at 90 degrees of shoulder abduction and 90 degrees of elbow flexion (Fig. 17-62).
- Plyometric weighted ball throws into IR at 0 degree of shoulder abduction (Fig. 17-63), and at 90 degrees of shoulder abduction (Fig. 17-64).
- Prone plyometric weighted ball throws with the patient's arm positioned at 90 degrees of shoulder abduction and 90 degrees of elbow flexion (Fig. 17-65).
- Plyometric wrist flips and snaps (Figs. 17-66 and 17-67)

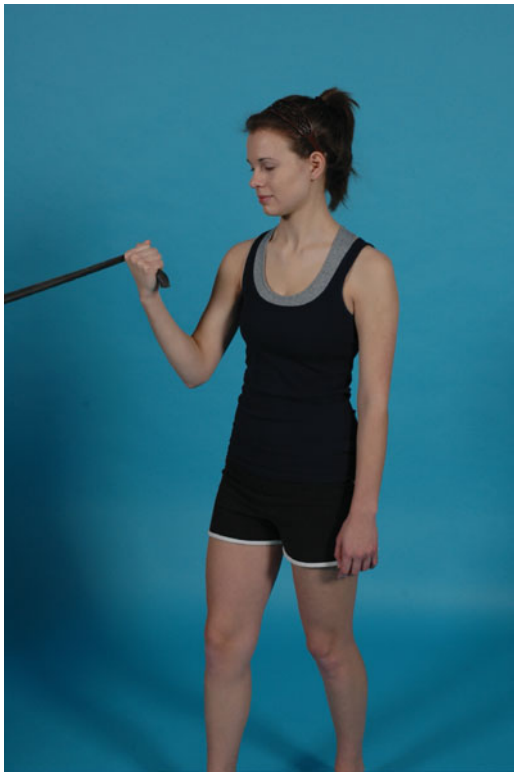

FIGURE 17-61 Plyometric exercise with elastic tubing.

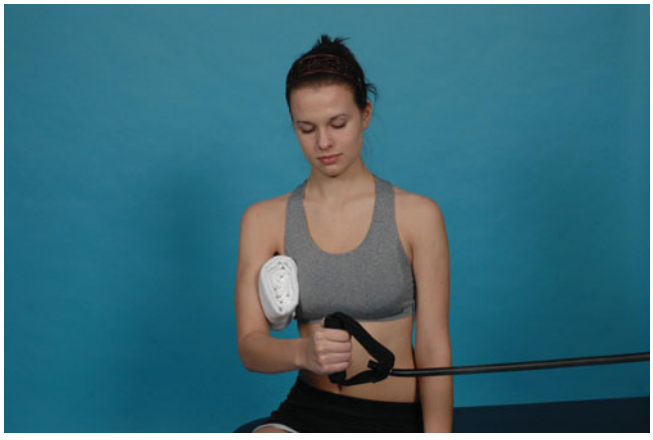

FIGURE 17-62 ER exercises performed at 90 degrees of shoulder abduction and 90 degrees of elbow flexion.

The shoulder stabilizers, triceps, and the wrist flexors–extensors can be trained as a unit using Swiss ball push-ups (Fig. 17-68), PNF patterns using T-band (Figs. 17-69 and Fig. 17-70), and medicine ball throws (Fig. 17-71).

Sport-specific training is essential before an athlete returns to play. There should be a gradual transition back to sports activities and other strenuous activities of daily living, depending on the recovery of the involved tissues and the restoration of the athletic skills required to perform the activity. Too often, patients return to full activity prematurely, with resulting reinjury. This is both frustrating and discouraging for the patient.

In order for the athlete to begin the return to sporting activities, the elbow must have full, pain-free range of motion; no pain or tenderness on physical examination; and adequate

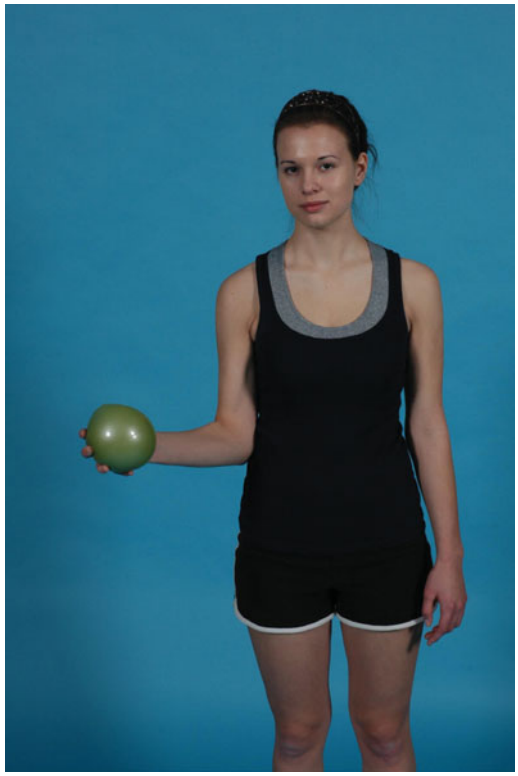

FIGURE 17-63 Plyometric medicine ball throws into IR at 0 degree of shoulder abduction.

muscle strength, power, and endurance that is 90% of the uninvolved side.[7]

Those athletes who are returning to throwing can undergo a strength comparison through isokinetic testing. This can be

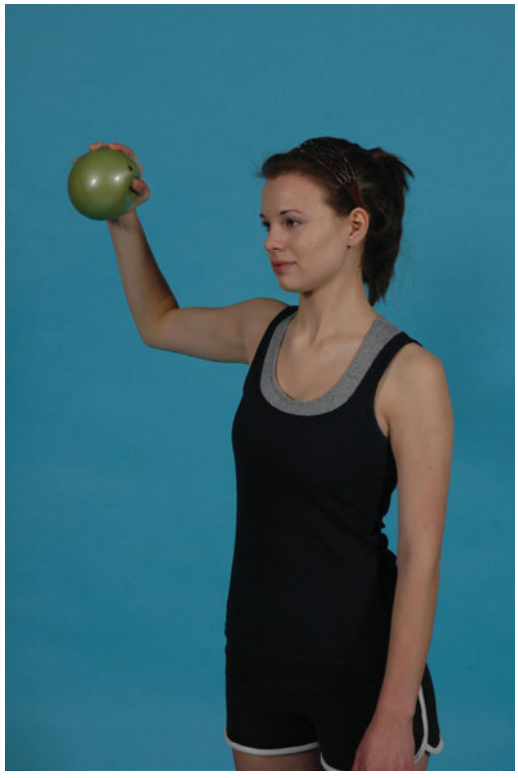

FIGURE 17-64 Plyometric medicine ball throws into IR at 90 degrees of shoulder abduction.

achieved with the patient in the seated position. Speeds of 180 degrees per second and 300 degrees per second are used. A bilateral comparison should indicate that the overhead athlete's elbow flexors are 10–20% stronger, the elbow extensors are 5–15% stronger when compared to the uninvolved

FIGURE 17-69 UE PNF using T-band.

side, and that the flexor–extensor ratio should be 70–80% at 180 degrees per second, and 63–69% at 300 degrees per second.[7]

Advanced strengthening exercises specific for the patient's activity/position are emphasized during the later part of this phase. These include high-speed/high-energy strengthening and eccentric muscular contractions performed in functional positions.[7]

PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Impairments involving capsular restriction include every form of arthritis. It is important that the clinician establish the cause of the arthritis using the history, the tests and measures, results from any imaging studies, and findings from any laboratory tests before initiating treatment.

Traumatic Arthritis

Trauma at the elbow has the potential to produce a traumatic arthritis. The most common mechanism is the hyperextension injury, resulting in a sprain of the anterior capsule and the anterior band of the medial (ulnar) collateral ligament. The patient typically complains of diffuse elbow pain, especially on the medial aspect. Upon examination, a capsular pattern of passive flexion more limited than extension is present, whereas the motions of pronation and supination are unaffected. Traumatic arthritis at the elbow is usually treated with a corticosteroid injection in adults, whereas in children a brief period of immobilization in a sling, followed by gentle passive and active range of motion (AROM), is recommended.

Arthrosis

See Chapter 5.

Osteochondritis Dissecans Capitellum

Osteochondritis dissecans occurs in many areas of the adolescent skeleton, and patients usually present with an insidious onset of diffuse lateral elbow pain accompanied by a decrease in the range of motion, including locking.[137] The etiology of this condition is not completely understood, but its occurrence in the elbows of adolescents probably relates to a focal arterial injury and subsequent bone necrosis resulting from increased radiohumeral lateral compression forces.[138]

Pain is usually felt at the radiocapitellar joint and is increased with activities that involve pronation and supination. Physical examination usually demonstrates a loss of full active and passive elbow extension. Resistive testing can produce crepitus, in addition to pain at the humeroradial joint.[138] X-rays may reveal a flattening or focal distortion of the capitellum and perhaps even loose bodies.

Intervention for this condition depends on the findings from the radiographic, clinical, and, on occasion, arthroscopic examination but usually focuses on the control of pain.[138] Usually 3–4 months of nonabusive activity with exercises directed toward minimizing the strength loss during the rest period often proves effective. The exercises prescribed are similar to those for lateral epicondylitis with an emphasis on

biceps and triceps strength and muscular balance to control elbow extension forces. A motion-limiting brace can be used to reduce stress.

Surgical intervention is reserved for patients who do not respond to conservative measures, or those with loose bodies or separation of the cartilage cap.[138]

Radiocapitellar Chondromalacia

Radiocapitellar chondromalacia of the elbow occurs because of repetitive valgus forces, such as those encountered in throwing sports. Such activities can result in lateral elbow joint compression of the radiocapitellar articulation, and sometimes subsequent damage to the radial head, the capitellum, or both. Frank osteochondral fracture and loose bodies may also occur (osteochondritis dissecans).

The typical presenting symptoms are crepitus, catching, locking, and lateral elbow pain with active flexion and extension and pronation–supination of the elbow. Swelling and localized tenderness are noted at the involved site.

An axial load applied with passive supination and pronation often provokes pain and can be helpful in differentiating this condition from lateral epicondylitis. Radiographs may show a loss of joint space, marginal osteophytes, and, possibly, loose bodies.

Mild cases of this condition respond to NSAIDs and those exercises prescribed for lateral epicondylitis. However, care must be taken to perform exercises within pain-free ranges only to ensure joint safety.

Posterior Elbow Impingement

Posterior elbow impingement results from mechanical abutment of bone and soft tissues in the posterior compartment of the elbow. Pathologic processes such as fibrous tissue deposits in the olecranon fossa, chondral injury, osteophytes, and loose bodies are sometimes responsible.[139] MCL insufficiency may also be present.

Radiography may show posterior or posteromedial osteophytes and loose bodies.

Surgical removal of the osteophytes and loose bodies is indicated if symptoms do not resolve with conservative treatment consisting of range-of-motion and strengthening exercises.

Malpositioning of the Elbow

Abducted Ulna Lesion

This lesion usually results from a FOOSH injury, forcing the ulna medially into full extension and abduction. Clinical findings include the following[140]:

- An increased carrying angle and apparent longer radius that is forced to glide distally. Initially, the hand is held in slight ulnar deviation due to a relative distal shift of the radius. However, this usually adapts, producing an ulnar carpal shift due to the pull of the radial deviators and wrist extensors.
- The elbow flexion may be decreased, but usually only an abnormal hard end-feel is detected.
- The forearm supination may be decreased, but usually only an abnormal hard end-feel is detected.
- The lateral glide at the elbow is decreased with an abnormally hard end-feel (the ulna is unable to adduct).
- decreased wrist extension.

There are potentially many and varied consequences of this lesion, including[140]

- the development of tennis-elbow symptoms as the radial deviators overwork to correct the ulnar deviation;
- an ulnar nerve traction injury, MCL sprain, and medial epicondylitis due to the increased carrying angle;
- carpal dysfunction due to the abnormal wrist biomechanics because of the distally displaced radius;
  - MCL laxity due to the adaptation occurring to correct the ulnar deviation;
  - hypertonicity and overuse of the radial deviators and extensors as the hand attempts to adopt a neutral position by attempting to radially deviate or extend.

The intervention for these conditions includes a correction of the malposition with either joint mobilizations or a high-velocity thrust.

Adducted Ulna Lesions

In the adducted ulna lesion, there is no involvement of the wrist. In fact, the head of the radius impacts the capitellum, resulting in decreased elbow extension and forearm pronation, and clinical findings that are exactly the opposite of those described above. The consequences of this lesion are less severe than with the abducted ulna, as the shift of the wrist is less due to the accommodation by the ulnar meniscus, but they include[140]:

- the development of tennis-elbow symptoms due to the prolonged stretch on the common extensor tendon;
- LCL laxity;
- minor carpal dysfunction;
- ulnar meniscus tearing due to continuous compression.

Posterior-Radial Head (External Rotation of the Ulna) Lesion

With this lesion, the radial head shifts posteriorly into extension on the humerus and the ulna. There is typically a history involving forced or excessive supination. Range-of-motion testing demonstrates decreased elbow extension and forearm pronation. Passive accessory motion testing reveals a decreased medial radial glide and decreased gapping space between the ulna and the radius.

Anterior-Radial Head (Internal Rotation of the Ulna) Lesion

With this lesion, the radial head shifts anteriorly into flexion on the humerus and the ulna. There is typically a history involving forced or excessive pronation. Range-of-motion testing demonstrates decreased elbow flexion and forearm supination. Passive accessory motion testing reveals a decreased lateral-radial glide.

Medial (Ulnar) Collateral Ligament Sprain

The most common mechanisms associated with MCL sprains are a chronic attenuation of valgus and external rotation forces,[22,31,60,141,142] as seen with a tennis serve or during a baseball throwing pitch,[143,144] and posttraumatic, usually following a FOOSH injury.[19] Related injuries after trauma may include fractures of the radial head, olecranon, or medial humeral epicondyle.[22,31] An MCL injury can also be iatrogenic, secondary to an excessive medial epicondylectomy for cubital tunnel syndrome,[145,146] or irritation of the ulnar nerve, secondary to inflammation of the ligamentous complex.[60,147,148]

The most common patient complaint is medial elbow pain at the site of the ligament's origin,[138] or at the insertion site in cases of an acute avulsion.[19] As the primary restraint to valgus stress is the anterior bundle of the MCL,[14,20–24,28] the physical examination of an individual with presumed medial joint insufficiency should focus on palpation of the course of the MCL.[19] Valgus stress testing of the elbow must also be performed.

An important secondary stabilizer of the elbow is the articular geometry of the joint complex.[3,21] Repetitive stress to the joint can lead to osteophyte formation and degenerative changes, which can produce medial elbow pain.

The intervention for an MCL injury includes rest and activity modification or restriction for about 2–4 weeks, range-of-motion exercises, modalities, and NSAIDs.[30] During the acute phase, the goals are as follows:

- To increase ROM
- To promote healing of MCL
- To retard muscular atrophy
- To decrease pain and inflammation (ice and compression)

Methods to increase range of motion during this period include:

- brace (optional) nonpainful ROM (20–90 degrees);
- active-assisted ROM, passive ROM elbow and wrist (nonpainful range).

Strengthening and stretching of the FCU, pronator teres, and FDS are initiated once the acute inflammatory stage has subsided. These exercises are performed in the pain-free mid-range of motion.[48,143,149,150] Emphasis is placed on isometric exercises of the forearm flexors, ulnar deviators, and pronators, in order to enhance their role as secondary stabilizers of the medial joint. In addition, strengthening of the shoulder and elbow muscles are incorporated to prevent or minimize injury and to facilitate rehabilitation of the upper extremity.[48,138] During the subacute phase, the goal is to gradually increase motion 0–135 degrees (increase 10 degrees/week). Concentric exercises are initiated, which should include:

- wrist curls;
- wrist extension PREs;
- pronation–supination PREs;
- biceps–triceps PREs.

Criteria to advance to the chronic phase include:

- full ROM;
- no pain or tenderness;
- no increase in laxity;
- strength $^{4}/_{5}$ of elbow flexors–extensors.

The goals during the chronic phase include:

- improve strength, power, and endurance;
- improve neuromuscular control.

These goals can be achieved using the following exercises:

- initiating exercise tubing and shoulder program;
- biceps–triceps program;
- supination–pronation PREs;
- wrist extension–flexion PREs;

As appropriate, a well-supervised throwing and conditioning program is initiated at approximately 3 months.[30] Criteria for progression to return to throwing include:

- full, nonpainful ROM;
- no increase in laxity;
- isokinetic testing fulfills criteria.

Operative repair of the MCL typically is required only in competitive throwing athletes or those involved in heavy manual labor,[19] as valgus laxity has been shown to cause minimal functional impairment with normal activities of daily living.[31] The surgical repair or reconstruction can be performed with or without ulnar nerve transposition.[151] The Tommy John technique is a surgical procedure in which the UCL is replaced with a tendon from elsewhere in the body. The palmaris longus tendon, which has been found to have a tensile strength of 357 N, is the most frequently used graft,[152] although the plantaris and toe extensor tendons can also be used.[141]

Lateral (Radial) Collateral Ligament (LCL) Sprain

Posterolateral rotatory instability results from insufficiency of the lateral soft-tissue support of the elbow, especially the LCL complex.[34,109,153] The mechanism of injury typically involves a combination of axial compression, external rotation, and valgus force applied to the elbow.[154,155] It may also have an iatrogenic origin and has been reported after overly aggressive debridement of the lateral soft tissues for patients with recalcitrant tennis elbow.[153,156]

Elbow Instability

Both the humeroulnar and the humeroradial articulation provide approximately 50% of the overall stability of the elbow.[21,24,25] Additional support is supplied by ligaments and muscles.

Although elbow instability has been documented for decades, the clinical tests for making the diagnosis of elbow instability are relatively recent.[109,154]

The following 5-item classification system for elbow instability is useful for correct diagnosing and treatment decision-making[157–159]:

1. ***The timing*** (acute, chronic, or recurrent).
2. ***The articulation(s) involved.*** Since the elbow is a complex joint, there are two categories of elbow instability, according to the articulation(s) involved, although the instability can involve both joints in a combined fashion[157]:
   a. ***The ulnohumeral joint.*** The instability of this hinge joint, which is most commonly predisposed to recurrent instability, can be congenital or acquired, although the former is rare.
   b. ***The proximal radioulnar joint.*** This involves a subluxation or dislocation of the radial head from the ulna, which can be congenital or acquired. Dislocation of the radial head from the ulna is usually traumatic and often part of a Monteggia fracture–subluxation.
3. ***The direction of displacement (valgus, varus, anterior, or posterolateral rotatory).***
   a. ***Valgus displacement.*** The medial stabilizers of the elbow are the strongest. The mechanism of injury for a valgus displacement is usually a FOOSH injury and occurs in individuals who perform overhead movements such as sledgehammer users and baseball pitchers and javelin throwers.[142] The instability is characterized by pain in the anteromedial aspect of the arm, a moderate-to-severe flexion limitation (acute), and a positive valgus test at 20 degrees of flexion. Valgus instability is seen in one of two varieties: posttraumatic or chronic overload.[157]

Posttraumatic Valgus Instability. This type is often associated with disruption of the soft tissues on the medial side of the elbow, including the MCL, and the common flexor and pronator origin.[160] Valgus instability is usually found in patients with radial head fractures associated with tears of the MCL, or in patients with severe elbow instability following a dislocation that has disrupted the lateral ligament complex.

Chronic. This type typically occurs from repetitive microtrauma or overload, resulting in attenuation or rupture of the anterior band of the MCL.

   b. ***Varus displacement.*** Because of the anatomic design of the elbow, any force across the elbow principally distorts the elbow in a valgus direction, usually in combination with external rotation rotatory force as occurs from a FOOSH injury. Thus a pure varus mechanism of injury is uncommon.[139] Lateral instability can also occur acutely in patients with elbow dislocations and in many patients with recurrent or chronic instability when the LCL fails to heal.[157] Patients with a varus instability are unlikely to complain of symptoms except when using their arms as weight-bearing extremities (using crutches).[157]
   c. ***Anterior displacements.*** These injuries, which are rare, usually occur from a blow to the flexed elbow, which drives the olecranon anteriorly.[161] Associated injuries include fractures of the olecranon, with varying degrees of sprain to the collateral ligaments and damage to the vessels and nerves around the joint. On examination, the arm appears shorter, while paradoxically the forearm appears elongated and held in supination. The elbow is usually held in extension.
   d. ***Posterior displacements.*** Posterior elbow displacements, which are much more common than anterior or lateral displacements, involve a posteriorly displaced ulna in relation to the distal humerus. The patient's arm is held in 45 degrees of flexion. Posterior displacements can be further subdivided into three types: posterior, posterior-medial, and posterior-lateral.[153,159] The most common is usually posterior-lateral rather than direct posterior, so that the coronoid passes inferior to the trochlea, and the ulnar displacement on the humerus is three dimensional (the radius moves with the ulna), such that the ulna supinates (externally rotates) away from the trochlea.[157] The most common mechanism for a posterolateral instability involves proximal attenuation or avulsion of the ligamentous and muscular origins from the lateral epicondyle during a traumatic event.[33] The LCL is the primary static restraint against posterolateral rotatory instability.[15434,160,162–164] The lateral pivot shift test, also called the posterolateral rotatory instability test, is commonly used to assist in the diagnosis.[139] The surgical intervention for posterolateral rotatory instability involves a repair of the common tendon and ligament origins to the lateral epicondyle.[19]
4. ***The degree of displacement (subluxation or dislocation).*** Posterolateral rotatory instabilities typically consist of three stages, each of which has specific clinical, radiographic, and pathologic features that are predictable and have implications for treatment[157]:
   a. *Stage 1.* The elbow subluxates in a posterolateral rotatory direction, and the patient has an associated positive lateral pivot shift test.
   b. *Stage 2.* The elbow dislocates incompletely so that the coronoid is perched under the trochlea.
   c. *Stage 3.* The elbow dislocates fully so that the coronoid rests behind the humerus.
5. ***The presence or absence of associated fractures.*** Elbow subluxations and dislocations can be associated with elbow fractures. Fracture–dislocations most commonly involve the coronoid and/or radial head, an injury so difficult to treat and prone to unsatisfactory results that it has been termed the "terrible triad" of the elbow.[165]

The diagnosis for elbow instability is made by the history and a careful physical examination. Patients typically present with a history of recurrent painful clicking, snapping, clunking, or locking of the elbow, that occurs in the extension portion of the arc of motion with the forearm in supination.[157] An examination of the peripheral nerves and distal pulses is necessary to help determine the severity of the instability. Swelling may make the diagnosis of elbow instability difficult. However, if the clinician palpates the two epicondyles and the tip of the olecranon, the following findings help determine the diagnosis:

- If the three points are on the same plane, a supracondylar fracture is suspected.
- If the olecranon is displaced from the plane of the epicondyles, a posterior dislocation is suspected.

The diagnosis of a dislocation can be confirmed by a radiograph.

With patients presenting with a history of dislocation, the diagnosis of recurrent elbow instability is to be suspected. This diagnosis should also be considered when there has been trauma without dislocation. Recurrent instability may also be caused by surgeries such as tennis-elbow surgery or surgery on the radial head.[109,153,156,157]

Conservative intervention for elbow instability should focus on the entire kinetic chain, including the lower extremities and trunk. Posterior capsular tightness in the shoulder must be addressed.[166,167,168,169]

During the inflammatory phase, the intervention includes:

- immobilization of the elbow positioned at 90 degrees of flexion in a well-padded posterior splint for 3–4 days;
- initiation of light gripping exercises (putty or tennis ball);
- avoidance of any passive ROM (patient to perform active ROM when the posterior splint is removed and replaced with a hinged elbow brace or sling), and any valgus stresses to the elbow;
  - use of cryotherapy and high-voltage galvanic stimulation.
  - At days 4–14 the posterior splint is replaced with a hinged elbow brace initially set at 15–90 degrees. Exercises during this phase should include:
- wrist- and finger-active ROM in all planes;
- active elbow ROM (while *avoiding* valgus stress)—flexion–extension–supination–pronation;
- multiangle flexion isometrics;
- multiangle extension isometrics (while avoiding valgus stress);
- wrist curls/reverse wrist curls;
- light biceps curls;
- Shoulder exercises (avoidance of external rotation of shoulder, because this places valgus stress at the elbow). The elbow should be stabilized during shoulder exercises.

At around 2–6 weeks, the hinged brace is set from 0 degree to full flexion. Exercises include:

- PRE progression of elbow and wrist exercises;
- gentle low-load, long-duration stretching is initiated around 5–6 weeks to enhance extension;
- gradual progression of weight with curls, elbow extension, and so on;
- initiation of sports-specific exercises and drills;
- External rotation and internal rotation exercises of the shoulder may be incorporated at 6–8 weeks.

An interval throwing program can be initiated at around 8 weeks, however there should be no return to play until strength is 85–90% of the uninvolved limb. PNF, rhythmic stabilization, and plyometric exercises are used to improve functional stabilization of the joint, beginning with two-handed exercises in the nonprovocative ranges with the elbow close to the body, and progressing to one-handed activities with the involved arm in functional or sports-related positions.[37]

Surgical intervention is reserved for those patients in whom conservative measures fail.

PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION ASSOCIATED WITH LOCALIZED INFLAMMATION

Overuse injuries at the elbow, which are relatively common, result from repetitive trauma that leads to inflammation and/or local tissue damage in the form of cellular and extracellular degeneration, which can be cumulative and result in tendinitis or tendinosis, stress fractures, ligament sprains, or muscle myositis. Both intrinsic and extrinsic factors contribute to overuse injuries. Intrinsic factors include biomechanical abnormalities; extrinsic factors are primarily training errors (incorrect technique, improper equipment, and changes in the duration or frequency of an activity).

Olecranon Bursitis

Because of its superficial location, the olecranon bursa is easily injured through direct trauma or can be irritated through repetitive grazing and weight bearing, resulting in bursitis. Olecranon bursitis is common in individuals who spend long periods weightbearing through the elbows, such as students, or where the potential for falling and striking an elbow on hard playing surfaces is high.[170]

Acute bursitis presents as a swelling over the olecranon process that can vary in size from a slight distension to a large mass several centimeters in diameter.[171] In chronic cases, the pain and swelling can be gradual, or sudden as in acute injury or an infection.[171] An inflamed bursa can occasionally become infected, requiring differentiation between septic and nonseptic bursitis.[172]

Redness and heat suggest infection, whereas exquisite tenderness indicates trauma or infection as the underlying cause. Patients often note a decreased range of motion or an inability to don a long-sleeved shirt.[173] While the simple posttraumatic bursitis can be treated with the principles of PRICEMEM, the infected bursa needs prompt medical attention.[173]

Included in the differential diagnoses of olecranon bursitis are acute fractures, rheumatoid arthritis, gout, and synovial cysts.[171] If the patient is experiencing significant pain or discomfort with movement of the elbow, a sling helps to reduce these symptoms and calm the joint.[171] In those cases of marked swelling, or to distinguish between a septic and nonseptic bursitis, aspiration is the appropriate management. Aspiration also helps to reduce the level of discomfort and restriction of movement. The aspirated fluid is cultured and evaluated for crystals to rule out infection or gout. After aspiration, the elbow should be maintained in a splint and sling and reevaluated after 1 week. Bursitis that recurs despite three or more repeated aspirations, or an infection that does not respond to antibiotics, requires evaluation for surgical excision.[171,173]

Injection of corticosteroids is used to manage chronic bursitis once the diagnosis of infection has been excluded.[171]

Olecranon Impingement Syndrome

Repetitive impingement of the olecranon in the olecranon fossa may occur with valgus stresses in throwing sports. Stress to both articular surfaces of the joint may result in the formation of loose bodies, osteophytes, chondromalacia, and synovitis.[174]

The patient may report catching, clicking, and crepitus, which are worsened by elbow extension. Full elbow extension may be limited by a mechanical block. X-rays confirm loose bodies, olecranon osteophytes, and commonly associated anterior elbow changes.

Mild cases respond to a rehabilitation program focusing on restoration of normal motion, strength, and endurance. Continued pain, loose bodies, or mechanical blockage are indications for surgery.

Tendon Injuries of the Elbow

Tendon injuries of this region can be divided into several categories on the basis of the nature of their onset and the tissues involved. While acute tendon injuries are traumatic in nature, chronic overuse injuries are the result of multiple microtraumatic events that cause disruption of the internal structure of the tendon and produce tendinitis or tendinosis.

Bicipital Tendinosis

Bicipital tendinosis typically results from repetitive hyperextension of the elbow with pronation, or repetitive flexion combined with stressful pronation–supination.[85] Typically the patient complains of pain located at the anterior aspect of the distal part of the arm, with tenderness to palpation of the distal biceps belly, the musculotendinous portion of the biceps, or the bicipital insertion of the radial tuberosity.[77,85] Other findings include a reproduction of pain with resisted elbow flexion and supination, and with passive shoulder and elbow extension.

The conservative intervention focuses on regaining the strength, endurance, and flexibility of the flexor/supinator mechanism, and on strengthening the shoulder stabilizers. Other approaches involve electrotherapeutic and thermal modalities, transverse friction massage, trigger point assessment, and specific elbow joint mobilizations.

Biceps Tendon Rupture

The biceps tendon can be avulsed partially or completely either at the musculotendinous junction or at the radial tuberosity.[175] Avulsions of the biceps tendon at the elbow occur almost exclusively in males,[176] and the most common scenario is a rupture of the dominant elbow of a muscular male in his fifth decade of life.[139] Biceps ruptures typically involve a sudden contracture of the biceps against a significant load with the elbow in 90 degrees of flexion.[177]

Clinical findings vary depending on the extent of the rupture; whether it is partial or complete. The typical history includes a report of a sharp, tearing pain concurrent with an acute injury in the antecubital fossa.[139] The objective findings may include ecchymosis in the antecubital fossa, a palpable defect of the distal biceps, loss of strength of elbow flexion and grip, but especially a loss of forearm supination strength.[178]

In active individuals, the normal recommendation is primary repair of the acute tendon avulsion as if not repaired, a 30% loss of elbow flexion and a 40% loss of supination strength can be expected.[178] Postoperatively, the elbow is protected for 6–8 weeks, after which unrestricted range of motion and gentle strengthening exercises are initiated. Return to unrestricted activity is usually not allowed until nearly 6 months of healing has passed.[139]

Triceps Tendinosis

Triceps tendinosis results from repetitive extension, which can occur in such activities as competitive weightlifting, boxing, gymnastics, throwing, and racquet sports.

Subjectively, the patient reports localized tenderness of the triceps insertion at the olecranon that is aggravated with resisted elbow extension.

X-rays are indicated to rule out olecranon apophysitis in adolescence and an avulsion fracture in adults.

The initial stages of the intervention emphasize the principles of PRICEMEM. Therapeutic exercises emphasize strength of the elbow extensor mechanism, with a focus on closed chain exercises for the involved upper extremity.[174] In addition, shoulder strengthening and scapular stabilization exercises are introduced.

Triceps Tendon Rupture

These ruptures usually occur when a deceleration force occurs during elbow extension or with an uncoordinated contraction of the triceps muscle against the flexing elbow.[179] As with the biceps tendon rupture, the physical findings depend on whether the avulsion is partial or complete, but the most common findings include a loss of elbow extension strength, and an inability to extend overhead against gravity. A tendon defect may be present if the tear is complete.[139]

Primary repair is the treatment of choice in acute complete ruptures. Partial injury may be treated conservatively with immobilization for about 3 weeks, followed by a gradual progression of range of motion and strengthening.

Brachialis Strain

A brachialis strain is relatively rare, but the brachialis is prone to myositis ossificans, a pathologic bone formation, due to the fact that it is likely to hemorrhage when injured (see later).

Typically, the patient reports pain that is felt on the anterior aspect of the distal part of the arm, and there is palpable tenderness in the muscle belly of the brachialis. Resisted supination is not painful, although resisted elbow flexion combined with forearm pronation is.

The conservative intervention involves electrotherapeutic and thermal modalities, transverse friction massage, trigger point assessment, correction of muscle imbalances, and specific elbow joint mobilizations.

Epicondylitis

The term epicondylitis suggests an inflammation at one of the epicondyles. Epicondylitis are common in persons who frequently overuse the upper arm, particularly with activities that involve rotation of the arm with flexion and extension. Two types of epicondylitis are commonly described: lateral epicondylitis (tennis elbow) and medial epicondylitis (golfer's elbow). Lateral epicondylitis is four to seven times more common than medial epicondylitis.[180]

Lateral Epicondylitis (Tennis Elbow)

Lateral epicondylitis represents a pathologic condition of the common extensor muscles at their origin on the lateral humeral epicondyle. Specifically, the condition involves the tendons of the muscles that control wrist extension and radial deviation resulting in pain on the lateral side of the elbow with contraction of these muscles.[138]

The first description of tennis elbow is attributed to Runge,[181] but the name derives from lawn tennis arm described by Morris in the *Lancet* in 1882.[182] This was followed in 1883 by Dr H.P. Major describing his own affliction in 1883.[183] In Runge's original description, he called it writer's cramp (Schreibekrampf) and attributed it to a periostitis of the lateral humeral epicondyle.[181] Since then, it has been referred to by a number of names including epicondylalgia, epicondyle pain, musician's palsy (Musikerlähmung), [184] and tennis pain (Tennisschmerz), although most authors have used the terms epicondylitis or tennis elbow.

Tennis elbow affects between 1 and 3% of the population, occurs most commonly between 35 and 50 years of age with a mean age of 45,[185] is seldom seen in those under 20 years of age, and usually affects the dominant arm.[186–188] Cyriax[189] noted that the origin of the ECRB was the primary site of this injury, and pathologic changes have been consistently documented at this location,[190–193] although findings are also found in the ECRL, and the ECU.[131] One-third of patients also have involvement of the origin of the EDC.[189,192,193]

The proposed presence of macro- or microtears in the ECRB tendon was based on findings extrapolated from abnormal physical and intraoperative examinations showing gross alterations in the ECRB tendon.[189–191,194]

However, a recent study involving gross and microscopic dissections found that it was not possible to separate the origin of the ECRB from that of the common extensor tendon and that at times the two tendons appeared to interdigitate, indicating that any pathology believed to be isolated to the ECRB must be common to both.[195]

Over 25 conditions have been suggested as causes of tennis elbow,[189] including periostitis,[181,186,189,196] infection,[197,198] bursitis,[186,189,199–203] fibrillation of the radial head,[204] radioulnar joint disease,[205] AL lesion,[183,206,207] nipped synovial fringe,[208–213] calcific tendinitis,[214] neurogenic causes,[215,216] osteochondritis dissecans, and radial nerve entrapment.[70,72,215,217–219]

Capsular and ligamentous lesions have been mentioned by a number of authors. Landelius[220] regarded the pull of the radial head on the orbicular ligament and the capsule to be the cause. Bosworth[207,221,222] considered the impingement of the orbicular ligament on the head of the radius to be the sole problem.

Dysfunction of the cervical spine has also been speculated to cause tennis elbow. Theoretically, a frank radiculopathy may weaken the extensor muscles to the point at which normal use is traumatic and induces a grade I tear in the muscle belly or tendon. Less definite compression of the nerve root may compromise axoplasmic transportation, producing a trophic malnutrition of the muscle, resulting in damage. A facilitated segment at C5–6, with its resulting hypertonicity, might lead to a chronic overuse syndrome, or poor coordination. Wright and colleagues[223] found that neuronal changes within the spinal cord may be more important than peripheral nociceptor sensitization in the development of such disorders as tennis elbow. Gunn and Milbrandt[224] discussed a reflex localization of pain from radiculopathy at the cervical spine in patients with an intervention-resistant tennis elbow who had hypomobility of the lower cervical motion segments.[225] Maitland[226] has also reported improving the symptoms of lateral epicondylitis with a program of heat, mobilization, and traction of the cervical segments.[225]

The shoulder has also been speculated to be a cause of tennis elbow, due to the effect of an abnormal tension in the clavipectoral fascia on the brachial plexus. This fascia is attached to the clavicle around the subclavius muscle. From there it passes down to the upper border of the pectoralis minor and extends from the anterior intercostal membrane to the coracoid process. The fascia encloses the pectoralis minor and becomes the suspensory ligament of the axilla. It is speculated that if the fascia is distorted due to clavicular malposition, the traction exerted on the brachial plexus could lead to similar problems as those encountered with a cervical lesion. In these cases, altering the position of the shoulder girdle (protracting, retracting, elevating, and depressing it) would alter the symptoms produced during the isometric tests.

Whatever the cause, tennis elbow usually results from overuse although it can be traumatic in origin. The overuse injuries tend to involve abusive tissue trauma secondary to repetitive activity, which promotes microtraumatic tissue failure. Those tendons that wrap around a convex surface or the apex of a concavity, and those that cross two joints, are particularly vulnerable to overuse injuries, as are those with areas of scant vascular supply, or those subjected to repetitive tension.[227–232] One possible etiology for overuse at the elbow is the fact that the hand does not have a supportive function but functions predominantly to grasp some object. Repetitive grasping, with the wrist positioned in extension, places the elbow particularly at risk. Participants of tennis, baseball, javelin, golf, squash, racquetball, swimming, and weight lifting are all predisposed to this risk.[139]

While the terms *epicondylitis* and *tendinitis* are commonly used to describe tennis elbow, histopathologic studies have demonstrated that this condition is often not an inflammatory condition; rather, it is a degenerative condition, a tendinosis.[180,192]

Nirschl previously categorized the stages of repetitive microtrauma[233]:

- A stage 1 injury is probably inflammatory, is not associated with pathologic alterations, and is likely to resolve.
- A stage 2 injury is associated with pathologic alterations such as tendinosis or angiofibroblastic degeneration. It is this stage that is most commonly associated with sports-related tendon injuries such as tennis elbow, and with overuse injuries in general. Within the tendon, there is a fibroblastic and vascular response (tendinosis) rather than an immune blood-cell response (inflammation).
- A stage 3 injury is associated with pathologic changes (tendinosis) and complete structural failure (rupture).
- A stage 4 injury exhibits the features of a stage 2 or 3 injury and is associated with other changes such as fibrosis, soft

matrix calcification, and hard osseous calcification. The changes that are associated with a stage 4 injury may also be related to the use of cortisone.

Nirschl[234] postulates that some patients who have tennis elbow may have a genetic predisposition that makes them more susceptible to tendinosis at multiple sites. He terms this condition *mesenchymal syndrome* on the basis of the stem-cell line of fibroblasts and the presence of a potentially systemic abnormality of cross-linkage in the collagen produced by the fibroblasts. Patients may have mesenchymal syndrome if they have two or more of the following conditions[229,234]:

- Bilateral lateral tennis elbow
- Cubital tunnel syndrome
- CTS
- De Quervain tenosynovitis
- Trigger finger
- Rotator cuff tendinosis

Clinical Presentation. Three types of tennis elbow are recognized based on the mode of onset:

- The acute onset (indirect) type of tennis elbow is associated with a recognizable mechanism with acute pain, associated bruising on occasion,[235] and a feeling of something giving way within the elbow.[189]
- Rupture of the ECRL with tenderness in the muscles[236,237] is associated with direct trauma to the lateral side of the elbow, but with no tearing of the ligaments.[186,238]
- The chronic type is associated with a gradual onset and is occasionally termed occupational neuralgia (Beschaftigungensneuralgie).[239]

The pain of tennis elbow is often related to activities that involve wrist extension/grasp, as it is the wrist extensors that must contract during grasping activities to stabilize the wrist. Diffuse achiness and morning stiffness are also common complaints.[138] Occasionally the pain is experienced at night and the patient may report dropping objects frequently, especially if they are carried with the palm facing down.

Palpable tenderness is usually found over the ECRB and ECRL, especially at the lateral epicondyle, with the site of maximum tenderness most commonly being over the anterior aspect of the lateral epicondyle.[138] The next most common site is tenderness over the radial head, or where the lateral part of the common extensor tendon arises from the bone.[189] Tenderness can be found in other sites as well, in addition to swelling, but not consistently.[189] Differentiation between the various tendons is obviously important. Five types of tendon lesions of the elbow are recognized:

- a lesion of the muscle origin of the ECRL, which is usually located just proximal to the lateral epicondyle (type 1);
- An insertion tendinopathy of the ECRB (type 2). This is the most common site and is usually associated with type 5. As the ECRB also originates from the radial collateral ligament, involvement of the tendon can produce pain here, or at the radial head (type 3).
- an ECRB muscle belly strain (type 4);
- inflammation at the origin of the extensor digitorum (type 5).

The range-of-motion tests typically reveal the following:

- active motions are usually painless, although there may be pain with wrist flexion when combined with elbow extension.
- passive motion can produce pain, especially with passive wrist flexion with the forearm pronated and the elbow extended.

The resisted tests typically reproduce symptoms with resisted wrist extension and radial deviation with the elbow extended. Pain on resisted finger extension has also been reported. Cozen's or Mills' special tests are typically positive.

The cervical spine, shoulder, and wrist must also be examined. As a large number of tennis elbows appear to be secondary to a dysfunction of either the cervical spine or the shoulder, testing isometric wrist extension in varying positions of the cervical spine or shoulder will help differentiate the cause. If the primary cause is remote, the amount of discomfort on testing will vary with changes of the head or shoulder girdle position. If the pain disappears entirely during these maneuvers, there can be no symptomatic pathologic changes at the elbow, and no local treatment is required. However, usually the pain is reduced rather than being eliminated, indicating that the cause may be remote and local pathologic changes have since supervened.

Tennis elbow is normally a self-limiting complaint; without intervention, the symptoms will usually resolve within 8–12 months.

Intervention. There are numerous interventions cited for this condition, both medical and surgical.[240] In fact, more than 40 treatments have been suggested, indicating that the ideal remedy has yet to be found, although there is agreement that the initial management should be conservative. Many studies of the use of physical therapy in the management of tennis elbow are poorly designed and statistically weak.[241,242] The effectiveness of ultrasound for tennis elbow is undetermined. One study[243] found ultrasound to be effective in a placebo-controlled, double-blind trial,[244] but another study[245] found no difference. A recent randomized pilot study by Struijs et al.[246] of 31 patients diagnosed with tennis elbow found that the manipulation of wrist was more effective at a follow-up of 3–6 weeks than ultrasound, friction massage, and muscle stretching and strengthening exercises. The wrist manipulation used was an anterior (ventral) manipulation of the scaphoid (refer to Chap. 18), which was repeated 15 times, two times a week, with a maximum of nine intervention sessions. In a randomized study of 18 subjects,[247] joint mobilization to the radial head combined with neurodynamic techniques to the radial nerve was compared with a program consisting of ultrasound, transverse friction massage, and strengthening and stretching exercises. At 3-month follow-up, only the group receiving joint mobilizations and neurodynamic interventions had improved.

More recently, there has been a trend toward treatment of the cervical and thoracic spines with this disorder. Vicenzino and colleagues[248] demonstrated that cervical lateral glides resulted in immediate improvement in pain at the lateral

elbow, in pain-free grip strength, and in increased range of motion during upper limb neurodynamic testing in patients with lateral epicondylalgia. A retrospective study by Cleland and colleagues[249] demonstrated that patients receiving manual therapy techniques directed at the cervical spine achieved similar success rates as a group who received treatment solely directed at the elbow, but that they achieved this success in significantly fewer visits ($p = 0.01$). Another clinical trial by Cleland et al.[250] which compared the outcomes of 10 patients with lateral epicondylalgia who were randomly assigned to receive localized treatment or localized treatment plus manual therapy to the cervicothoracic spine, found that the latter group demonstrated greater improvement in all outcome measures as compared to the treatment group receiving the localized management. Replication of these results is needed in a large-scale randomized clinical trial with a control group and a longer-term follow-up before any meaningful conclusions can be drawn.

In a randomized trial by Bisset and colleagues[251] investigated the efficacy of physical therapy for tennis elbow (combining mobilizations with movement (MWM) techniques and exercise) compared with a wait-and-see approach or corticosteroid injections over a 52-week period concluded that the physical therapy intervention had a superior benefit to wait and see in the first 6 weeks and to cortisone injections after 6 weeks.

Other forms of physical therapy including electrotherapy and thermotherapy have not been proven to be effective.[243]

The patient may be prescribed an orthotic device as a treatment strategy, and many different types of braces and other orthotic devices are available. The main type is a band or strap around the muscle belly of the wrist extensors. Theoretically, binding the muscle with a clasp, band, or brace should limit expansion and thereby decrease the contribution to force production by muscle fibers proximal to the band.[252] However, the benefits of tennis-elbow braces remain unproven. Snyder-Mackler and Epler reported on a comparison of a "standard" tennis-elbow brace and one with an air-filled bladder,[253] but it is not possible to extrapolate from their findings to the efficacy of tennis-elbow braces in the management of tennis elbow. Counterforce bracing[194] (such as the Count-R-Force brace from Medical Sports, Arlington, VA) has been shown to

- beneficially impact force couple imbalances and altered movements[127,254,255];
- decrease angular acceleration at the elbow[256];
- decrease EMG activity.[256]

However, tennis-elbow braces have been shown to have little effect in vibrational dampening.[257] As an alternative to bracing, Gellman[258] recommends a protective 20-degree wrist extension splint for tennis elbow to help offload the ECRB.[138] In a study by Struijs and colleagues[252] a total of 180 patients were randomized into three groups: brace-only treatment, physical therapy, and a combination of these. Main outcome measures were success rate, severity of complaints, pain, disability, and satisfaction. Physical therapy was superior to brace only at 6 weeks for pain, disability, and satisfaction. Contrarily, brace-only treatment was superior on ability of daily activities. Combination treatment was superior to brace on severity of complaints, disability, and satisfaction. At 26 and 52 weeks, no significant differences were identified.[252] The results from the study would tend to indicate that the brace treatment might be useful as an initial therapy.

The Mills' manipulation (see Intervention section), a thrust technique that is intended to maximally stretch the ECRB tendon in order to try to pull apart the two surfaces of the painful scar, has been recommended to treat true tennis elbow.[189] Manipulation of this kind has also been advocated in other studies.[259–261]

Nirschl and Sobel[119] have attempted to determine whether the presenting symptoms are helpful in both diagnosing and directing the intervention. This information was previously published in the form of a table.[119]

- ***Types 1 and 2.*** Benign (nonharmful) pain: Type 1 pain is characterized by stiffness or mild soreness after activity and resolves within 24 hours. Type 2 pain is marked by stiffness or mild soreness after exercise, lasts more than 48 hours, is relieved with warm-up exercises, is not present during activity, and resolves within 72 hours after the cessation of activity. The pain associated with types 1 and 2 may be due to peritendinous inflammation.
- ***Type 3.*** Semibenign (likely nonharmful) pain: Type 3 pain is characterized by stiffness or mild soreness before activity and is partially relieved with warm-up exercises. The pain does not prevent participation in activity and is only mild during activity. However, minor adjustments in the technique, intensity, and duration of activity are needed to control the pain. Type 3 pain may necessitate the use of nonsteroidal anti-inflammatory medications.
- ***Type 4.*** Semiharmful pain: Type 4 pain is more intense than type 3 pain and produces changes in the performance of a specific sport- or work-related activity. Mild pain accompanies the activities of daily living. Type 4 pain may reflect tendon damage.
- ***Types 5–7.*** Harmful pain: Type 5 pain, which is characterized as moderate or severe before, during, and after exercise, greatly alters or prevents performance of the activity. Pain accompanies but does not prevent the performance of activities of daily living. Complete rest controls the pain. Type 5 pain reflects permanent tendon damage. Type 6 pain, which is similar to type 5 pain, prevents the performance of activities of daily living and persists despite complete rest. Type 7 pain is a consistent, aching pain that intensifies with activity and that regularly interrupts sleep.

The pain of types 1 and 2 is usually self-limiting when proper precautions are taken. Types 3 and 4 usually respond to nonoperative medical therapy. The pain types of 5–7 are more likely to necessitate operative treatment.[119]

Johnson[262] recommends an exercise regimen consisting of PREs to the wrist extensors, with the elbow flexed to 90 degrees and also with the elbow straight is recommended. The exercises are performed as a 10-repetition maximum, morning and night. Gradually, the weight is increased so that the 10-repetition maximum is always maintained. The pain may increase for the first week or two or three, but by the fifth

or sixth weeks, the elbow pain will be better. An ice pack or heating pad can be used during the painful period.[262]

The goals during the acute phase are to decrease inflammation/pain, promote tissue healing, increase flexibility, and retard muscle atrophy. Methods to accomplish this include[88]:

- cryotherapy;
- whirlpool;
- HVGS;
- phonophoresis;
- iontophoresis (with an anti-inflammatory such as dexamethasone);
- stretches for
  - wrist extension–flexion;
  - elbow extension–flexion;
  - forearm supination–pronation;
- avoidance of painful movements (such as gripping).

During the subacute phase, the goals should be to[88]

- improve flexibility;
- increase muscular strength and endurance;
- increase functional activities and return to function;
- emphasize concentric–eccentric strengthening with a focus on:
  - wrist extension–flexion;
  - forearm pronation–supination;
  - elbow flexion—extension;
- initiate shoulder strengthening (if deficiencies are noted);
- continue flexibility exercises;
- use counterforce brace;
- continue use of cryotherapy after exercise or function;
- initiate gradual return to stressful activities;
- gradually reinitiate previously painful movements.

During the chronic phase, the goal should be to:[88]

- improve muscular strength and endurance;
- maintain/enhance flexibility;
- gradually return to high-level sport activities;
- continue strengthening exercises (emphasize eccentric–concentric);
- continue to emphasize deficiencies in shoulder and elbow strength;
- continue flexibility exercises;
- gradually diminish use of the counterforce brace;
- continue to use cryotherapy as needed;
- initiate gradual return to sport activity;
- equipment modifications (grip size, string tension, and playing surface); and
- emphasize maintenance.

Incorrect technique, particularly with racquet sports, is the cause of many elbow problems. Emphasis should be placed on recruiting the whole of the shoulder and trunk when hitting the ball, so as to dissipate the forces as widely as possible. It is important to hit strokes with a firm wrist and not by means of wrist movements to return the ball. A late backhand in tennis should be corrected as this stroke is the most common cause of stress to the elbow if performed incorrectly.[130,180,233] Whereas the forehand demonstrates good weight transfer, the faulty backhand has no forward weight transfer, and the front shoulder is usually elevated.[173] The trunk leans away from the net at the time of impact, and the racquet head is down.[173] The elbow and wrist extend before impact, and the power source is forearm extension in the pronated position, resulting in a stroke that is nonrhythmic and jerky and with sharp pronation at follow-through.[173] Sometimes the use of a two-handed backhand may be helpful. One theory to support this is that the one-handed backhand links five body parts prior to impact (hips to trunk to shoulder to elbow to wrist), while the two-handed backhand only links two body parts (hips to trunk) prior to impact with the ball.[138]

The ball should be hit with the center point of the strings, or "sweet spot." When the ball is hit incorrectly, the forces are transmitted as an acute strain up and along the muscle mass to the extensor origin at the elbow.[233]

In addition to correcting poor technique, patient education should address racquet size, grip size, and string tension. A fiberglass, graphite, or wood racquet is more forgiving than a metal one. Tennis racquets with larger head sizes reduce arm vibration.[263] Tennis racquets should be strung with gut, as it is more resilient than nylon strings, to 52–55 pounds to allow the impact to be spread over slightly more time and decrease the forces transmitted to the forearm muscles.[264,265] Currently, the use of a mid-sized medium-flex, graphite tennis racquet with loosely strung nylon monofilament is recommended. The grip size should not be too large or too small,[266] and an increased racquet handle diameter is helpful for players with relatively weak wrist extensors.

If the symptoms are not controlled with the above measures, local injection of corticosteroid may be helpful. It was not until the 1950s that the injection of corticosteroids was first reported.[213,267,268] Freeland and Gribble found that hydrocortisone was neither more nor less effective than procaine and concluded that the short-term relief of pain was a nonspecific response that may be due to the volume of fluid injected or to the trauma of introducing the needle.[267] Subsequently a number of studies have shown steroids to be beneficial, and this has remained one of the mainstays of conservative treatment.[269–271]

Operative Intervention. Surgery is indicated if the symptoms do not resolve despite a properly performed conservative intervention lasting 6 months.[139] A simple handshake test can help to determine whether surgical intervention is required.[272] The patient is asked to perform a firm handshake with the elbow extended, and then supinate the forearm against resistance. The clinician notes whether the patient reports having pain at the origin of the extensors of the wrist. The elbow is then flexed to 90 degrees, and the same maneuver is performed. If pain is decreased in the flexed position, operative treatment is less likely to be needed. If the pain is equally severe with the elbow flexed and extended, then operative intervention is more likely to be needed.[272]

The goals of operative treatment of tendinosis of the elbow are to resect the pathologic material to stimulate neovascularization by producing focused local bleeding, and to create a healthy scar while doing the least possible structural damage to the surrounding tissues. Postoperatively, a carefully guided resistance-based rehabilitation program is recommended.

Medial Epicondylitis (Golfer's Elbow)

Medial epicondylitis is only one-third as common as lateral epicondylitis.[100] It primarily involves a tendinopathy of the common flexor origin, specifically the FCR and the humeral head of the pronator teres.[48,100,185] To a lesser extent, the palmaris longus, FCU, and FDS may also be involved.[233]

The mechanism for medial epicondylitis is not usually related to direct trauma, but rather to overuse. This commonly occurs for three reasons:

- Fatigue of the flexor–pronator tissues in response to repeated stress.
- A predisposition for medial ligamentous injury due to a sudden change in the levels of stress.[273]
- The MCL fails to sufficiently stabilize against the valgus forces.[274]

Medial epicondylitis usually begins as a microtear at the interface between the pronator teres and FCR origins with subsequent development of fibrotic and inflammatory granulation tissue.[30] An inflammation develops in an attempt to speed up tissue production to compensate for the increased rate of microdamage caused by increased use and decreased recovery time.[275] Chronic symptoms result from a loss of extensibility of the tissues, leaving the tendon unable to cope effectively against tensile loads.

Clinical Presentation. The typical clinical presentation for medial epicondylitis is pain and tenderness over the flexor–pronator origin, slightly distal and anterior to the medial epicondyle. The symptoms are typically reported to be exacerbated with either resisted wrist flexion and pronation or passive wrist extension and supination.[30,100]

Differential diagnosis for medial elbow symptoms includes[276]:

- MCL injury or insufficiency[22,277,278];
- ulnar nerve entrapment;
- medial elbow intra-articular pathology.[279]

Intervention. Conservative intervention for medial epicondylitis has been shown to have success rates as high as 90%.[100] The conservative intervention for this condition initially involves rest, activity modification, and local modalities. Complete immobilization is usually not recommended as it eliminates the stresses necessary for maturation of new collagen tissue. Once the acute phase has passed, the focus switches to restoring range of motion and correcting any imbalances of flexibility and strength. The strengthening program initially includes multi-angle isometrics, and then concentric and eccentric exercises of the flexor–pronator muscles.

Splinting or the use of a counterforce brace may be a useful adjunct.[30]

INTEGRATION OF PRACTICE PATTERNS 4F AND 5F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION, OR REFLEX INTEGRITY SECONDARY TO SPINAL DISORDERS, PERIPHERAL NERVE ENTRAPMENTS, COMPARTMENT SYNDROME, AND MYOFASCIAL PAIN DYSFUNCTION

Compressive Neuropathies

In the region of the elbow, there are a multitude of sites where the peripheral nerves can be entrapped or compressed (Table 17-9), with involvement of the ulnar and median and radial

TABLE 17-9 Nerve Injuries about the Elbow

Nerve	Motor Loss	Sensory Loss	Functional Loss
Median nerve (C6–8, T1)	Pronator teres Flexor carpi radialis Palmaris longus Palmaris longus Flexor digitorum superficialis Flexor pollicis longus Lateral half of flexor digitorum profundus Pronator quadratus Thenar eminence Lateral two lumbricals	Palmar aspect of hand with thumb, index, middle, and lateral half of ring finger Posterior (dorsal) aspect of distal third of index, middle, and lateral half of ring finger	Pronation weakness Wrist flexion and abduction weakness Loss of radial deviation at wrist Inability to oppose or flex thumb Thumb abduction weakness Weak grip Weak or no pinch (ape hand deformity)

(Continued)

TABLE 17-9 Nerve Injuries about the Elbow *(Continued)*

Nerve	Motor Loss	Sensory Loss	Functional Loss
Anterior interosseous nerve (branch of median nerve)	Flexor pollicis longus Lateral half of flexor digitorum profundus Pronator quadratus Thenar eminence muscles Lateral two lumbricals	None	Pronation weakness, especially at 90-degree elbow flexion Weakness of opposition and thumb flexion Weak finger flexion Weak pinch (no tip to tip)
Ulnar nerve (C7–8, T1)	Flexor carpi ulnaris Medial half of flexor digitorum profundus Palmaris brevis Hypothenar eminence Adductor pollicis Medial two lumbricals All interossei	Posterior (dorsal) and palmar aspect of little and medial half of ring finger	Weak wrist flexion Loss of ulnar deviation at wrist Loss of distal flexion of little finger Loss of abduction and adduction of fingers Inability to extend second and third phalanges of little and ring fingers (benediction hand deformity) Loss of thumb adduction
Radial nerve (C5–8, T1)	Anconeus Brachioradialis Extensor carpi radialis longus and brevis Extensor digitorum Extensor pollicis longus and brevis Abductor pollicis longus Extensor carpi ulnaris Extensor indicis Extensor digiti minimi	Posterior aspect of hand (lateral two-thirds) Posterior aspect and lateral aspect of thumb Proximal two-thirds of posterior aspect of index, middle, and half of ring finger	Loss of supination Loss of wrist extension (wrist drop) Inability to grasp Inability to stabilize wrist Loss of finger extension Inability to abduct thumbs
Posterior interosseous nerve (branch of radial nerve)	Extensor carpi radialis and brevis Extensor digitorum Extensor pollicis longus and brevis Abductor pollicis longus Extensor carpi ulnaris Extensor indicis Extensor digiti minimi	None	Weak wrist extension Weak finger extension Difficulty stabilizing wrist Difficulty with grasping Inability to abduct thumb

Data from Magee DJ: *Orthopaedic Physical Assessment*, 2nd ed. Philadelphia, PA. WB Saunders, 2008.

nerves and their branches being by far the most common.[67] Table 17-10 outlines a summary of conservative management strategies for the various nerve entrapments.

Ulnar Nerve Entrapment (Cubital Tunnel Syndrome)

Although the ulnar nerve is well protected above the elbow, the nerve can be compressed or entrapped at a number of locations. Nirschl has divided the medial epicondylar groove into three zones[280,281]:

- zone I: proximal to the medial epicondyle;
- zone II: the level of the medial epicondyle (retrocondylar groove);
- zone III: distal to the medial epicondyle (cubital tunnel).

Repetitive overuse can result in compression of the ulnar nerve in zone III by a tight FCU muscle.[174] Entrapment can also be precipitated in zones II and III by a subluxating ulnar nerve, in zone II by elbow synovitis, in zone I or II by a cubitus valgus deformity, or in zone I by the medial intermuscular septum, which slopes from a thick wide base at the medial epicondyle, to a weak and thin edge more proximal on the humeral shaft.[59,65,174]

It has been suggested that because of the superficial location of the ulnar nerve, repetitive motion may initiate a cycle of inflammation and edema that inhibits the normal gliding of the nerve.[54,282] Additional injury occurs when traction forces caused by elbow flexion produce an additional compressive force on the internal architecture of the nerve.[57,283] The severity of nerve injury will be dependent on the magnitude, duration, and character of the applied forces.[54,282]

TABLE 17-10 Summary of Conservative Management for Nerve Entrapments

Nerve	Entrapment Site	Intervention
Median	Carpal tunnel Proximal forearm	Splint wrist in neutral position at night Stretching exercises for pronator teres Rest periods in supination
Ulnar	Guyon's canal Cubital tunnel	Splint wrist in neutral position at night Elbow pad Education: positioning in elbow extension and decreasing direct pressure on nerve Stretch the flexor carpi ulnaris
Radial (posterior interosseous) Radial (sensory)	Arcade of Fröhse Forearm	Positioning in supination and avoid repetitive pronation and supination activities Positioning in supination and avoid repetitive pronation and supination activities
Brachial plexus	Supraclavicular	Avoid provocative positions Stretch shortened muscles and strengthen weakened scapular muscles

The anconeus has also been reported as a cause of cubital tunnel syndrome and has been found to occur in 3–28% of human anatomic specimen elbows,[56,284] and in as many as 9% of patients undergoing surgical treatment for cubital tunnel syndrome.[285]

The clinical findings for an ulnar nerve entrapment depend on the location of the lesion and may include[286]:

- activity-related pain or paresthesias involving the fourth and fifth digits, accompanied by pain that may extend proximally or distally in the medial aspect of the elbow;
- pain or paresthesias worse at night;
- decreased sensation in the ulnar distribution of the hand;
- progressive inability to separate the fingers;
- loss of grip power and dexterity;
- atrophy or weakness of the ulnar intrinsic muscles of the hand (late sign);
- clawing contracture of the ring and little fingers (late sign)[287];
- positive elbow flexion and pressure-provocative test;
- positive Wartenberg's sign and Froment's sign (see Chap. 18);
- positive Tinel's sign at the elbow.

Conservative intervention is recommended for patients with intermittent symptoms and without changes in two-point discrimination or muscle atrophy. Activity modification with protection over the cubital tunnel with an elbow pad placed on the medial-posterior aspect,[286] limiting repetitive extreme elbow flexion, and night splinting at 40–60 degrees may be helpful.[57] In severe cases, the splint is worn during the day, or the elbow is cast at about 45 degrees. Exercises must not reproduce the distal nerve symptoms and may, therefore, initially need to be performed in limited arcs of motion.[174] For those patients who fail to respond to conservative management after 3–4 months, and who have muscle atrophy, persistent sensory changes, or persistent symptoms, surgical decompression, or an anterior transposition of the ulnar nerve is available.[65]

Median Nerve Entrapment (Humeral Supracondylar Process Syndrome)

Median nerve entrapment at the elbow is relatively rare, although it is often misdiagnosed as CTS.[97] The most proximal site at which the median nerve can be compressed is in the distal arm by the ligament of Struthers, an anatomic variant present in 0.7–2.7% of the population.[288] Very few cases of a ligament of Struthers neuropathy are described in the literature.[66,289,290] The patient may complain of pain in the wrist or medial forearm, which is exacerbated with full elbow extension or pronation of the forearm.[66,290] The patient may also report paresthesias in the index or long finger.[66]

In the antecubital area, there are three sites of potential median nerve entrapment.[97] One site is as the nerve passes under the lacertus fibrosus, or bicipital aponeurosis, a fascial band extending from the biceps tendon to the forearm fascia.[291] The second site is at the level of the pronator teres muscle, after the nerve crosses the elbow. The third potential site is as the median nerve travels under the FDS. Compression of the median nerve at any one of these three sites constitutes what is described in the literature as the pronator syndrome (PS).

Pronator Syndrome. The patient typically complains of an insidious onset of pain that is usually felt on the anterior aspect of the elbow, radial side of the palm, and the palmar side of the first, second, third, and half of the fourth digits. There is often associated "heaviness" of the forearm.[97] Unlike CTS, there is no Tinel's sign at the wrist, and there are no nocturnal symptoms.[292,293] Pain can be reproduced with[63]:

- pressure applied over the pronator teres 4 cm distal to the cubital crease with concurrent resistance against pronation, elbow flexion, and wrist flexion[294];
- resisted supination (due to compression of the lacertus fibrosus);

- resistance of the long finger flexors (due to compression by the FDS arch).

Diagnosis is confirmed electromyographically. PS typically responds well to activity modification (removing the causative activity), rest, NSAIDs, ice, and the restoration of proper flexibility and strength of the wrist flexors and forearm pronators. Rehabilitation will most benefit those cases in which compression is related to medial elbow tendinosis. In these cases, gentle massage along the fibers may aid in the breaking of adhesions. Surgical relief may be needed in recalcitrant cases.[292]

Anterior Interosseous Syndrome. Anterior interosseous syndrome was first described by Tinel in 1918, and was further delineated by Kiloh and Nevin in 1952.[292]

Potential sources of entrapment of the AIN include the Gantzer's muscle (an accessory head of the FPL), and the FCR muscle.[97,291,295]

Compression of the AIN results in forearm pain, and motor loss of the FPL, pronator quadratus, and the lateral half of the FDP, such that the patient is unable to perform the "OK" sign with the index finger and thumb. This must be differentiated from a rupture of the muscle or its tendon. No sensory changes occur, even though the AIN carries sensory information from the distal radioulnar joint, radiocarpal joint, and intercarpal joints.[296]

Pain and weakness are typically provoked with resisted flexion of the interphalangeal (IP) joint of the thumb and with the distal interphalangeal (DIP) joint of the index finger.

The differential diagnosis includes neuralgic amyotrophy, FPL tendon rupture, and index finger FDP rupture. Most cases of AIN syndrome typically resolve spontaneously.[297]

Although PS and AIN syndrome are relatively rare, it is important to be able to differentially diagnose the syndromes in cases of suspected CTS. Paresthesia is absent in AIN and present in both PS and CTS.[298] CTS involves paresthesia in the lateral $3^1/_2$ digits, whereas PS involves paresthesia in the lateral $3^1/_2$ digits and often in the distribution of the palmar cutaneous branch of the median nerve.[298] The paresthesia in CTS may be reproduced by compression over the wrist or Phalen's test, whereas PS requires compression at the pronator teres to reproduce paresthesia. Tinel's sign is present at the wrist in 80% of cases of CTS and is present at the pronator teres in PS in less than 50% of cases.[298] AIN syndrome is easily differentiated from CTS by the lack of paresthesia complaints.[298]

Radial Nerve Entrapment

The radial nerve is the most commonly injured peripheral nerve (see Chap. 3) and, because of its spiral course across the back of the mid-shaft of the humerus, and its relatively fixed position in the distal arm as it penetrates the lateral intermuscular septum, it is the most frequently injured nerve associated with fractures of the humerus.

A number of radial nerve entrapments are recognized and are named according to the location at which they occur. Four radial nerve entrapments are commonly cited: high radial nerve palsy, posterior interosseous nerve syndrome (PINS), radial tunnel syndrome (RTS), and superficial radial nerve palsy. The various symptoms of these entrapments can aid the clinician to determine the level of entrapment.

CLINICAL PEARL

There is motor and sensory involvement with the high radial nerve palsy, motor involvement with the PINS, pain with the RTS, and sensory disturbances with the superficial radial nerve palsy.[299] Symptoms of pain, cramping, and tenderness in the proximal posterior (dorsal) forearm, without muscle weakness, are associated with RTS, whereas PINS involves the loss of motor function of some or all of the muscles innervated by the PIN and is thus characterized by weakness.[299]

High Radial Nerve Compression. A spontaneous nerve compression may occur in the mid-arm at the level of the lateral head of the triceps due to strenuous muscular exercise.[300] A mid-shaft humerus fracture can result in a radial neuropathy at the spiral groove of the humerus in 14% of humeral fractures.[301] Regardless of the cause, a high radial nerve palsy will result in a loss of wrist extension, an inability to extend the fingers and thumb, and a decrease in sensibility of the first posterior (dorsal) web space.[299] Involvement of the triceps muscle is dependent on the level of compression. A cervical radiculopathy and thoracic outlet syndrome must be considered in the differential diagnosis.

Posterior Interosseous Nerve Syndrome (PINS). There are five potential sites of compression of the PIN as it traverses through the radial tunnel[67,70,216,299]:

- the fibrous bands that connect the brachialis to the brachioradialis[72,302];
- the vascular leash of Henry, a fan of blood vessels that cross the nerve at the level of the radial neck[70,72,303];
- medial proximal portion (leading edge) of the ECRB[70,72];
- Between fibrous bands at the proximal and distal edge of the supinator.[304] The proximal border of the supinator, through which the radial nerve passes, is referred to as the arcade of Fröhse.

Symptoms of PIN entrapment include lateral elbow pain that radiates into the distal forearm and is aggravated by repetitive pronation and supination, most specifically resisted supination. Tenderness is noted 3–4 cm distal to the lateral epicondyles where the radial nerve crosses the radial head and penetrates the supinator muscle. PIN palsy produces an inability to extend the MCP joints of the thumb, index, long, ring, or small fingers either individually or in combination.[305,306] Additionally, there is a loss of thumb IP extension and radial abduction of the thumb.[299] Since the PIN can innervate the ECRB prior to the nerve's entrance into the radial tunnel, this muscle may not be involved in the PIN palsy. Thus, when compression within the radial tunnel is sufficient to cause paralysis but there is no palsy, the condition is termed PINS.[292]

Initial conservative intervention includes rest, activity modification, and the use of a cock-up splint. Regular gentle stretching of the wrist extensor muscles, with the elbow held in full extension is begun after a spontaneous recovery.[292]

Radial Tunnel Syndrome. RTS involves compression of the deep branch of the radial nerve. Michele and Krueger[307] have been credited with recognizing RTS as a distinct entity and

gave it the name radial PS. The term RTS was introduced by Roles and Maudsley,[72] who suggested that RTS was the cause of resistant tennis-elbow pain.

The same structures implicated in PIN compression syndrome can cause RTS, although RTS is often thought of as a dynamic compression syndrome.[218] This is because compression of the nerve occurs during elbow extension, forearm pronation, and wrist flexion, which causes the ECRB and the fibrous edge of the superficial part of the supinator to tighten around the nerve. The symptoms from this compression can mimic those of tennis elbow, namely tenderness over the lateral aspect of the elbow, pain on passive stretching of the extensor muscles, and pain on resisted extension of the wrist and fingers.[72,218] Men and women are equally affected, and the compression appears to be common in the fourth to sixth decades of life.[70]

Pain, which is poorly localized over the radial aspect of the proximal forearm, is the most common primary presenting symptom in RTS. In fact, it is the only nerve compression syndrome in which the signs and symptoms are not based on the nerve distribution.[308]

Upon palpation, maximal tenderness is usually elicited over the radial tunnel, some 5 cm distal to the lateral epicondyle, anterior to the radial neck. Resisted middle finger extension,[72] which tightens the fascial origin of the ECRB, and resisted supination of the forearm with the elbow fully extended[70] should reproduce the pain at the point of maximal tenderness. Positioning the arm in elbow extension, forearm pronation, and wrist flexion produces significant compression of the radial nerve.[292]

Conservative intervention should focus on education to avoid the provocative positioning of the arm into forceful extension and supination of the wrist and forearm and should include rest, stretching, and splinting.[72,309]

If a wrist immobilization splint is used, it is fitted in 45 degrees of extension for continual wear.

Surgical intervention is reserved for patients whose symptoms are not relieved by conservative intervention.

Radial Sensory Nerve Entrapment. The term *Wartenberg's syndrome*[310] or *cheiralgia paresthetica* is used to describe a mononeuritis of the superficial radial nerve, which can become entrapped where it pierces the fascia between the brachioradialis and ECRL tendons.[291,299] Symptoms include shooting or burning pain along the posterior-radial forearm, wrist, and thumb, associated with wrist flexion and ulnar deviation.[299] These symptoms can lead the clinician to believe that the first carpometacarpal joint and/or tendons of the anatomic snuffbox are involved and that de Quervain's disease is present.

Musculocutaneous Nerve Entrapment

The brachialis is a pure elbow flexor, whereas the biceps brachii is an elbow flexor and supinator of the forearm.[45,311] With complete loss of motor function of these two muscles due to a lesion of the musculocutaneous nerve, functional elbow flexion strength can still be obtained with contraction of the brachioradialis and pronator teres.[312] The ECRL, FCU, FCR, and palmaris longus may also assist with flexing the elbow.[313] The brachioradialis has a better mechanical advantage when the elbow is flexed to 90 degrees and is more active when the forearm is in the pronated or neutral position.[313] The pronator teres can produce full elbow flexion, but this is accompanied by forearm pronation.[312,314] Thus, with a complete musculocutaneous nerve palsy, full antigravity elbow flexion can still be obtained but is strongest with the elbow flexed at 90 degrees and the forearm pronated.

Acute Compartment Syndrome

See Chapter 5.

Myofascial Pain Dysfunction

Elbow pain, when not related to the joint or to microtearing of the common flexor or extensor tendons, is commonly referred into the elbow from a number of sources, including myofascial. Even if microtearing is present, trigger points can also be present in the relevant muscles, placing a chronic strain on that tendon.

Supinator

This muscle refers pain and tenderness primarily to the lateral epicondyle of the elbow, but also to the posterior (dorsal) web space between the thumb and index finger. According to Travell and Simons,[315] each of the common sites for tennis elbow can be accounted for by trigger points in the supinator, ECRL, and triceps muscles.

Supinator pain referral is activated by playing tennis with an extended elbow, which does not allow the biceps brachii to take part in the supination required to control the head of the tennis racquet.[316]

Triceps Brachii

A trigger point in the medial head of the triceps is a common cause of lateral elbow pain from the lateral side of this muscle or of medial elbow pain from the medial side of this muscle.[316]

INTEGRATION OF PRACTICE PATTERNS 4G AND 4I: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION, ASSOCIATED WITH FRACTURES AND BONY OR SOFT-TISSUE SURGICAL PROCEDURES

Radial Head Fractures

Radial head fractures and dislocations are traumatic injuries (except for the occurrence of congenital radial head dislocations), usually from a FOOSH with the force of impact transmitted up the hand through the wrist and forearm to the radial head, which is forced into the capitellum. Both of these conditions require adequate treatment to prevent disability from stiffness, deformity, posttraumatic arthritis, nerve damage, or other serious complications.[317] These fractures and dislocations may be isolated just to the radial head (and neck) and the lateral elbow (and proximal forearm), or they may be part of a combined complex fracture pattern, involving other structures

of the elbow, and even the distal humerus, or forearm and wrist. Blunt or penetrating trauma rarely causes radial head injury. The wrist, especially the distal radioulnar joint, may be damaged simultaneously, and the presence of wrist pain, grinding, or swelling should be determined. The presence of bleeding, even with small puncture wounds, should alert the clinician to the possibility of open injury. Neurovascular symptoms of numbness, tingling, or loss of sensation should be identified to rule out nerve or vascular injury. The presence of severe pain should alert the clinician to the possibility of compartment syndrome.

Patients with radial head fractures and dislocations present with localized swelling, tenderness, and decreased motion. The clinician should palpate the elbow, especially the radial head, feeling for deformity, and the wrist should be examined, especially feeling for stability of the distal radioulnar joint. All three major nerves of the forearm are at risk with elbow fractures and dislocations, so the clinician should also carefully assess neurovascular function for all of the nerves of the forearm and hand.

Radial head fractures present several challenges, as the radial head is a secondary stabilizer for valgus forces at the elbow as well as a restraint against longitudinal forces along the forearm.[318] Compromise of the MCL makes the radial head a more important stabilizer of the elbow.[5,318,319] A successful outcome correlates directly with the accuracy of anatomic reduction, restoration of mechanical stability that allows early motion, and consideration of the soft tissues. Surgical options for radial head fractures or dislocations include closed reduction with casting or early motion or open reduction with internal fixation (ORIF), replacement, or resection. Open management (including internal fixation, replacement, or excision depending on the fracture) is associated with better long-term function.

In the Mason classification, the fracture is type I if it is undisplaced and is generally treated nonoperatively with a splint or a sling for 3 days, and active elbow flexion exercises being initiated immediately. The fracture is type II if a single fragment is displaced, but may still be treated nonoperatively if the displacement is minimal. A type III fracture is comminuted and usually requires operative intervention but may occasionally be treated closed with early motion if the radial head is not reconstructible.

Following immobilization, as much early mobilization as the patient can tolerate is the key to a favorable outcome. Strengthening, initially involving isometric exercises, begins at 3 weeks and progresses to concentric exercises at 5–6 weeks. Heavy resistance is not performed until after 8 weeks, or when adequate healing is demonstrated on radiographs. What follows is a postfracture or postsurgical protocol for type I fracture, or a type II or III fracture that has been stabilized with ORIF.[82,88]

Acute Phase

During the acute phase, the goals are to decrease pain and inflammation, regain full wrist and elbow range of motion, and to retard muscular atrophy. Active-assisted and active range-of-motion exercises are initiated at the elbow with the goal to regain a minimum of 15–105 degrees after two weeks. Gripping exercises using putty can be initiated in addition to isometric strengthening exercises of the elbow and wrist. Finally, concentric strengthening exercises for the wrist can be initiated.

Subacute Phase

The goals during this phase are to maintain full elbow range of motion, progress to elbow strengthening, and to gradually increase functional demands. Shoulder strengthening exercises are initiated and progressed that focus on the rotator cuff, while the range-of-motion exercises for the elbow are continued. Active-assisted range of motion and passive range of motion exercises are initiated into supination–pronation to tolerance.

Chronic Phase

The goals during this phase are to maintain full elbow range of motion, increase strength, power, and endurance, and to gradually initiate sporting activities as appropriate. Eccentric elbow flexion–extension and plyometric exercises are initiated and continued until about 12 weeks.

Fractures with radial head surface involvement of more than 30%, fracture fragment displacement, and type III characteristics require management by an orthopaedic surgeon.[171]

Monteggia Fracture

Monteggia fracture–dislocations are a particular type of radial head injury, involving a combination of a dislocation of the proximal end of the radius and a fracture of the ulna. Instead of the radial head dislocation, the radial head or neck may be fractured. These lesions typically result from a direct blow to the forearm or a FOOSH injury with the arm positioned in either hyperextension or hyperpronation. The classification of Monteggia fracture–dislocations is outlined in Table 17-11.

Although relatively rare, these fractures can present with serious problems and poor functional outcomes without proper care.[222,320] Such complications include damage to the

TABLE 17-11 Classification of Monteggia Fracture Dislocations

Type	Description	Equivalent(s)	%
Type I	Anterior dislocation of the radial head and anterior angulation of the ulna fracture	Radial head or neck fracture instead of dislocation	60
Type II	Posterior dislocation of the radial head and posterior angulation of the ulna fracture	Posterior elbow dislocation. Radial head or neck fracture instead of dislocation	105
Type III	Lateral dislocation of the radial head with proximal ulna fracture	Radial head or neck fracture instead of dislocation	20
Type IV	Anterior dislocation of the radial head and proximal shafts of both bones fractured at same level	Radial head or neck fracture instead of dislocation	5

Data from Rabin SI: *Radial Head Fractures*. Available at: http://www.emedicine.com/orthoped/topic276.htm, 2005.

posterior branch of the radial nerve, AIN, and the ulnar nerve, as well as nonunion and poor AROM.[222]

For Monteggia fracture–dislocations, best treatment includes open reduction internal fixation of the ulna diaphyseal fracture. Following the surgery, the elbow is immobilized for about 4 weeks in 90–120 degrees of elbow flexion, after which AROM exercises for elbow flexion and forearm supination are initiated. AROM into extension beyond 90 degrees begins 4–6 weeks postoperatively.

Coronoid Fracture

The coronoid forms a significant portion of the articular surface of the proximal ulna. It serves as an important attachment site for muscles and ligaments about the elbow, and is essential for elbow stability.[1] Coronoid fractures, which are most commonly seen with high-energy injuries, are classified according to the size of the fragment type[1,321]:

- Type I: Tip avulsion. These fractures are generally stable and can be treated as simple dislocations with early motion.
- Type II: involves less than 50% of the height of the coronoid. Many of these are unstable and require ORIF.
- Type III: involve more than 50% of the height of the coronoid and frequently are accompanied by instability of the elbow. ORIF or a hinged external fixator may be required to maintain reduction.

Essex-Lopresti Fractures

This type of fracture is defined as a fracture of the radial head with proximal radius migration and disruption of the distal radioulnar joint and interosseous membrane,[322] which typically results from a FOOSH injury.[323]

Gentle AROM for forearm rotation is initiated about 6 weeks after surgery and immobilization in a Muenster cast.

Panner's Disease

Panner's disease (osteochondrosis deformans or osteochondritis) is an aseptic or osteonecrosis of the epiphysis.[324] Although related to direct trauma or to changes in the circulation, the actual etiology is unknown. Panner's disease is rarely seen before the age of 5 years and after the age of 16 years, and it almost exclusively (90%) affects boys. The main presenting symptoms are pain to the lateral aspect of the elbow, swelling, and a limitation of elbow movement in a noncapsular pattern. If a displaced fragment is present, there is often a painless limitation of elbow extension, with a soft end-feel, but a hard end-feel when flexion is limited.[12]

Conservative intervention involves rest from throwing or impact-loading stress, with a short period of splint immobilization sometimes being necessary. The exercise progression is based on clinical findings and patient tolerance.

Olecranon Fracture

An olecranon process fracture is fairly common due to its subcutaneous location and is usually caused by either a high- or a low-energy injury, such as a fall backward onto the elbow or a FOOSH injury, which produces passive elbow flexion combined with a sudden powerful contraction of the triceps muscle, resulting in an avulsion fracture of the olecranon.[325,326]

The classic signs of an avulsion fracture involving the triceps is a loss of active elbow extension; a palpable gap, pain, and swelling at the fracture site; and a large hematoma developing into diffuse ecchymosis.[327]

The focus on the intervention for the nondisplaced or minimally displaced fractures is to allow restoration of the articular surfaces and maintaining triceps function, while allowing early range of motion. The elbow is immobilized in a posterior splint or elbow immobilizer, with the elbow flexed at 90 degrees. Pronation and supination are started at 2–3 days, and pain-free flexion and extension motions begin at 2 weeks. The range of motion exercises avoid full flexion for up to 2 months, and resistance exercises are avoided for up to 3 months. Protected immobilization should continue until there is evidence of union ($\sim$ 6 weeks).

All other fractures require an ORIF or excision of the bone fragments with repair of the extensor mechanism.[222,325,326,328] Rehabilitation following the surgical procedure is dependent on the extent of the surgery and the length of the immobilization, although the emphasis on regaining early motion remains the same.

Pathologic Bone Formation

Pathologic bone formation about the elbow occurs in several distinct forms, which include heterotopic ossification, myositis ossificans, periarticular calcification, and ectopic ossification. [329]

Heterotopic ossification is defined as the formation of mature lamellar bone in nonosseous tissues.

Myositis ossificans refers to heterotopic ossification that forms in inflammatory muscle. Although heterotopic ossification and myositis ossificans are radiographically and histologically similar, these processes are distinguished by their anatomic locations.[330]

Periarticular calcification refers to collections of calcium pyrophosphates within soft tissues such as the collateral ligaments or joint capsule.

The term ectopic ossification includes heterotopic ossification and myositis ossificans. Since most cases of pathologic bone formation about the elbow consist of heterotopic ossification and myositis ossificans, ectopic ossification is the most appropriate descriptive term for this process.

Ectopic ossification about the elbow can result from direct injury, neural axis trauma, burns, and genetic disorders,[331] although direct elbow trauma is the most common cause.[332] Although elbow ectopic ossification may be asymptomatic, it frequently causes severe elbow stiffness or even ankylosis, and a resultant loss of function.[85,102]

Regan and Reilly[333] outlined following three factors that predispose the elbow to posttraumatic stiffness:

- The high degree of articular congruity
- The conformity of the elbow joint
- The covering of the anterior joint capsule by the brachialis, predisposing it to posttraumatic ectopic ossification.

Posttraumatic elbow ectopic ossification typically begins to form 2 weeks after trauma, surgery, burn, or neurologic insult,[333–335] resulting in localized tissue swelling and tenderness, hyperemia, and pain.

Mobilization after elbow injury often is delayed, because it is difficult to achieve rigid internal fixation of comminuted elbow fractures. Furthermore, posttraumatic elbow stiffness may occur despite early aggressive motion and prophylactic measures.

Elbow stiffness may develop 1–4 months after an initial phase of motion recovery after injury.[336] The patient's chief complaint may be pain, stiffness, instability, sensory loss, weakness, or locking. If pain is present, it is located anteriorly, in the middle third of the arm.

Limited active and passive elbow flexion and extension are characteristics of ectopic ossification formation about the elbow. However, in some patients, active and passive elbow motion may remain normal, especially in the early phase. However, even with aggressive intervention, including static and dynamic splinting and frequent active and passive ROM exercises, elbow motion may diminish. Strength testing reveals weak and painful elbow flexion and extension, and the end-feels of elbow ROM become rigid or abrupt. Once the ectopic ossification matures, usually at 3–9 months after injury, elbow ROM remains stable as long as the active and passive ROM program is continued.

Ectopic ossification about the elbow may lead to delayed nerve palsy. The ulnar nerve is most commonly affected; however, tardy median and radial palsies have also been reported.[337–339] This complication may occur several months or many years after the formation of ectopic bone.

Plain radiographs establish the diagnosis of ectopic ossification, define its location, and show its maturity. Radiographs show ectopic ossification as early as 2 weeks after injury, and joint incongruity, osteophytes, and/or malunion will also be apparent.

Nearly all patients who present with elbow stiffness and ectopic ossification should be started on an aggressive active motion program to combat the progressive loss of motion that occurs during ectopic ossification maturation. In some patients, elbow motion may improve; however, in others, loss of motion occurs and ankylosis may result. Active exercises, passive exercises, continuous passive motion, dynamic splinting, and static splinting have all been advocated, although some authors suggest that passive elbow exercises enhance elbow ectopic ossification formation and exacerbate elbow stiffness,[340] even though there is little evidence to support this belief. Until there is a prospective study comparing patients with elbow injuries treated with passive stretching with patients treated without passive stretching, the relationship between passive elbow motion and ectopic ossification formation will remain unclear. However, the passive force should be applied slowly and progressively so as not to cause any further damage to the soft tissues and thereby provoke an exacerbation.

Unless there is a contraindication, all patients are started on an active and active-assisted ROM program.

Splinting is also commonly used to restore elbow ROM. Spring-loaded hinged dynamic splints may be used to counteract flexion and extension contractures. Patients are instructed to wear these splints for six 1-hour sessions daily and while they sleep. If flexion and extension are limited, the patient is issued a dynamic flexion splint and a dynamic extension splint and instructed to alternate use of them. Turnbuckle splints also are available and are typically used for rigid contractures. This splint allows the patient to impart a static constant stretch to the soft tissues by tightening the turnbuckle.[332]

Elbow ectopic ossification can be prevented in many cases with prophylactic measures. Patients who sustain an elbow injury and have a risk factor for ectopic ossification should be treated to prevent this complication. Two forms of prophylaxis are available:

- ***Chemotherapeutic agents.*** These include NSAIDs. NSAIDs have been shown to decrease the incidence and severity of ectopic ossification about the hip. No studies exist regarding its effect on elbow ectopic ossification.
- ***Low-dose external beam radiation.*** Clinical studies showed that this modality inhibits ectopic ossification formation after total hip arthroplasty.[341,342]

PEDIATRIC PATHOLOGY

Acquired and congenital pediatric conditions of the elbow are described in Chapter 30.

Supracondylar Fracture of Humerus

This type of fracture, which occurs most commonly in children, involves the flat and flared distal metaphysis of the humerus, as a result of hyperextension or a fall on a flexed elbow. The forces are transmitted through the elbow joint to the distal humerus. The distal humeral fragment is usually posteriorly displaced (extension type). Sometimes, a "follow-through" of fragments results in a proximal fragment piercing the anterior periosteum, brachialis muscle, and possibly the brachial artery and median nerve (flexion type). If the brachial artery is pierced, the injury is potentially limb threatening.

The child typically presents with marked swelling above the elbow with an obvious deformity and ecchymosis. Because of the nature of this condition, peripheral circulation and nerve function must be assessed.

The intervention is dependent on severity. Nondisplaced fractures are immobilized in a simple sling or shoulder immobilizer, with the elbow flexed for 3 weeks, whereas displaced fractures require closed reduction and immobilization in a cast that does not constrict circulation, for 3 weeks. During the period of immobilization, the patient is closely monitored for changes in peripheral circulation. Following the period of immobilization, if the postreduction evaluation is acceptable, AROM exercises are initiated in an effort to regain full extension. Strengthening of the biceps and triceps is also addressed.

THERAPEUTIC TECHNIQUES

TECHNIQUES TO INCREASE JOINT MOBILITY

A number of techniques exist to increase joint mobility and range of motion from general techniques to very specific techniques.

Passive Accessory Mobilizations

With some slight variations, the same techniques that are used to examine the passive accessory motions of the elbow complex can be used to mobilize the joints, with the clinician varying the amplitude and the velocity of the technique (i.e., grade) of the mobilizations based on the intent of the treatment, the patient response, the stage of tissue healing, and the irritability of the joint.

Ulnohumeral

Distraction/Compression

These are general techniques that can be used to improve overall elbow motion into flexion and extension.

Medial Glide. This technique is commonly used as part of the intervention for medial epicondylitis.

Lateral Glide. This technique is commonly used as part of the intervention for lateral epicondylitis.

Radiohumeral

Anterior Glide (Fig. 17-36). This technique can be used to improve elbow flexion.

Posterior Glide (see Fig. 17-36). This technique can be used to improve elbow extension.

Distraction (Fig. 17-37). This technique is commonly used as part of the intervention for a humeroradial joint compression positional fault.

Compression (Fig. 17-37). This technique is commonly used as part of the intervention for a humeroradial joint distraction positional fault.

Proximal Radioulnar Joint

Anteromedial/Posterolateral Glide (see Fig. 17-38)

The clinician glides the radial head anteromedially (to increase supination)/posterolaterally (to increase pronation) at the proximal radioulnar joint.

Mobilizations with Movements

To Increase Motion at the Elbow and for Tennis Elbow[343,344]

The patient is positioned in supine with the involved arm on the bed and the forearm supinated. A belt is wrapped around the posterior aspect of the clinician and around the patient's forearm so that the belt edge is level with the elbow joint (Fig. 17-72). Using one hand, the clinician stabilizes the patient's humerus, while the other hand supports the patient's forearm and wrist (see Fig. 17-72). From this position, the ulna is glided laterally as the clinician gently moves their hips backward. Adjustments in the direction of the mobilization glide are made with respect to the carrying angle of the elbow. If there is no pain, the patient actively flexes or extends their elbow while the mobilization force is maintained. The active motion can be progressed to resisted wrist extension or resisted gripping performed during the mobilization.

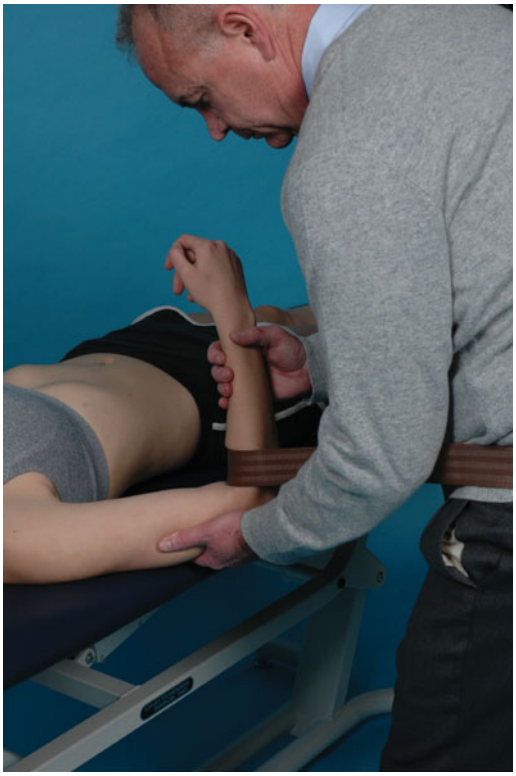

FIGURE 17-72 Mobilizations with movement to increase elbow motion.

Transverse Frictional Massage

TFM is used to treat a number of soft-tissue structures around the elbow.

Strain or Overuse of the Brachialis Muscle Belly. Although uncommon, lesions of the brachialis muscle belly are most often seen in long-distance cross-country skiers with inadequate training. In the following example, the right brachialis is treated.

The patient is positioned next to the short side of the treatment table, sitting, with the elbow in 90 degrees of flexion and the forearm resting on the table in maximal supination. The clinician sits next to the long side of the treatment table diagonally facing the patient. The clinician locates the site of the lesion by palpation. In most cases, the involved site is directly in the middle (between medial and lateral) of the muscle belly, at the level of the biceps musculotendinous junction. The clinician places the middle finger just lateral to the musculotendinous junction of the biceps (Fig. 17-73). The other hand holds the patient's forearm. The biceps musculotendinous junction is passively moved medially, as far as possible, with the thumb. After exerting pressure posteriorly, the clinician performs TFM in a lateral direction.

Strain or Overuse of the Muscle Belly—Musculotendinous Junction of the Biceps. Lesions of the biceps muscle belly or musculotendinous junction can occur as a result of carrying a heavy object or from forceful throwing activities. In the following example, the right biceps tendon is treated.

FIGURE 17-73 TFM to brachialis muscle belly.

The patient is positioned next to the short side of the treatment table, sitting, with the elbow in 90 degrees of flexion and the forearm resting on the table in supination. The clinician sits next to the long side of the treatment table diagonally facing the patient. The clinician locates the site of the lesion by palpation.

This is done by means of a pinch grip between the clinician's thumb and index finger of the right hand, which grasps the posterior aspect of the muscle belly, while the other hand fixes the patient's forearm. The transverse friction occurs through a "flat" pinching together of the thumb and index finger. Simultaneous extension of the wrist can be added to pull the muscle belly fibers transversely through the fingers.

The biceps musculotendinous junction is treated in much the same way.

Insertion Tendinopathy of the Triceps. Transverse friction is indicated for lesions in the musculotendinous junction (rare), the tendon, or the teno-osseous insertion of the triceps. Insertion tendinopathy of the triceps can occur as a result of chronic abuse or macrotrauma.

The patient is positioned prone on the treatment table, with the upper arm resting on the table and the forearm hanging over the edge of the table. The clinician sits next to the patient at the patient's involved side. The exact site of the lesion is confirmed by palpation. With one hand, the clinician holds the patient's elbow in slightly more than 90 degrees of flexion. The fingers of the other hand are placed at the site of the lesion (Fig. 17-74).

FIGURE 17-74 TFM to triceps.

Static stretching of the triceps is combined with the transverse friction.

Insertion Tendinopathy at the Medial Humeral Epicondyle (Golfer's elbow). The patient sits with the involved arm elevated sideways to just below the horizontal. The elbow is extended and the forearm, supinated. The clinician sits on a chair or stool next to the patient. If the right elbow is to be treated, the clinician stabilizes the patient's forearm and holds the elbow in slight flexion. To determine the most painful site of the lesion, the tip of the index finger carefully palpates the anterior plateau of the medial humeral epicondyle (Fig. 17-75). During the friction, the joint position of the finger does not change. The friction motion consists of minimal wrist extension and an even smaller amount of adduction of the arm.

FIGURE 17-75 TFM of medial epicondyle.

FIGURE 17-76 TFM at radial head for ECRB.

Tendinitis of the Extensor Carpi Radialis Brevis. The patient is positioned, sitting, next to the short end of the treatment table. The upper arm is positioned in 45 degrees of abduction, with the elbow in approximately 80 degrees of flexion and the forearm in pronation. The clinician sits diagonally facing the patient. The tendon of the ECRB brevis is located. In the pronated forearm, the ECRB tendon runs over the radial head (Fig. 17-76). In most cases, the tendon felt is, in fact, the common tendon of the ECRB and the extensor digitorum. Sometimes, two tendons are palpated; the medial one is the ECRB. TFM is performed by moving the finger in a medial-to-lateral direction over the tendon.

Techniques to Increase Soft-Tissue Extensibility

An increase in flexibility is achieved through a routine stretching program that may be instituted early in the course of treatment, with emphasis on stretching the entire hand, forearm, and shoulder complex. Stretching should follow the application of local heat such as that afforded by a hot pack, ultrasound or transverse friction massage. Patients should be taught how to perform these techniques on themselves at the earliest opportunity.

In each of the following techniques, the stretch is maintained for approximately 30 seconds.

Biceps

The patient stands by a table and places the back of the hand on the tabletop with the forearm supinated. The elbow is gradually extended and the forearm is moved into further supination (Fig. 17-77).

Elbow and Wrist Flexors

The patient is positioned in standing. A stretching strap is secured to the patient's foot and grasped by the hand of the involved side. Maintaining the forearm in a supinated position and the elbow extended as far as possible, the patient raises their arm out to the side (Fig. 17-51) until a stretch it felt.

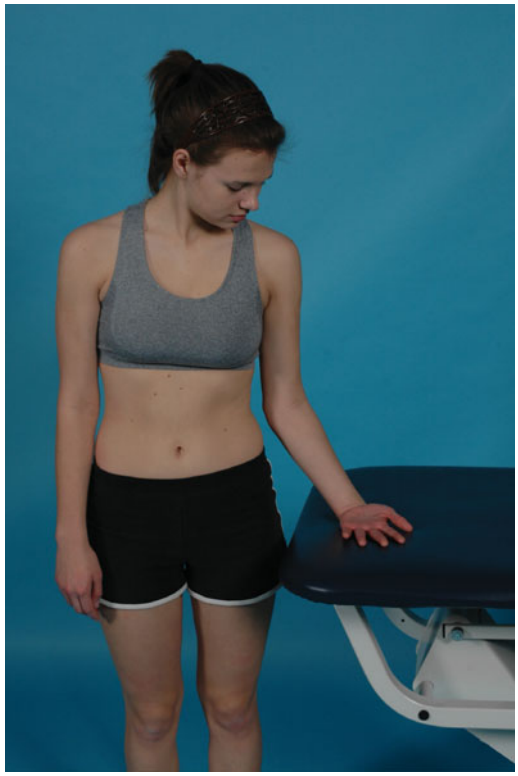

FIGURE 17-77 Biceps stretch.

Wrist and Finger Extensors

Stretching of the ECRB is always combined with stretching of the ECRL and extensor digitorum and is indicated in all types of tennis and golfer's elbow.

The patient is positioned in sitting. The upper arm is held horizontally, with the elbow flexed 90 degrees, the forearm pronated, and the wrist flexed. The patient uses the left hand to grasp their right hand and positions the wrist in maximal flexion and ulnar deviation, with the forearm in maximal pronation (Fig. 17-78). The elbow is brought very slowly into extension.

Stretch for Golfer's Elbow

The function of the long wrist flexors is flexion of the elbow, pronation of the forearm, and flexion of the wrist. The patient sits on a chair, with the involved arm elevated approximately 60 degrees. The elbow is slightly flexed, the forearm supinated, and the wrist extended (Fig. 17-52). The patient brings the wrist and fingers into as much extension as possible using the uninvolved hand (see Fig. 17-52). While holding the wrist in maximal extension, the clinician very slowly extends the patient's elbow. As soon as pain or muscle guarding occurs, the motion is stopped and the elbow is brought slightly back into more flexion. If the pain disappears after a few seconds, the elbow can be brought further into extension.

Weight-Bearing Wrist Flexor Stretch

This stretch is performed by asking the patient to position the hand palm side down on a table and to position the elbow in slight flexion, the wrist into maximal ulnar

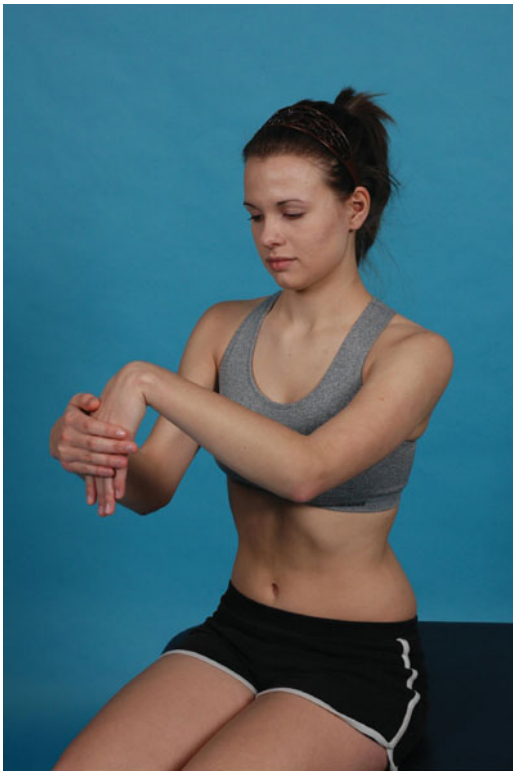

FIGURE 17-78 Wrist and finger extensor stretch.

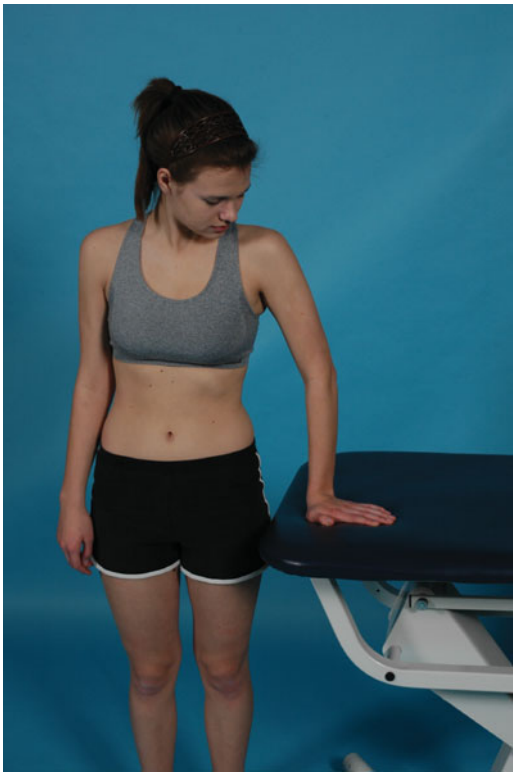

FIGURE 17-79 Weight-bearing wrist flexor stretch.

deviation and extension, and the forearm in maximal pronation (Fig. 17-79). Being careful to avoid pain and muscle splinting, the patient slowly straightens the elbow. The stretch should be held for approximately 40 seconds. At this point, the patient can gently pull the fingers up from the table to stretch the flexor muscles of the palm. Against very slight resistance (performed by the other hand), the arm is then brought back to the original position. This stretching procedure is repeated six times before repeating the entire procedure on the uninvolved side.

High-Velocity, Low-Amplitude Thrusting

Mills' Manipulation[12]

This technique is designed to break adhesions of the common extensor tendon and let the orbicular ligament slip back to its normal position. The Mills' manipulation is used instead of slowly stretching the tissues during the last few degrees of maximal elbow extension.

This manipulation is indicated only for certain patients, namely, those

- who demonstrate full active and passive elbow extension with a normal end-feel;
- whose elbow demonstrates only a slight limitation of motion with a myofascial end-feel.

Prior to the manipulation, transverse frictions should be applied to the site in order to soften the scar.

The patient is positioned in sitting, with the clinician standing behind the patient's shoulder (see Fig. 17-42). The patient's wrist is flexed. Maintaining the position of the patient's wrist, the clinician extends the elbow. The Mills' maneuver involves a forcible extension of the elbow, while simultaneous digital pressure is exerted over the point of maximum tenderness. If the wrist flexion is not maintained, the force will be through the elbow joint. Mills stressed the need to elicit an audible click during the procedure, although in practice many normal elbows can be made to click by the same maneuver,[345] indicating that the click is probably coincidental.

A modification to the patient position can be used for this manipulation. The patient is positioned in supine, with their arm off the edge of the table. The clinician adjusts the table height so that the patient's elbow joint can be rested on their thigh, while the clinician's foot is in contact with the floor. The patient's arm is then placed in slight shoulder extension and full internal rotation (palm down). In this position, the various tendons can be tested as to their level of involvement by having each one contract. The involved tendon is then softened up using transverse friction before the manipulation is applied using the aforementioned positions. The patient's elbow is then slightly raised off the clinician's thigh and then dropped quickly back onto the thigh.

Following the manipulation, exercises to stretch the scar should be carried out.

CASE STUDY

LATERAL ELBOW PAIN

HISTORY

History of Current Condition

A 43-year-old female patient presents with complaints of left elbow pain, which she reports having for about a year. The patient describes the onset of elbow pain as gradual and attributes it to her work as an electronics assembler, where she spends the day pulling out plugs. Over time, the pain has worsened to the point where it hurts all of the time. Although the patient has tried a course of anti-inflammatories, they were discontinued due to an adverse reaction. The patient has been placed on light duty at work, with a lifting restriction of 10 lb.

Past History of Current Condition

No past history of left elbow pain.

Past Medical and Surgical History

Unremarkable.

Medications

None.

Living Environment

Lives in a two-story house.

Occupational, Employment, and School

Assembly line worker. High school education.

Functional Status and Activity Level

The patient's goals were to decrease pain with activities of daily living and to be able to return to work without pain.

Health Status (Self-Report)

In general good health, but pain interferes with tasks at home and at work.

Questions

1. What is the most common diagnosis characterized by lateral elbow pain?
2. What can a history of gradual onset tell the clinician?
3. What can a history of repetitive activity tell the clinician?
4. What findings do you expect to note in the physical examination in terms of palpation, resistive tests, and special tests?
5. What additional questions would you ask to help rule out referral of pain from the cervical spine or shoulder?
6. List the various diagnoses that could present with these signs and symptoms, and the tests you would use to rule out each one.
7. Does this presentation and history warrant an upper quarter scanning examination? Why or why not?

CASE STUDY

MEDIAL ELBOW PAIN

HISTORY

History of Current Condition

A 23-year-old apprentice carpenter was seen in the clinic with complaints of right elbow pain, which he reported having for the last few months. The patient described the onset of elbow pain as gradual and attributed it to his work, where he spends most of the day using carpentry tools. Over time, the pain had worsened to the point where it hurt all of the time. The patient went to see his physician who prescribed a course of anti-inflammatory medications and physical therapy and placed the patient on light duty at work.

Past History of Current Condition

No past history of elbow pain.

Past Medical and Surgical History

Unremarkable.

Medications

Ibuprofen, 800 mg a day.

Functional Status and Activity Level

The patient's goals were to decrease pain with activities of daily living and recreational sports and to be able to return to work without pain.

Health Status (Self-Report)

In general good health, but pain interferes with tasks at home and at work.

Questions

1. What structure(s) do you suspect to be at fault with complaints of medial elbow pain?
2. What is the probable mechanism of injury for this patient?
3. What type of activities would you expect to exacerbate this condition?
4. What additional questions would you ask?
5. List the various diagnoses that could present with these signs and symptoms and the tests you would use to rule out each one.

REVIEW QUESTIONS*

1. True/False: The primary restraint to valgus stress at the elbow is bony congruity.
2. What is the maximal close-packed position of the humeroulnar joint?
3. Which muscles are involved with forearm pronation?
4. In which direction do most elbow dislocations occur?
5. Which muscle could flex the elbow if the three major elbow flexors were *not* available?
   A. The pronator teres
   B. The FPL
   C. The supinator
   D. The pronator quadratus

*Additional questions to test your understanding of this chapter can be found in the Online Learning Center for *Orthopaedic Assessment, Evaluation, and Intervention* at www.duttononline.net.

The Forearm, Wrist, and Hand

CHAPTER 18

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joints, ligaments, muscles, blood and nerve supply that comprise the forearm, wrist, and hand.
2. Describe the biomechanics of the forearm, wrist, and hand, including open- and close-packed positions, normal and abnormal joint barriers, and stabilizers.
3. Describe the purpose and components of the tests and measures for the forearm, wrist, and hand.
4. Describe the relationship between muscle imbalance and functional performance of the forearm, wrist, and hand.
5. Perform a comprehensive examination of the forearm, wrist, and hand, including palpation of the articular and soft-tissue structures, specific passive mobility and passive articular mobility tests, and stability tests.
6. Outline the significance of the key findings from the tests and measures and establish a diagnosis.
7. Summarize the various causes of forearm, wrist, and hand dysfunction.
8. Develop self-reliant intervention strategies based on clinical findings and established goals.
9. Evaluate the intervention effectiveness in order to progress or modify an intervention.
10. Plan an effective home program and instruct the patient in same.

OVERVIEW

A hand is a very personal thing. It is the interface between the patient and his or her world. It is an emblem of strength, beauty, skill, sexuality and sensibility. When it is damaged it becomes a symbol of vulnerability of the whole patient.

—Paul W. Brand (1914–2003)

In a sense, the shoulder, elbow, and wrist joints (Fig. 18-1) are merely mechanical devices that contribute to the usefulness of the hand.[1] The correct synchronization of these biological devices, coupled with patient motivation, produce a remarkable level of dexterity and precision.

The carpus, or wrist, represents a highly complex anatomic structure, comprising a core structure of 8 bones; more than 20 radiocarpal, intercarpal, and carpometacarpal (CMC) joints; 26 named intercarpal ligaments; and 6 or more parts of the triangular fibrocartilage complex (TFCC).[2] While these structures can be differentiated anatomically, they are functionally interrelated with movement in one joint having an effect on the motion of neighboring joints. This relationship extends as far as the elbow.

The hand accounts for about 90% of upper limb function.[3] The thumb, which is involved in 40–50% of hand function, is the more functionally important of the digits.[3] The index and middle fingers are each involved in about 20% of hand function, and are the second most important, with the ring finger being the least important. The middle finger is the strongest finger and is important for both precision and power functions.[3]

The following sections describe the respective bones, joints, soft tissues, and nerves, detailing both their individual and collective functions. For simplicity's sake, the forearm, wrist, and hand are separated into their various compartments.

ANATOMY

Distal Radioulnar Joint

The distal radioulnar joint (DRUJ) plays an important role in wrist and forearm function. The DRUJ is a uniaxial pivot joint that joins the distal radius and ulna and an articular disk (Fig. 18-1). The articular disk, known as the TFCC, assists in binding the distal radius and is the main stabilizer of the DRUJ (see next section).[4]

At its distal end, the radius widens to form a broad concave articular surface. The articular surface has an ulnar inclination in the frontal plane, which averages 23 degrees, and a anterior (palmar) inclination in the sagittal plane, which averages 11 degrees.[5] The distal end of the ulna expands slightly laterally into a rounded head and medially into an ulnar styloid process

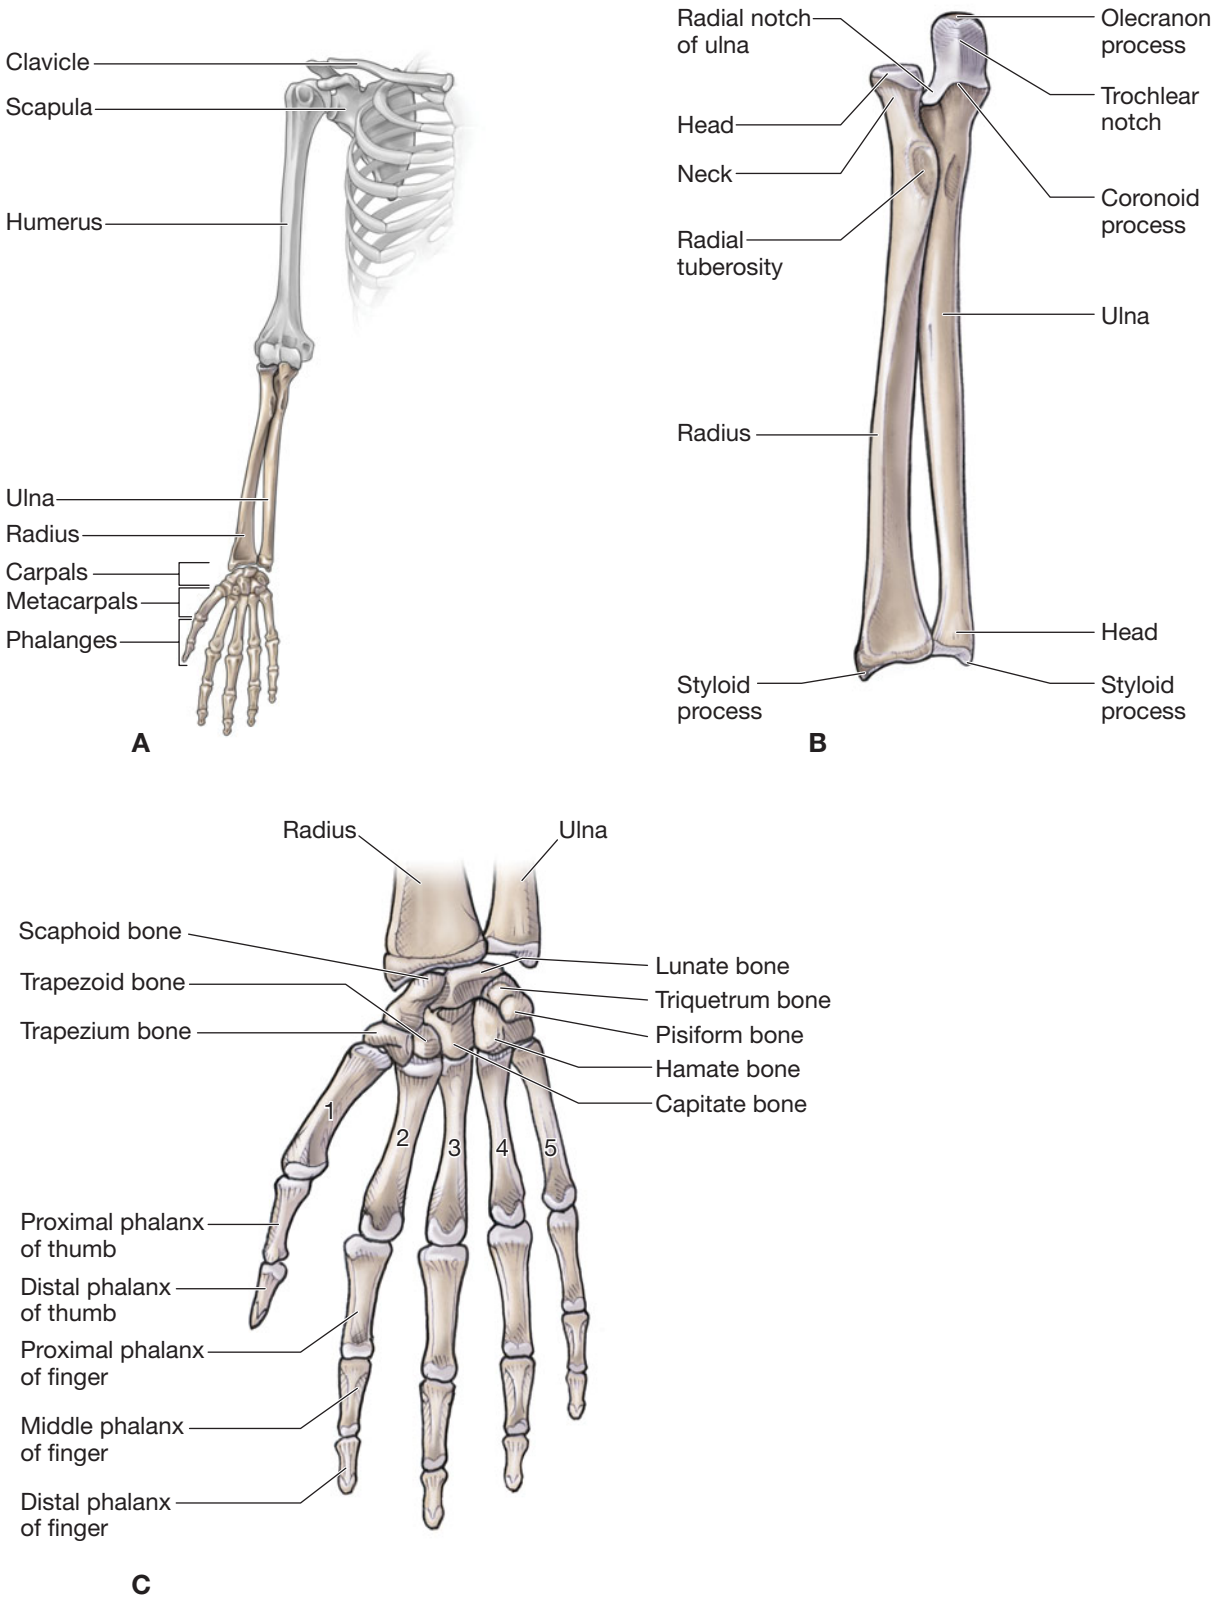

FIGURE 18-1 Arm, wrist, and hand joint structures. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

(Fig. 18-1). The rounded head of the ulnar head contacts both the ulnar notch of the radius laterally and the TFCC distally.[6] The ulnar styloid process is approximately one-half inch shorter than the radial styloid process, resulting in more ulnar deviation than radial deviation being available.[6] The articular capsule, which attaches to the articular margins of the radius and ulna and to the disk enclosing the inferior radioulnar joint, is lax. Anterior (palmar) and posterior (dorsal) radioulnar ligaments strengthen the capsule anteriorly and posteriorly. Forearm supination tightens the anterior capsule and

pronation tightens the posterior part, adding to the overall stability of the wrist.[7]

The DRUJ functions to transmit the loads from the hand to the forearm.

CLINICAL PEARL

The resting or open-packed position for the DRUJ is 10 degrees of supination.

The close-packed position for the DRUJ is 5 degrees of supination.

The capsular pattern for the DRUJ is pain at extremes of pronation/supination.

Triangular Fibrocartilage Complex

The TFCC essentially comprises a fibrocartilage disk interposed between the medial proximal row and the distal ulna within the medial aspect of the wrist.[8] The primary function of the TFCC is to enhance joint congruity and to cushion against compressive forces. Indeed the TFCC transmits about 20 percent of the axial load from the hand to the forearm.[7] The broad base of the disk is attached to the medial edge of the ulnar notch of the radius, and its apex is attached to the lateral aspect of the base of the ulnar styloid process. The disk's anterior and posterior borders are thickened.

A number of ligaments originate from the TFCC and provide support to it. These include the ulnolunate and ulnotriquetral ligaments, the ulnar collateral and the radioulnar ligaments. Other structures that lend support to the TFCC include the following:

- The ulnocarpal ligaments.
- The sheath of the extensor carpi ulnaris (ECU) tendon, which is the only wrist tendon that broadly connects to the TFCC.

Both the superior and the inferior articular surfaces of the TFCC are smooth and concave.[8] The disk separates the distal ulna from direct contact with the carpals but allows gliding between the carpals, disk, and ulna during forearm pronation and supination.[8,9]

The TFCC is innervated by branches of the posterior interosseous, ulnar, and posterior (dorsal) sensory ulnar nerves.[9]

The Wrist

The wrist comprises the distal radius and ulna, eight carpal bones, and the bases of five metacarpals (Fig. 18-1). The carpal bones lie in two transverse rows. The proximal row contains (lateral to medial) the scaphoid (navicular), lunate, triquetrum, and pisiform. The distal row holds the trapezium, trapezoid, capitate, and hamate.

Radiocarpal Joint

The radiocarpal joint, a biaxial ellipsoid joint, is formed by the large articular concave surface of the distal end of the radius, the proximal carpal row, and the TFCC. The lunate and triquetrum articulate with the TFCC. A radial styloid process projects distally from the lateral side of the radius. A cartilage-covered ulnar notch occupies the distal medial side of the radius.[10] Posteriorly, a posterior (dorsal) (Lister's) tubercle arises near the center of the radius, forming a pulley around which the extensor pollicis longus (EPL) tendon passes.[9] Lister's tubercle is a common site of attritional changes and potential tendon rupture.[11]

CLINICAL PEARL

The resting or open-packed position for the radiocarpal joint is neutral with slight ulnar deviation.

The close-packed position for the radiocarpal joint is extension with radial deviation.

The capsular pattern for the radiocarpal joint is flexion and extension equally limited.

The Carpals

Scaphoid. The scaphoid (Fig. 18-1) is the largest of the proximal carpal row bones, and its shape resembles that of a boat or canoe (thus the old term *navicular*).[9] The scaphoid bone links the proximal and distal carpal rows and helps provide stability to the wrist joint.

The scaphoid is tethered to the proximal carpal row by a number of strong ligamentous attachments, and two-thirds of its surface area is articular. The proximal surface of the scaphoid is convex and articulates with the radius. The medial surface is concave and articulates with the capitate.[10] The articulating surface for the lunate is flat. The distal surface consists of two convex facets for articulation with the trapezium and trapezoid (the scaphotrapeziotrapezoid joint).[9] The round tubercle on the inferolateral part of its anterior (palmar) surface serves as the attachment of the flexor retinaculum and the abductor pollicis brevis (APB).[10] The blood vessels to this bone enter the scaphoid at or distal to the wrist. This configuration predisposes a fracture on the proximal aspect to aseptic necrosis.[12] In addition, as the scaphoid plays a critical role in coordinating and stabilizing movements between the proximal and the distal rows of the carpals, damage to the intrinsic and extrinsic ligaments that support the scaphoid can result in persistent pain and dysfunction with loading activities.[13–15]

Lunate. The lunate (Fig. 18-1) articulates between the scaphoid and the triquetrum in the proximal carpal row. Its smooth convex proximal surface articulates with the radius and the TFCC at the lunate fossa.[10] Its lateral surface contains a flat semilunar facet for the scaphoid. The medial surface articulates with the triquetrum. The distal surface is deeply concave and articulates with the edge of the hamate in adduction and the medial aspect of the capitate.[10]

Triquetrum. The triquetrum (Fig. 18-1) is a pyramid-shaped bone. It articulates with the pisiform on its distal anterior (palmar) surface at the pisiform–triquetral joint.[10] The almost square distal–medial surface of the triquetrum articulates with the concavo–convex surface of the hamate. The ulnar collateral ligament (UCL) attaches to the medial and posterior (dorsal) surfaces of the triquetrum.[10] The proximal surface of the triquetrum articulates with the TFCC in full adduction.[9] The lateral surface of the triquetrum articulates with the lunate.

Pisiform. The pisiform (Fig. 18-1), as its name implies, is shaped like a "P" with a posterior (dorsal) flat articular facet for

the triquetrum.[10] The pisiform, formed within the tendon of the flexor carpi ulnaris (FCU), is a sesamoid bone and serves as an attachment for the flexor retinaculum, abductor digiti minimi (ADM), UCL, pisohamate ligament, and pisometacarpal ligament. The pisiform also functions to increase the flexion moment of the FCU.[9]

As mentioned, the pisiform articulates with the anterior (palmar) surface of the triquetral and is thus separated from the other carpal bones, all of which articulate with their neighbors. The pisiform is closely related to the ulnar artery and nerve on its radial border, the nerve being the closer.[16]

Trapezium. The trapezium (Fig. 18-1) has a groove on its medial anterior (palmar) surface which contains the tendon of the flexor carpi radialis (FCR).[10] To its margins are attached two layers of the flexor retinaculum. The opponens pollicis (OP) is between the flexor pollicis brevis (FPB) distally and the APB proximally.[10] The lateral surface serves as an attachment site for the radial collateral ligament and capsular ligament of the first CMC joint. The distal articulating surface of the trapezium is saddle shaped. Medially, its concave surface articulates with the trapezoid, whereas more distally its convex surface articulates with the second metacarpal base.[10] Proximally, its concave surface articulates with the scaphoid.

Trapezoid. The trapezoid (Fig. 18-1) is small and irregular. The distal surface articulates with the grooved second metacarpal base. The medial surface articulates via a concave facet with the distal part of the capitate. The lateral surface of the trapezoid articulates with the trapezium, and its proximal surface articulates with the scaphoid bone.[10]

Capitate. The capitate (Fig. 18-1) is the most central and the largest of the carpal bones. Its distal aspect articulates with the third metacarpal base. Its lateral border articulates with the medial side of the second metacarpal base.[10] The convex proximal head of the capitate articulates with the lunate and scaphoid. The medial surface of the head articulates with the lunate, and the lateral aspect of the head articulates with the scaphoid.[10] Medially, the capitate articulates with the hamate.

With its central location, the capitate serves as the keystone of the proximal transverse arch. This arch is important to the prehensile activity of the hand.[9,17,18]

Hamate. The hamate (Fig. 18-1) is a cuneiform bone and contributes to the medial wall of the carpal tunnel. To the hook (hamulus) of the hamate is attached the flexor retinaculum. The hamate articulates with three carpal bones and two metacarpals.[9] The medial surface articulates with the triquetrum and by association with the pisohamate ligament, the pisiform. The lateral surface articulates with the capitate.[10] On its distal aspect the hamate articulates with the fourth and fifth metacarpal heads.

CLINICAL PEARL

The resting or open-packed position for the intercarpal joint is neutral or slight flexion.

The close-packed position for the intercarpal joint is extension.

There is no recognized capsular pattern of the intercarpal joints.

Midcarpal Joints

The midcarpal joint lies between the two rows of carpals. It is referred to as a "compound" articulation because each row has both a concave and a convex segment. Wrist flexion, extension, and radial deviation are mainly midcarpal joint motions. Approximately 50 percent of the total arc of wrist flexion and extension occur at the midcarpal level with more flexion (66 percent) occurring than extension (34 percent).[19]

The proximal row of the carpals is convex laterally and concave medially. The scaphoid, lunate, trapezium trapezoid, and triquetrum present with a concave surface to the distal row of carpals. The scaphoid, capitate, and hamate present a convex surface to a reciprocally arranged distal row.

CLINICAL PEARL

The resting or open-packed position for the midcarpal joint is neutral or slight flexion with ulnar deviation.

The close-packed position for the midcarpal joint is extension with ulnar deviation.

The capsular pattern for the midcarpal joint is equal limitation of flexion and extension.

First CMC Joint

The thumb is the most important digit of the hand and greatly magnifies the complexity of human prehension.[20,21] Functionally, the sellar (saddle-shaped) CMC joint is the most important joint of the thumb and consists of the articulation between the base of the first metacarpal and the distal aspect of the trapezium.

The articular surfaces of the trapezium and the proximal end of the first metacarpal are reciprocally shaped. Three other adjacent articulations are functionally related to this joint, which include the joints between the trapezium and the scaphoid, the trapezium and the trapezoid, and the base of the first metacarpal and the radial side of the base of the second metacarpal.[20,21]

Motions that can occur at this joint include flexion/extension, adduction/abduction, and opposition, the latter of which includes varying amounts of flexion, internal rotation, and anterior (palmar) adduction (see "Biomechanics"). Although the joint capsule of the first CMC joint is large and relatively loose, motions at the joint are controlled and supported by muscle actions and by at least five ligaments: anterior oblique, ulnar collateral, intermetacarpal, posterior oblique, and radial collateral. In general, most of the thumb ligaments are placed on tension with abduction, extension, and opposition.[20,21]

CLINICAL PEARL

The resting or open-packed position of the first CMC joint is midway between abduction and adduction, and flexion and extension.

The close-packed position of the first CMC joint is full opposition.

The capsular pattern of the first metacarpal joint is thumb abduction, then extension.

Other CMC Joints

The distal borders of the distal carpal row bones articulate with the bases of the metacarpals, thereby forming the CMC joints. The CMC articulations of the fingers permit only gliding movements. The CMC joints progress in mobility from the second to the fifth, with the second and third metacarpal joints being relatively immobile, and thus the primary stabilizing joints of the hand. The fourth and fifth CMC joints are more mobile to permit the hand to adapt to objects of different shapes during grasping.

Stability for the CMC joints is provided by the anterior (palmar) and posterior (dorsal) CMC and intermetacarpal ligaments. While the trapezoid articulates with only one metacarpal, all of the other members of the distal carpal row combine one carpal bone with two or more metacarpals.

CLINICAL PEARL

The resting or open-packed position of the CMC joints of the fingers is midway between flexion and extension.

The close-packed position of the CMC joints of the fingers is full flexion.

The capsular pattern of the CMC joints of the fingers is equal limitation in all directions.

Metacarpophalangeal Joints

The five metacarpals resemble miniature versions of the long bones of the body, with elongated shafts and expanded ends. The metacarpophalangeal (MCP) joint of the thumb is a hinge joint. Its bony configuration, which resembles the interphalangeal (IP) joints, provides it with some inherent stability. In addition, support for the joint is provided by anterior (palmar) and collateral ligaments. The MCP joint of the thumb consists of a convex surface on the head of the metacarpal and a concave surface on the base of the phalanx. The area of the articulating surface is increased by the presence of a volar plate, which allows greater range of motion than would be available otherwise. Approximately 75–80 degrees of flexion is available at this joint. The extension movements as well as the abduction and adduction motions are negligible. Traction, gliding, and rotatory accessory movements are also present.

The second through fifth metacarpals articulate with the respective proximal phalanges within biaxial joints. Their widened, proximal bases articulate with the carpals and with one another in plane joints.[10] Their biconvex distal heads are broader anteriorly than posteriorly, the significance of which is discussed later.

The MCP joints allow flexion–extension and medial–lateral deviation associated with a slight degree of axial rotation. The design of the MCP joint allows for great amplitude of movement, at the expense of stability.

Approximately 90 degrees of flexion is available at the second MCP, with the amount of available flexion progressively increasing toward the fifth MCP. Active extension at these joints is 25–30 degrees, while 90 degrees can be obtained passively. A loss of flexion and extension at the CMC joint of the little finger reduces the amount of opposition available, resulting in dysfunction of the prehensile pattern and difficulty in making a fist.[6] Approximately 20 degrees of abduction/adduction can occur in either direction at the MCP, with more being available in extension than in flexion. Abduction–adduction movements of the MCP joints are restricted in flexion and free in extension.

CLINICAL PEARL

The resting or open-packed position of the MCP joints is slight flexion.

The close-packed position of the MCP joints is full opposition (thumb)/full flexion (fingers).

The capsular pattern of the MCP joints is flexion, then extension.

The joint capsules are attached to the articular margins of the metacarpals and phalanges and surround the MCP joints. The joint capsule of these joints is relatively lax and redundant, but is endowed with collateral ligaments that pass posterior to the joint axis for flexion/extension of the MCP joints (Fig. 18-11). Although, these collateral ligaments are lax in extension, they become taut in approximately 70–90 degrees of flexion of the MCP joint.[22]

CLINICAL PEARL

Contracture of the collateral ligaments is a major cause of loss of MCP flexion. The MCP joints should never, under any circumstances, be immobilized in extension or hyperextension by a retraction of the collateral ligaments, which would result in their locking.[23] Instead the fingers should be splinted with the MCP joints flexed to 70–90 degrees.

The posterior (dorsal) hood apparatus reinforces (or replaces) the posterior (dorsal) joint capsules. The fibrocartilaginous volar plates reinforce the anterior (palmar) aspects of the joints (Fig. 18-12). The volar plates attach firmly to the phalangeal bases but connect only loosely to the metacarpal heads by membranous fibers. Their posterior (dorsal) surface contributes to the joint area, whereas their anterior (palmar) surface channels the finger flexor tendons.[23]

The asymmetry of the metacarpal heads as well as the difference in length and direction of the collateral ligaments also explains the rotational movement of the proximal phalanx during flexion–extension and why the ulnar deviation of the digits normally is greater than the radial deviation.[23] The rotary movements that occur are called conjunct rotations. The index finger has a conjunct rotation of internal rotation with abduction and flexion, whereas the ring and little finger each have a conjunct rotation of external rotation with abduction and flexion. The middle finger is not thought to have a conjunct rotation.

CLINICAL PEARL

In contrast to the IP articulations, which are stable throughout most of their range of movements, the MCP joints are stable only in flexion.[23]

IP Joints

Adjacent phalanges articulate in hinge joints that allow motion in only one plane: sagittal. The congruency of the IP joint surfaces contributes greatly to IP joint stability. In addition, the IP joints are surrounded by joint capsules that are attached to the articular margins of the phalanges.

Proximal Interphalangeal Joint

The proximal interphalangeal (PIP) joint is a hinged joint capable of flexion and extension. The supporting ligaments and tendons provide the bulk of the static and dynamic stability of this joint as it travels through a normal range of 110 degrees.[22,24–27] The capsule surrounding the articular surface of the joint is composed of the volar plate, lateral and accessory collateral ligaments, and extensor expansion.

The proximal IP joint is stable in all positions. The configuration of the volar plate allows it to function as a static restraint to hyperextension and to influence the mechanical advantage of the flexor tendons at the initiation of PIP joint flexion.[22] The volar plate also increases the surface area. This allows for a greater range of motion than would be available otherwise.

The thick collateral ligaments (true and accessory) of the PIP joint combine with the volar plate to provide lateral stability: the collateral ligaments of the PIP joints are maximally taut at 25 degrees of finger flexion.[22] For this reason, the IP joints are usually splinted in 25 degrees of flexion following surgery to prevent joint contractures. The splinting position is changed as the patient resumes function.

The flexor tendon system at the level of the PIP joint is less complex than the extensor mechanism and contributes very little to injuries about the PIP joint.[22]

The phalangeal bases effectively form a sellar surface, with bone projections allowing for a wide range of accessory movements to accommodate the gripping of a large array of irregular surfaces.

The motions available at these joints consist of approximately 110 degrees of flexion at the PIP joints and 90 degrees at the thumb IP joint. Extension reaches 0 degrees at the PIP joints and 25 degrees at the thumb IP joint. Traction, gliding, and accessory movements also occur at the IP joints.

Distal Interphalangeal Joints

The distal interphalangeal (DIP) joint has similar structures as the PIP joint but less stability and allows some hyperextension. The motions available at these joints consist of approximately 90 degrees of flexion and 25 degrees of extension. Traction, gliding, and accessory movements also occur at the DIP joints.

CLINICAL PEARL

The resting or open-packed position for the IP joints is slight flexion.

The close-packed position for the IP joints is full extension.

The capsular pattern of the IP joints is flexion, and then extension.

TABLE 18-1 Ligaments of the Wrist

Interosseous	Intrinsic Midcarpal	Extrinsic Radiocarpal/ Ulnocarpal
Distal row	*Posterior (dorsal)*	*Posterior (dorsal)*
Trapezium-trapezoid	Scaphotriquetral	Posterior (dorsal) radiocarpal
Trapezoid-capitate	Posterior (dorsal) intercarpal	
Capitohamate		
Proximal row	*Anterior (palmar)*	*Anterior (palmar)*
Scapholunate	Scaphotrapeziotrapezoid	Radioscaphocapitate
Lunotriquetral	Scaphocapitate	Long radiolunate
Triquetrocapitate	Short radiolunate	
Triquetrohamate	Radioscapholunate	
		Ulnolunate Ulnotriquetral Ulnocapitate

Carpal Ligaments

Excessive migration of the carpal bones is prevented by strong ligaments (Table 18-1) and by the ulnar support provided by the TFCC. The major ligaments of the wrist are depicted in Fig. 18-2.

The ligaments of the wrist provide support for the region. These ligaments can be divided into two types: extrinsic and intrinsic (Table 18-1). The extrinsic anterior (palmar) ligaments provide the majority of wrist stability. The intrinsic ligaments serve as rotational restraints, binding the proximal row into a unit of rotational stability.[28] The proximal row of carpals has no muscle insertions. Its stability depends entirely on the capsular and interosseous ligaments between the scaphoid, lunate, and triquetrum.[29] The ligaments between the proximal and the distal carpal rows provide support, centering especially on the capitate.[10] The midcarpal ligaments, which are longer than the interosseous ligaments, cross the midcarpal joint and connect bones of the distal and proximal rows on both the posterior (dorsal) and the anterior (palmar) surfaces.[9] No midcarpal ligaments directly attach to the lunate.

Antebrachial Fascia

The antebrachial fascia is a dense connective tissue that encases the forearm and maintains the relationships of the tendons that cross the wrist. The fascia is firmly attached to the subcutaneous border of the ulna, from which it sends a septum to the radius. This septum divides the forearm into an anterior compartment and a posterior compartment (see Muscles of the Wrist and Forearm).

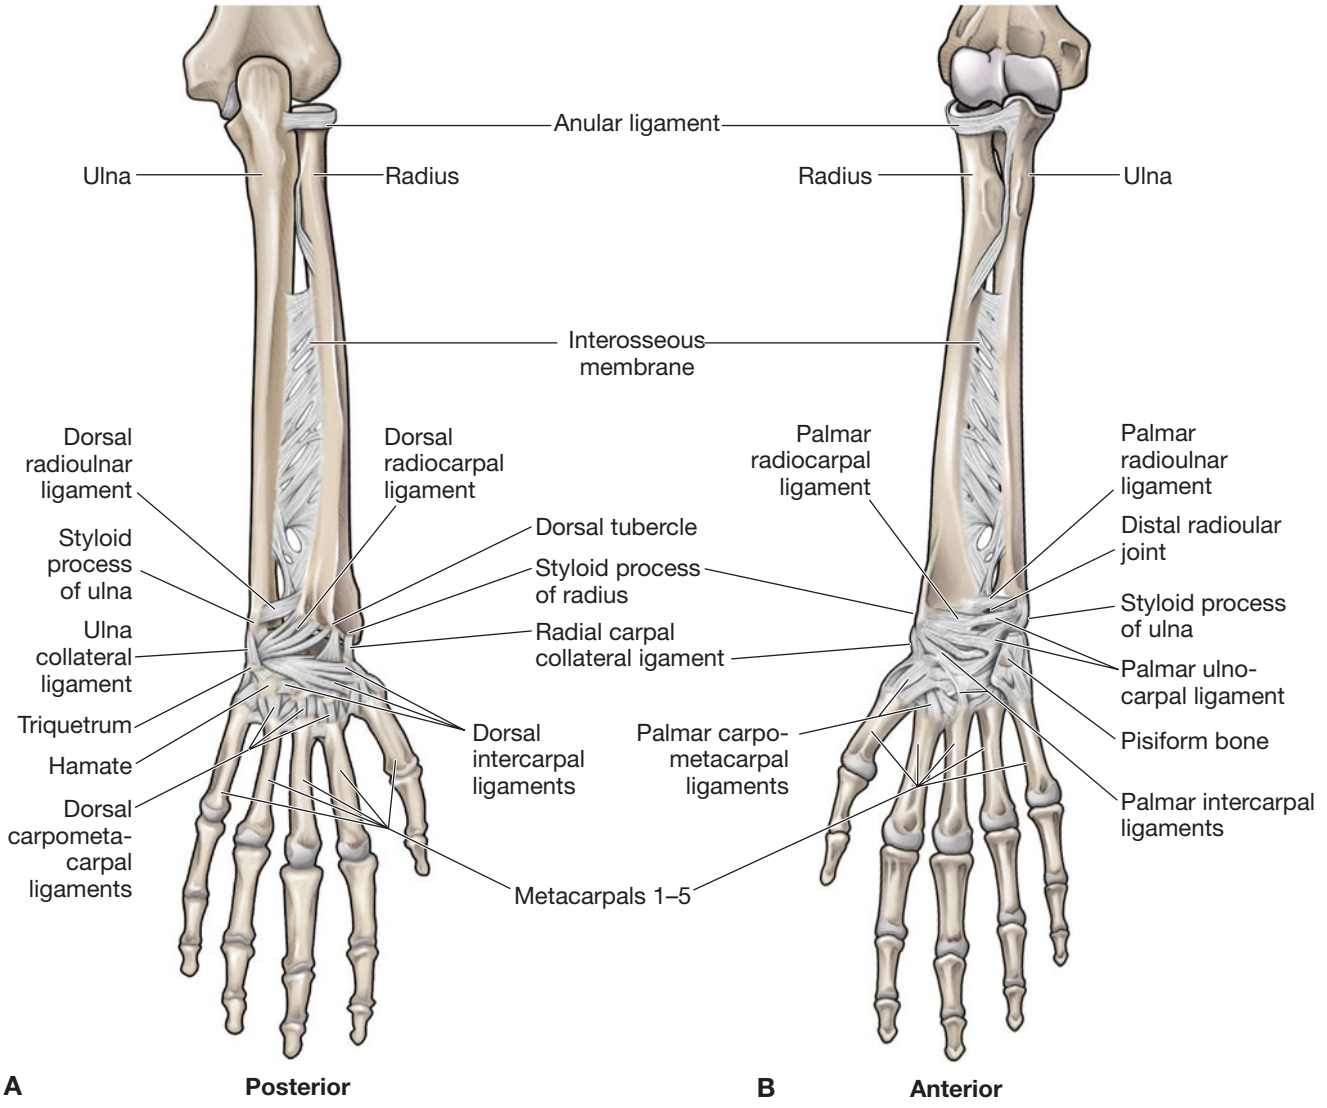

FIGURE 18-2 The major ligaments of the wrist. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

The Extensor Retinaculum

At the point where the tendons cross the wrist, there is a ligamentous structure called a retinaculum that appears to lay over the tendons and their sheaths (Fig. 18-3). This retinaculum serves to prevent the tendons from "bowstringing" when the tendons turn a corner at the wrist.[30] The extensor retinaculum extends from the lateral border of the distal radius across the posterior (dorsal) surface of the distal forearm onto the posterior surface of the distal ulna and ulnar styloid process. It then wraps part way around the ulna to attach to the triquetrum and pisiform bones. The retinaculum and the underlying bones form six tunnel-like structures called fibro-osseous compartmentson the dorsum of the wrist (Fig. 18-3). The compartments, from lateral to medial, contain the tendons of

1. abductor pollicis longus (APL) and extensor pollicis brevis (EPB)
2. extensor carpi radialis longus (ECRL) and brevis (ECRB)
3. extensor pollicis longus (EPL)
4. extensor digitorum (ED) (four tendons) and extensor indicis (EI) (not shown)
5. extensor digiti minimi (EDM)
6. ECU.

CLINICAL PEARL

The mnemonic 2 2 1 2 1 1 can be used to remember the number of tendons in each compartment.[9]

As these tendons pass through the compartments, they are invested with synovial sheaths.

The posterior (dorsal) compartments serve to enhance the efficiency and effectiveness of the wrist and finger extensors (see "Extensor Hood") (Fig. 18-4). Proximal to the metacarpal heads, juncturae tendineae connect the four tendons of the ED muscles, limiting their independent motion.[6] For example, flexion of the middle and little fingers restricts extension of the ring finger MCP joint because the juncturae tendineae pulls the ring finger extensor tendon distally. Conversely, extension

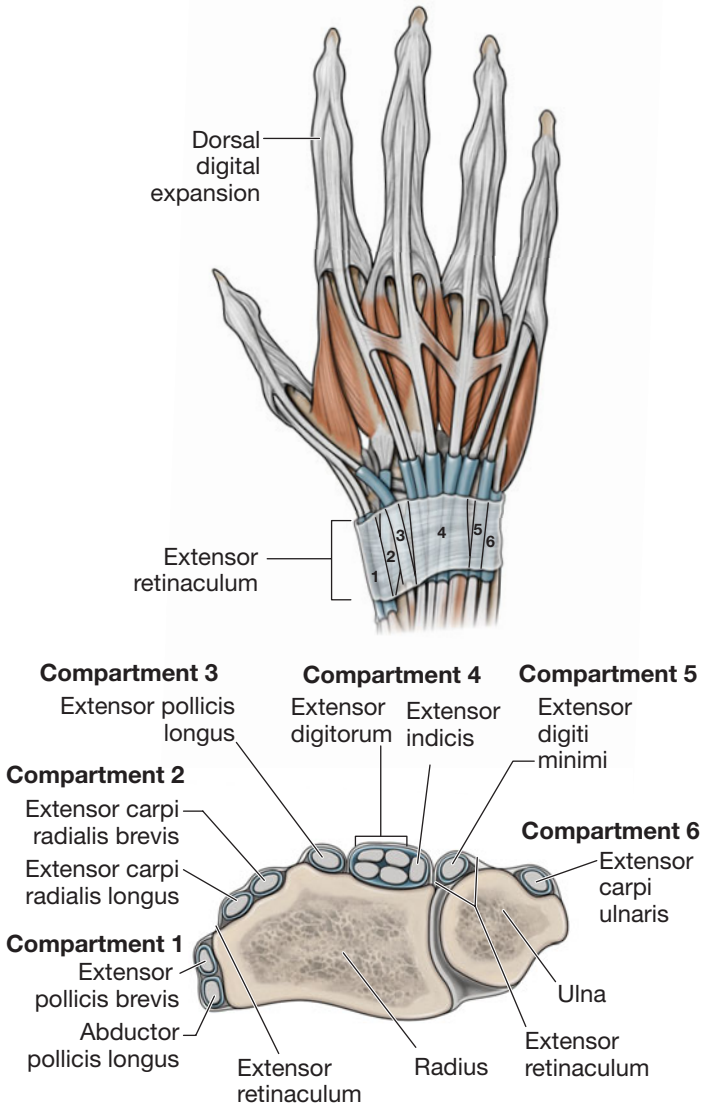

FIGURE 18-3 Extensor retinaculum and extensor tendons. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

of the ring finger exerts an extensor force upon its neighbors, such that they can be actively extended even if the middle and little finger extensor tendons are severed proximal to the juncturae.[6]

The Flexor Retinaculum

The flexor retinaculum (transverse carpal ligament) spans the region between the pisiform, hamate, scaphoid, and trapezium, transforming the carpal arch into a tunnel, through which the median nerve and some of the tendons of the hand pass. (Fig. 18-5) The proximal attachment of the retinaculum is at the tubercle of the scaphoid and the pisiform. The hook of the hamate and the tubercle of the trapezium serve as its distal attachment. The retinaculum also[6]

- serves as an attachment site for the thenar and hypothenar muscles;
- helps maintain the transverse carpal arch;
- acts as a restraint against bowstringing of the extrinsic flexor tendons,
- protects the median nerve.

In the condition known as carpal tunnel syndrome (CTS), the median nerve is compressed in this relatively unyielding space (see "Intervention Strategies"). The structures that pass *deep* to the flexor retinaculum (Fig. 18-5) include

- flexor digitorum superficialis (FDS),
- flexor digitorum profundus (FDP),
- flexor pollicis longus (FPL),
- flexor carpi radialis (FCR).

The structures that pass *superficial* to the flexor retinaculum include

- the ulnar nerve and artery,
- the tendon of the palmaris longus,

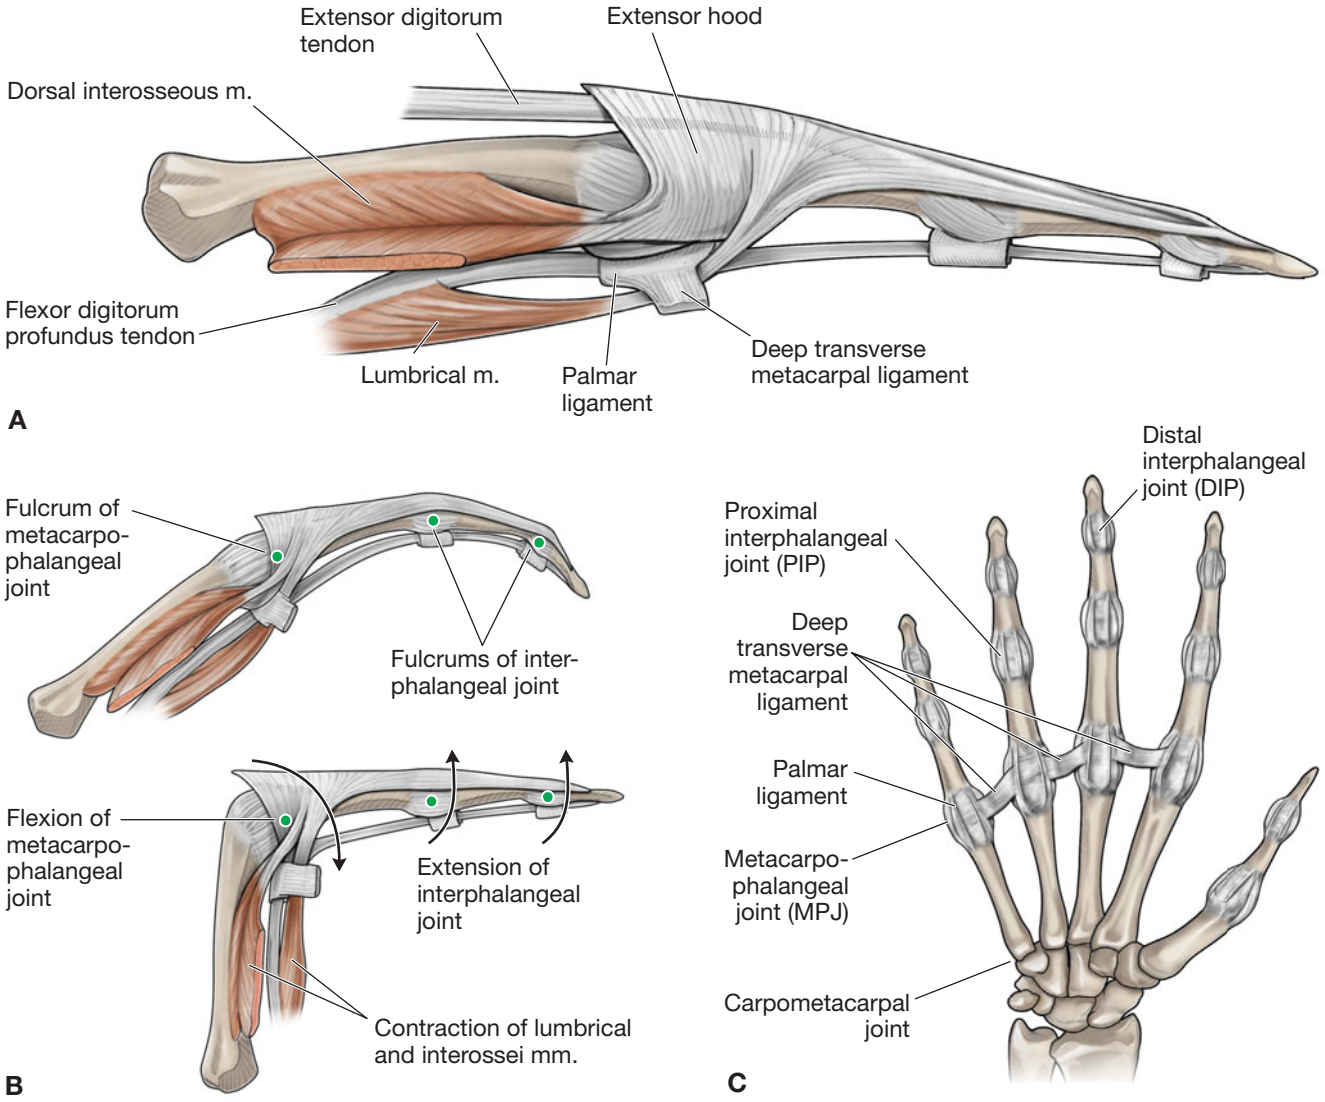

FIGURE 18-4 Extensor hood and smaller ligaments of the hand. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

- the sensory branch (anterior (palmar) branch) of the median nerve.

Fibrous sheaths between the distal anterior (palmar) crease and the PIP joints bind the flexor tendons to the fingers. Some surgeons refer to the area where the sheaths contain two tendons as "no man's land."[6]

Carpal Tunnel

The carpal tunnel serves as a channel for the median nerve and nine flexor tendons (Fig. 18-5). The floor of the tunnel is formed by the anterior (palmar) radiocarpal ligament and the anterior (palmar) ligament complex. As mentioned previously, the roof of the tunnel is formed by the flexor retinaculum. The radial and ulnar are formed by carpal bones (hook of hamate and trapezium , respectively). The median nerve divides into a motor branch and distal sensory branches within the tunnel.

Tunnel of Guyon

The tunnel of Guyon is located superficial to the flexor retinaculum, between the hook of the hamate and the pisiform bones. The anterior (palmar) carpal ligament, palmaris brevis muscle, and the anterior (palmar) aponeurosis form its roof. Its floor is formed by the flexor retinaculum (transverse carpal ligament), pisohamate ligament, and pisometacarpal ligament.[6] The tunnel functions as a passageway for the ulnar nerve and artery into the hand.

Phalanges

The 14 phalanges each consist of a base, shaft, and head (Fig. 18-1). Two shallow depressions, which correspond to the pulley-shaped heads of the adjacent phalanges, mark the concave proximal bases. Two distinct convex condyles produce the pulley-shaped configuration of the phalangeal heads.[6]

Anterior (palmar) Aponeurosis

The anterior (palmar) aponeurosis, which consists of a dense fibrous structure continuous with the palmaris longus tendon and fascia covering the thenar and hypothenar muscles, is located just deep to the subcutaneous tissue

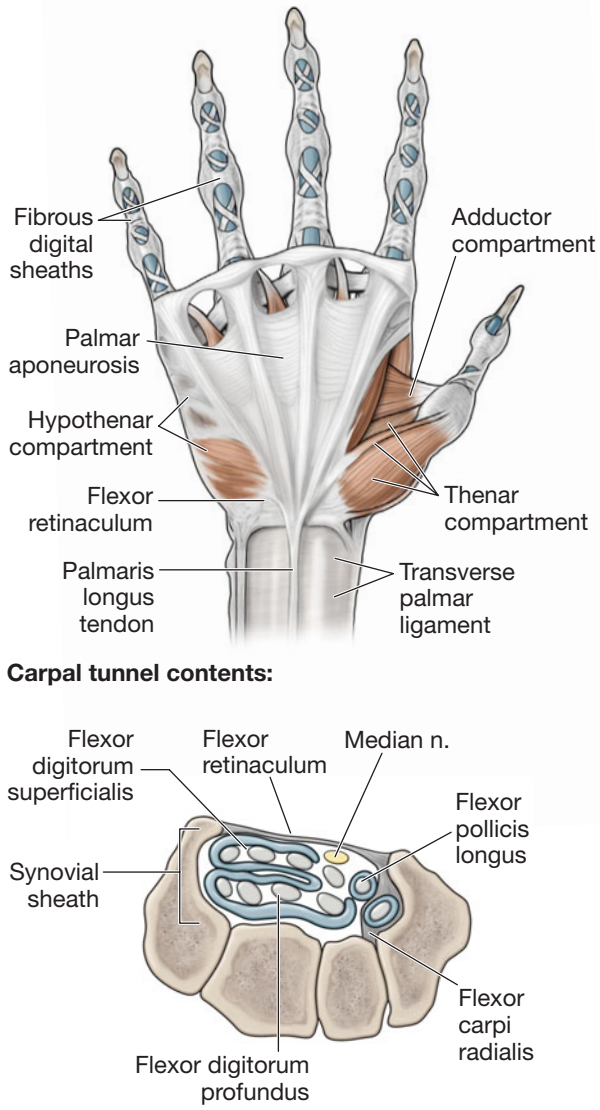

FIGURE 18-5 Flexor retinaculum and flexor tendons. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

(Fig. 18-5). The aponeurosis travels distally to attach to the transverse metacarpal ligaments and flexor tendon sheaths. The aponeurosis offers some protection for the ulnar artery and nerve, and digital vessels and nerves. From the central region of the palm, the aponeurosis continues toward the fingers and splits into four slips. As these slips approach the MCP joints, they split and wrap around the tendons of their respective digit. Dupuytren contracture is a fibrotic condition of the anterior (palmar) aponeurosis that results in nodule formation or scarring of the aponeurosis and which may ultimately cause finger flexion contractures (see "Intervention Strategies").

Extensor Hood

At the level of the MCP joint, the tendon of the ED fans out to cover the posterior (dorsal) aspect of the joint in a hood-like structure (Fig. 18-4). A complex tendon that covers the posterior (dorsal) aspect of the digits is formed from a combination of the tendons of insertion from the ED, EI, and

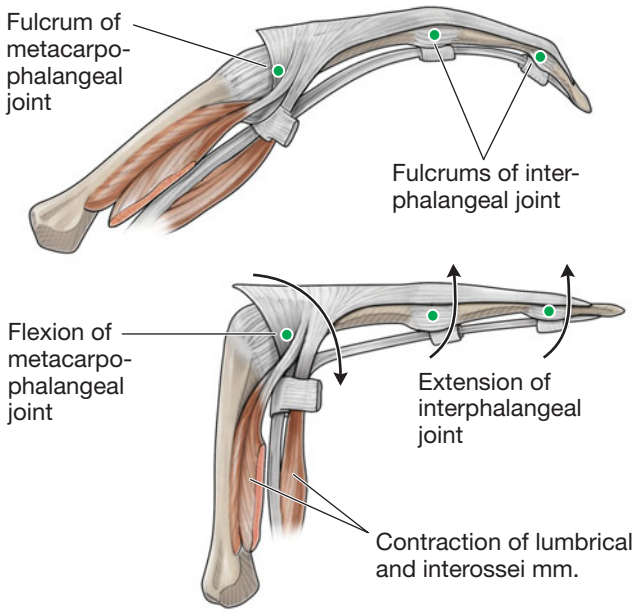

FIGURE 18-6 The tendons of the intrinsic muscles in relation to the joints. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

EDM. The distal portion of the hood receives the tendons of the lumbricals and interossei over the proximal phalanx. The tendons of the intrinsic muscles pass anterior (palmar) to the MCP joint axes but posterior (dorsal) to the PIP and DIP joint axes (Fig. 18-6). Between the MCP and the PIP joints, the complete, complex ED tendon (after all contributions have been received) splits into three parts: a central slip and two lateral bands[6]:

- ***A central band.*** This band inserts into the proximal posterior (dorsal) edge of the middle phalanx.
- ***The lateral bands.*** These bands rejoin over the middle phalanx into a terminal tendon, which inserts into the proximal posterior (dorsal) edge of the distal phalanx. Rupture of the tendon insertion into the distal phalanx produces a "mallet" finger (see "Intervention Strategies"). The lateral bands, comprise fibers from both extrinsic and intrinsic tendons, are prevented from dislocating posteriorly (dorsally) by the transverse retinacular ligaments, which link them to the volar plates of the PIP joints.[6]

The arrangement of the muscles and tendons in this expansion hood creates a cable-like system that provides a mechanism for extending the MCP and IP joints and allows the lumbrical and possibly interosseous muscles to assist in the flexion of the MCP joints.

Stretching or laxity of these supporting structures allows "bowstringing" of the lateral bands, which transmit excessive extension force to the PIP joint.[6]

The oblique retinacular ligament (Landsmeer ligament) assists in the extensor hood mechanism. The ligament attaches between the PIP volar plate, where it is anterior (palmar) to the PIP joint axis, and the terminal tendon, where it is posterior (dorsal) to the DIP joint axis. This relationship to the PIP and DIP joints is essentially the same as that of the

intrinsic muscles (lumbricals and interosseous) to the MCP and PIP joints—when the PIP joint extends, the oblique retinacular ligament exerts a passive extensor force on the DIP joint, and when the PIP joint flexes, it allows the DIP joint to flex.[31]

PIP joint position also may influence DIP joint position through lateral band action. The lateral bands normally slip palmarly upon PIP joint flexion, decreasing the excursion required for full DIP joint flexion. If scar tissue tethers the lateral bands so that they do not move palmarly, then simultaneous full flexion at both the PIP and the DIP joints is not possible.[6]

Synovial Sheaths

Synovial sheaths can be thought of as long narrow balloons filled with synovial fluid, which wrap around a tendon so that one part of the balloon wall (visceral layer) is directly on the tendon, while the other part of the balloon wall (parietal layer) is separate.[30] During wrist motions, the sheaths move longitudinally, reducing friction.

At the wrist, the tendons of both the FDS and the FDP are essentially covered by a synovial sheath and pass posterior (dorsal) (deep) to the flexor retinaculum. The FDP tendons are posterior (dorsal) to those of the FDS.

In the palm, the FDS and FDP tendons are covered for a variable distance by a synovial sheath.

At the base of the digits, both sets of tendons enter a "fibro-osseous tunnel" formed by the bones of the digit (head of the metatarsals and phalanges) and a fibrous digital tendon sheath on the anterior (palmar) surface of the digits.

Flexor Pulleys

Annular (A) and cruciate (C) pulleys restrain the flexor tendons to the metacarpals and phalanges and contribute to fibro-osseous tunnels through which the tendons travel.[11] The A1 pulley arises from the MCP joint and volar plate; A2 from the proximal phalanx; A3 from the PIP joint volar plate; A4 from the middle phalanx; and A5 from the DIP joint volar plate.[11] The C1 pulley originates near the head of the proximal phalanx; C2 near the base of the middle phalanx; and C3 near the head of the middle phalanx.[11]

The pulley system of the thumb includes the A1 arising from the MCP joint anterior (palmar) plate, A2 from the IP joint anterior (palmar) plate, and the oblique pulley from the proximal phalanx.[11]

Anatomic Snuffbox

The anatomic snuffbox (Fig. 18-7) is a depression on the posterior (dorsal) surface of the hand at the base of the thumb, just distal to the radius. This structure can be observed during active radial abduction of the thumb. The radial border of the snuffbox is formed by the tendons of the APL and EPB, while the ulnar border is formed by the tendon of the EPL. Along the floor of the snuffbox are the deep branch of the radial artery and the tendinous insertion of the ECRL. Underneath these structures, the scaphoid and trapezium bones are found.

FIGURE 18-7 Anatomic snuffbox. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

CLINICAL PEARL

Tenderness with palpation in the anatomic snuffbox suggests a scaphoid fracture but also can be present in minor wrist injuries or other conditions.[4]

MOBILE ARCH SYSTEMS

The bones and soft tissues of the hand form a number of functional arches of the hand that provide a perfect balance of force distribution in an equiangular spiral. The arches of the hand, which are all concave palmarly, serve to enhance prehensile function. This prehensile function is best illustrated by the ability of the human hand to grasp an egg. A number of arches are commonly recognized:

- ***The transverse arch.*** The proximal, relatively immobile transverse arch is formed within the anterior (palmar) concavity of the carpal bones.[6] This carpal arch, deepened by the anterior (palmar) projections of the scaphoid and trapezium laterally and the pisiform and hamate medially, should correspond to the concavity of the wrist. The distal transverse arch is more mobile and is defined by the alignment of the metacarpals. This arch allows the hand to adapt to objects held in the palm.[11]
- ***The metacarpal arch.*** This arch, formed by the metacarpal heads, is a relatively mobile transverse arch.
- ***The longitudinal arch.*** This is specifically the arch of the middle finger and the arch of the index finger. The longitudinal arch, which contributes to powerful gripping, spans the hand lengthwise, with its keystone at the MCP joints.[6]
- ***The oblique arches.*** These arches are formed by the thumb in opposition to the other fingers.

TABLE 18-2 Muscles of the Wrist and Hand: Their Actions and Nerve Supply

Action	Muscles	Nerve Supply
Wrist extension	Extensor carpi radialis longus	Radial
	Extensor carpi radialis brevis	Posterior interosseous
	Extensor carpi ulnaris	Posterior interosseous
Wrist flexion	Flexor carpi radialis	Median
	Flexor carpi ulnaris	Ulnar
Ulnar deviation of wrist	Flexor carpi ulnaris	Ulnar
	Extensor carpi ulnaris	Posterior interosseous
Radial deviation of wrist	Flexor carpi radialis	Median
	Extensor carpi radialis longus	Radial
	Abductor pollicis longus	Posterior interosseous
	Extensor pollicis brevis	Posterior interosseous
Finger extension	Extensor digitorum communis	Posterior interosseous
	Extensor indicis	Posterior interosseous
	Extensor digiti minimi	Posterior interosseous
Finger flexion	Flexor digitorum profundus	Anterior interosseous, lateral two digits
		Ulnar, medial two digits
	Flexor digitorum superficialis	Median
	First and second: median	
	Lumbricals	Third and fourth: ulnar
	Interossei	Ulnar
	Flexor digiti minimi	Ulnar
Abduction of fingers	Posterior (dorsal) interossei	Ulnar
	Abductor digiti minimi	Ulnar
Adduction of fingers	Anterior (palmar) interossei	Ulnar
Thumb extension	Extensor pollicis longus	Posterior interosseous
	Extensor pollicis brevis	Posterior interosseous
	Abductor pollicis longus	Posterior interosseous
Thumb flexion	Flexor pollicis brevis	Superficial head: median
		Deep head: ulnar
	Flexor pollicis longus	Anterior interosseous
	Opponens pollicis	Median
Abduction of thumb	Abductor pollicis longus	Posterior interosseous
	Abductor pollicis brevis	Median
Adduction of thumb	Adductor pollicis	Ulnar
Opposition of thumb and little finger	Opponens pollicis	Median
	Flexor pollicis brevis	Superficial head: median
	Abductor pollicis brevis	Median
	Opponens digiti minimi	Ulnar

Muscles of the Wrist and Forearm

The muscles of the forearm, wrist, and hand (Table 18-2) (Figs. 18-8 through 18-10) can be subdivided into 19 intrinsic muscles and 24 extrinsic muscles.[4] The intrinsic muscles are located entirely within the hand; they arise and insert within the hand. The extrinsic muscles, whose muscle bellies lie proximal to the wrist, originate in the forearm and insert within the hand. The flexors, which are located in the anterior compartment, flex the wrist and digits while the extensors, located in the posterior compartment, extend the wrist and the digits.

The design of the extrinsic and intrinsic muscle groups provides for a large number of muscles to act on the hand without excessive bulkiness. The extrinsic tendons enhance wrist stability by balancing flexor and extensor forces and compressing the carpals.

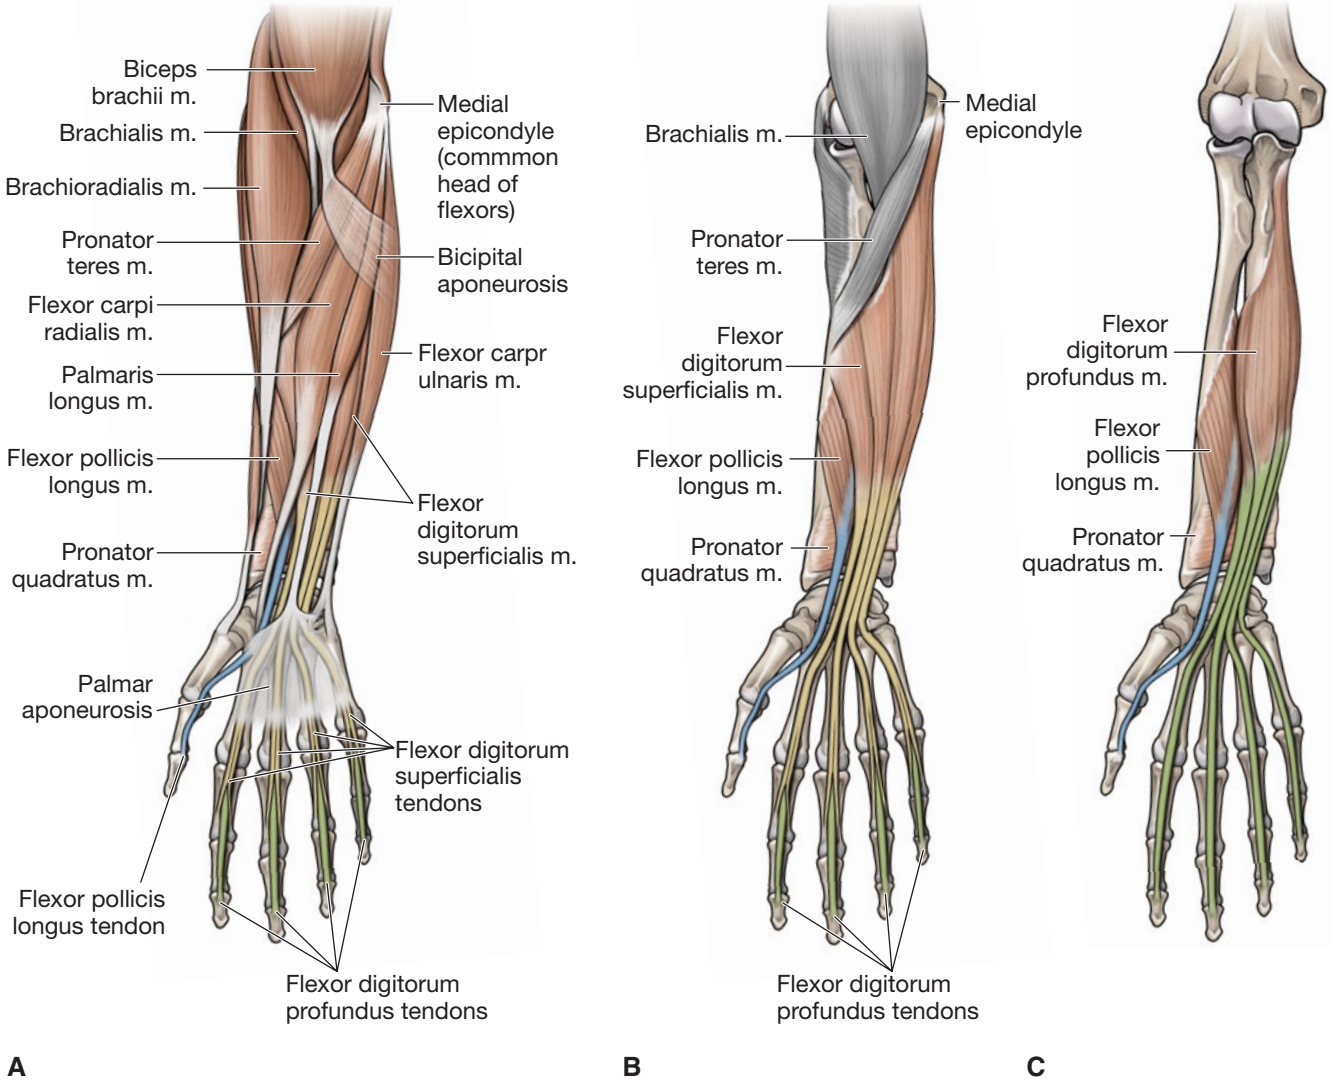

FIGURE 18-8 Muscles of the forearm, wrist, and hand. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

The amount of tendon excursion determines the available range of motion at a joint. To calculate the amount of tendon excursion needed to produce a certain number of degrees of joint motion involves an appreciation of geometry. A circle's radius equals approximately 1 radian (57.29 degrees). The mathematical radius, which is equivalent to the moment arm, represents the amount of tendon excursion required to move the joint through 1 radian.[32] For example, if a joint's moment arm is 10 mm, the tendon must glide 10 mm to move the joint 60 degrees (approximately 1 radian) or 5 mm to move the joint 30 degrees (1/2 radian).[11]

Anterior Compartment of the Forearm

Superficial Muscles

Pronator Teres. The pronator teres is described in Chapter 17.

Flexor Carpi Radialis. The FCR originates from the medial humeral epicondyle as part of the common flexor tendon. It inserts on the anterior surface and base of the second metacarpal, possibly providing a slip to the third metacarpal. The FCR is innervated by the median nerve and functions to flex and radially deviate the wrist.

Palmaris Longus. The inconsistent palmaris longus arises from the medial humeral epicondyle as part of the common flexor tendon and inserts on the transverse carpal ligament and anterior (palmar) aponeurosis. It receives its innervation from the median nerve. The function of the palmaris longus is to flex the wrist, and it may play a role in thumb abduction in some people.[18]

Flexor Carpi Ulnaris. The FCU arises from two heads. The humeral head arises from the medial humeral epicondyle as part of the common flexor tendon, while the ulnar head arises from the proximal portion of the subcutaneous border of the ulna. The FCU inserts directly onto the pisiform, the hamate via the pisohamate ligament, and onto the anterior surface of the base of the fifth metacarpal, via the pisometacarpal

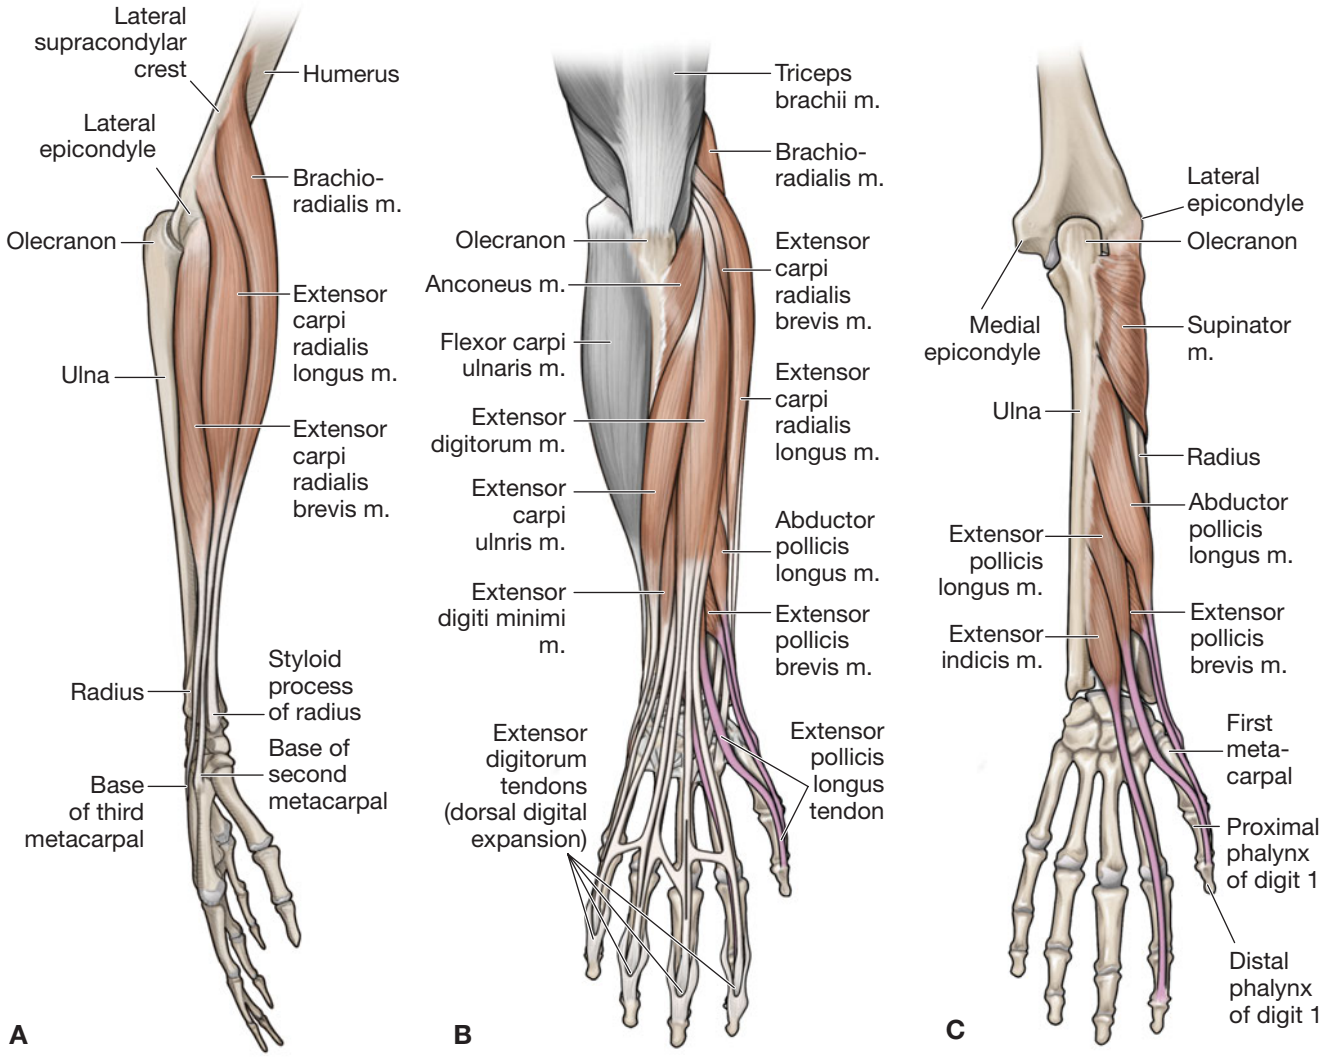

FIGURE 18-9 Muscles of the forearm, wrist, and hand. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

ligament. The FCU is innervated by the ulnar nerve and functions to flex and ulnarly deviate the wrist.

Intermediate Muscle

Flexor Digitorum Superficialis. The FDS has a three-headed origin. The humeral head arises from the medial humeral epicondyle as part of the common flexor tendon. The ulnar head arises from the coronoid process of the ulna. The radial head arises from the oblique line of the radius. The FDS inserts on the middle phalanx of the medial four digits via a split, "sling" tendon. This muscle is innervated by the median nerve and serves to flex the proximal and middle IP joints of the medial four digits and assist with elbow flexion and wrist flexion. The FDS possesses tendons that are capable of relatively independent action at each finger.

Deep Muscles

Flexor Pollicis Longus. The FPL has its origin on the ventral surface of the radius, medial border of the coronoid process of the ulna, and the adjacent interosseous membrane. It inserts on the distal phalanx of the thumb. The FPL is innervated by the anterior interosseous branch of the median nerve, and it functions to flex the thumb.

Flexor Digitorum Profundus. The FDP arises from the medial and anterior (ventral) surfaces of the proximal ulna, the adjacent interosseous membrane, and the deep fascia of the forearm. The FDP inserts on the base of the distal phalanges of the medial four digits. The FDP has a dual nerve supply: the medial two heads are supplied by the ulnar nerve, while the lateral two heads are supplied by the anterior interosseous branch of the median nerve. The FDP functions to flex the DIP joints, after the FDS flexes the second phalanges, and assists with flexion of the wrist. The tendons of the FDS and FDP are held against the phalanges by a fibrous sheath. At strategic locations along the sheath, the previously mentioned five dense annular pulleys (designated A1, A2, A3, A4, and A5) and three thinner cruciform pulleys (designated C1, C2, and C3) prevent tendon bowstringing.[33]

Unlike the FDS tendons, the FDP tendons cannot act independently. To isolate the PIP joint flexor function of these two muscles, a clinician holds the adjoining finger(s) in extension while the patient attempts to flex the finger being tested. This anchors the profundus muscle of the finger being tested distally and allows the superficialis muscle to act alone at the PIP joint.

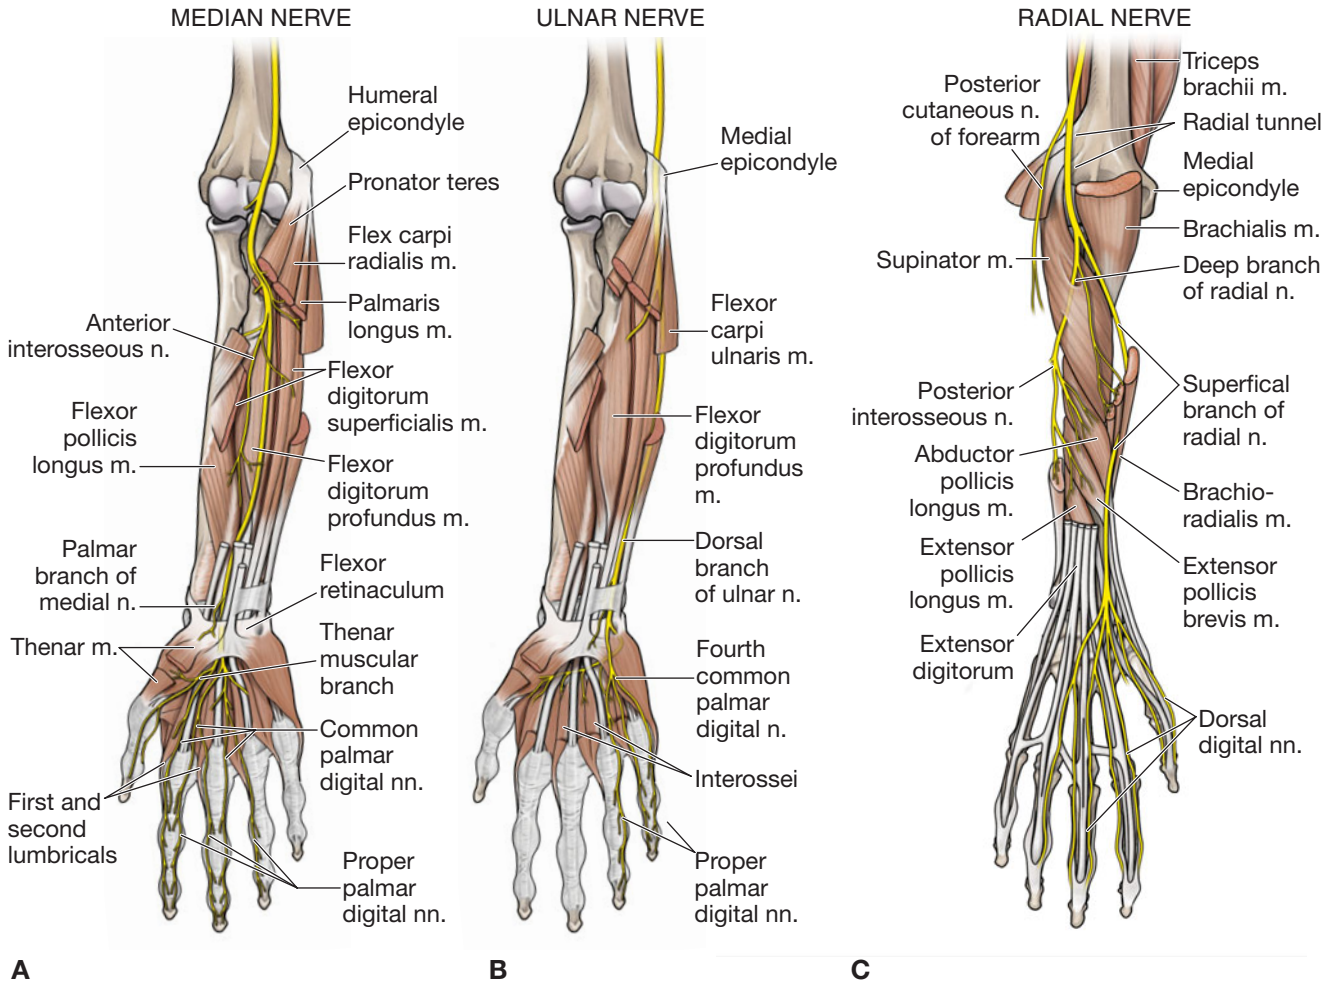

FIGURE 18-10 Muscles and nerve supply of the forearm, wrist, and hand. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Tendinous connections between the FDP and the FPL are a common anatomic anomaly, which have been linked to a condition causing chronic forearm pain, called Linburg syndrome,[34] although the association is by no means conclusive.[35]

Pronator Quadratus. The pronator quadratus arises from the anterior (ventral) surface and distal quarter of the ulna and inserts on the anterior (ventral) surface and distal quarter of the radius. The muscle functions to pronate the forearm, and it is innervated by the anterior interosseous branch of the median nerve. The pronator quadratus is well-designed biomechanically as an effective torque producer and a stabilizer of the DRUJ—its line of force is oriented almost perpendicular to the forearm's axis of rotation.[36]

Posterior Compartment of the Forearm

Superficial Muscles

Extensor Carpi Radialis Longus. The ECRL takes its origin at the supracondylar ridge of the humerus about 4–5 cm proximal to the epicondyle, and the thickest part of the muscle is proximal to the elbow joint. The ECRL inserts on the base of the second metacarpal and functions to extend and radially deviate the wrist. It also plays a role in elbow flexion, losing a part of its wrist action when the elbow is flexed.[23]

Extensor Carpi Radialis Brevis. The ECRB arises from the common extensor tendon on the lateral epicondyle of the humerus (see Chap. 17) and from the radial collateral ligament. It inserts on the posterior surface of the base of the third metacarpal bone and receives its nerve supply from the posterior interosseous branch of the radial nerve. The muscle stretches across the radial head during forearm pronation, resulting in increased tensile stress when the forearm is pronated, the wrist is flexed, and the elbow is extended. The more medial location of the ECRB compared to the ECRL makes it the primary wrist extensor, but it has also a slight action of radial deviation.

ED and EDM. The ED arises from the lateral humeral epicondyle, part of the common extensor tendon, while the EDM arises from a muscular slip from the ulnar aspect of the ED muscle. The ED inserts on the lateral and posterior (dorsal) aspect of the medial four digits, while the EDM inserts on the proximal phalanx of the fifth digit. Both muscles are innervated by the posterior interosseous branch of the radial nerve. While the ED functions to extend the medial four digits, the EDM extends the fifth digit.

Extensor Carpi Ulnaris. The ECU arises from the common extensor tendon on the lateral epicondyle of the humerus and the posterior border of the ulna. It inserts on the medial side of the base of the fifth metacarpal bone. It is innervated by the posterior interosseous branch of the radial nerve. The ECU is

an extensor of the wrist in supination and primarily causes ulnar deviation of the wrist in pronation, working in synergy with the FCU to prevent radial deviation during pronation.[23]

Extension of the wrist is dependent on three muscles:

- ECRL
- ECRB
- ECU

The ECRB and ECRL are commonly considered to be similar muscles, but in fact they differ in many respects and have very different moment arms of extension.[37] The ECRB, because of its origin on the epicondyle, is not affected by the position of the elbow, so that all of its action is on the wrist, making it the most effective extensor of the wrist (because it has the greatest tension and the most favorable moment arm).[23] Taken together, both ECR tendons comprise about 10 percent of the muscle mass of the forearm and 76 percent of the muscle mass of the extensors of the wrist.[38] The ECRL has longer muscular fibers, mostly at the level of the elbow. The ECRL only becomes a wrist extensor after radial deviation is balanced against the ulnar forces of the ECU.

The ECU, the antagonist of EPL, has the weakest moment of extension, which becomes zero when the wrist is in complete pronation.

Deep Muscles

Abductor Pollicis Longus. The APL arises from the posterior (dorsal) surface of the proximal portion of the radius, ulna, and interosseous membrane and inserts on the ventral surface of the base of the first metacarpal. The APL is innervated by the posterior interosseous branch of the radial nerve and functions in abduction, extension, and external rotation of the first metacarpal.

Extensor Pollicis Brevis. The EPB arises from the posterior (dorsal) surface of the radius and interosseous membrane, just distal to the origin of the APL. It inserts on the posterior (dorsal) surface of the proximal phalanx of the thumb via the extensor expansion. The EPB is innervated by the posterior interosseous branch of the radial nerve and functions to extend the proximal phalanx of the thumb.

Extensor Pollicis Longus. The EPL arises from the posterior (dorsal) surface of the midportion of the ulna and interosseous membrane. It inserts on the posterior (dorsal) surface of the distal phalanx of the thumb via the extensor expansion. The EPL is innervated by the posterior interosseous branch of the radial nerve. It functions in extension of the distal phalanx of the thumb and is thus involved in extension of the middle phalanx and the MCP joint of the thumb.

Extensor Indicis. The EI arises from the posterior (dorsal) surface of the ulna, distal to the other deep muscles, and inserts on the extensor expansion of the index finger. It is innervated by the posterior interosseous branch of the radial nerve and is involved in extension of the proximal phalanx of the index finger.

Muscles of the Hand

The muscles of the hand (Fig. 18-11) are those that originate and insert within the hand and are responsible for fine finger movements.

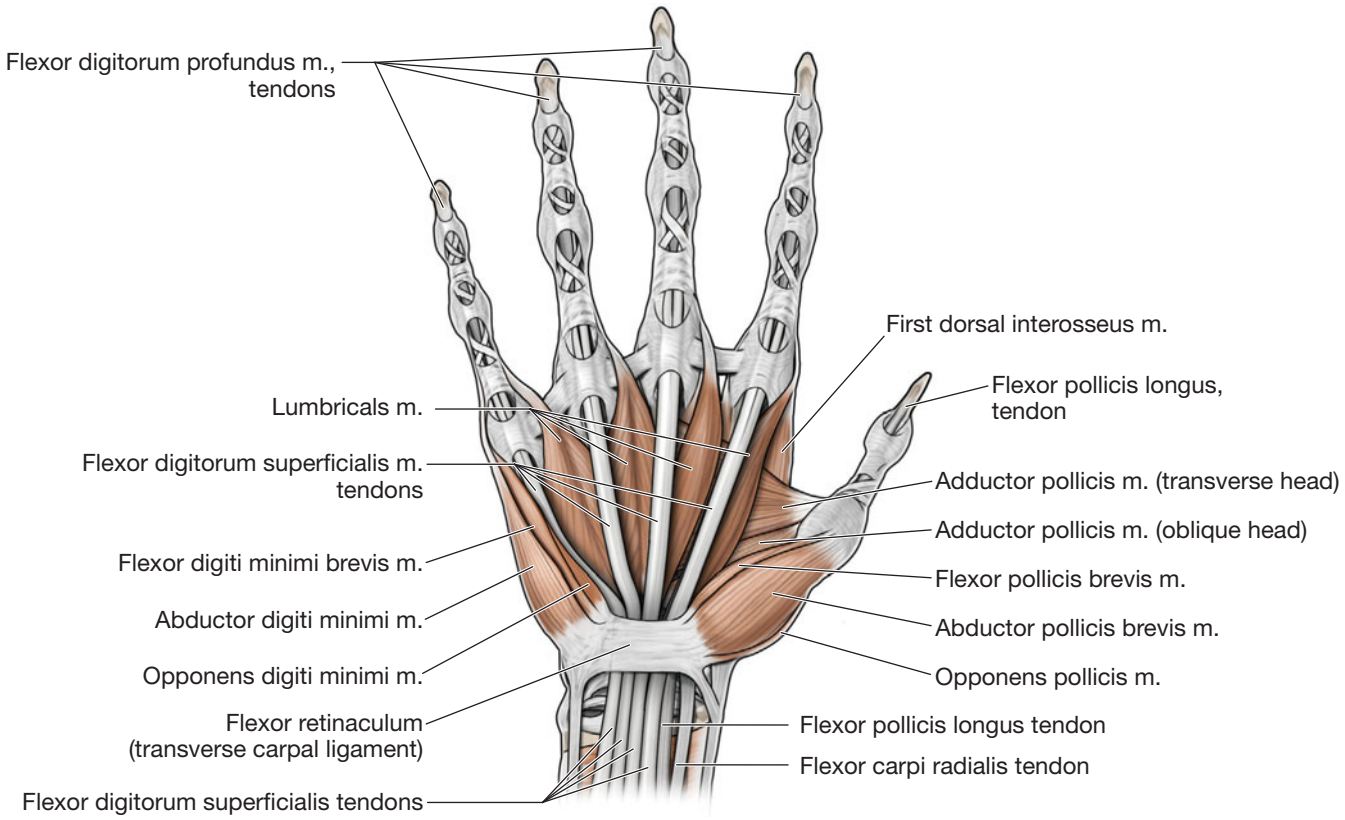

FIGURE 18-11 Muscles of the hand. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Short Muscles of the Thumb

Abductor Pollicis Brevis. The APB arises from the flexor retinaculum and the trapezium bone and inserts on the radial aspect of the proximal phalanx of the thumb. It is innervated by the median nerve and functions to abduct the first metacarpal and proximal phalanx of the thumb.

Flexor Pollicis Brevis. The FPB arises from two heads. The superficial head arises from the flexor retinaculum and the trapezium bone, while the deep head arises from the floor of the carpal canal. The FPB inserts on the base of the proximal phalanx of the thumb. The superficial head receives its innervation from the median nerve, while the deep head is innervated by the ulnar nerve. The FPB functions to flex the proximal phalanx of the thumb.

Opponens Pollicis. The OP arises from the flexor retinaculum and the trapezium bone and inserts along the radial surface of the first metacarpal. The OP is innervated by the median nerve and functions to flex, rotate, and slightly abduct the first metacarpal across the palm to allow for opposition with each of the other digits.

Adductor Pollicis (AP). The AP arises from two heads. The transverse head originates from the ventral surface of the shaft of the third metacarpal, while the oblique head originates from the trapezium, trapezoid, and capitate bones, and the base of the second and third metacarpal bone. The AP inserts on the ulnar side of the base of the proximal phalanx of the thumb and is innervated by the deep branch of the ulnar nerve. The AP functions to adduct the thumb and aids in thumb opposition.

Short Muscles of the Fifth Digit

Abductor Digiti Minimi. The ADM arises from the pisiform bone and the tendon of the FCU. It inserts on the ulnar aspect of the base of the proximal phalanx of the fifth digit, together with the flexor digiti minimi (FDM) brevis. It is innervated by the deep branch of the ulnar nerve and functions to abduct the fifth digit.

Flexor Digiti Minimi. The FDM originates from the flexor retinaculum and the hook of the hamate bone. It inserts on the ulnar aspect of the base of the proximal phalanx of the fifth digit, together with the ADM. It is innervated by the deep branch of the ulnar nerve and functions to flex the proximal phalanx of the fifth digit.

Deep branches of the ulnar artery and nerve enter the thenar mass and course into the deep region of the hand by passing between the ADM and the FDM.

Opponens Digiti Minimi (ODM). The ODM arises from the flexor retinaculum and the hook of the hamate bone and inserts on the ulnar border of the shaft of the fifth metacarpal bone. It is innervated by the deep branch of the ulnar nerve and functions to provide a small amount of flexion and external rotation of the fifth digit.

Interosseous Muscles of the Hand

The interossei muscles of the hand are divided by anatomy and function into anterior (palmar) and posterior (dorsal) interossei.

Anterior (palmar) Interossei. The three anterior (palmar) interossei have a variety of origins and insertions. The first interosseus originates from the ulnar surface of the second metacarpal bone and inserts on the ulnar side of the proximal phalanx of the second digit. The second anterior (palmar) interosseus arises from the radial side of the fourth metacarpal bone and inserts into the radial side of the proximal phalanx of the fourth digit. The third anterior (palmar) interosseus originates from the radial side of the fifth metacarpal bone and inserts into the radial side of the proximal phalanx of the fifth digit. The anterior (palmar) interossei are innervated by the deep branch of the ulnar nerve, and each muscle functions to adduct the digit to which it is attached toward the middle digit. The anterior (palmar) interossei also function to extend the distal and then the middle phalanges.

Posterior (dorsal) Interossei. The four posterior (dorsal) interossei have a similar varied origin and insertion as their anterior (palmar) counterparts. The posterior (dorsal) interossei originate via two heads from adjacent sides of the metacarpal bones. The first posterior (dorsal) interosseus muscle inserts into the radial side of the proximal phalanx of the second digit. The second inserts into the radial side of the proximal phalanx of the third digit. The third inserts into the ulnar side of the proximal phalanx of the third digit and the fourth inserts into the ulnar side of the proximal phalanx of the fourth digit. The posterior (dorsal) interossei receive their innervation from the deep branch of the ulnar nerve. The posterior (dorsal) interossei abduct the index, middle, and ring fingers from the midline of the hand.

Lumbricals

The lumbrical muscles are usually four small intrinsic muscles of the hand that originate from the FDP tendons and insert into the posterior (dorsal) hood apparatus. Occasionally, more than four lumbricals are found in one hand.[39]

During contraction, they pull the FDP tendons distally, thus possessing the unique ability to relax their own antagonist.[6] They function to perform the motion of IP joint extension with the MCP joint held in extension and can assist in MCP flexion.[23]

The lumbrical muscles also serve an important role in the proprioception of the hand, providing feedback about the position and movement of the hand and finger joints.[6]

In instances of lumbrical spasm or contracture, attempts to flex the fingers via the profundus result in transmission of force through the lumbricals into the extensor apparatus, producing extension rather than flexion.[6] A "lumbrical plus" deformity occurs if there is excessive lumbrical force or if there is imbalance of opposing forces, which produces exaggerated lumbrical action (i.e., MCP joint flexion and IP joint extension).[6]

The lumbricals have dual innervation. Lumbricals I and II are innervated typically by the median nerve, while the third and fourth lumbricals are innervated by the ulnar nerve.

Neurology

The three peripheral nerves that supply the skin and muscles of the wrist and hand include the median, ulnar, and radial nerves (Fig. 18-12).

Median Nerve

The median nerve enters the forearm by coursing anteriorly through the medial aspect of the cubital fossa and passing deep

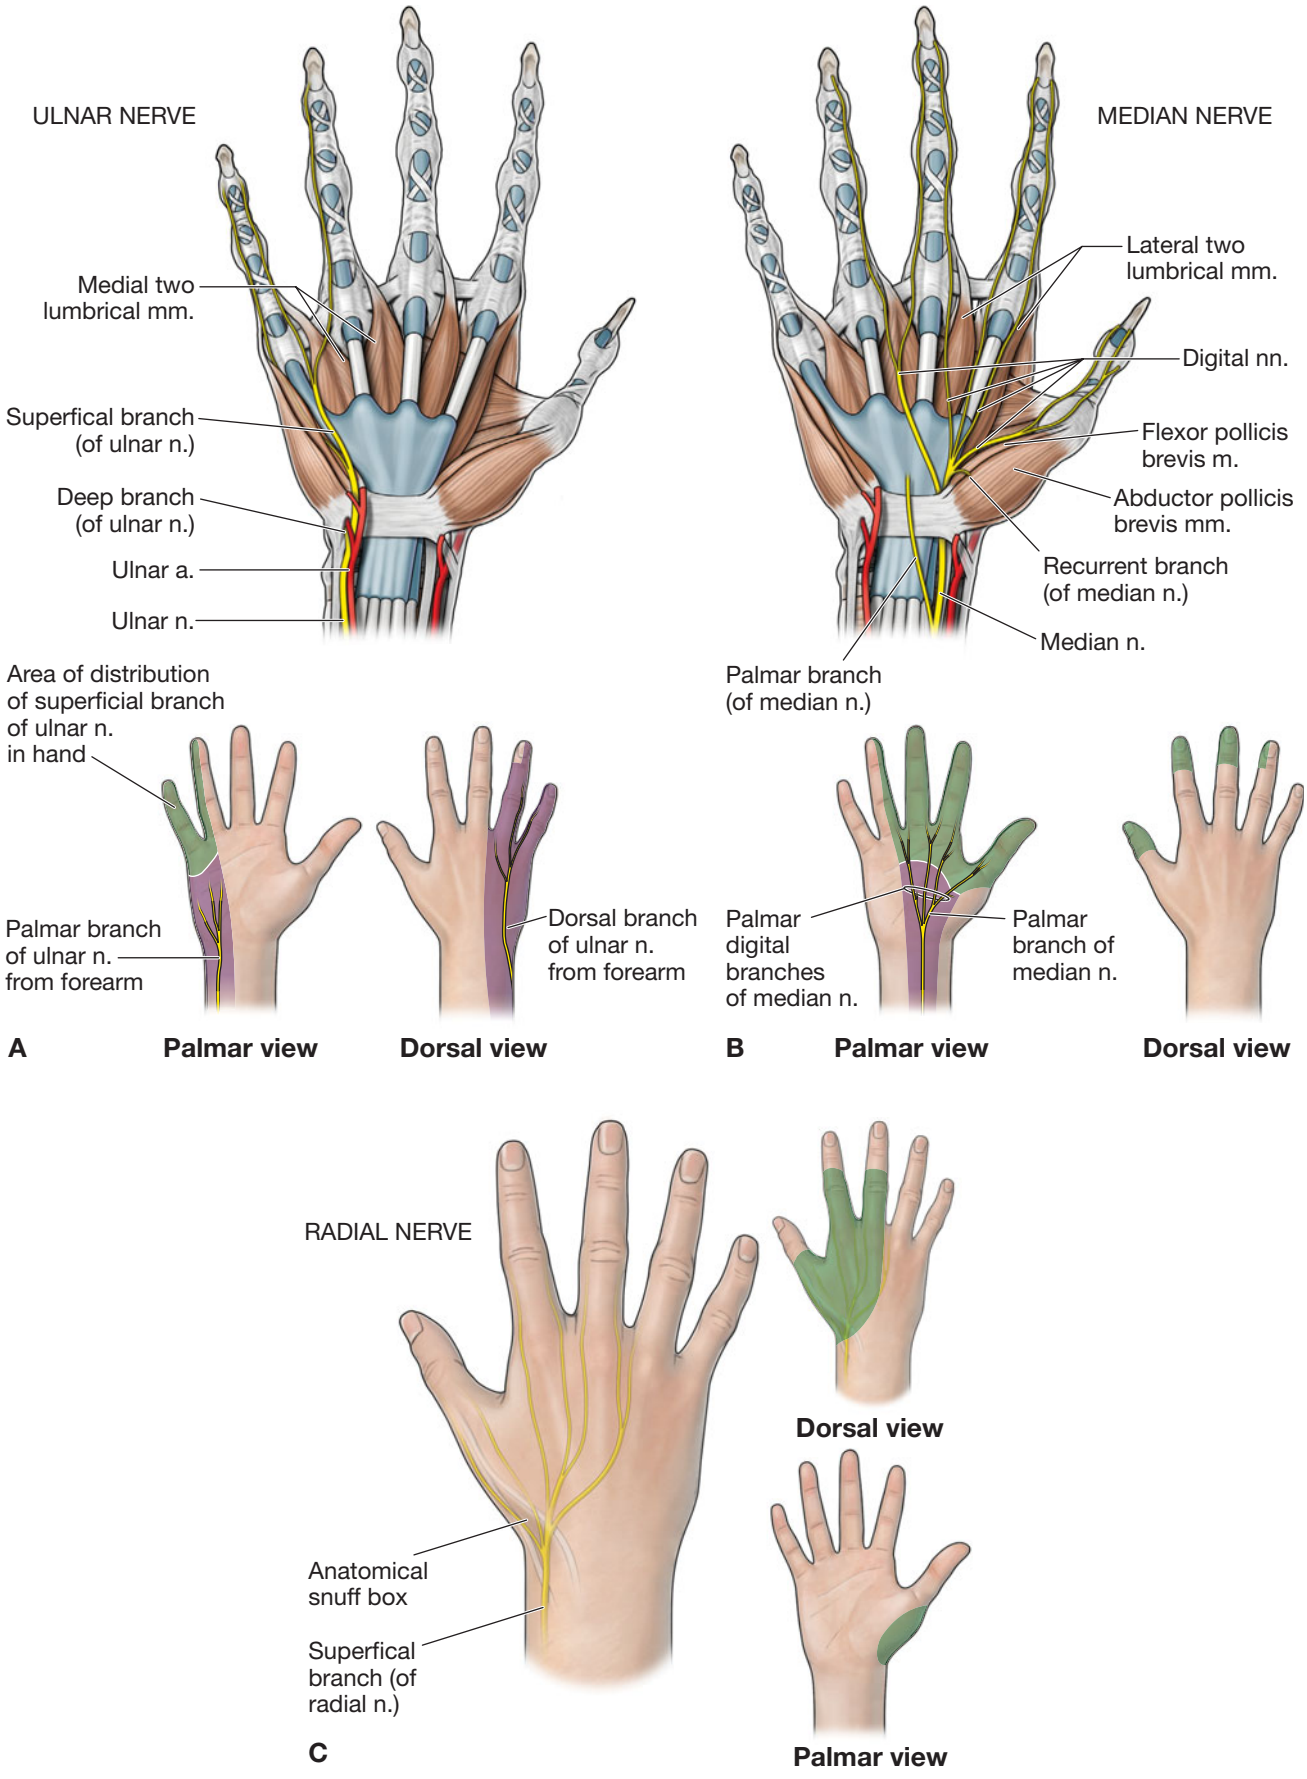

FIGURE 18-12 Nerves of the hand. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

to the lacertus fibrosis, between the heads of the pronator teres muscle. Below the elbow, muscular branches leave the nerve and innervate the FCR, palmaris longus, and pronator teres muscles. The anterior interosseous branch innervates the pronator quadratus, FPL, and the FDP to the index finger and middle fingers and sometimes the ring finger.

Approximately 8 cm proximal to the wrist, the median nerve gives off a sensory branch, the anterior (palmar) cutaneous nerve that passes superficial to the flexor retinaculum and remains outside the carpal tunnel. This nerve innervates the skin in the central aspect of the palm, over the thenar eminence. The rest of the median nerve passes distally to the wrist, where it enters the carpal tunnel, which passes deep to the flexor retinaculum.

The nerve enters the hand through the carpal tunnel, deep to the tendon of the palmaris longus and in between the tendons of the FPL and FDS (the more radial of the two). From this point, the nerve divides into two branches: a motor branch which passes posterior (dorsal) to the flexor retinaculum and a sensory branch.

Motor Branch. This short branch enters the thenar eminence, where it usually supplies the APB and OP muscles, the FPB (occasionally), and the first and second lumbrical muscles.

Sensory Branch. The sensory anterior (palmar) digital branch innervates the anterior (palmar) surface and posterior (dorsal) aspect of the distal phalanges of the thumb, second and third fingers, and the radial half of the forefinger.

A number of median nerve entrapment syndromes exist (refer to "Peripheral Nerve Entrapment"), each with their own clinical features and functional implications. For example, entrapment of the median nerve in the carpal tunnel may result in numbness, pain, or paresthesia of the fingers and thumb and may severely hinder a patient's ability to perform precision maneuvers due to loss of critical sensory and motor function in the thumb, index, and middle fingers.

Ulnar Nerve

The ulnar nerve has been referred to as the nerve of fine movements of the hand. The ulnar nerve originates from the inferior roots of the brachial plexus (C 8–T 1). Two branches of the ulnar nerve arise in the midforearm:

1. ***The anterior (palmar) cutaneous branch.*** The anterior (palmar) cutaneous branch supplies a portion of the skin over the hypothenar eminence.
2. ***The posterior (dorsal) cutaneous branch.*** About 8–10 cm proximal to the ulnar styloid process, the posterior (dorsal) cutaneous branch of the ulnar nerve splits from the main trunk. The posterior (dorsal) cutaneous branch terminates into two posterior (dorsal) digital branches that supply sensation to the posterior (dorsal) and ulnar aspect of the middle phalanx of the ring and little fingers.[40]

Before reaching the wrist, the ulnar nerve branches to innervate the FDP and the FCU.

At the wrist, the ulnar nerve emerges just lateral to the tendon of the FCU as it passes superficial to the flexor retinaculum. The ulnar nerve passes into the hand via the tunnel of Guyon, where it divides into its superficial and deep terminal branches. The deep (motor) branch supplies the FDM, ADM, ODM, AP, palmaris brevis, third and fourth lumbricals, deep head of the FPB, and the interossei. The superficial branch, which is primarily sensory with the exception of its innervation to the palmaris brevis, divides into three branches.[40] The first of these three branches is a sensory branch to the ulnar aspect of the little finger, and the second is a sensory branch to the central ulnar anterior (palmar) area. The third branch, often referred to as the common digital nerve, innervates the fourth intermetacarpal space. The common digital nerve further divides into two proper digital nerves supplying the ulnar portion of the ring finger and the radial portion of the little finger.[40]

A number of ulnar nerve entrapment syndromes exist (refer to "Peripheral Nerve Entrapment"), each with their own clinical features and functional implications.

Radial Nerve

As the radial nerve enters the cubital fossa, it typically splits into a superficial and deep branch. The superficial branch typically courses distally along the lateral border of the forearm under cover of the brachioradialis muscle and tendon. At the wrist this branch divides into four to five digital branches, which provide cutaneous and articular innervation. The cutaneous innervation includes the lateral two-thirds of the dorsum of the hand and the posterior (dorsal) lateral 2 1/2 fingers to the proximal phalanx.

All of the motor branches of the radial nerve are located in the forearm. The deep branch (posterior interosseous nerve) typically penetrates the anterior (ventral) surface of, and passes through, the supinator muscle. It reaches the deep region of the posterior forearm by passing through the arcade of Fröhse. The nerve courses subcutaneously from the midportion of the forearm to an area adjacent to the styloid process of the radius and terminates on the posterior aspect of the wrist.

CLINICAL PEARL

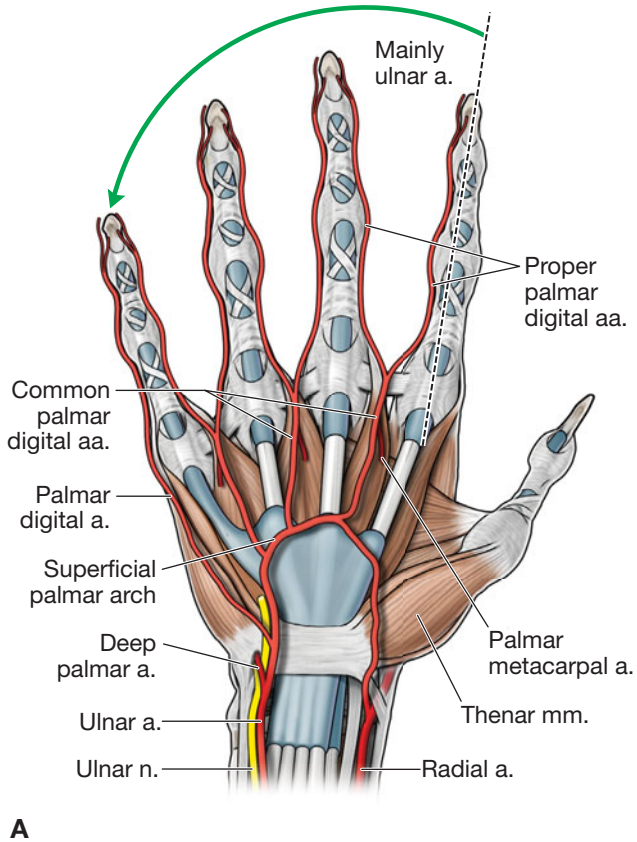
Radial nerve entrapment (refer to "Peripheral Nerve Entrapment") may result in a loss of extension at the wrist and MCP joints of the fingers, and thumb extension and abduction. Since the wrist extensor muscles are synergists and stabilizers for the finger flexor muscles during gripping, this loss can significantly hamper hand function.

Vasculature of the Wrist and Hand

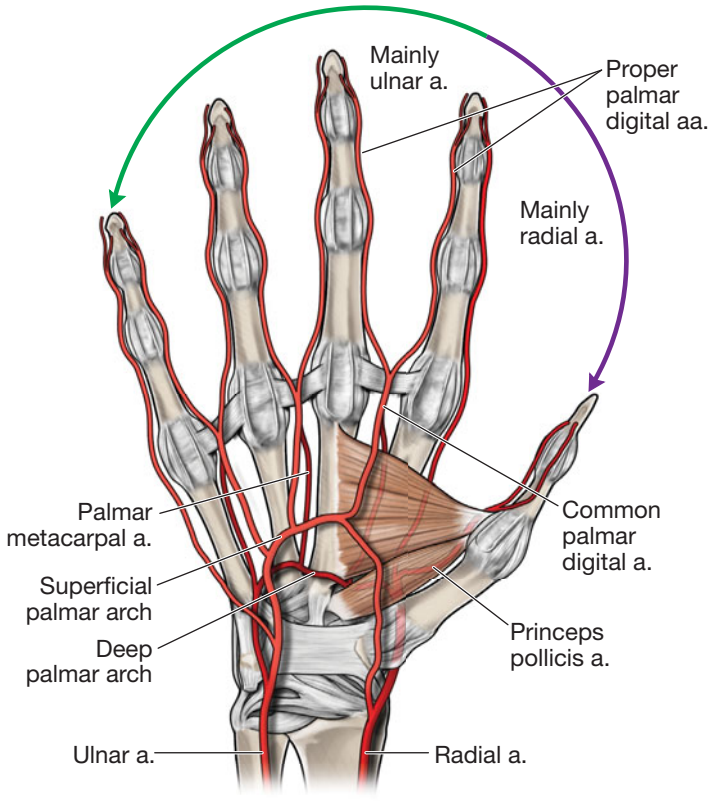
The brachial artery bifurcates at the elbow into radial and ulnar branches, which are the main arterial branches to the hand (Fig. 18-13).

Radial Artery

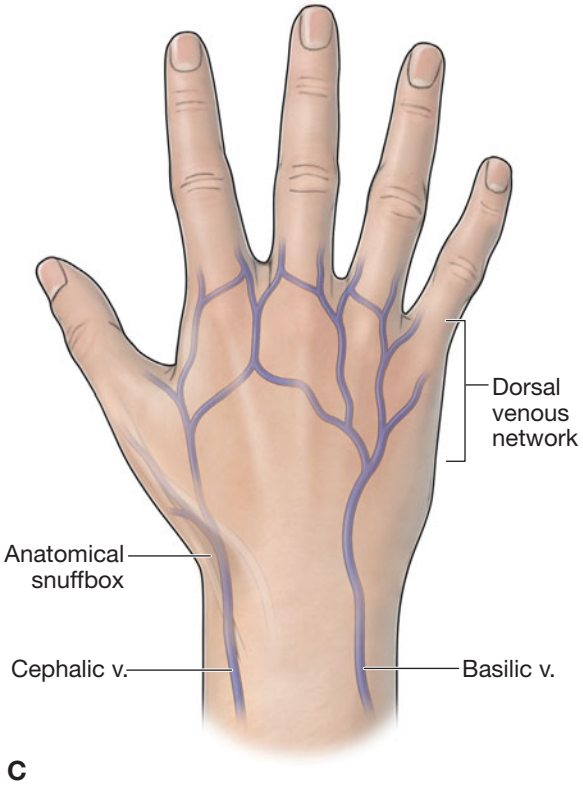
The radial artery is formed from the lateral branch of the bifurcation of the brachial artery. The artery gives off branches in the proximal portion of the forearm that form an anastomosis around the elbow joint. It runs distally under the cover of the brachioradialis muscle. Just proximal to the wrist, it is located between the brachioradialis and the FCR tendons. A small branch called the superficial anterior (palmar) artery leaves the radial artery 5–8 mm proximal to the tip of the radial



A



B



C

FIGURE 18-13 Vascular supply to the hand. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

styloid, passes between the FCR and the brachioradialis, and continues distally to contribute to the superficial anterior (palmar) arch, which supplies the thenar mass. The radial artery has seven major carpal branches: three posterior (dorsal), three anterior (palmar), and a final branch that continues distally (see below).

Ulnar Artery

The ulnar artery originates as the medial branch from the bifurcation of the brachial artery. It too gives off branches in the proximal portion of the forearm that form an anastomosis around the elbow joint. The artery passes posterior (dorsal) to the ulnar head of the pronator teres and courses distally deep to the FDS, at which point it passes in the groove between the FCU and FDP, in the company of the ulnar nerve. In the proximal portion of the forearm, the artery gives off a common interosseous branch. The artery bifurcates, giving rise to the anterior and posterior interosseous arteries, which provide blood to structures in the deep anterior and posterior compartments of the forearm. The artery emerges at the wrist, just lateral to the tendon of the FCU. It then passes through the tunnel of Guyon and enters the superficial compartment of the hand. At the level of the carpus, the ulnar artery gives off a latticework of fine vessels that span the posterior (dorsal) and anterior (palmar) aspects of the medial carpals. Proximal to the end of the ulna, there are three branches: a branch to the posterior (dorsal) radiocarpal arch, one to the anterior (palmar) radiocarpal arch, and one to the proximal pole of the pisiform and to the anterior (palmar) aspect of the triquetrum.[41]

Vascular Arches of the Hand

Posterior (dorsal) Arches. The posterior (dorsal) arches are connected longitudinally at their medial and lateral aspects by the ulnar and radial arteries. They are connected centrally by the posterior (dorsal) branch of the anterior interosseous artery. There are three posterior (dorsal) transverse arches: the radiocarpal, the intercarpal, and the basal metacarpal[41]:

- ***Posterior (dorsal) radiocarpal.*** The radiocarpal arch is supplied by branches of the radial and ulnar arteries and the posterior (dorsal) branch of the anterior interosseous artery.
- ***Posterior (dorsal) intercarpal.*** The posterior (dorsal) intercarpal arch has a variable supply, which can include the radial, ulnar, and anterior interosseous arteries.
- ***Basal metacarpal.*** The basal metacarpal arch is supplied by perforating arteries from the second, third, and fourth interosseous spaces. It contributes to the vascularity of the distal carpal row through anastomoses with the intercarpal arch.

Anterior (palmar) Arches. Similar to the posterior (dorsal) vascularity, the anterior (palmar) vascularity is composed of three transverse arches: the anterior (palmar) radiocarpal, the anterior (palmar) intercarpal, and the deep anterior (palmar) arch[41]:

- ***Anterior (palmar) radiocarpal.*** This arch supplies the anterior (palmar) surface of the lunate and triquetrum.
- ***Anterior (palmar) intercarpal.*** This arch is small and is not a major contributor of nutrient vessels to the carpals.
- ***Deep anterior (palmar).*** This arch contributes to the radial and ulnar recurrent arteries and sends perforating branches to the posterior (dorsal) basal metacarpal arch and to the anterior (palmar) metacarpal arteries.

BIOMECHANICS

The wrist is the key joint of the hand and contains several segments whose combined movements create a total range of motion that is greater than the sum of its individual parts.[23] The osteokinematics of the wrist are limited to two degrees of freedom: flexion–extension and ulnar–radial deviation (Fig. 18-14). Wrist circumduction—a full circular motion made by the wrist—is a combination of these movements.[42] The apparent axial rotation of the palm—called pronation and supination—occurs at the proximal and DRUJs, with the hand moving with the radius, not separately from it.[42]

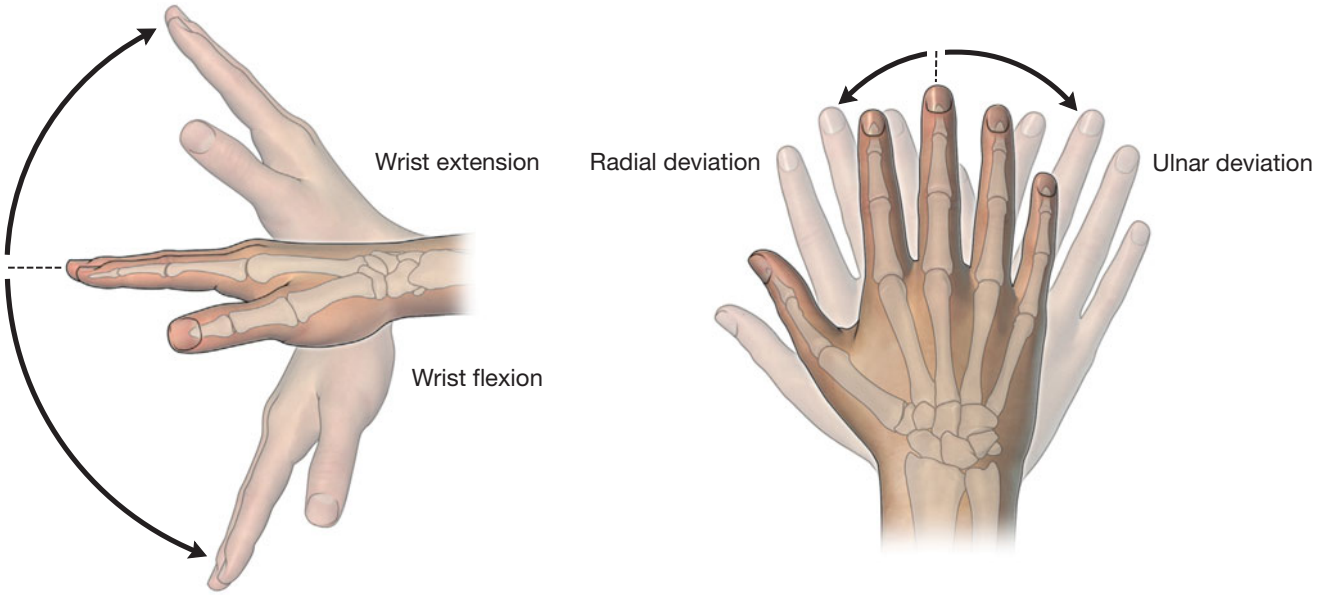


FIGURE 18-14 Movements of the wrist. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Pronation and Supination

The true axis for pronation–supination at the wrist may be situated anywhere between the radial and ulnar styloid, resulting in not one, but many pronation–supination axes.[43,44]

- Approximately 75–90 degrees of forearm pronation is available. During pronation, the concave ulnar notch of the radius glides around the peripheral surface of the relatively fixed convex ulnar head. Pronation is limited by the bony impaction between the radius and the ulna.
- Approximately 85–90 degrees of forearm supination is available. Supination is limited by the interosseous membrane and the bony impaction between the ulnar notch of the radius and the ulnar styloid process.

Congruency of the DRUJ surfaces is maximal at midrange of motion, although the joint is not considered to be truly locked in this position.[6] At this position, the TFCC is maximally stretched and the interosseous membrane is relatively lax.

The proximal and DRUJs are intimately related biomechanically, with the function and stability of both joints dependent on the configuration of, and distance between, the two bones. This configuration and distance maintains ligament and muscle tension.[45] A change in the length of the ulna of as little as 2 mm results in a change in the transmission of forces of 5–40 percent.[46]

Movement of the Hand on the Forearm

Due to the morphology of the wrist, movement at this joint complex involves a coordinated interaction between a number of articulations. These include the radiocarpal joint, the proximal row of carpals, and the distal row of carpals. All of these joints permit motion to occur around two axes: anterior–posterior in flexion–extension, and transverse in radial and ulnar deviation. Wrist extension is accompanied by a slight radial deviation and pronation of the forearm. Wrist flexion is accompanied by a slight ulnar deviation and supination of the forearm.

A number of concepts have been proposed over the years to explain the biomechanics of wrist motion.[47–60] The essential kinematics of the sagittal plane involve the mechanism of the carpal bone motions related to the central column of the wrist formed by the series of articulations among the radius, lunate, capitate, and third metacarpal bone.[42] Within this concept

- the radiocarpal joint is represented by the articulation between the radius and lunate composed of the radius, scaphoid, trapezoid, trapezium, and the column of the thumb;
- the CMC joint is assumed to be a rigid articulation between the capitate and the base of the third metacarpal;
- The ulnar or medial compartment of the midcarpal joint is represented by the articulation between the lunate and capitate. This column strongly supports the movements in the central column, while simultaneously anchoring the wrist to the radius.[48]

Under the column concept, the radial and ulnar columns are proposed to move with the central column due to mutual displacements between the proximal facets of the scaphoid and lunate. In addition, the proximal carpals are considered to move at the radiocarpal and midcarpal levels.[23,49]

Flexion and Extension Movements of the Wrist

The movements of flexion and extension of the wrist are shared between the radiocarpal articulation and the intercarpal articulation in varying proportions.[19] The arthrokinematics are based on synchronous convex-on-concave rotations at the radiocarpal and midcarpal joints.[42]

- During wrist extension, most of the motion occurs at the radiocarpal joint (66.5 percent or 40 degrees versus 33.5 percent or 20 degrees at the midcarpal joint) and is accompanied with slight radial deviation and pronation of the forearm.[19]
- During wrist flexion, most of the motion occurs in the midcarpal joint (60 percent or 40 degrees, versus 40 percent or 30 degrees at the radiocarpal joint) and is accompanied with slight ulnar deviation and supination of the forearm.[19]

Extension

At the radiocarpal joint, extension occurs as the convex surface of the lunate rolls posteriorly (dorsally) on the radius and simultaneously slides anteriorly (palmarly).[42] Rotation directs the lunate's distal surface in an extended, posterior (dorsal) direction. At the midcarpal joint, the head of the capitate rolls posteriorly (dorsally) on the lunate and simultaneously slides in an anterior (palmar) direction.[42] When the wrist is extended, the radiolunotriquetral and radiocapitate ligaments are stretched and tension develops within the wrist and finger flexor muscles. Tension within the structures stabilizes the wrist in its close-packed position of extension.[42,61,62]

Loss of active extension in the wrist constitutes a considerable functional impairment, including the following[23]:

- A reduction in grip strength.
- Changes in muscle length-tension relationships, which has serious implications when considering the action of the extrinsic muscles of the hand. For example, the strength of the thumb and finger flexors requires normal motion and function of wrist extension.

Flexion

The arthrokinematics of wrist flexion are similar to those described in extension, but occurs in a reverse fashion.

Frontal Lateral Movements of the Wrist

Like flexion and extension, the movements of ulna and radial deviation of the wrist are shared between the radiocarpal articulation and the intercarpal articulation in varying proportions (Fig. 18-15).[19] The amount of deviation is approximately 40 degrees of ulnar deviation and 15 degrees of radial deviation. There is a physiological ulnar deviation at rest, which is easily demonstrated clinically and radiographically.

Ulnar Deviation

Ulnar deviation occurs primarily at the radiocarpal joint.[62] When the hand is observed at rest, there is a physiological ulnar deviation. During ulnar deviation, the radiocarpal and midcarpal joints contribute fairly equally to the overall

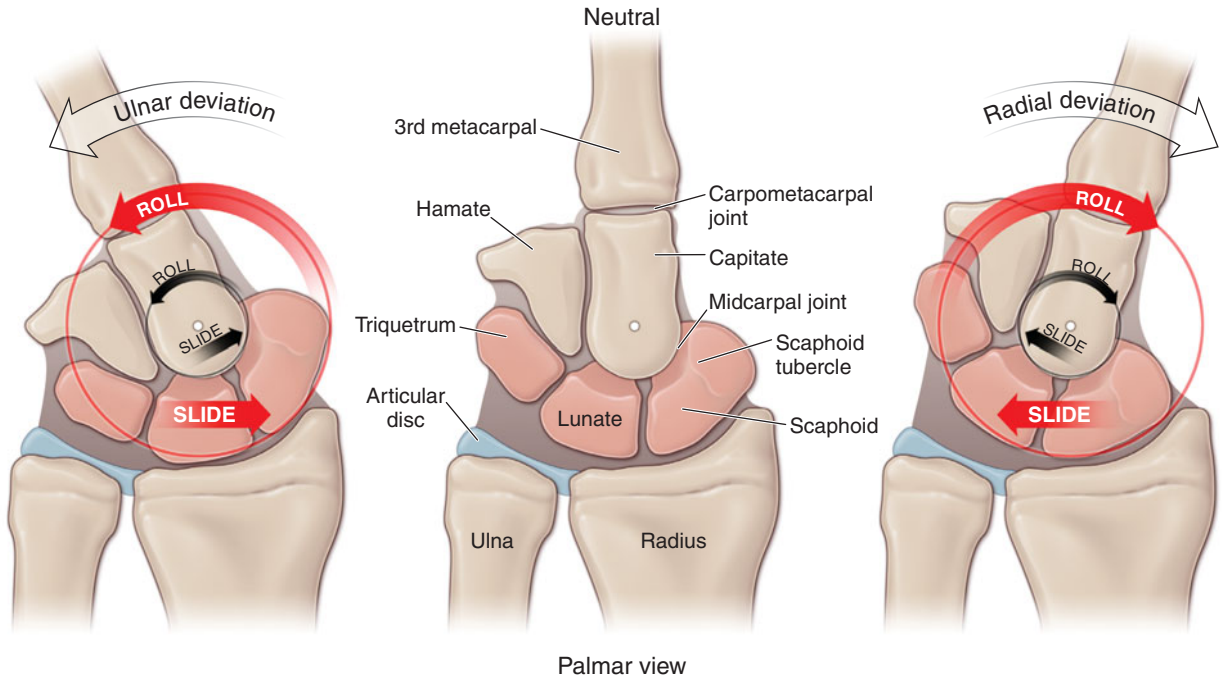

FIGURE 18-15 A model of the central column of the right wrist showing ulnar and radial deviation.

motion (Fig. 18-15).[42] At the radiocarpal joint, the scaphoid, lunate, and triquetrum roll ulnarly and slide a significant distance radially.[42] Ulnar deviation of the midcarpal joint occurs primarily from the capitate rolling ulnarly and sliding slightly radially.[42] Ulnar deviation is limited by the radial collateral ligament.[62] Although ulnar deviation brings the triquetrum into contact with the TFCC, the lack of direct ulnar-triquetral articulation permits a greater range of ulnar deviation. The muscle with the best biomechanical advantage to produce ulnar deviation of the wrist in pronation is the ECU.[23]

Radial Deviation

Radial deviation at the wrist occurs through similar arthrokinematics as described for ulnar deviation (Fig. 18-15).[42] Radial deviation occurs primarily between the proximal and the distal rows of the carpal bones. The motion of radial deviation is limited by impact of the scaphoid onto the radial styloid and the UCL. The APL and EPB are best suited to produce radial deviation of the wrist.[23]

CLINICAL PEARL

Extension of the wrist is accompanied by radial deviation, and flexion of the wrist is accompanied by ulnar deviation. The wrist also allows relatively extensive traction and gliding accessory movements.

A number of studies have examined the necessary range of motion at the wrist to perform functional activities. These studies report that at least 5 degrees of wrist flexion, 35 degrees of wrist extension, 10 degrees of radial deviation, and 15 degrees of ulnar deviation are needed to perform common personal care activities comfortably.[63,64] Less motion is required for 90 percent of personal care activities: 5 degrees of flexion, 6 degrees of extension, 7 degrees of radial deviation, and 6 degrees of ulnar deviation.[65]

Wrist Movements and the Digits

The position of the wrist in flexion or extension influences the tension of the long or "extrinsic" muscles of the digits. The position of the wrist also has important repercussions on the position of the thumb and fingers. Neither the flexors nor the extensors of the fingers are long enough to allow maximal range of motion at the wrist and the fingers simultaneously.[23] In fact, due to the restraining action of the long antagonistic muscles, complete flexion of the fingers is possible only if the wrist is in approximately 20 degrees of extension, which corresponds to the optimal position for hand function.[23] Thus the movements of the wrist reinforce the action of the extrinsic muscles of the fingers, and are synergistic with the more powerful digital flexors. As the wrist position changes, the functional lengths of the digital flexor tendons change and the resultant forces in finger flexion vary. In order for grip to be effective and have maximal force, the wrist must be stable and positioned in slight extension and ulnar deviation.[23]

CLINICAL PEARL

Studies have evaluated the effect of wrist position on the force generated at the middle and distal phalanges and found that the greatest force is exerted in ulnar deviation and then extension, with the least force being generated in flexion.[66]

Articulations of the Fingers

There are notable differences between the IP and MCP articulations of the digits and even between the articulations at the same level for each digit.[23] These differences are produced by

- the shape of the articulations;
- the orientation of the articular surface;
- the synovial insertion;
- the disposition of the collateral ligaments;
- the degree of play in the volar plate.

These elements determine the degree of mobility and stability of these articulations and the orientation of the distal segments. As the thumb pulp pronates in opposition, the pulps of the fingers supinate in external rotation when the MCP joints flex, or when the index finger moves radially. These variations in orientation allow for optimal use of the finger pulps for functional tasks of the hand (see Functional Position of the Hand).[23]

CLINICAL PEARL

The goal of functional restoration for the MCP joint flexion is 75 degrees for the index finger and middle finger, 80 degrees for the ring finger, and 85 degrees for the little finger.[23]

Thumb Movements

The first CMC joint is a saddle joint. The characteristic feature of a saddle joint is that each articular surface is concave in one diameter and convex in the other. Within the first CMC joint, the longitudinal diameter of the articular surface of the trapezium is generally concave from an anterior (palmar) to posterior (dorsal) direction, while the transverse diameter is generally convex along a medial to lateral direction. The proximal articular surface of the first metacarpal is reciprocally shaped to that of the trapezium. This articular relationship produces the following (Fig. 18-16):

- Thumb flexion and extension occur around an anterior–posterior axis in the frontal plane that is perpendicular to the sagittal plane of finger flexion and extension. In this plane, the metacarpal surface is concave, and the trapezium surface is convex. Flexion is accompanied by a conjunct rotation of internal rotation of the metacarpal. Extension is accompanied bya conjunct rotation of external rotation of the metacarpal. A total range of 50–70 degrees is available.
- Thumb abduction and adduction occur around a medial–lateral axis in the sagittal plane that is perpendicular to the frontal plane of finger abduction and adduction. During thumb abduction and adduction, the convex metacarpal surface moves on the concave trapezium. Abduction is accompanied by a conjunct rotation of internal rotation. Adduction is accompanied bya conjunct rotation of external rotation. A total range of 40–60 degrees is available.
- Opposition of the thumb involves a wide arc motion comprising sequential anterior (palmar) abduction and flexion from the anatomic position, accompanied by internal rotation of the thumb. Retroposition of the thumb returns the thumb to its anatomic position, a motion that incorporates the elements of adduction with extension and external rotation of the metacarpal.

Normal Ulnar Inclination of the Fingers

A normal ulnar inclination of the fingers occurs at the MCP joints due to a number of factors[23]:

- Asymmetry of the metacarpal heads and the collateral ligaments.
- Tendon factors: the extrinsic tendons, extensors, and flexors cross into the hand on the ulnar side of the longitudinal axis of the MCP joint.
- Muscle factors: the intrinsic muscles have a predominantly ulnar inclination and predominate over those with a radial inclination.
- The physiologic action of the thumb, which in lateral grip pushes the fingers in an ulnar direction.

The inclination is most marked in the index finger, less in the middle and little fingers, and almost nonexistent in the ring finger. The ulnar inclination is normally limited by the capsuloligamentous resistance at the MCP joints and by the action of the interosseous muscles, which act in a radial direction.[23] The weakness of these stabilizing elements, particularly in rheumatoid arthritis (RA), allows the ulnar inclination to be accentuated, resulting in pathologic ulnar deviation.

Functional Position of the Hand

Grips

The grip is typically divided into following stages[67,68]:

- Opening of the hand.
- Positioning and closing of the fingers to grasp an object and adapt to the object's shape.

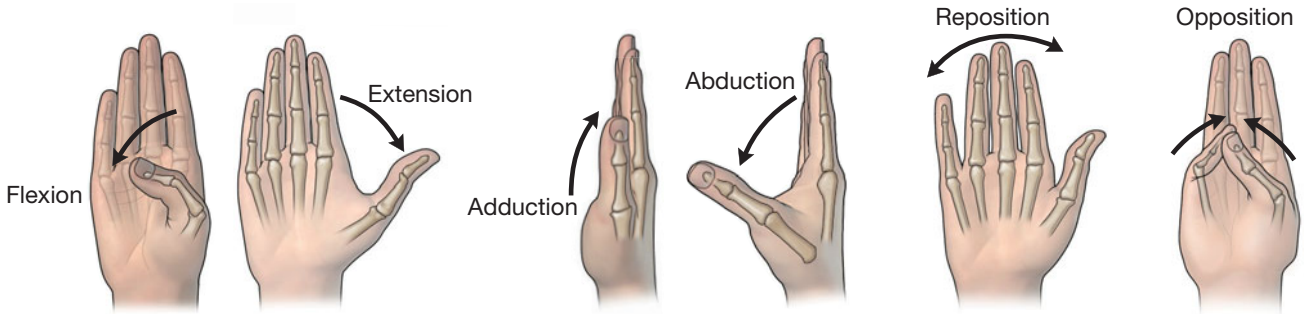

FIGURE 18-16 Thumb motions.

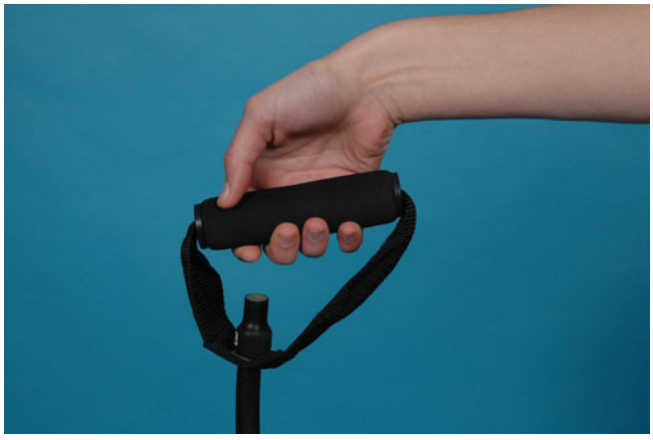

FIGURE 18-17 Hook grasp.

- Controlled approach and purposeful closing of the fingers and/or palm. The amount of force exerted is determined by the weight, surface characteristics, and fragility of the object.[69]
- Maintenance and stabilization of the grip. This phase is not used in precision tasks.
- The release of the object.

Two major types of grips have been recognized: power grip and the precision or prehension grip.

Power Grip. The power grip involves the use of force to stabilize an object in the hand. The strength and power of a grip comes from a combination of

- thumb adduction,
- isometric flexion,
- an approximation of the thenar and hypothenar eminences,
- intact function of the ulnar side of the hand.

The power grips include the following:

- ***Hook grasp.*** This grasp involves all or the second and third fingers (the IP joint only for the IP and MCP joints of the fingers) and is controlled by the forearm flexors and extensors (Fig. 18-17).
- ***Fist grasp.*** In this grasp the hand moves around a narrow object (Fig. 18-18)
- ***Cylindrical grasp.*** In this grasp, the thumb is used and the entire hand wraps around an object (Fig. 18-19)
- ***Spherical grasp.*** This grasp involves the hand moving around a spherical object as it moves into position (Fig. 18-20)

Participation of the intrinsic muscles follows specific patterns in the various power grips. For example,

- the hook grip involves the fourth posterior (dorsal) interosseus, fourth lumbrical, and the ADM;
- the spherical grip involves all of the interossei (except the second), the ADM, and the fourth lumbrical.[70,71]

Precision Grip. In the precision grip, the muscles primarily function to provide exact control of finger and thumb position, so the position of the handled object can be changed either in space or about its own axis.[67,71] Due to the higher levels of sensory input required during these tasks, the areas with the most sensory receptors are used. A number of precision grips are recognized[23,62]:

FIGURE 18-18 Fist grasp.

FIGURE 18-19 Cylindrical grasp.

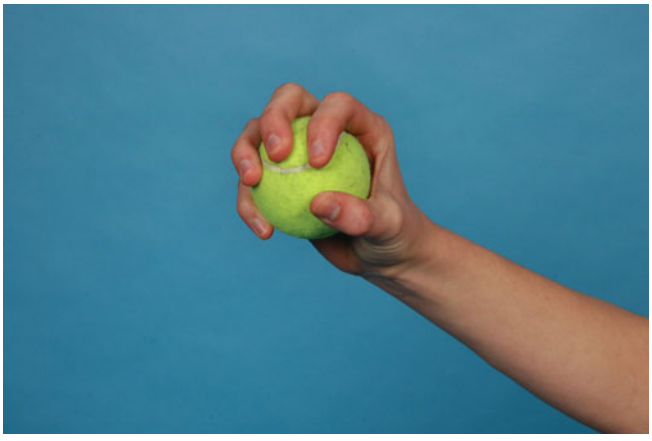

FIGURE 18-20 Spherical grasp.

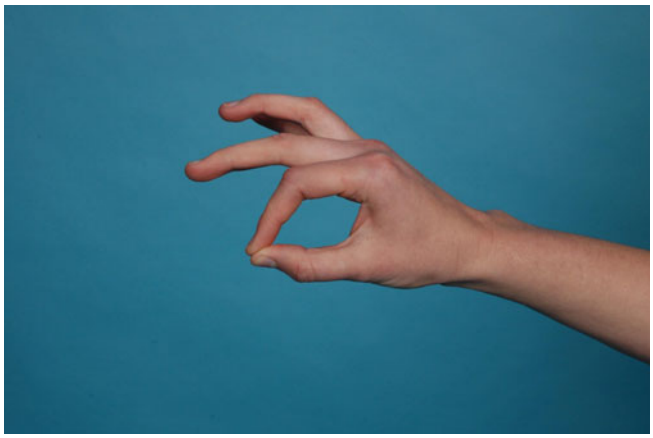

FIGURE 18-21 Pulp-to-pulp pinch prehension.

FIGURE 18-22 Lateral prehension.

- *Pulp-to-pulp pinch,* in which the pad of the thumb is opposed to the pad of one or more fingers (Fig. 18-21).
- *Lateral prehension,* where the anterior (palmar) aspect of the thumb presses against the radial aspect of the first phalanx of the index finger (Fig. 18-22).
- *Tip prehension,* in which the extreme tip of the thumb pad is opposed to the tip of the index or middle finger.
- *Three-fingered pinch* (thumb, index finger, and middle finger), as in sprinkling herbs, and multi-fingered pinch (Fig. 18-23).

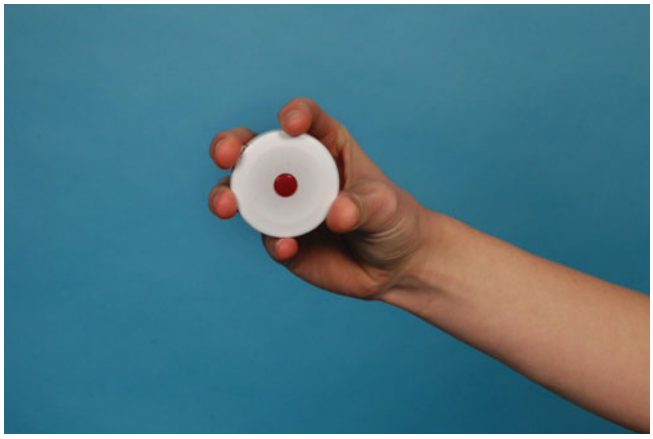

FIGURE 18-23 Multi-fingered pinch.

FIGURE 18-24 Five-fingered pinch.

- *Five-fingered pinch,* as in picking up a face towel (Fig. 18-24).

The radial side of the hand and the MCP joints are involved more in the precision or prehensile types of grips.[23,62]

Different grip patterns are used regularly during daily functional activities (Table 18-3).[1,72]

EXAMINATION

Elucidating the cause of forearm, wrist, and hand pain can be challenging. The examination must include all regions that may contribute to the symptoms of forearm, wrist, and hand pain or numbness. This requires a sound knowledge of differential diagnosis and often incorporates an examination of the entire upper kinetic chain, including the cervical and thoracic spine.

The common pathologies for the forearm, wrist, and hand and their interventions are detailed after the "Examination" section. An understanding of both is obviously necessary. As mention of the various pathologies occurs with reference to the tests and measures and vice versa, the reader is encouraged to switch between the two.

History

The assessment of the forearm, wrist, and hand begins by recording a detailed history to help focus the examination. All

TABLE 18-3 Estimated Use of Grips for Activities of Daily Living

Type of Grip	Estimated Use (%)
Pulp-to-pulp pinch	20
Lateral pinch	20
Five-fingered pinch	15
Fist grip	15
Cylinder grip	14
Three-fingered pinch	10
Spherical grip	4
Hook grip	2

Data from McPhee SD: Functional hand evaluations: a review. *Am J Occup Ther* 41:158–163, 1987.

relevant information must be gathered about the site, nature, behavior, and onset of the current symptoms. This should include information about the patient's age, hand dominance, avocational activities, and occupation.

CLINICAL PEARL

The non-neutral position of the hand is extension, flexion, or ulnar deviation.[73,74] Sustained non-neutral positions of the hand and wrist subject nerves to prolonged stretch and periods of high pressure.[75] In addition, these positions place muscles in inefficient length–tension relationships,[74] resulting in decreased transmission of contractile forces to the fingers.[74,76]

In addition to those questions covered in Chapter 4, the following questions should be asked:

- ***When did the symptoms occur?*** The date of injury is particularly important, especially as simple traumatic arthritis of the wrist does not last more than a few days if the wrist is rested.
- ***Was there a mechanism of injury?*** If the problem is trauma related, the clinician should ascertain the following:
  - The forces applied. For example, a rotational force applied to the wrist region may lead to a fracture of the radius and dislocation of the distal end of the ulna (Galeazzi fracture).
  - Where and when the injury occurred.
  - The position of the wrist and hand at the time of the trauma. For example, a fall on the outstretched hand (FOOSH) injury can lead to a lunate dislocation, Colles fracture, or scaphoid fracture.
  - Whether the environmental conditions were clean or dirty (if a wound is present).
  - Whether there was an accompanying "pop" or "click."
  - Whether swelling occurred.

If the problem is nontrauma related, the onset of pain or sensory change, swelling, or contracture should be ascertained.

- ***Are there any local areas of tenderness?*** Localized tenderness may indicate a carpal fracture, particularly of the scaphoid. Scaphoid fractures are associated with a load applied to the radial side of the palm when the wrist is in extreme extension,[77] and can be ongoing sources of pain and dysfunction (refer to "Intervention Strategies"). Pain along the radial aspect of the wrist and forearm is a common symptom for several pathoanatomical diagnoses, including de Quervain disease, intersection syndrome, intercarpal instabilities, scaphoid fracture, superficial radial neuritis, C6 cervical radiculitis/radiculopathy, and arthrosis of the first CMC, intercarpal, or radiocarpal joints.[78]
- ***How does the patient rate his or her pain?*** The patient's perception of their pain can be measured using a visual analog scale.
- ***What is the behavior of the symptoms?*** The clinician should note the sequence of symptoms, the level of functional impairment, the progression of symptoms, the time of day the symptoms are worse, and whether the symptoms appear to be posture related or work related. Knowledge of the past behavior of previous wrist, hand, and finger disorders and their interventions can help in assessing the nature and prognosis of the patient's current problem.
- ***Which hand is the dominant hand (DH) of the patient?*** Dysfunction of the DH can be very disabling, so inquiries concerning the functional demands of the patient must be made.

Systems Review

A complete review of the medical history and general health of the patient should be included along with a review of systems, and the presence of other orthopaedic, neurologic, or cardiopulmonary conditions. An upper quarter scanning examination is performed to provide an overview of the upper extremity, the direction for a more detailed examination, and to rule out referral from the cervical, thoracic, shoulder girdle, and elbow joints.

The clinician should be able to determine the suitability of the patient for physical therapy. All inflammatory conditions, whether infectious or not, are accompanied by diffuse pain or tenderness with movement. RA often affects this region with more severity and frequency than elsewhere. Therefore questions concerning other joint involvement and general debility must be asked. The presence of CTS, which is usually felt more at night, may also indicate RA.

If the clinician is concerned with any signs or symptoms of a visceral, vascular, neurogenic, psychogenic, spondylogenic, or systemic disorder that is out of the scope of physical therapy (see Chapter 5), the patient should be referred back to their physician.

Tests and Measures

Observation

The physical examination should begin with a general observation of the patient's posture—especially the cervical spine, the thoracic spine, and the position of the hand in relation to the body. For example, is the arm held against the chest in a protective manner, does the arm swing during the gait pattern, or does it just hang loosely? The patient's hands can be highly informative (Table 18-4). Although very subtle, the DH tends to be larger than the nondominant hand. The posture and alignment of the involved wrist and hand are examined. Wrist angulation into ulnar deviation increases shearing in the first posterior (dorsal) compartment. This angulation can predispose the patient to de Quervain syndrome (see "Intervention Strategies").[79] A prominence of the distal ulna may indicate DRUJ instability.[80] The posture of the hand should be analyzed. The clinician should observe how the patient appears to relate to the involved hand and if or how the patient attempts to use the hand.[11] The contour of the anterior (palmar) surface, including the arches, should be examined. If a finger

TABLE 18-4 Outline of Physical Findings of the Hand

Variations in size and shape of hand
- A. Large, blunt fingers (spade hand)
  - 1. Acromegaly
  - 2. Hurler disease (gargoylism)
- B. Gross irregularity of shape and size
  - 1. Paget disease of bone
  - 2. Maffucci syndrome
  - 3. Neurofibromatosis
- C. Spider fingers, slender palm (arachnodactyly)
  - 1. Hypopituitarism
  - 2. Eunuchism
  - 3. Ehlers–Danlos syndrome, pseudoxanthoma elasticum
  - 4. Tuberculosis
  - 5. Asthenic habitus
  - 6. Osteogenesis imperfecta
- D. Sausage-shaped phalanges
  - 1. Rickets (beading of joints)
  - 2. Granulomatous dactylitis (tuberculosis, syphilis)
- E. Spindliform joints (fingers)
  - 1. Early rheumatoid arthritis
  - 2. Systemic lupus erythematosus
  - 3. Psoriasis
  - 4. Rubella
  - 5. Boeck sarcoidosis
  - 6. Osteoarthritis
- F. Cone-shaped fingers
  - 1. Pituitary obesity
  - 2. Frohlich dystrophy
- G. Unilateral enlargement of hand
  - 1. Arteriovenous aneurysm
  - 2. Maffucci syndrome
- H. Square, dry hands
  - 1. Cretinism
  - 2. Myxedema
- I. Single, widened, flattened distal phalanx
  - 1. Sarcoidosis
- J. Shortened fourth and fifth metacarpals (bradymetacarpalism)
- K. Shortened, incurved fifth finger (symptom of DuBois)
  - 1. Mongolism
  - 2. Behavioral problem
  - 3. Gargoylism (broad, short, thick-skinned hand)
- L. Malposition and abduction, fifth finger
  - 1. Turner syndrome (gonadal dysgenesis, webbed neck, etc.)
- M. Syndactylism
  - 1. Congenital malformations of the heart, great vessels
  - 2. Multiple congenital deformities
  - 3. Laurence-Moon-Biedl syndrome
  - 4. In normal individuals as an inherited trait
- N. Clubbed fingers
  - 1. Subacute bacterial endocarditis
  - 2. Pulmonary causes
    - a. Tuberculosis
    - b. Pulmonary arteriovenous fistula
    - c. Pulmonic abscess
    - d. Pulmonic cysts
    - e. Bullous emphysema
    - f. Pulmonary hypertrophic osteoarthropathy
    - g. Bronchogenic carcinoma
  - 3. Alveolocapillary block
    - a. Interstitial pulmonary fibrosis
    - b. Sarcoidosis
    - c. Beryllium poisoning
    - d. Sclerodermatous lung
    - e. Asbestosis
    - f. Miliary tuberculosis
    - g. Alveolar cell carcinoma
  - 4. Cardiovascular causes
    - a. Patent ductus arteriosus
    - b. Tetralogy of Fallot
    - c. Taussig-Bing complex
    - d. Pulmonic stenosis
    - e. Ventricular septal defect
  - 5. Diarrheal states
    - a. Ulcerative colitis
    - b. Tuberculous enteritis
    - c. Sprue
    - d. Amebic dysentery
    - e. Bacillary dysentery
    - f. Parasitic infestation (gastrointestinal tract)
  - 6. Hepatic cirrhosis
  - 7. Myxedema
  - 8. Polycythemia
  - 9. Chronic urinary tract infections (upper and lower)
    - a. Chronic nephritis
  - 10. Hyperparathyroidism (telescopy of distal phalanx)
  - 11. Pachydermoperiostosis (syndrome of Touraine, Solente, and Gole)
- O. Joint disturbances
  - 1. Arthritides
    - a. Osteoarthritis
    - b. Rheumatoid arthritis
    - c. Systemic lupus erythematosus
    - d. Gout
    - e. Psoriasis
    - f. Sarcoidosis
    - g. Endocrinopathy (acromegaly)
    - h. Rheumatic fever
    - i. Reiter syndrome
    - j. Dermatomyositis
    - 2. Anaphylactic reaction-serum sickness
    - 3. Scleroderma

II. Edema of the hand
- A. Cardiac disease (congestive heart failure)
- B. Hepatic disease
- C. Renal disease
  - 1. Nephritis
  - 2. Nephrosis
- A. Hemiplegic hand
- B. Syringomyelia
- C. Superior vena caval syndrome
  - 1. Superior thoracic outlet tumor
  - 2. Mediastinal tumor or inflammation
  - 3. Pulmonary apex tumor
  - 4. Aneurysm
- A. Generalized anasarca, hypoproteinemia
- B. Postoperative lymphedema (radical breast amputation)
- C. Ischemic paralysis (cold, blue, swollen, numb)
- D. Lymphatic obstruction
  - 1. Lymphomatous masses in axilla
- A. Axillary mass
  - 1. Metastatic tumor, abscess, leukemia, Hodgkin disease
- A. Aneurysm of ascending or transverse aorta or of axillary artery
- B. Pressure on innominate or subclavian vessels
- C. Raynaud disease
- D. Myositis
- E. Cervical rib
- F. Trichiniasis
- G. Scalenus anticus syndrome

III. Neuromuscular effects
- A. Atrophy
  - 1. Painless
    - a. Amyotrophic lateral sclerosis
    - b. Charcot–Marie–Tooth peroneal atrophy
    - c. Syringomyelia (loss of heat, cold, and pain sensation)
    - d. Neural leprosy
  - 2. Painful
    - a. Peripheral nerve disease
  - 3. Radial nerve (wrist drop)
    - a. Lead poisoning, alcoholism, polyneuritis, trauma

(Continued)

TABLE 18-4 Outline of Physical Findings of the Hand *(Continued)*

- b. Diphtheria, polyarteritis, neurosyphilis, anterior poliomyelitis
- 4. Ulnar nerve (benediction palsy)
  - a. Polyneuritis, trauma
- 5. Median nerve (claw hand)
  - a. Carpal tunnel syndrome
- 6. Rheumatoid arthritis
- 7. Tenosynovitis at wrist
- 8. Amyloidosis
- 9. Gout
- 10. Plasmacytoma
- 11. Anaphylactic reaction
- 12. Menopause syndrome
- 13. Myxedema

B. Extrinsic pressure on the nerve (cervical, axillary, supraclavicular, or brachial)
- 1. Pancoast tumor (pulmonary apex)
- 2. Aneurysms of subclavian arteries, axillary vessels, or thoracic aorta
- 3. Costoclavicular syndrome
- 4. Superior thoracic outlet syndrome
- 5. Cervical rib
- 6. Degenerative arthritis of cervical spine
- 7. Herniation of cervical intervertebral disk

C. Shoulder–hand syndrome
- 1. Myocardial infarction
- 2. Pancoast tumor
- 3. Brain tumor
- 4. Intrathoracic neoplasms
- 5. Discogenic disease
- 6. Cervical spondylosis
- 7. Febrile panniculitis
- 8. Senility
- 9. Vascular occlusion
- 10. Hemiplegia
- 11. Osteoarthritis
- 12. Herpes zoster

D. Ischemic contractures (sensory loss in fingers)
- 1. Tight plaster cast applications

E. Polyarteritis nodosa

F. Polyneuritis
- 1. Carcinoma of lung
- 2. Hodgkin disease
- 3. Pregnancy
- 4. Gastric carcinoma
- 5. Reticuloses
- 6. Diabetes mellitus
- 7. Chemical neuritis
  - a. Antimony, benzene, bismuth, carbon tetrachloride, heavy metals, alcohol, arsenic lead, gold, emetine
- 8. Ischemic neuropathy
- 9. Vitamin B deficiency
- 10. Atheromata
- 11. Arteriosclerosis
- 12. Embolic

G. Carpodigital (carpopedal spasm) tetany
- 1. Hypoparathyroidism
- 2. Hyperventilation
- 3. Uremia
- 4. Nephritis
- 5. Nephrosis
- 6. Rickets
- 7. Sprue
- 8. Malabsorption syndrome
- 9. Pregnancy
- 10. Lactation
- 11. Osteomalacia
- 12. Protracted vomiting
- 13. Pyloric obstruction
- 14. Alkali poisoning
- 15. Chemical toxicity
  - a. Morphine, lead, alcohol

H. Tremor
- 1. Parkinsonism
- 2. Familial disorder
- 3. Hypoglycemia
- 4. Hyperthyroidism
- 5. Wilson disease (hepatolenticular degeneration)
- 6. Anxiety
- 7. Ataxia
- 8. Athetosis
- 9. Alcoholism, narcotic addiction
- 10. Multiple sclerosis
- 11. Chorea (Sydenham, Huntington)

Data from Berry TJ: *The Hand as a Mirror of Systemic Disease*. Philadelphia: FA Davis Co, 1963; Juddge RD, Zuidema GD, Fitzgerald FT: General appearance. In: Judge RD, Zuidema GD, Fitzgerald FT, eds. *Clinical Diagnosis*, 4th ed. Boston, Little, Brown and Company, 1982:29–47.

is involved, its attitude should be observed. Digital deformities are the hallmark of RA.[81]

A visual inspection of the involved wrist and hand is made and is compared with the uninvolved side. The clinician inspects for lacerations, surgical scars, masses, swelling, or erythema.

- Scars should be examined for degree of adherence, degree of maturation, hypertrophy (excess collagen within the boundary of the wound), and keloid (excess collagen that no longer conforms to wound boundaries).
- The location and type of edema should be noted. Edema, the accumulation of fluid in the intercellular spaces, is a common consequence of surgery or injury to the hand. A determination is made as to whether the swelling is generalized or localized, hard or soft. Anterior effusion over the flexor tendons at the wrist may indicate rheumatoid tenovaginitis. Swelling that persists more than a few days following trauma probably suggests a carpal fracture. Localized swelling accompanied by redness and tenderness may indicate an infection. Measuring edema is an important part of the physical examination of individuals with conditions affecting the wrist and hand. Volumetry, a clinical application of Archimedes principle of water displacement as a measure of volume, is considered the gold standard for measuring hand size.[82] This method involves lowering the limb into a water-filled Plexiglass or metal tank (the volumeter) and measuring the amount of water displaced.[83] The reliability and validity of volumetric measurements is well established.[82] However, this method is time consuming and requires specialized equipment. An alternative method of measuring is the figure-of-eight method. Compared to volumetric method, the figure-of-eight method is more practical for clinical use as the procedure takes less time to perform and requires equipment that is less expensive and is readily available in most clinical settings.[82] The correct application of the tape is described in Table 18-5. Leard and colleagues[82] reported the figure-of-eight method to be a reliable and valid measure of hand size in individuals with conditions affecting the hand.

TABLE 18-5 Figure-of-Eight Taping Method

Step	Description
1	The starting point for the tape measure is the outermost aspect (medial surface using anatomical position as a reference) of the most distal aspect of the ulna styloid process.
2	The tape measure is drawn across the ventral surface of the wrist to the most distal aspect of the radial styloid process.
3	The tape measure is placed diagonally across the posterior (dorsal) aspect of the hand with the proximal surface of the tape measure placed over the fifth metacarpophalangeal (MCP) joint line.
4	The tape measure is then brought across the ventral surface of the MCP joints and the proximal surface of the tape measure is positioned over the second MCP joint line.
5	The tape measure is wrapped diagonally across the dorsum of the hand back to the starting point.

Data from Leard JS, Breglio L, Fraga L, et al: Reliability and concurrent validity of the Figure-of-Eight method of measuring hand size in patients with hand pathology. *J Orthop Sports Phys Ther* 34:335–340, 2004.

CLINICAL PEARL

The normal physiologic angles for relaxed hand posture are 14–15 degrees of ulnar deviation for the index finger, 13 degrees for the middle finger, 4 degrees for the ring finger, and 7–8 degrees for the little finger.

The swan-neck deformity is one of the most frequently encountered deformities of the fingers (see "Intervention Strategies").[81] When it occurs at the thumb it is referred to as a zigzag deformity. Any other finger deformities such as mallet finger and boutonniere (see "Rheumatoid Arthritis") are noted (Table 18-6). Other hand deformities include the following:

- ***Ulnar drift.*** The classic deformity of ulnar shift and ulnar deviation is associated with RA (although it can occur in other conditions) and the MCP joints. The deformity occurs due to the cumulative effects of various factors. Initially, the MCP joint capsule and ligamentous structures are stretched by the proliferation of the synovium, which loosens the collateral ligaments and decreases joint stability (see "Rheumatoid Arthritis").
- ***Extensor plus.*** This deformity results from either shortening of the extensor communis tendon or adherence of the tendon to the first part of the proximal phalanx at the extensor hood. It results in the inability to flex the PIP and MCP joints simultaneously, although each joint can be flexed normally individually.
- ***Myelopathy hand.*** This deformity, which is characterized by a loss of power in abduction and extension of the ulnar fingers, is caused by cervical spinal cord pathology in conjunction with cervical spondylosis.[86] Confirmation of this finding is made when lower motor neuron findings are seen at the level of the lesion while upper motor neuron findings are seen below the level of the lesion.

The nails should be inspected to see if they are healthy and pink (Table 18-7). Local trauma to the nails seldom involves more than one or two digits. The nails should be checked for hangnail infection or whether they appear ridged, which could indicate a RA dysfunction. Clubbed nails are an indication of hypertrophy of underlying structures. The presence of a paronychia or a pale paronychia should prompt the clinician to probe the axilla and neck lymph nodes for tenderness and swelling. Beau lines are transverse furrows that begin at the lunula and progress distally as the nail grows. They result from a temporary arrest of growth of the nail matrix occasioned by trauma or systemic stress.[87] With the knowledge that nails grow about 0.1 mm/day, by measuring the distance between the Beau lines and the cuticle, one may be able to approximately determine the date of the stress. For example, if the distance is 5 mm, the stress event occurred approximately 50 days before. Spoon nails (koilonychias) may occur in a form of iron deficiency anemia (Plummer–Vinson syndrome), coronary disease, and with the use of strong detergents.[87] Clubbing of the nails, characterized by a bulbous enlargement of the distal portion of the digits, may occur in association with cardiovascular disease, subacute endocarditis, advanced cor pulmonale, and pulmonary disease.[87]

Finger color should be observed. Fingers that are white in appearance might indicate Raynaud disease. Blotchy or red fingers might indicate liver disease. Blue fingers may indicate a circulatory problem.

Intrinsic muscle fibrosis is characterized by stiffness at the IP joints. On flexion of the MCP joint, extension of the fingers becomes tight and flexion is restricted. On extension of the MCP joint, flexion of the IP joints is possible.

- Adhesions proximal to the MCP joint allow lumbrical action (i.e., MCP flexion and PIP and DIP joint extension).
- Adhesions distal to the MCP joints result in the ability to extend the MCP and flex the PIP and DIP joints, but there is no extension possible in the fingers.

Palpation. Palpation of the wrist and hand is an integral component of the physical examination. Palpation may be performed separately or with the range-of-motion tests. Fortunately, most of the structures are superficial (Fig. 18-25), so a sound knowledge of surface anatomy is essential. The findings from palpation can often be confirmed using a specific special test (see "Special Tests"). Palpation of the following muscles, tendon, insertions, ligaments, capsules, and bones should occur as indicated and be compared with the uninvolved side for tenderness and/or swelling.

Trapezium. The trapezium is located immediately proximal to the base of the first metacarpal bone, just distal to the scaphoid. The tubercle of the trapezium lies anteriorly at the base of the thenar eminence. It can be made more prominent by opposing the thumb to the little finger and ulnarly deviating the wrist. Tenderness over this carpal may

TABLE 18-6 Hand and Finger Deformities and Their Possible Causes

Deformity	Possible Cause
MCP joint flexion	Rupture of the extensor tendon just proximal to the MCP joint
Hyperextension of the MCP joint	Paralysis of the interossei
Deepening of the anterior (palmar) gutter and an inability to fully stretch out the palm	Tightness of the anterior (palmar) aponeurosis
Wasting of the hypothenar eminence and a clawed hand with flexion of the fourth and fifth digits (hand of benediction)	Ulnar nerve palsy
Wrist drop with increased flexion of the wrist, flexion of the MCP joint, and extension of the DIP joints	Radial nerve lesion
Isolated thenar atrophy	Arthritis of the carpometacarpal joint Median nerve lesion C8 or T1 nerve root lesion
Ape-hand deformity with a wasting of the thenar eminence and an inability to oppose or flex the thumb or abduct it in its own plane[84]	Median nerve palsy
Z-deformity of the wrist	Pattern of deformity in the rheumatoid hand[85]
Atrophy of the hand intrinsics	Pancoast tumor
Claw-hand deformity	Loss of ulnar nerve motor innervation to the hand, with resultant paralysis of the interosseous muscles, and muscle atrophy of the hypothenar eminence; this deformity is more severe in lesions distal to innervation of the FDP muscle, as this muscle adds to the flexion force upon the IP joints[6]
PIP hyperextension and slight flexion of the DIP	Rupture or paralysis of the flexor digitorum superficialis (FDS)
A fixed flexion deformity of the MCP and PIP joints, especially in the ring or little finger	Dupuytren contracture
A hook-like contracture of the flexor muscles, which is worse with wrist extension as compared to flexion	Volkmann ischemic contracture

DIP, distal interphalangeal; FDP, flexor digitorum profundus; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

indicate scaphotrapezial arthritis secondary to scaphoid instability.[13]

Thumb CMC Joint. To examine the thumb CMC joint, the clinician palpates carefully along the shaft of the thumb metacarpal down to its proximal flare. Just proximal to this flare is a small depression where the CMC joint is located. By applying direct radial and ulnar stresses to the joint, the clinician can determine the overall stability of the joint as compared to the other thumb. Tenderness here is usually indicative of degenerative arthritis.

EPB, APL, and FCR Tendons. The EPB and APL tendons make up the first extensor compartment on the dorsum of the wrist and together form the radial border of the anatomic snuffbox. The APL is the first prominent tendon medially. Prominence of these tendons can be enhanced by extending and radially abducting the thumb. Tenderness over these tendons may indicate de Quervain tenosynovitis. Just medial to the APL is the radial artery with the FCR tendon, which inserts on the second metacarpal, situated medially.

Flexor Retinaculum. The flexor retinaculum, which can be palpated just medial to the FCR, transforms the carpal arch into the carpal tunnel. It is attached medially to the pisiform and hook of the hamate and laterally to the tubercle of the scaphoid and tubercle of the trapezium. Its proximal edge is at the distal crease of the wrist. The retinaculum can be the location for a retinacular cyst which, because of its firmness, is frequently mistaken for a bony spur.

Hamate. The hook of the hamate is palpated just distal and radial (in the direction of the thumb web space) to the pisiform on the anterior (palmar) aspect. Locating the hamate can be made easier if the clinician places the middle of the distal phalanx of the thumb on the pisiform, with the thumb pointing between the web space between the index and long finger. The clinician flexes the IP joint of the thumb and presses into the hypothenar eminence to feel the firm hook. The hook of the hamate is concave laterally, and the ulnar nerve's superficial division, which is just lateral and proximal to the hook, can be rolled on it. Tenderness over this carpal is common, and so the clinician should compare

TABLE 18-7 Glossary of Nail Pathology

Condition	Description	Occurrence
Beau lines	Transverse lines or ridges marking repeated disturbances of nail growth	Systemic diseases, toxic or nutritional deficiency states of many types, trauma (from manicuring)
Defluvium unguium (onychomadesis)	Complete loss of nails	Certain systemic diseases such as scarlet fever, syphilis, leprosy, alopecia areata, and exfoliative dermatitis; dermatoses such as nail infection, psoriasis, eczema; arsenic poisoning.
Diffusion of lunula unguis	Spreading of lunula	Dystrophies of the extremities
Eggshell nails	Nail plate thin, semitransparent bluish-white, with a tendency to curve upward at the distal edge	Syphilis
Fragilitas unguium	Friable or brittle nails	Dietary deficiency, local trauma
Hapalonychia	Nails very soft, split easily	Following contact with strong alkalis; endocrine disturbances, malnutrition, syphilis, chronic arthritis
Hippocratic nails	Watch-glass nails associated with drumstick fingers	Chronic respiratory and circulatory diseases, especially pulmonary tuberculosis; hepatic cirrhosis
Koilonychia	"Spoon nails"; nails are concave on the outer surface	Dysendocrinisms (acromegaly), trauma, dermatoses, syphilis, nutritional deficiencies, hypothyroidism
Leukonychia	White spots or striations or rarely the whole nail may turn white (congenital type)	Local trauma, hepatic cirrhosis, nutritional deficiencies, and many systemic diseases
Mees lines	Transverse white bands	Hodgkin granuloma, arsenic and thallium toxicity, high fevers, local nutritional derangement
Moniliasis of nails	Infections (usually paronychial) caused by yeast forms (*Candida albicans*)	Occupational (common in food handlers, dentists, dishwashers, and gardeners)
Onychatrophia	Atrophy or failure of development of nails	Trauma, infection, dysendocrinism, gonadal aplasia, and many systemic disorders.
Onychauxis	Nail plate is greatly thickened	Mild persistent trauma, systemic diseases such as peripheral stasis, peripheral neuritis, syphilis, leprosy, hemiplegia, or at times may be congenital
Onychia	Inflammation of the nail matrix causing deformity of the nail plate	Trauma, infection, many systemic diseases
Onychodystrophy	Any deformity of the nail plate, nail bed, or nail matrix	Many diseases, trauma, or chemical agents (poisoning, allergy)
Onychogryposis	"Claw nails"; extreme degree of hypertrophy, sometimes with horny projections arising from the nail surface	May be congenital or related to many chronic systemic diseases (see "Onychauxis")
Onycholysis	Loosening of the nail plate beginning at the distal or free edge	Trauma, injury by chemical agents, many systemic diseases
Onychomadesis	See defluvium unguium.	
Onychophagia	Nail biting	Neurosis
Onychorrhexis	Longitudinal ridging and splitting of the nails	Dermatoses, nail infections, many systemic diseases, senility, injury by chemical agents, hyperthyroidism
Onychoschizia	Lamination and scaling away of nails in thin layers	Dermatoses, syphilis, injury by chemical agents

(Continued)

TABLE 18-7 Glossary of Nail Pathology *(Continued)*

Condition	Description	Occurrence
Onychotillomania	Alteration of the nail structures caused by persistent neurotic picking of the nails	Neurosis
Pachyonychia	Extreme thickening of all the nails; the nails are more solid and more regular than in onychogryposis	Usually congenital and associated with hyperkeratosis of the palms and soles
Pterygium unguis	Thinning of the nail fold and spreading of the cuticle over the nail plate	Associated with vasopastic conditions such as Raynaud phenomenon and occasionally with hypothyroidism

Data from Berry TJ: *The Hand as a Mirror of Systemic Disease*. Philadelphia, PA: FA Davis Co, 1963; Judge RD, Zuidema GD, Fitzgerald FT: General appearance. In: Judge RD, Zuidema GD, Fitzgerald FT, eds. *Clinical Diagnosis*, 4th ed. Boston, MA: Little, Brown and Company, 1982:29–47.

findings with the other side. Severe tenderness could indicate a fracture of the hamate, especially if associated with a FOOSH injury or a missed hit swing of a racket or bat.[88] The FCU tendon surrounds the hamate as it inserts on the pisiform.

Pisiform. The pisiform is located on the flexor aspect of the palm, on top of the triquetrum, at the distal crease. Tenderness of this structure may indicate pisotriquetral arthritis or inflammation of the FCU tendon.[4] The pisiform may be fractured from a direct fall or blow to the hypothenar aspect of the hand.

Triangular Fibrocartilage Complex. The TFCC is located distal to the ulnar styloid and proximal to the pisiform. Tenderness over this structure indicates an injury to the TFCC.[4]

Ulnar Head and Styloid Process. The ulnar head forms a rounded prominence on the ulnar side of the wrist, which is easily palpated on the posterior aspect of the hand with the forearm in pronation.[80] The ulnar styloid process is ulnar and distal to the head of the ulna. It is best located with the forearm in supination.

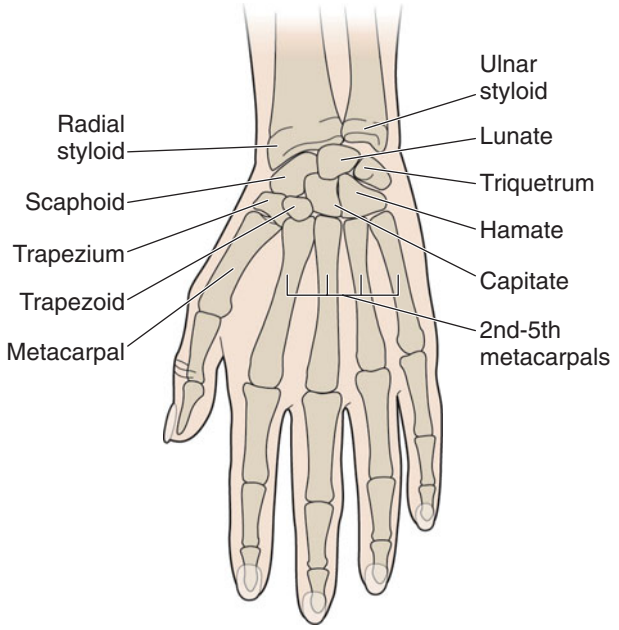

FIGURE 18-25 Bony structures of the hand.

Radial Styloid Process. The radial styloid process is larger and rounder than the ulnar styloid process. It is best palpated at the most proximal point of the anatomic snuffbox (see below), during radial abduction of the thumb. With simultaneous radial deviation of the wrist, this prominence becomes visible. Tenderness over the styloid, especially with radial deviation, may indicate contusion, fracture, or radioscaphoid arthritis.[89]

Lister's Tubercle. This is a small bony prominence on the posterior (dorsal) and distal end of radius. It is found by sliding a finger proximally from a point between the index and the middle fingers. Just distal to Lister's tubercle is the joint line of the scaphoid and radius. The ECRL and ECRB tendons travel radial to Lister's tubercle and insert on the base of the second and third metacarpals. The extensor digitorum communis (EDC) tendon travels ulnarly to Lister's tubercle. Radial to Lister's tubercle and proceeding further radially are the tendons of the ECRB, ECRL, EPB, and APL.

Scaphoid. The scaphoid is palpated just distal to the radial styloid in the anatomic snuffbox. The neck of the scaphoid is located on the floor of the anatomic snuffbox. Palpation can be made easier by positioning the wrist in ulnar deviation. The scaphoid may be grasped and moved passively by firm pressure between an opposed index finger and thumb applied to the anterior (palmar) surface and anatomic snuffbox simultaneously. In most individuals, the scaphoid is mildly tender to palpation, but those with a scaphoid fracture, nonunion, or scaphoid instability have severe discomfort (see "Special Tests").[2,90]

Lunate. The lunate is located just distal and ulnar to Lister's tubercle with the wrist flexed and is immediately proximal to, and in line with, the capitate. The mobile lunate can be felt to glide posteriorly (dorsally) with extension. It is the most commonly dislocated carpal and the scapholunate articulation is the most common area for carpal instability. Scapholunate synovitis (posterior (dorsal) wrist syndrome) or a scapholunate ligament injury presents with tenderness or fullness in

this region.[2] Tenderness specific to the lunate can indicate Kienböck disease or osteonecrosis of the lunate.[91,92]

Capitate. The capitate is localized by palpating proximally over the posterior (dorsal) aspect of the third metacarpal until a small depression is felt. While palpating in this depression, as the wrist is flexed, the clinician should feel the capitate, the central bone of the carpals, move posteriorly (dorsally). Tenderness in this depression may indicate scapholunate or lunotriquetral instability, or capitolunate degenerative joint disease.

Second and Third Metacarpals. The base of the second and third metacarpals and the CMC joints are localized by palpating proximally along the posterior (dorsal) surfaces of the index and long metacarpals to their respective bases.[80] A bony prominence found at the base of the second or third metacarpal may be a carpal boss, a variation found in some individuals due to hypertrophic changes of traumatic origin.[80]

Triquetrum. The triquetrum is located by radially deviating the wrist while palpating just distal to the ulnar styloid. With ulnar deviation, the triquetrum articulates with the TFCC, which functions as a buffer between the styloid and the triquetrum. Tenderness and swelling in the triquetral hamate region are often present with midcarpal instability, which occurs when the anterior (palmar) triquetral–hamate–capitate ligament is ruptured or sprained.[93]

Tunnel of Guyon. The tunnel of Guyon is located in the space between the hamate and the pisiform.[6]

Carpal Tunnel. The distal wrist crease marks the proximal edge of the carpal tunnel. The boundaries of the carpal tunnel are as follows:

- ***Radial:*** scaphoid tubercle and trapezium.
- ***Ulnar:*** pisiform and hamate.
- ***Posterior (dorsal):*** the carpal bones.
- ***Anterior (palmar):*** transverse carpal ligament.
- ***Proximal:*** antebrachial fascia.
- ***Distal:*** distal edge of the retinaculum at the CMC level, FCR, and scaphoid tubercle.

PIP Joints. Palpation of the PIP joint offers important information. Palpation of the joint over four planes (posterior (dorsal), anterior (palmar), medial, and lateral) allows assessment of point tenderness over ligamentous origins and insertions that is highly suggestive of underlying soft-tissue disruption.[22] In cases in which the joint is grossly swollen and tender, this part of the examination may provide more accurate information several days after the injury.[22]

Active Range of Motion (AROM), then Passive Range or Motion with Overpressure. The gross motions of wrist, hand, finger, and thumb flexion, extension, and radial and ulnar deviations are tested (Fig. 18-14), first actively and then passively (Table 18-8). Horger[94] conducted a reliability study to determine (a) the intrarater and interrater reliability of goniometric measurement of active and passive wrist motions under clinical conditions and (b) the effect of a therapist's specialization on the reliability of measurement. The results indicated that measurement of wrist motion by individual therapists is highly reliable and that intrarater reliability is higher than interrater reliability for all active and passive motions.[94] Interrater reliability was generally higher among specialized therapists for reasons not immediately apparent from this study.[94] With the exception of pain, identified sources of error were found to have surprisingly little effect on the reliability of measurement.[94]

TABLE 18-8 Active Range-of-Motion Norms for the Forearm, Wrist, and Hand

Motion	Degrees
Forearm pronation	85–90
Forearm supination	85–90
Radial deviation	15
Ulnar deviation	30–45
Wrist flexion	80–90
Wrist extension	70–90
Finger flexion	MCP: 85–90; PIP: 100–115; DIP: 80–90
Finger extension	MCP: 30–45; PIP: 0; DIP: 20
Finger abduction	20–30
Finger adduction	0
Thumb flexion	CMC: 45–50; MCP: 50–55; IP: 85–90
Thumb extension	MCP: 0; IP: 0–5
Thumb adduction	30
Thumb abduction	60–70

CMC, carpometacarpal; DIP, distal interphalangeal; IP, interphalangeal; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

Any loss of motion compared with the contralateral, asymptomatic wrist and hand should be noted.

During measurement of motion, one must be aware that finger joint positions may affect wrist joint ranges (and vice versa) due to the constant length of the extrinsic tendons that cross multiple joints. Forearm pronation and supination can have a similar impact on joint ranges. For example,

- greater wrist flexion occurs with finger extension than with finger flexion because the ED tendons are not stretched maximally;
- less deviation range of motion is available when the wrist is fully extended or flexed.

Thus during the examination, the clinician should maintain all joints in a consistent position (usually neutral), except the one being measured. In addition, the clinician should identify wrist and finger joint position when measuring the strength of related muscles.

Somatic dysfunction of the wrist permits motion toward the dysfunction; motion away from the dysfunction will be restricted.

Fanning and folding of the hand is performed by palpating the anterior (palmar) surface of the pisiform, scaphoid, hamate, and trapezium with the index and middle fingers and the posterior (dorsal) surface of the capitate with the

thumbs as the hand is alternately fanned and folded. During these motions, the clinician should note the quantity and quality of the conjunct rotations. An absence of the conjunct rotations may indicate an intercarpal dysfunction.

The uninvolved joint should always be examined first. This allows for a determination of the normal function, allays the patient's anxiety, and allows for a true comparison of function.[4] During palpation, the clinician should be on the alert for any thickening over tendons, tenderness, or areas of fluctuation.[4] During active and passive testing, the presence of crepitus must be determined. The presence of crepitus with motion may indicate a tendon sheath synovitis or vaginitis.

CLINICAL PEARL

Crepitus usually accompanies a particularly acute tendonitis.

Pronation and supination. Pronation and supination of the wrist on the forearm will provisionally test the TFCC and the proximal and DRUJs. Full forced pronation–supination without evoking pain eliminates the DRUJ and the TFCC as potential sources of the patient's complaints.[2] Normal ranges for pronation and supination are approximately 85–90 degrees with approximately 75 degrees occurring in the forearm articulations and the remaining 15 degrees the result of wrist action. The normal end feel for these motions is tissue stretch, although in cachexic patients, the end feel of pronation may be bone to bone.

Radial and ulnar deviation. Normal radial deviation is approximately 15 degrees, while normal ulnar deviation is between 30 and 45 degrees. The normal end feel for these motions is bone to bone.

Wrist flexion. The normal range of motion of wrist flexion is 80 to 90 degrees with an end feel of tissue stretch. According to Watson,[2] any loss of passive wrist flexion is a sign of underlying organic carpal pathology. To determine whether painful wrist flexion is due to a problem between the scaphoid and radius, or the scaphoid and the trapezium and trapezoid, the wrist is placed in full flexion, with the posterior (dorsal) surface of the hand resting on the treatment table. The clinician pushes on the scaphoid and second metacarpal in a posterior (dorsal) direction. An increase in pain with this maneuver may indicate a problem at the scaphoid–radius articulation.

If there is no increase in pain with this maneuver, the wrist is placed in a neutral position with regard to flexion and extension. The clinician stabilizes the trapezium and trapezoid and pushes the scaphoid posteriorly (dorsally). An increase in pain with this maneuver may indicate a problem at the trapezium/trapezoid–scaphoid articulation.

To determine whether the painful wrist flexion is due to a problem between the capitate and the lunate or the lunate and the radius, the wrist is placed in full flexion. The clinician pushes the lunate in an anterior (palmar) direction. An increase in pain with this maneuver may indicate a problem at the capitate–lunate articulation. If the pain is not increased with this maneuver, the wrist is placed in full flexion and the clinician pushes the lunate in a posterior (dorsal) direction. An increase in pain with this maneuver may indicate a problem at the lunate–radius articulation. A decrease in pain with this maneuver may indicate a problem at the capitate–lunate articulation.

Wrist extension. The normal range of motion for wrist extension is 70–90 degrees with an end feel of the tissue stretch. According to Watson,[2] any loss of passive wrist extension is a sign of underlying organic carpal pathology. To determine whether the pain with wrist extension is due to a problem between the scaphoid and the radius or the scaphoid and the trapezium/trapezoid, the wrist is positioned in full extension with the palm positioned on the table. The clinician pushes on the radius in an anterior (palmar) direction, thus increasing the amount of wrist extension. An increase in pain with this maneuver may indicate a problem at the scaphoid–radius articulation. If this maneuver does not increase pain, the wrist is positioned as before. The clinician now pushes on the radius in a posterior (dorsal) direction. A decrease in pain with this maneuver may indicate a problem at the scaphoid–radius articulation. An increase in pain with this maneuver may indicate a problem at the scaphoid and trapezium/trapezoid articulation.

This is confirmed by placing the wrist as before in full extension and pushing on the scaphoid in a posterior (dorsal) direction. A decrease in pain with this maneuver indicates a problem between the scaphoid and the radius, whereas an increase in pain with this maneuver indicates the problem is between the scaphoid and the trapezium/trapezoid.

The clinician fixes the scaphoid and pushes the trapezium/trapezoid in an anterior (palmar) direction. A decrease in pain with this maneuver may indicate a problem at the scaphoid–trapezium/trapezoid articulation. If the pain remains unchanged with this maneuver, the problem is likely to be at the scaphoid–radius articulation. To confirm this hypothesis, the scaphoid can be pushed in an anterior (palmar) direction while the wrist is maintained in the position of full extension. This should increase the pain if the hypothesis is correct.

To determine whether pain is due to a problem between the capitate and lunate or the lunate and radius, the wrist is positioned in full extension, with the palm of the hand on the table. The clinician pushes on the radius in an anterior (palmar) direction. An increase in pain with this maneuver indicates a problem at the capitate–lunate articulation.

If the pain is increased by pushing the lunate and capitate in an anterior (palmar) direction, this may indicate a problem at the lunate–radius articulation.

If fixing the lunate and pushing the capitate in an anterior (palmar) direction (a relative motion of the lunate posteriorly [dorsally] in relation to the capitate) increases the pain, the problem is likely at the capitate–lunate articulation.

Thumb. The following motions are tested in varying degrees of wrist flexion and extension:

- CMC abduction, adduction, flexion, extension, and opposition (Fig. 18-16). During opposition, the clinician

should observe for the conjunct rotation component of the motion.

- MCP and IP flexion and extension.

Fingers. It should never be assumed that lack of full active flexion or extension of the PIP is merely secondary to joint pain or fusion, because closed rupture of the middle slip of the extensor hood is easily missed until the appearance of a boutonniere deformity.[22] During flexion of the fingers, the overall area of the fingers should converge to a point on the wrist corresponding to the radial pulse. This can only occur if the index finger flexes in a sagittal plane and all the others in an increasingly oblique plane. A skyline view of the knuckles is made. In full flexion, a posteriorly (dorsally) subluxed capitate may be seen as a local swelling on the back and middle of the flexed wrist.

Total active motion of the fingers is the sum of all angles formed by the MCP, PIP, and DIP joints in simultaneous maximum active flexion, minus the total extension deficit at the MCP, PIP, and DIP joints (including hyperextension at the IP joints) in maximum active extension.

A normal value for total AROM in the absence of a normal contralateral digit for comparison is 260 degrees, based on 85 degrees of MCP flexion, 110 degrees of PIP motion, and 65 degrees of DIP motion.[95]

A comparison of active and passive motion indicates the efficiency of flexor and extensor excursion and/or degree of muscle strength within the available passive range of motion (PROM).[95] Instances of greater passive than active motion may indicate a limited tendon glide due to adherence of the tendon to surrounding structures or relative lengthening of the tendon due to injury or surgery, weakness, or pain.[95]

Due to the multitude of joints and multiarticular muscles found in the hand, the clinician may need to differentiate between various structures in order to determine the cause of a motion restriction (see "Special Tests").[95] For example, adherence of the extrinsic flexors is tested by passively maintaining the fingers and thumb in full extension while passively extending the wrist. In the presence of flexor tightness, the increasing flexor tension that develops as the wrist is passively extended will pull the fingers into flexion. Adherence of the extensor tendons is simply a reverse process. The digits are passively maintained in full flexion while the wrist is passively flexed. If tension pulling the fingers into extension is detected by the clinician's hand as the wrist is brought into flexion, extrinsic extensor tightness exists.

Strength Testing

Isometric tests are carried out in the extreme range, and if positive, in the neutral range. These isometric tests must include the interossei and lumbricals. The straight plane motions of wrist flexion, extension, and ulnar and radial deviation are tested initially. Pain with any of these tests requires a more thorough examination of the individual muscles. The clinician should be able to extrapolate hand placements for these tests by noting the anatomy of these muscles from the figures. The muscles controlling wrist extension (see Chapter 17), wrist flexion (see Chapter 17), radial deviation, and ulnar deviation are tested first.

Wrist

FCR/FCU. During the testing of these muscles, substitution by the finger flexors should be avoided by not allowing the patient to make a fist. The clinician applies the resistive force into extension and radial deviation for the FCU, and extension and ulnar deviation for the FCR.

ECRL/ECRB. Any action of the EDC should be ruled out by having the patient make a fist while extending the wrist. The clinician applies the resistive force on the dorsum of the second and third metacarpals, with the force directed into flexion and ulnar deviation.

Extensor Carpi Ulnaris. The ECU is tested by having the patient make a fist in wrist extension, while the clinician applies resistance on the ulnar dorsum of hand, with the force directed into flexion and radial deviation.

Thumb

APL/APB. The forearm is positioned midway between pronation and supination, or in maximal supination. The MCP and IP joints are positioned in flexion. The muscles are tested with anterior (palmar) abduction of the thumb in the frontal plane for the longus and in the sagittal plane for the brevis.

Opponens Pollicis. The forearm is positioned in supination and the posterior (dorsal) aspect of the hand rests on the table. The patient is asked to touch the finger pads of the thumb and little finger together. Using one hand, the clinician stabilizes the first and fifth metacarpals and the palm of the hand. With the other hand, the clinician applies a force to the distal end of the first metacarpal in the opposite direction of opposition (retroposition).

FPL/FPB. The forearm is positioned in supination and supported by the table, and the hand is positioned so that the posterior (dorsal) aspect rests on the table. The thumb is adducted. The longus is tested by resistance applied to the distal phalanx, whereas both heads of the brevis are tested by resistance applied to the proximal phalanx.

Adductor Pollicis. This muscle is tested by having the patient hold a piece of paper between the thumb and radial aspect of the index finger's proximal phalanx while the clinician attempts to remove it. If weak or nonfunctioning, the IP joint of the thumb flexes during this maneuver due to substitution by the FDP (Froment sign).

Extensor Pollicis Longus/EPB. Both of these muscles can be tested with the patient's hand flat on the table, palm down, and asking the patient to lift only the thumb off the table. To test each individually, resistance is applied to the posterior (dorsal) aspect of the distal phalanx for the EPL while stabilizing the proximal phalanx and metacarpal and to the posterior (dorsal) aspect of the proximal phalanx for the EPB while stabilizing the first metacarpal.

Intrinsics

Lumbricals. The four lumbricals are tested by applying resistance to the posterior (dorsal) surface of the middle and distal phalanges, while stabilizing under the proximal phalanx of the finger being tested. The anterior (palmar) and posterior (dorsal) interossei act with the lumbricals to achieve MCP flexion coupled with PIP and DIP extension.

Anterior (palmar) Interossei. The three anterior (palmar) interossei adduct the second, fourth, and fifth fingers to midline.Resistance is applied by the clinician to the radial aspect of the distal end of the proximal phalanx of the second, fourth, and fifth fingers, after first stabilizing the hand and fingers not being tested.

Posterior (dorsal) Interossei/ADM. The four posterior (dorsal) interossei abduct the second, third, and fourth fingers from midline. The ADM abducts the fifth finger from midline.

The intrinsic muscles are tested in the frontal plane to avoid substitution by the extrinsic flexors and extensors. Resistance is applied by the clinician to the ulnar aspect of the distal end of the proximal phalanx of each of the four fingers, after first stabilizing the hand and fingers not being tested.

Fingers

Flexor Digitorum Profundus. This muscle is tested with DIP flexion of each digit, while the MCP and PIP are stabilized in extension and wrist neutral. Due to the variability of nerve innervation for this muscle group, each of the fingers can be tested to determine whether a peripheral nerve lesion is present. The index finger is served by the anterior interosseous nerve, the middle finger by the main branch of the median nerve, and the ring and little finger by the ulnar nerve.

Flexor Digitorum Superficialis. There is normally one muscle tendon unit for each finger; however, an absent flexor digitorum superficialis to the little finger is common. The clinician should only allow the finger to be tested to flex by firmly blocking all joints of the nontested fingers, with the wrist in neutral.

ED/Extensor Indicis Proprius. There is only one muscle belly for this four-tendon unit. These three muscles are the sole MCP joint extensors. With the wrist in neutral, the strength is tested with the metacarpals in extension and the PIP/DIP flexed. The extensor indicis proprius can be isolated by positioning the index finger and hand in the "number one" position—the index finger in extension with other fingers clenched in a fist. The EDM muscle is tested with resistance of little finger extension with the other fingers maintained in a fist.

To isolate intrinsic muscle function, the patient is asked to actively extend the MCP joint and then to attempt to actively extend the PIP joint. Because the ED, EI, and EDM tendons are "anchored" at the MCP joint by active extension, only the intrinsic muscles can now extend the PIP joint.[17] To test the terminal extensor tendon function, the clinician stabilizes the middle phalanx and asks the patient to extend the DIP joint.[11]

Flexor Digiti Minimi. The forearm is positioned in supination and the posterior (dorsal) aspect of the hand rests on the table. The clinician stabilizes the fifth metacarpal and the palm with one hand, and then applies resistance to the anterior (palmar) surface of the proximal phalanx of the fifth digit with the other hand.

Opponens Digiti Minimi. The forearm is positioned in supination and the posterior (dorsal) aspect of the hand rests on the table. The patient is asked to touch the finger pads of the thumb and little finger together. Using one hand, the clinician stabilizes the first and fifth metacarpals and palm of the hand. With the other hand, the clinician applies a force to the distal end of the fifth metacarpal in the opposite direction of opposition (retroposition).

FIGURE 18-26 Grip strength.

Grip Strength. A loss of grip or pinch is a measurable factor used in the determination of permanent disability by compensation boards in some states.[96]

The assessment of grip strength (Fig. 18-26) and pinch strength (Fig. 18-27) is used to assess function of the hand, using a dynamometer. The average values for grip strength are given in Table 18-9. Normal grip strength, which provides statistical analysis of males versus females.[97] The mean value for the nondominant hand can be calculated from the values of the DH and the ratio.

FIGURE 18-27 Pinch meter.

TABLE 18-9 Grip Strength in Normal Men and Women of Various Ages for the Dominant Hand (DH) in Kilopound per Square Centimeter (kp/cm^2) and the Ratio dominant Hand/Nondominant Hand (DH/NDH), Based on 25 Determinations

Age	Men		Women	
	DH	DH/NDH	DH	DH/NDH
21–25	1.13 ± 0.18	1.07 ± 0.08	1.03 ± 0.16[a]	1.10 ± 0.12 NS

Data from Thorngren KG, Werner CO: Normal grip strength. *Acta Orthop Scand* 50:255–259, 1979.

A number of protocols using a sealed hydraulic dynamometer, such as the Jamar dynamometer (Fig. 18-26) (Asimow Engineering Co., Santa Monica, CA), have been shown to be accurate, reliable, and valid in measuring grip strength.[98,99] These dynamometers register force in pounds per square inch, or kilopound per square centimeter, and have adjustable handles to accommodate any sized hand, or any hand that may have a limitation of finger joint motion.[100]

Studies have demonstrated that the second handle setting of the Jamar dynamometer allows for the maximum grip strength from the patient.[100,101] The widest grip uses mostly the profundus muscles. At the narrowest grip, the profundus and superficialis muscle excursion are fully used, preventing much in the way of their contribution to the overall grip strength.[96,100]

Unfortunately, these tests are not purely objective, as they rely on the sincerity of effort from the patient.[102] Thus a number of tests have been introduced in an attempt to aid in the detection of insincerity of effort:

- ***The five-position grip strength test.***[96] This test uses the Jamar dynamometer and uses the five handle settings to measure grip strength at the five different grip widths. In normal and motivated patients, maximum grip strength occurs at the second or third grip width. The maximum grip strength, recorded at the first or fifth width setting, is supposed to be indicative of an insincerity of effort, although the reliability of the five-position grip strength test has been questioned.[101,103]
- ***The rapid exchange grip test, rapid simultaneous grip strength tests.*** The first test was developed by Lister.[104] Both of these tests use the Jamar dynamometer and compare the maximum grip strength during a five-position static grip strength test, with the maximum grip strength recorded when gripping the dynamometer repeatedly at a fast rate (80 times per minute).[105,106] In normal and motivated patients the static measure of grip strength of grip strength should be approximately 15 percent greater than the dynamic measure, while in patients demonstrating insincerity of effort, the dynamic measure is equal to or greater than the initial static measure.[106] The rapid exchange and the rapid simultaneous grip strength tests are time consuming and frequently performed erroneously in the clinical setting.[102]
- ***The rapid repeat test.*** The patient is seated with their arm by their side, the elbow in 90 degrees of flexion, and the forearm and wrist in neutral. The dynamometer, set at the second handle setting, is supported by the clinician and the patient alternately grips with both right and left hands on ten occasions, or until the patient has to stop due to fatigue or discomfort. This test has been found to be an unreliable discriminator of true and faked hand weakness.[102]

It is probably wise to combine the results of different grip strength tests before making any decisions.[107]

Functional Assessment. The hand serves many important functions that allow us to interact with others and the environment. In addition to providing a wealth of sensory information, the hand functions to grasp objects.

Hand functions have been further categorized by adding the terms *grasp* and *prehension*. These terms are used to describe functions of power or precision.[20,21]

The *functional position* of the wrist is the position in which optimal function is likely to occur.[62,108] This position involves wrist extension of between 20 and 35 degrees, ulnar deviation of 10 to 15 degrees, slight flexion of all of the finger joints, midrange thumb opposition, and slight flexion of the thumb

MCP and IP joints.[62] In this position, which minimizes the restraining action of the long extensor tendons, the pulps of the index finger and thumb are in contact.

A number of motions can be used to quickly assess hand function, including the following:

1. Opposition of the thumb and little finger.
2. Pad to pad mobility of the thumb and other fingers. The majority of the functional activities of the hand require at least 5 cm of opening of the fingers and thumb.[109]
3. The ability to make three different fists:
   a. The hook fist (placing fingertips onto MCP joints).
   b. Standard fist.
   c. Straight fist (placing fingertips on the thenar and hypothenar eminences). The ability to flex the fingers to within 1–2 cm of the distal anterior (palmar) crease is an indication of functional range of motion for many hand activities.[109]

The *functional range of motion* for the hand is the range in which the hand can perform most of its grip and other functional activities (Table 18-10).

The percentage losses of digital function are as follows: thumb, 40–50%; index finger, 20%; long finger, 20%; ring finger, 10%; little finger, 5%. Loss of the hand is 90% of the upper extremity and 54% of the whole person.

Function of the digits is related to nerve distribution. Flexion and sensation of the radial digits, important in precision grips, are controlled mainly by the median nerve, whereas flexion and sensation of the ulnar digits, important to the power grip, are controlled by the ulnar nerve. The muscles of the thumb, used in all forms of gripping, are controlled by both the median and the ulnar nerves. The release of a grip or opening of the hand is controlled by the radial nerve. A loss of the relationship between the thumb and the index finger results in an inability to perform fine motor skills that involve pulp-to-pulp pinch, as well as functions that require power.

TABLE 18-10 Functional Range of Motion of the Hand and Wrist

Joint Motion	Functional Range of Motion (Degrees)
Wrist flexion	5–40
Wrist extension	30–40
Radial deviation	10–20
Ulnar deviation	15–20
MCP flexion	60
PIP flexion	60
DIP flexion	40
Thumb MCP flexion	20

DIP, distal interphalangeal; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

London: Mosby, 1996; Palmer AK, Werner FW, Murphy D, et al: Functional wrist motion: A biomechanical study. *J Hand Surg Am* 10A:39–46, 1985; Ryu J, Cooney WP, Askew LJ, et al: Functional ranges of motion of the wrist joint. *J Hand Surg Am* 16A:409–420, 1991.

Hand Disability Index.[84] The patient is asked to rate the following seven questions on a scale of zero to three, with three being the most difficult.

Unable to perform task = 0

Able to complete task partially = 1

Able to complete task but with difficulty = 2

Able to perform task normally = 3

Are you able to do the following:

1. Dress yourself, including tying shoelaces and doing buttons?
2. Cut your meat?
3. Lift a full cup or glass to your mouth?
4. Prepare your own meal?
5. Open car doors?
6. Open jars that have previously been opened?
7. Turn taps on and off?

A variety of evaluation tools have been devised for the hand, and they can be categorized into assessments of the neurovascular system, range of motion, sensibility, and function (Table 18-11).[109]

Dexterity tests include the following:

Minnesota Rate of Manipulation Test. This test, which primarily measures gross coordination and dexterity, consists of following five functions:

1. Placing
2. Turning
3. Displacing
4. One-hand turning and placing
5. Two-hand turning and placing

The activities are timed and compared with the time taken by the other hand and then compared with normal values.[109,110]

Jebsen–Taylor Hand-Function Test.[111] This test, which requires the least amount of extremity coordination, measures prehension and manipulative skills and consists of following seven subtests:

1. Writing
2. Card turning
3. Picking up small objects
4. Simulated feeding
5. Stacking
6. Picking up large, light objects
7. Picking up large, heavy objects

The subtests are timed and compared with the time taken by the other hand. The results are also compared with normal values.[109,110]

Nine-Hole Peg Test. This test was designed to assess finger dexterity of each hand.[112] The patient is asked to use one hand to place nine 3.2-cm (1.3-inch) pegs in a 12.7 by 12.7 cm (5 by 5 in.) board and is then asked to remove them. The task is timed and compared with the time taken by the other hand. The results are compared with normal values.[109,110]

TABLE 18-11 Functional Testing of the Wrist and Hand

Starting Position	Action	Functional Test
1. Forearm supinated, resting on table	Wrist flexion	Lift 0 lb: Nonfunctional Lift 1–2 lb: functionally poor Lift 3–4 lb: functionally fair Lift 5+ lb: functional
2. Forearm pronated, resting on table	Wrist extension lifting 1–2 lb	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
3. Forearm between supination and pronation, resting on table	Radial deviation lifting 1–2 lb	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
4. Forearm between supination and pronation, resting on table.	Thumb flexion with resistance from rubber band around thumb	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
5. Forearm resting on table, rubber band around thumb and index finger	Thumb extension against resistance of rubber band	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
6. Forearm resting on table, rubber band around thumb and index finger	Thumb abduction against resistance of rubber band	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
7. Forearm resting on table	Thumb adduction, lateral pinch of piece of paper	Hold 0 s: nonfunctional Hold 1–2 s: functionally poor Hold 3–4 s: functionally fair Hold 5+ s: functional
8. Forearm resting on table	Thumb opposition, pulp-to-pulp pinch of piece of paper	Hold 0 s: nonfunctional Hold 1–2 s: functionally poor Hold 3–4 s: functionally fair Hold 5+ s: functional
9. Forearm resting on table	Finger flexion, patient grasps mug or glass using cylindrical grasp and lifts off table	0 repetitions: nonfunctional 1–2 repetitions: functionally poor 3–4 repetitions: functionally fair 5+ repetitions: functional
10. Forearm resting on table	Patient attempts to put on rubber glove keeping fingers straight	21+ s: nonfunctional 10–20 s: functionally poor 4–8 s: functionally fair 2–4 s: functional
11. Forearm resting on table	Patient attempts to pull fingers apart (finger abduction) against resistance of rubber band and holds	Hold 0 s: Nonfunctional Hold 1–2 s: functionally poor Hold 3–4 s: functionally fair Hold 5+ s: functional
12. Forearm resting on table	Patient holds piece of paper between fingers while clinician pulls on paper	Hold 0 s: nonfunctional Hold 1–2 s: functionally poor Hold 3–4 s: functionally fair Hold 5+ s: functional

Data from Palmer ML, Epler M: *Clinical Assessment Procedures in Physical Therapy*. Philadelphia, PA: JB Lippincott, 1990.

Purdue Pegboard Test.[113,114] This test evaluates finer coordination, requiring prehension of small objects, with measurement categories divided into

1. right hand
2. left hand
3. both hands
4. right, left, and both hands
5. assembly.

The subtests are timed and compared with normal values based on gender and occupation.[109,110]

Crawford Small Parts Dexterity Test.[115] This test involves the use of tweezers and a screwdriver and requires patients to control not only their hands but also small tools. This test correlates positively with vocational activities that demand fine coordination skills.[109]

The problem with most of these tests and others is that the critical measure of function used is time, even though time is not an accurate measure of function.

Although not standardized, a few other simple tests can be used to assess hand dexterity. These include writing in a straight line, buttoning and unbuttoning different-sized buttons, and zipping and unzipping using a variety of zipper sizes. The following scale can be used to grade these activities:

Unable to perform task = 0.

Able to complete task partially = 1.

Able to complete task but with difficulty = 2.

Able to perform task normally = 3.

Passive Accessory Joint Mobility Tests

In the following tests, the patient is positioned in sitting or supine, with the arm resting comfortably. In each of the tests, the clinician notes the quantity of joint motion as well as the joint reaction. The tests are always repeated on, and compared to, the same joint in the opposite extremity.

Distal Radioulnar Joint

Anterior–Posterior Glide. The patient is positioned in sitting with the forearm resting on the table. Using a pinch grip with both hands, the clinician places both thumbs on the posterior (dorsal) aspects of the ulnar and radial styloid processes (Fig. 18-28). The distal radius is stabilized and the distal ulna is moved posteriorly (dorsally) or anteriorly (palmarly) relative to the distal radius (Fig. 18-28). Alternatively, the distal ulna may be stabilized and the distal radius moved. This technique is used to assess joint plane motions necessary for pronation (posterior glide) and supination (anterior glide), or in the case of joint mobilizations to increase the joint play necessary for these motions.

Radiocarpal Joint. The patient's hand rests on the table with the wrist supported with a towel. The radiocarpal and ulnocarpal joints are placed in the resting position.

Distraction. Using one hand, the clinician grasps the distal radius and ulna. Using the other hand, the clinician grips the proximal row of carpals. A perpendicular distraction force is applied to separate the proximal level of carpals from the distal radius and ulna (Fig. 18-29).

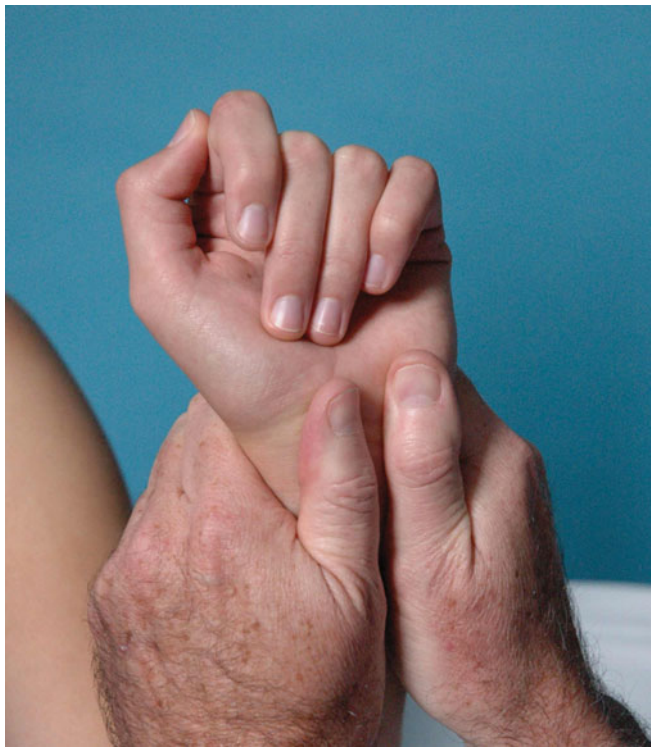

FIGURE 18-28 Mobility testing of the distal radioulnar joint.

Posterior–anterior glide. Using one hand to stabilize the patient's distal forearm, the clinician grasps the patient's hand with the other hand using the styloid processes and pisiform for landmarks. The proximal row of carpals is then moved posteriorly (dorsally) and anteriorly (palmarly) (Fig. 18-30). The posterior glide tests the joint's ability to flex, whereas the anterior glide assesses the ability of the joint to extend.

Ulnar and radial glide. The patient's hand rests on the table with the wrist supported with a towel (Fig. 18-31). Using one hand to stabilize the patient's distal forearm, the clinician grasps the patient's hand with the other hand using the styloid processes and pisiform for landmarks. The proximal row of carpals is then moved posteriorly (dorsally) and anteriorly (palmarly). The ulnar (medial) glide tests the joint's ability to radially deviate, whereas the radial (lateral) glide assesses the ability of the joint to ulnarly deviate.

Intercarpal Joints

Distal row. The patient's hand rests on the table or is held forward by the clinician. The clinician grasps the patient's hand with both hands, with the index fingers and thumbs of each

FIGURE 18-29 Radiocarpal distraction.

FIGURE 18-30 Anterior glide of the radiocarpal joint.

FIGURE 18-32 Assessment of joint mobility of distal carpals.

hand used to pinch an individual carpal and the adjacent carpal (Fig. 18-32). One carpal is moved anteriorly relative to the other and the clinician assesses the motion of the carpal in relation to the other. For example, the clinician assesses the motion of the capitate in relation to the hamate. An anterior glide of one carpal on another is a relative posterior glide of the other. For example, an anterior glide of the capitate on the hamate is a relative posterior glide of the hamate on the capitate.

Proximal row. The same technique is used to assess the proximal row of carpals.

Midcarpal Joints. The articulation between the proximal row of carpals and the distal row of carpals can be assessed using distraction, anterior glide, posterior glide, radial glide, and ulnar glide (Fig. 18-33). While assessing the distraction and anterior and posterior glides provides little information, the assessment of the radial glide can provide information about the ability of the wrist joint to ulnarly deviate, and the assessment of the ulnar glide can provide information about the ability of the wrist joint to radially deviate.

CMC Joints. Using one hand, the clinician uses a pinch grip of the index finger and thumb to palpate and stabilize the carpal bone that articulates with the metacarpal bone being tested (Fig. 18-34). With a pinch grip of the index finger and thumb of the other hand, the clinician palpates the metacarpal (Fig. 18-34).

The carpal bone is stabilized and the metacarpal is distracted (Fig. 18-35) and then glided posterior anteriorly along the plane of the CMC joint.

First CMC (trapeziometacarpal) Joint. The patient is positioned in sitting or supine.

Ulnar (medial) glide. The clinician applies a glide in an ulnar direction through the thenar eminence toward the radial

FIGURE 18-33 Assessment of joint mobility of intercarpals between distal and proximal rows.

FIGURE 18-31 Ulnar glide of the radioulnar joint.

FIGURE 18-34 Carpometacarpal joint testing.

FIGURE 18-35 Distraction of the carpometacarpal joint.

FIGURE 18-37 Long axis distraction of the MCP or IP joints.

aspect of the patient's metacarpal (Fig. 18-36). The ulnar glide is used to assess trapeziometacarpal joint flexion.

Radial (lateral) glide. The clinician applies a glide in a radial direction through the thenar eminence toward the ulnar aspect of the patient's metacarpal. The radial glide is used to assess trapeziometacarpal joint extension.

Distraction. The distraction technique may be used to decrease pain and to stretch the joint capsule.

MCP/IP Joints. Using a pinch grip of the index finger and thumb of one hand, the clinician palpates and stabilizes the metacarpal/phalanx. With a pinch grip of the index finger and thumb of the other hand, the clinician palpates the adjacent phalanx.

Distraction. The clinician stabilizes the proximal bone, and then applies a long axis distraction (Fig. 18-37).

Posterior–Anterior Glide. The clinician stabilizes the proximal bone, and then glides the phalanx posteroanteriorly along the plane of the joint (Fig. 18-37).

Ulnar (Medial)–Radial (Lateral) Glide. The clinician stabilizes the proximal bone, and then glides the phalanx mediolaterally along the plane of the joint (Fig. 18-37).

First MCP Joint. Using a pinch grip of the index finger and thumb of one hand, the clinician stabilizes the trapezium on the radial and ulnar surfaces. With a pinch grip of the index finger and thumb of the other hand, the clinician grips the proximal metacarpal on the radial and ulnar surfaces. A radial–ulnar glide is then performed by the mobilizing hand. A radial glide is necessary for trapeziometacarpal extension, whereas the ulnar glide is necessary for trapeziometacarpal flexion.

Distal and PIP Joints. Using a pinch grip of the index finger and thumb of one hand, the clinician stabilizes the distal end of the more proximal phalanx. Using the other hand the clinician grips the proximal end of the more distal phalanx. The PIP joint (Fig. 18-38) and DIP joint (Fig. 18-39) can then be distracted, or glided anteriorly or posteriorly. The anterior glide assesses the ability of the joint to move into flexion, whereas posterior glide assesses the ability of the joint to move into extension.

Special Tests

The special tests for the wrist and hand can be subdivided based on intent:

- Motion restriction
- Pain provocation
- Tendinous integrity
- Ligamentous stability
- Neurovascular status
- Sensibility testing
- Adverse neural tension.

FIGURE 18-36 Ulnar glide of the first carpometacarpal joint.

FIGURE 18-38 Assessment of proximal interphalangeal joint.

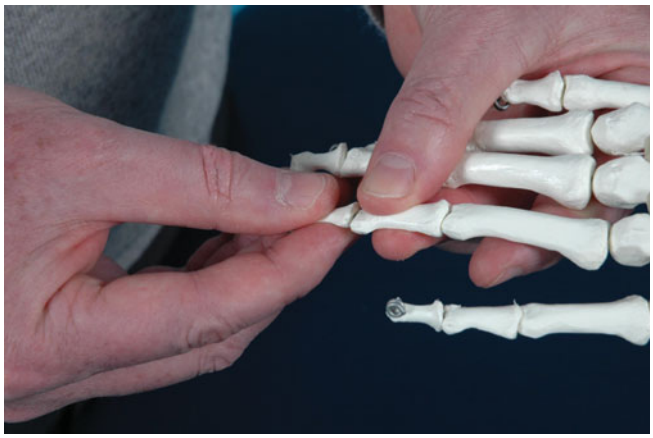

FIGURE 18-39 Assessment of distal interphalangeal joint.

FIGURE 18-41 Haines–Zancolli test.

Motion Restriction

- The Bunnell–Littler test is used to determine whether flexion restriction of the PIP is due to tightness of the intrinsic muscles or due to a restriction of the MCP joint capsule. The MCP joint is held by the clinician in a few degrees of extension with one hand, while the other hand attempts to flex the PIP joint. If the joint cannot flex, tightness of the intrinsics or a joint capsular contraction should be suspected.[116] From this position, the clinician now slightly flexes the MCP joint, thereby relaxing the intrinsics, and attempts to flex the PIP joint (Fig. 18-40). If the joint can now flex, the intrinsics are tight. If the joint still cannot flex, the restriction is probably due to a capsular contraction of the joint. This test is also called the intrinsic-plus test.[23]
- The Haines–Zancolli test is used to determine whether restricted flexion in the DIP joints is due to a restriction of the PIP joint capsule or tightness of the oblique retinacular ligament. The test for a contracture of this ligament is the same as the Bunnell–Littler test, only at the PIP and DIP joints. The clinician positions and holds the PIP joint in a neutral position with one hand and attempts to flex the DIP joint with the other hand (Fig. 18-41). If no flexion is possible, it can be due to either a tight retinacular ligament or capsular contraction. The PIP joint is then slightly flexed to relax the retinacular ligament. If the DIP can now flex, the restriction is due to tightness in the retinacular ligament. If the DIP cannot flex, then the restriction is due to a capsular contraction.

FIGURE 18-40 Bunnell–Littler test.

Pain Provocation Tests

Thumb CMC Grind Test. The grind test is used to assess the integrity of the thumb CMC joint by axially loading the thumb metacarpal into the trapezium.[9,117] The clinician grasps the thumb metacarpal using the thumb and index finger of one hand and the proximal aspect of the thumb CMC joint with the other hand (Fig. 18-42). An axial compressive force, combined with rotation, is applied to the thumb CMC joint. Reproduction of the patient's pain and crepitus is a positive test for arthrosis and synovitis.

Lichtman Test. The Lichtman test is a provocative test for midcarpal instability.[9] The patient's forearm is positioned in

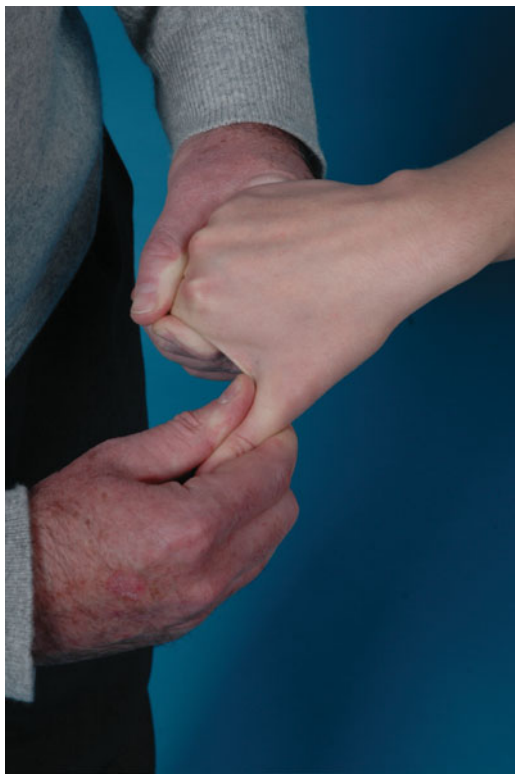

FIGURE 18-42 CMC grind test.

FIGURE 18-43 Lichtman test.

pronation and the hand is held relaxed and supported by the clinician. The clinician gently moves the patient's hand from radial to ulnar deviation while compressing the carpus into the radius (Fig. 18-43). A positive test is when the midcarpal row appears to jump or snap from an anteriorly (palmarly) subluxed position to the height of the proximal row.[9]

Linscheid Test. The Linscheid test is used to detect ligamentous injury and instability of the second and third CMC joints. The test is performed by supporting the metacarpal shafts and pressing distally over the metacarpal heads in anterior (palmar) (Fig. 18-44) and posterior (dorsal) directions.[80] A positive test produces pain localized to the CMC joints.[118]

Carpal Shake Test. This test is used if intercarpal synovitis is suspected.[9] The clinician grasps the patient's distal forearm (Fig. 18-45). The patient is asked to relax and the clinician

FIGURE 18-45 Carpal shake test.

shakes the wrist (Fig. 18-45). Pain or resistance to this test indicates a positive test.

Wrist flexion and finger extension test. The patient is positioned in sitting with the elbow placed on the table. The clinician holds the patient's wrist in flexion and asks the patient to extend the fingers against manual resistance (Fig. 18-46). A positive test for scapholunate pathology is identified by pain over the scaphoid. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Press (Sit to Stand) Test. This test is used if a tear of the TFCC is suspected.[9] The patient is instructed to place both hands on the armrests of a chair and attempt to lift their body slightly off the chair (Fig. 18-47). Pain or resistance to this test indicates a positive test. Lester and colleagues[119] reported a sensitivity of 100% compared with arthroscopic surgery and a sensitivity of 79% when compared with magnetic resonance imaging (MRI) arthrogram. Specificity could not be determined based on the methodology of this test design.

Supination lift test.[120] The patient is positioned in sitting with the elbows flexed to 90 degrees and the forearms supinated. The patient is asked to place the palms flat on the underside of the heavy table or against the clinician's hands. The patient is asked to lift the table or push up against the resisting clinician's hands (Fig. 18-48). A positive test for a TFCC tear is pain

FIGURE 18-44 Linscheid test.

FIGURE 18-46 Wrist flexion and finger extension test.

FIGURE 18-47 Press (sit to stand) test.

localized to the ulnar side of the wrist with difficulty applying force.

Ulnar Impaction Test. This test is used to assess the articulation between the ulnar carpus and the TFCC.[9] The patient is positioned in sitting, with the elbow flexed to about 90 degrees and the wrist positioned in ulnar deviation, and the fingers positioned in a slight fist. The clinician loads the wrist by applying a compressive force through the ring and small metacarpals (Fig. 18-49). Pain with this test indicates a possible tear of the TFCC or ulnar impaction syndrome (see "Intervention Strategies").

Finkelstein Test.[121] This test is used to detect stenosing tenosynovitis of the APL and EPB. The clinician grasps the patient's thumb, stabilizes the forearm with one hand, and then deviates the wrist to the ulnar side with the other hand

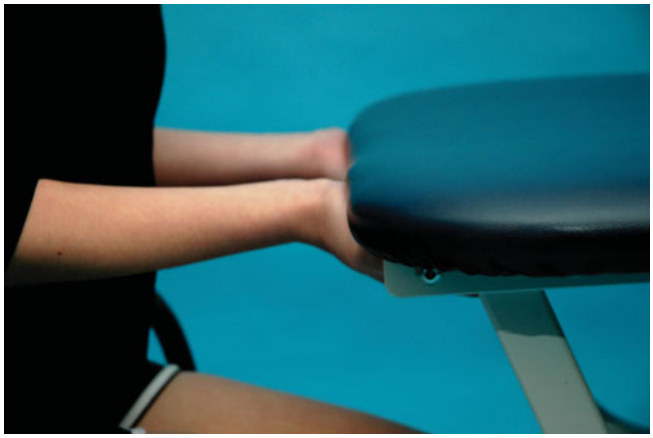

FIGURE 18-48 Supination lift test.

FIGURE 18-49 Ulnar impaction test.

(Fig. 18-50). No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test, so the results of this test must be interpreted with caution,[122] as it may also be positive in Wartenberg syndrome (entrapment of the superficial radial sensory nerve),[123–125] basilar thumb arthrosis, EPB entrapment, or intersection syndrome (see "Intervention Strategies").[125] Deviating the wrist using pressure over the index metacarpal avoids confusion with thumb conditions.[126] A variation of Finkelstein test can be used to rule out an incomplete release of previous de Quervain disease.[127] If the usual Finkelstein test is positive, full abduction of the APL followed by flexion of the thumb's MCP joint will isolate the action of the EPB. Pain with this test will occur if the EPB lies in a separate sheath and was not released (EPB

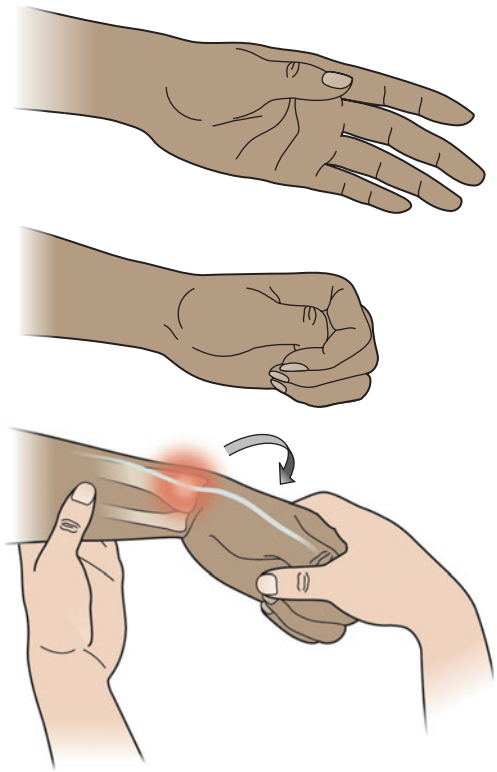

FIGURE 18-50 Finkelstein test.

FIGURE 18-51 Radioulnar ballottement test.

FIGURE 18-52 Wartenberg Test.

entrapment syndrome).[127] This test has been found to have a sensitivity of 81% and a specificity of 50%.[128]

Radioulnar Ballottement Test. The radioulnar ballottement test is used to assess DRUJ instability. The patient's elbow is flexed and the clinician uses their thumb and index finger to stabilize the radius radially and the ulnar head ulnarly (Fig. 18-51). Stress is applied in an anterior–posterior direction. Normally there is no movement in the anterior or posterior direction in maximum supination or pronation. Pain or mobility with this test is suggestive of radioulnar instability.

Wartenberg Test. The Wartenberg test is used with patients who complain of pain over the distal radial forearm associated with paresthesias over the posterior (dorsal) radial hand (Wartenberg syndrome). These patients frequently report symptom magnification with wrist movement or when tightly pinching the thumb and index digit together. The Wartenberg test involves tapping the index finger over the superficial radial nerve (similar to the Tinel test for CTS) on the posterior and radial side of the wrist (Fig. 18-52). A positive test is indicated by local tenderness and paresthesia with this maneuver. Hyperpronation of the forearm can also cause a positive Tinel sign.

Finger Extension Test. This test is used to demonstrate posterior (dorsal) wrist syndrome, a localized scapholunate synovitis.[13] The clinician instructs the patient to fully flex the wrist and then actively extend the digits at both the IP and MCP joints. The clinician then applies pressure on the fingers into flexion at the MCP joints while the patient continues to actively extend (Fig. 18-53). A positive test occurs when there is production of central posterior (dorsal) wrist pain and indicates the possibility of Kienböck disease, carpal instability, joint degeneration, or synovitis (see "Intervention Strategies").[9]

Scapholunate Shear Test. The patient is positioned in sitting with their forearm pronated. With one hand, the clinician grasps the scaphoid. With the other hand, the clinician grasps the lunate between the thumb and the index finger (Fig. 18-54). The lunate and scaphoid are then sheared in an anterior (palmar) and then posterior (dorsal) direction.[2] Laxity and reproduction of the patient's pain are positive signs for this test.[9]

Tendinous Integrity

FDS Test. This test is used to test the integrity of the FDS tendon. The clinician holds the patient's fingers in extension

FIGURE 18-53 Finger extension test.

FIGURE 18-54 Scapholunate shear test.

FIGURE 18-56 Flexor digitorum profundus test.

except for the finger being tested (this isolates the FDS tendon). The patient is instructed to flex the finger at the PIP joint (Fig. 18-55). If this is possible, the FDS tendon is intact. Since this tendon can act independently because of the position of the finger, it is the only functioning tendon at the PIP joint. The DIP joint, motored by the FDP, has no power of flexion when the other fingers are held in extension.

FDP Test. These tendons work only in unison. To test the FDP, the PIP joint and the MCP joints are stabilized in extension (Fig. 18-56). The patient is asked to flex this finger at the DIP joint. If flexion occurs, the FDP is intact. If no flexion is possible, the tendon is severed or the muscle denervated.

Integrity of the Central Slip (Extensor Hood Rupture).[129] The patient flexes the finger to 90 degrees at the PIP joint over the edge of the table. The patient is then asked to extend the PIP joint while the clinician palpates the middle phalanx (Fig. 18-57). The absence of extension force at the PIP joint, and fixed extension at the distal joint, indicates complete rupture of the central slip.[22] No diagnostic accuracy studies have been performed to determine the sensitivity and the specificity of the clinical test.

Ligamentous Stability. A number of tests are available to evaluate the ligamentous stability of the forearm, wrist, hand, and finger joints. In the following tests, the patient is positioned in sitting, and the clinician is standing or sitting, facing the patient. The clinician must remember to perform these tests on the uninvolved side to provide a basis for comparison.

Piano Key Test. The piano key test evaluates the stability of the ulnomeniscotriquetral joint.[4] The clinician firmly stabilizes the distal radius with one hand and grasps the head of the ulna between the thumb and the index finger of the other hand. The ulnar head is depressed in an anterior direction (as in depressing a key on a piano) (Fig. 18-58).[9] The test is positive for a TFCC tear or triquetral instability if there is excessive movement in an anterior (palmar) direction or if upon release of the ulna, the bone springs back into its high posterior (dorsal) position. There may also be discomfort reported during the test.[80] LaStayo and Howell[130] found this test to have a sensitivity of 66% and a specificity of 64%.

Lunotriquetral Shear (Reagan) Test. This test is designed to assess the integrity of the lunotriquetral ligament.[4] The clinician grasps the triquetrum between the thumb and the second finger of one hand and the lunate with the thumb and second finger of the other hand. The lunate is moved posteriorly (dorsally) with the thumb of one hand, while the triquetrum is pushed palmarly in the anteroposterior (AP) plane by the index finger of the other hand (Fig. 18-44). Crepitation, clicks, or discomfort in this area suggests injury to the ligament.[9,131] LaStayo and Howell[130] found this test to have a sensitivity of 64% and a specificity of 44% (LR+ 1.14; LR− 0.82).

FIGURE 18-55 Flexor digitorum superficialis (FDS) test.

FIGURE 18-57 Integrity of the central slip (extensor hood rupture).

FIGURE 18-58 Piano key test.

The Pisotriquetral Shear Test. The pisotriquetral shear test assesses the integrity of the pisotriquetral articulation.[9] The clinician stabilizes the wrist with the fingers posterior (dorsal) to the triquetrum and the thumb over the pisiform. The pisiform is rocked back and forth in a medial and lateral direction. A positive test is manifested with pain during this maneuver. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Pivot Shift Test of the Midcarpal Joint. The patient is positioned in sitting with the elbow flexed to 90 degrees and the forearm supinated. The clinician uses one hand to stabilize the forearm, while using the other hand to take the patient's hand into full radial deviation (Fig. 18-59). The patient's hand is then taken into full ulnar deviation. A positive test results if the capitate is felt to shift away from the lunate and indicates an injury to the anterior capsule and interosseous ligaments.[23] No diagnostic accuracy studies have been performed to determine the sensitivity and the specificity of this test.

Watson Test for Carpal Instability. The scaphoid shift maneuver examines the dynamic stability of the wrist, in particular the integrity of the scapholunate ligament.[13] The patient is positioned in sitting with their elbow in approximately 90 degrees of flexion, the forearm slightly pronated, and the wrist ulnarly deviated. The clinician grasps the wrist from the radial side and stabilizes the scaphoid tubercle with the thumb and the posterior (dorsal) aspect of the scaphoid with the index finger. The clinician uses the other hand to grasp the metacarpals. Starting in ulnar deviation in slight extension, the wrist is moved into radial deviation and slight flexion. As the wrist is brought passively into radial deviation, the normal flexion of the proximal row forces the scaphoid tubercle into an anterior (palmar) direction (into the clinician's thumb). The clinician attempts to prevent the anterior (palmar) motion of the scaphoid. When the scaphoid is unstable, its proximal pole is forced to sublux posteriorly (dorsally).[9] Pain at the posterior (dorsal) wrist or a clunk suggests instability.[26,29] The results are compared with the other hand. The results from the scaphoid shift test, which has been found to have a sensitivity of 69 percent and a specificity of between 64 and 68 percent,[91,92,130,132] should be used with caution, as the test can be positive in up to one-third of uninjured individuals.[14]

FIGURE 18-59 Pivot shift test of the midcarpal joint.

Scaphoid shift test. This is a slight modification to the Watson test. The patient positioning is similar to the Watson test except that the wrist is positioned in neutral to slight (0–10 degrees) radial deviation and neutral wrist flexion/extension. The clinician then quickly pushes the tubercle of the scaphoid in a posterior (dorsal) direction, noting a clunk, crepitus, or pain in comparison to the opposite wrist.[133] No diagnostic accuracy studies have been performed to determine the sensitivity and the specificity of this test.

Gamekeeper's or skier's thumb. The patient is positioned in sitting. The clinician stabilizes the patient's hand with one hand and takes the patient's thumb into extension with the other hand. While maintaining the thumb into extension, the clinician applies a valgus stress to the MCP joint of the thumb to stress the UCL (Fig. 18-60). A positive test is present

FIGURE 18-60 Gamekeeper's or skier's thumb.

if the valgus movement is greater than 30–35 degrees, indicating a complete tear of the UCL and the accessory collateral ligaments. Heymen and colleagues[134] reported a high sensitivity with this test (94%) and a 100% sensitivity and 46% specificity for detection of a palpable mass proximal to the MCP joint to indicate a complete tear of the UCL of the thumb.

Murphy Sign. The patient is asked to make a fist. If the head of the third metacarpal is level with the second and fourth metacarpals, the sign is positive for the presence of a lunate dislocation.[135]

Neurovascular Status. The assessment of sensibility and vasculature of the hand is an important component of every hand examination. Sensation is essential for precision movements and object manipulation. A number of tests can be used to document the neurovascular status of the wrist and hand.

Allen Test. The Allen test is used to determine the patency of the vessels supplying the hand. The clinician compresses both the radial and ulnar arteries at the wrist (Fig. 18-61), and then asks the patient to open and clench the fist three to four times to drain the venous blood from the hand. The patient is then asked to hold the hand open while the clinician releases the pressure on the ulnar artery and then the radial artery. The fingers and palm should be seen to regain their normal pink color. This procedure is repeated with the radial artery released and compression on the ulnar artery maintained. Normal filling time is usually less than 5 seconds. A distinct difference in the filling time suggests the dominance of one artery filling the hand.[131]

Tinel (Percussion) Test for CTS. The Tinel test is used to assist in the diagnosis of CTS. The area over the median nerve is tapped gently at the anterior (palmar) surface of the wrist (Fig. 18-62). If this produces tingling in the median nerve distribution, then the test is positive.[136] Variations exist between studies on the location and number of taps necessary to elicit a positive response, and in some studies the test is performed by tapping the median nerve in 20 degrees of wrist extension, while others tap along the path of the median nerve up to where the median nerve enters the carpal tunnel. The Tinel test has demonstrated a sensitivity of 60 percent and a specificity of 67 percent,[137] indicating that it is moderately acceptable for use in clinical practice.[138–141]

FIGURE 18-62 Tinel test at the wrist.

APB Weakness for CTS. The patient is positioned in sitting with their hand resting on the table. The clinician asked the patient to touch the pads of the thumb and small finger together. After asking the patient to keep the pads of the thumb and small finger together, the clinician applies a strong force in order to resist thumb abduction (Fig. 18-63). A positive test is weakness in some abduction with resisted testing as compared to the other hand. Studies performed to determine weakness in the APB are relatively consistent, demonstrating moderate diagnostic accuracy. For example, in a study by Gerr and Letz[142] the test was found to have a sensitivity of 63% and a specificity of 62%, compared to a Kuhlman and Hennessy study[143] that found the sensitivity to be 66% and the specificity to be 66%.

Phalen Test for CTS.[144,145] For the Phalen test, the patient sits comfortably with the wrists and elbows flexed (Fig. 18-64). The test is positive if the patient experiences numbness or tingling throughout the median nerve distribution of the hand within 45 seconds. For some patients, performance of this test recreates their wrist, thumb, or forearm ache.[146] Some studies have varied this test to be performed by the patient with wrist in complete flexion and elbow extended, bilateral wrist flexion with the posterior aspect of the hand pressing against one another, or passive wrist flexion by the clinician. The original Phalen test has demonstrated a sensitivity of 75 percent and a

FIGURE 18-61 Allen test.

FIGURE 18-63 Abductor pollicis brevis weakness.

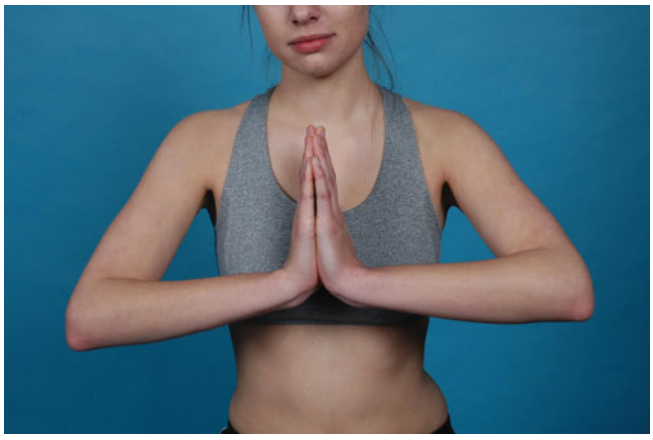

FIGURE 18-64 Phalen test.

specificity of 47 percent,[147] making it moderately acceptable for use in clinical practice.

Reverse Phalen Test for CTS. A reverse Phalen position is the same as the Phalen except the palms are placed together (Fig. 18-65). The patient is asked to keep both hands with the wrists in complete extension for 60 seconds (wrist and finger extension). A study by de Krom and colleagues[148] found the test to have a sensitivity of 41 percent and a specificity of 55 percent (LR+ 0.9; LR– 1.1). In another study, Werner and colleagues[149] showed that this maneuver results in a significantly higher intracarpal canal hydrostatic pressure as compared to a traditional Phalen or a modified Phalen maneuver and may add to the sensitivity of conventional screening methods.[136,150]

Hand Elevation Test for CTS. The patient is seated or standing and is asked to elevate both arms above the head (Fig. 18-66) and maintain them in this position until the patient feels paresthesia or numbness.[151] A positive test is the reproduction of symptoms such as paresthesia and numbness along the median nerve distribution after raising the arms for no greater than 2 minutes. A study by Ahn[152] found this test to have a sensitivity of 76 percent and a specificity of 99 percent (LR+ 76; LR– .24). In another study[151], this test was found to be more specific than the Phalen and Tinel tests. Although this clinical test has high diagnostic values there are numerous procedural biases in both study designs. In addition the test may be positive in patients with thoracic outlet syndrome.

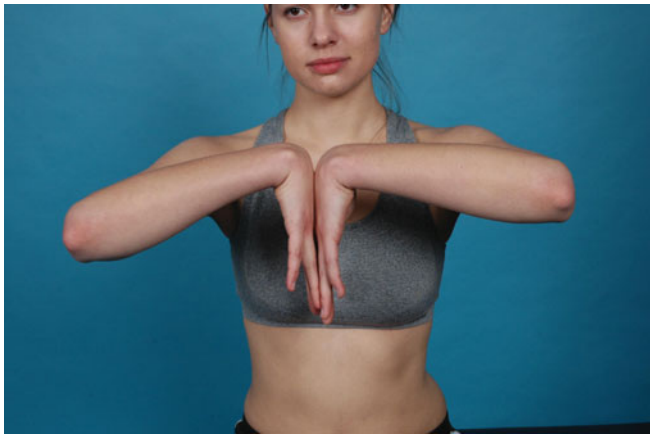

FIGURE 18-65 Reverse Phalen test.

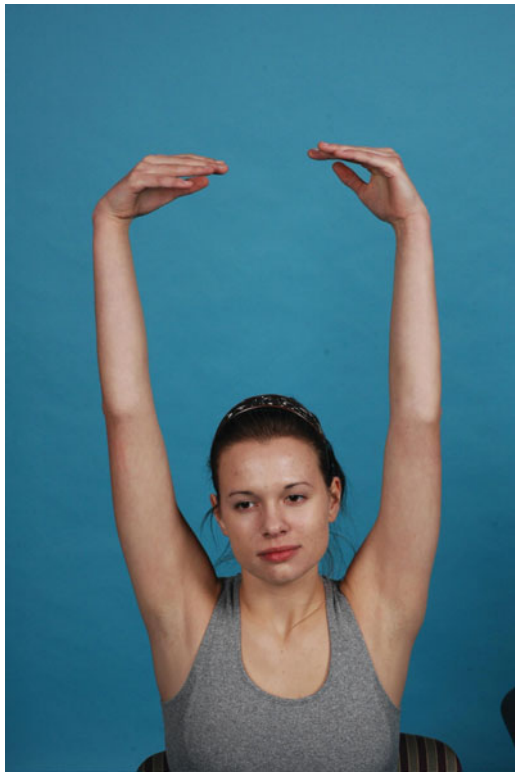

FIGURE 18-66 Hand elevation test.

Wrist flexion and median nerve compression. The patient is positioned in sitting with the elbow fully extended, the forearm in supination, and the wrist flexed to 60 degrees. The clinician applies an even constant pressure over the median nerve at the carpal tunnel using the thumb. A positive test for CTS is the reproduction of symptoms along the median nerve distribution within 30 seconds. Tetro and colleagues found this test to have a sensitivity of 86 percent and a specificity of 95 percent (LR+ 17; LR– 0.1).[153]

Median nerve compression test/pressure provocation test. The clinician sits opposite to the patient and holds the patient's hand with the clinician's thumbs directly over the course of the median nerve as it passes under the flexor retinaculum between the FCR and the palmaris longus. The clinician places gentle sustained pressure with the thumbs for 15 seconds to 2 minutes. The clinician then removes the pressure and questions the patient on the relief of symptoms, which may take a few minutes. A positive test is the reproduction of pain, paresthesia, or numbness distal to the site of compression during the compression in the distribution of the median nerve. Williams and colleagues[154] found this test to have a sensitivity of 100 percent and a specificity of 97 percent (LR+ 33; LR– 0).

Flick maneuver. The patient is positioned in sitting and is asked to vigorously shake his or her hands (Fig. 18-67). A positive test, indicating CTS, is the resolution of the paresthesia symptoms during or following administration of flicking the wrist. There appears to be some confusion as to what constitutes a flick. Some studies define a flick as a rapid, alternating movement up and down of the wrist, whereas

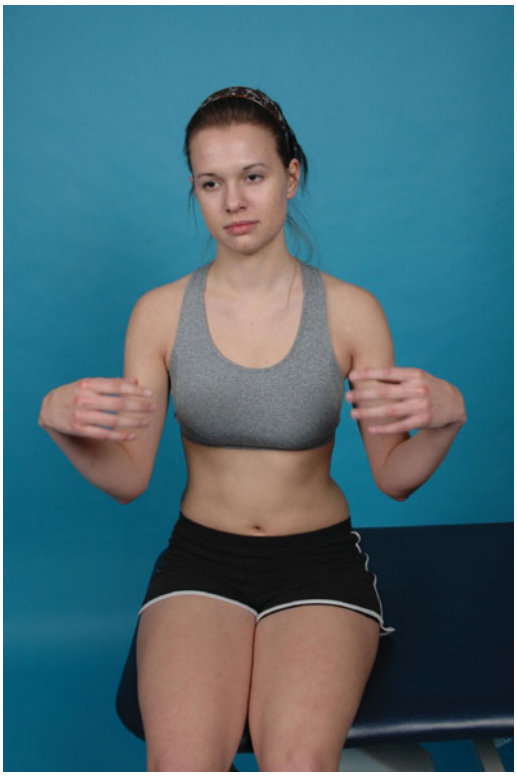

FIGURE 18-67 Flick maneuver.

FIGURE 18-68 Semmes–Weinstein monofilament testing.

others describe the positive flick with as little movement as elbow extension. The diagnostic usefulness of this test is outlined in Table 18-12.

Semmes–Weinstein Monofilament Testing. The palm of the hand is divided into several areas, and only one point (usually in the center) is tested in each area.

- Between the fingertip and DIP joint.
- Between the DIP joint and PIP joint.
- Between the PIP joint and finger web.
- Between the finger web and the distal anterior (palmar) crease.
- Between the distal anterior (palmar) crease and the central palm.
- Base of palm and wrist.
- Superficial radial nerve distribution (Fig. 18-68)

The clinician applies a monofilament perpendicular to the surface, and the pressure is increased until the monofilament begins to bend (Fig. 18-69). Filament 2.83 MN is considered the "Normal" filament and indicates normal light touch perception. A positive test for CTS is when the patient with eyes closed cannot report which digit is receiving pressure at 2.83 mg. Normal values are depicted in Table 18-13. The diagnostic usefulness of this test based on some of the studies is outlined in Table 18-14.

Weber (Moberg) Two-Point Discrimination Test. The two-point discrimination tests were first introduced by Weber in

TABLE 18-12 The Diagnostic Usefulness of the Flick Maneuver

Study Description	Reliability	Sensitivity	Specificity	LR+	LR–	DOR	QUADAS Score
Hundred persons referred with suspected carpal tunnel syndrome underwent clinical and neurophysiological examinations blinded from each other. The gold standard for the CTS diagnosis was based on the results of these examinations but relief of CTS symptoms after surgery was also required[a]	NT	90	30	1.3	0.3	3.9	13
One hundred forty-two subjects referred for electrodiagnostic evaluation of possible CTS were first clinically evaluated with the flick, Phalen, and Tinel maneuvers before undergoing nerve conduction studies[b]	NT	37	74	1.4	0.9	1.7	11
The validity of 12 provocative tests for CTS in a random sample of 504 people from the general population was assessed[c]	NT	50	61	1.3	0.8	1.6	10

1953 using calipers and by Moberg in 1958[155] using a paper clip.

Today it is recommended that a two-point aesthesiometer tool such as a Disk-Criminator (Fig. 18-69) be used. The instrument is explained and demonstrated to the patient until an appreciation can be made between one and two points in an area of normal sensibility. The instrument is applied, in a perpendicular fashion, to all of the fingertips in a mixed series of two and one points for five consecutive applications. The patient should be able to recognize at least four out of the five or seven out of ten.[23] The clinician repeats the tests in an attempt to find the minimal distance at which the patient can distinguish between the two stimuli, decreasing or increasing the distance between the points depending on the response by the patient.[23] This distance is called the threshold for discrimination. Normal discrimination distance is less than 6 mm, although this can vary between individuals, and in the area of the hand, with normal fingertip scores between 2 and 5 mm and finger surface scores between 3 and 7 mm.[156] Studies investigating the sensitivity and the specificity of this test indicate that the test has a high specificity but low sensitivity. For example, Buch-Jaeger and Foucher[157] found the test to have a sensitivity of 6 percent and a specificity of 99 percent. Another study by Gellman and colleagues[138] found the sensitivity to be 33 percent and the specificity to be 100 percent. These findings suggest that the test is useful for ruling in CTS.

Froment Sign. This is more of a sign than a test and may present as a complaint from the patient who reports an inability to pinch between the index finger and the thumb without flexion occurring at the DIP joint (Fig. 18-70).[158] A positive Froment sign, which results from a weakness in the AP and short head of the FPB muscles, indicates an ulnar nerve entrapment at the elbow or at the wrist.

Wrist ratio index. Sliding calipers are used to measure the mediolateral wrist width and then the AP height in centimeters. The caliper jaws are aligned with the distal wrist crease for both measurements. The wrist ratio index is calculated by dividing the AP measurement by the mediolateral measurement. A positive test for CTS is a wrist ratio of greater than 0.67. When used in isolation, the wrist ratio index does not appear to have strong diagnostic accuracy (Table 18-15).

FIGURE 18-70 Froment sign.

The Katz Hand Diagram. Katz and colleagues[159] developed a hand symptom diagram rating system, which categorizes the distribution of current neuropathic hand symptoms using a key of numbness, tingling, pain, and decreased sensation. The diagram is designed to help diagnose those patients who have classic, probable, possible, and unlikely categories for CTS based on completion of the diagram. A number of studies have examined the diagnostic usefulness of the Katz Hand Diagram (Table 18-16).

The Wazir sign.[160] The patient, wrist is rested in extension, supination, and a relaxed position supported by the clinician. Using a reflex hammer or finger tip, the clinician gently taps on the extended wrist around the palmaris longus tendon (Fig. 18-71). A positive sign, indicating cervical myelopathy, exaggerates response of finger flexion, thumb flexion, and wrist flexion. The basis of this sign can be explained on the basis of disinhibition of tendon stretch reflex of the long flexor tendons of the fingers (C7 and C8), wrist flexors (C6 and C7), and/or with the involvement of pyramidal tracts.

Adverse Neural Tension

The Median Nerve. The patient is positioned in supine lying or sitting. The cervical spine is side bent and rotated to the

FIGURE 18-71 The Wazir sign.

opposite side. The shoulder girdle is positioned in retraction, depression, extension, and external rotation. The elbow is positioned in extension, the forearm in supination, and the wrist in extension (Chapter 11). The fingers are positioned in extension. Nerve irritation is suspected if

- with the cervical spine in the resting position, the upper extremity position described above results in symptoms in the anterior (palmar)/radial side of the hand;
- if the symptoms increase with cervical side bending and rotation away from the tested extremity;
- if the symptoms decrease with side bending and rotation toward the tested extremity.

If adherence of the nerve is suspected at the wrist, the cervical spine is positioned in the resting position and the extremity is positioned as before. Neural involvement should be suspected if

- with wrist flexion the symptoms decrease, but increase when the cervical spine is side bent and rotated away from the tested extremity;
- with wrist extension and the cervical spine side bent and rotated to the tested extremity, the symptoms decrease.

Radial Nerve. The patient is positioned in a supine or sitting position and the shoulder is positioned in retraction, depression, extension, and internal rotation. The elbow is positioned in extension, the forearm in pronation, the wrist in flexion and ulnar deviation, and the fingers in flexion (Chapter 11). If a nerve adhesion is suspected at the wrist, the procedure is as for the median nerve, except that the wrist is placed in extension and then taken back into flexion.

The posterior (dorsal) sensory nerve, which can become implicated (Wartenberg syndrome; see "Intervention Strategies") in a variety of radial-sided injuries because of its superficial location, can be stretched with a combination of wrist flexion and ulnar deviation.

Ulnar Nerve. The shoulder girdle positioning used to describe the test for the median nerve is used. The elbow is flexed and supinated, the wrist is extended and radially deviated, and the fingers extended (Chapter 11). If a nerve adhesion at the wrist is suspected, the procedure is as for the median nerve.

Diagnostic Imaging

Diagnostic testing of the forearm, wrist, and hand is limited to plain radiographs for most patients (see chapter 7). Bony tenderness with a history of trauma or a suspicion of bone or joint disruption indicates a need for radiographs. Standard projections for the wrist are the posteroanterior, lateral, and oblique. For the patient with a suspicion of a scaphoid injury, a scaphoid view should be added.[4] Wrist conditions rarely require computed tomography scans and MRI scans.[131]

The Evaluation

Following the examination, and once the clinical findings have been recorded, the clinician must determine a specific diagnosis or a working hypothesis, based on a summary of all of the findings. This diagnosis can be structure related (medical diagnosis) (Tables 18-17 and 18-18) or a diagnosis based on the preferred practice patterns as described in the Guide to Physical Therapist Practice.

INTERVENTION STRATEGIES

To restore the balance and beauty and power to a disabled hand is an adventure. The stakes are high. The rewards are exciting. The penalties of failure are grievous.

—Paul W. Brand (1914–2003)

Functional rehabilitation of the upper extremity emphasizes the restoration of functional use of the hand.[109] Hand functions can range from activities that require a strong gripping action to those that require fine precision and gentle touch. Stability of the wrist and hand is provided by a combination of muscular effort and ligamentous support. Motion of the hand and wrist is provided by a vast array of muscles and tendons and several articulated linkages. The hand and wrist can be involved in both open- and closed-kinetic chain activities.

Pain is perhaps the most common complaint with wrist and hand injuries, with stiffness following closely behind. Some conditions, such as peripheral nerve injury (as a result of fracture, dislocation, disease, etc.), diabetes mellitus, Raynaud, and complex regional pain syndrome (CRPS), are characterized by a loss of sensibility to varying degrees. Sensory recovery progresses in time and space according to the following successive stages:[161]

- Perception of pain and temperature—establishment of protective sensation
- Perception of low-frequency vibratory stimuli (30 Hz) as well as moving sense
- Per static tactile sense, at the same time as perception of high-frequency vibratory stimuli (256 Hz)
- Two-point discrimination—the last form of sensation to develop

Motor recovery is always slower than sensory recovery with the first sign of motor recovery being the regression of the atrophy in the territory normally supplied by the injured nerve.[161] Later, a weak contraction can be detected in the first muscle supplied by the nerve distal to the lesion, although this contraction is not powerful enough to produce joint movement or to overcome gravity.[161]

TABLE 18-17 Differential Diagnosis for Common Causes of Wrist and Hand Pain

Condition	Patient Age	Mechanism of Injury	Symptoms Aggravated by	Observation	AROM	PROM	End Feel	Resisted	Special Tests	Tenderness with Palpation
Carpal tunnel syndrome	35–55	Gradual overuse Wide-variety of factors	Repetitive activities of wrist Sustained positioning of wrist in flexion	Thenar muscle atrophy (later stages)	Full and pain-free			Weakness of grip on radial side (chronic) Strong and pain free (acute)	Tinel Phalen	Reproduction of symptoms with compression applied on anterior aspect of wrist
Wrist extensor tendonitis	20–50	Repetitive or prolonged activities, forceful exertion, awkward and static postures, vibration, and localized mechanical stress		Unremarkable		Wrist pain with finger flexion combined with radial/ulnar deviation		Pain with wrist extension		Anterior carpus
Wrist flexor tendonitis	20–50	Forceful gripping, rapid wrist movements, moving the wrist and fingers to the extremes of range	Activities involving wrist extension	Unremarkable	Wrist extension	Pain with combined wrist extension and elbow extension		Pain with wrist flexion		Pisiform In palm over base of second metacarpal
OA of first CMC Joint	40–60	Repetitive trauma Degeneration	Repetitive use of thumb Strong gripping	Soft-tissue thickening at base of thumb	Midlimitation of all thumb movements	Pain with thumb rotation Pain on thumb extension and abduction		Weakness of grip on radial side (chronic)		Anatomic snuff box

(Continued)

TABLE 18-17 Differential Diagnosis for Common Causes of Wrist and Hand Pain *(Continued)*

Condition	Patient Age	Mechanism of Injury	Symptoms Aggravated by	Observation	AROM	PROM	End Feel	Resisted	Special Tests	Tenderness with Palpation
Trigger finger	50+	Disproportion between the flexor tendon and its tendon sheath		Thickening/ puckering of skin in palm	Decreased finger extension Clicing or jerking with movements	Full and pain-free	Soft-tissue resistance to finger extension	Strong and pain free		No pain, but snapping of flexor tendon felt with finger extension
De Quervains tenosynovitis	50+	Repetitive finger-thumb gripping combined with radial deviation	Overuse, repetitive tasks which involve overexertion of the thumb	Swelling over lateral wrist/ thumb	Decreased ulnar deviation Decreased thumb flexion	Pain on thumb flexion combined with ulnar deviation of wrist		Pain with abduction and extension of thumb	Finkelstein	Lateral wrist and thumb
Duputryens contracture	40+	Multifactorial (alcohol, diabetes, epilepsy, smoking, trauma)		Thickening/ puckering of skin in palm	Decreased finger extension		Soft-tissue resistance to finger extension	Strong and pain free	Inability to place the palm of your hand completely flat on a hard surface	No tenderness, but thickening of soft tissues evident
Thumb ulnar collateral ligament injury	Varies	Forced hyperabduction and/or hyperextension stress of the thumb MCP joint	Extension of the thumb	Swelling at the ulnar side of the MCP joint	Usually unremarkable	Pain with passive hyperextension/ yperabduction		Usually unremarkable	Stress testing of the UCL	Ulnar side of the MCP joint of the thumb
Wrist sprain	20–40	Trauma (FOOSH injury)	Taking weight through the hand	Possible swelling around wrist joint	Extremes of all ranges	Wrist pain with ulnar or radial deviation		Pain with strong resistance in any direction		Medial or lateral joint line

TABLE 18-18 Findings in Common Conditions of the Hand and Wrist

Condition	Findings
de Quervain stenosing tenosynovitis	Tenderness and swelling over the first posterior (dorsal) compartment at the radial styloid Finkelstein test aggravates pain
Dupuytren disease	Palpable nodules and pretendinous cords in anterior (palmar) aponeurosis, most commonly affecting the ring or the little finger Secondary flexion contracture of the MCP and, occasionally, PIP joints
Flexor tendon sheath infection	Cardinal signs of Kanavel present Finger held in flexed position at rest Swelling along the volar surface of the finger Tenderness on the volar surface of the finger along the course of the flexor tendon sheath Pain exacerbated by passive extension of the involved finger
Injury to the ulnar collateral ligament of the MCP joint of the thumb (skier's or gamekeeper's thumb)	Swelling and tenderness over the ulnar aspect of the thumb MCP joint Pain exacerbated by stress of the UCL Increased laxity of the thumb UCL (more severe injuries)
Scapholunate instability	Swelling over the radial wrist. X-rays show increased scapholunate gap on clenched fist view (>1 mm) Tenderness over the posterior (dorsal) wrist over the scapholunate ligament Scaphoid shift test produces abnormal popping and reproduces the patient's pain
Mallet finger	Flexed or dropped posture of the finger at the DIP joint History of jamming injury (impact of a thrown ball) Inability to actively extend or straighten the DIP joint
Jersey finger (FDP avulsion)	Mechanism is hyperextension stress applied to a flexed finger (e.g., grabbing a player's jersey) Patient lacks active flexion at the DIP joint (FDP function lost) Swollen finger often assumes a position of relative extension compared to the other more flexed fingers
Degenerative arthritis of the fingers	Heberden nodes (most common) Bouchard nodes (common) Mucous cysts (occasional) Decreased motion at involved IP joints Instability of involved joints (occasional)

Data from Mass DP, Reider B: Hand and wrist. In: Reider B, ed. *The Orthopaedic Physical Examination*. Philadelphia, PA: WB Saunders, 1999:99–158.

Physical therapy techniques that can be used to help with motor and sensory recovery include the following:

- Activities and techniques to increase tactile input including electrical stimulation, high-frequency vibration, and tapping
- Contrast baths (for vasomotor disturbances)
- Protection through splinting
- Dexterity activities
- Weight-bearing activities through the affected extremity
- Neurodynamic mobilizations (Chapter 11)

The techniques to increase joint mobility and the techniques to increase soft-tissue extensibility are described in "Therapeutic Techniques".

Acute Phase

The goals of the acute phase include the following:

- Protection of the injury site to allow healing.
- Control pain and inflammation.
- Control and then eliminate edema.
- Restoration of pain-free range of motion in the entire kinetic chain.
- Improve patient comfort by decreasing pain and inflammation.
- Retard muscle atrophy.
- Minimize detrimental effects of immobilization and activity restriction.[162–167]
- Scar management if appropriate.
- Maintain general fitness.
- Patient to be independent with home exercise program.

Pain and inflammation control is the major focus of the intervention program in the acute phase. This may be accomplished using the principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication). Icing for 20–30 minutes, three to four times a day, concurrent with nonsteroidal anti-inflammatory drugs (NSAIDs), or aspirin can aid in reducing pain and swelling.

One of the most significant problems a clinician faces with a hand-injured patient is the control and the elimination of edema. Edema can increase the risk of infection, decrease motion, and inhibit arterial, venous, and lymphatic flow.[168] Methods to control edema include elevation of the upper extremity and hand above the level of the heart, cryotherapy, active exercise, retrograde massage, intermittent compression, continuous compression wrapping, and contrast baths.

Therapeutic exercises are performed with the goal of regaining adequate soft-tissue rebalancing of the wrist by restoring the alignment of the extensor and the flexor tendons as near to normal as possible, and to prevent scarring or soft-tissue contractures by influencing the physiologic process of collagen formation. Movement is necessary to maintain joint mobility and gliding tendon function. Range-of-motion exercises are introduced as early as tolerated. These may be passive, active assisted, or active, as appropriate. If protected motion is necessary, it can be provided with taping, bracing, or in extreme cases, casting.

PROM exercises are performed through the available range of motion to maintain joint and soft-tissue mobility, or a passive stretch can be applied at the end range of motion to lengthen pathologically shortened soft-tissue structures, thereby increasing motion. Depending on the focus of the intervention, the PROM exercises may include

- MCP flexion and extension (Fig. 18-72).
- PIP and DIP flexion and extension (Fig. 18-73) and combined flexion and extension (Fig. 18-74).

AROM exercises should include specific and composite exercises. Composite exercises, which include fisting and thumb opposition to each digit in addition to exercises involving the wrist, elbow, and shoulder are designed to reproduce normal functional activities. Fast ballistic movements are discouraged if the goal is to restore mobility in the presence of increasing tissue resistance.[169] Examples of AROM exercises include the following:

- Active wrist and finger flexion and extension, wrist ulnar and radial deviation, finger adduction and abduction, and thumb opposition (Fig. 18-75), flexion, extension, abduction, and adduction. The wrist and hand muscles are usually exercised as a group if their strength is similar.

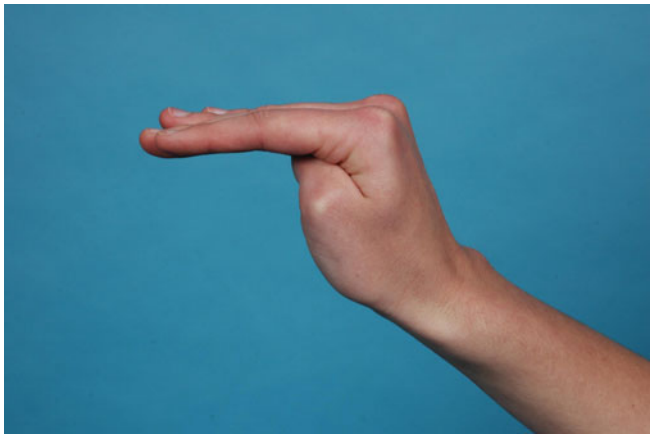

FIGURE 18-72 Isolated MCP flexion.

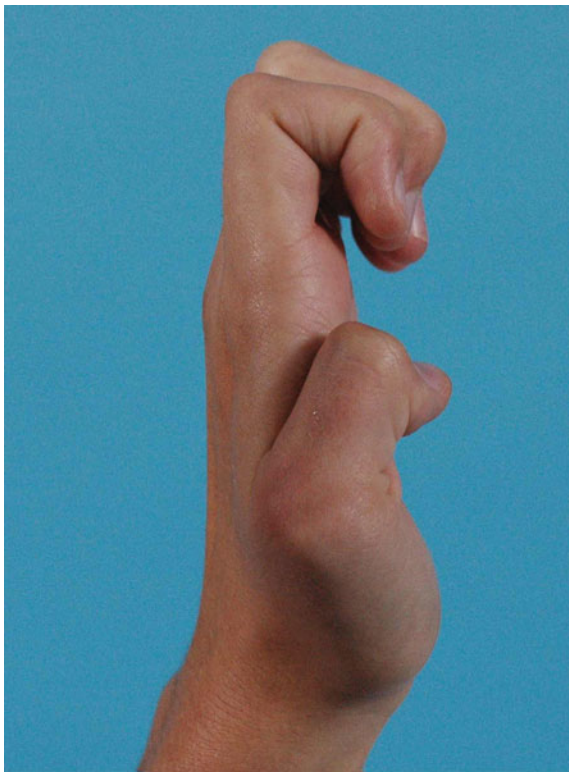

FIGURE 18-73 Isolated PIP and DIP flexion and extension.

Weaker muscles should be isolated in a similar fashion as that used when isolating the muscle for manual muscle testing. Protected range-of-motion exercises are performed to selectively mobilize joints and tendons while minimizing stress on repairing structures. As their name suggests, protected range-of-motion exercises are accomplished by placing the repaired structure in a protected position while adjacent tissues are carefully mobilized. An example of protective exercise can be seen following a radial nerve injury, where tendon transfers of the pronator teres, FCU,

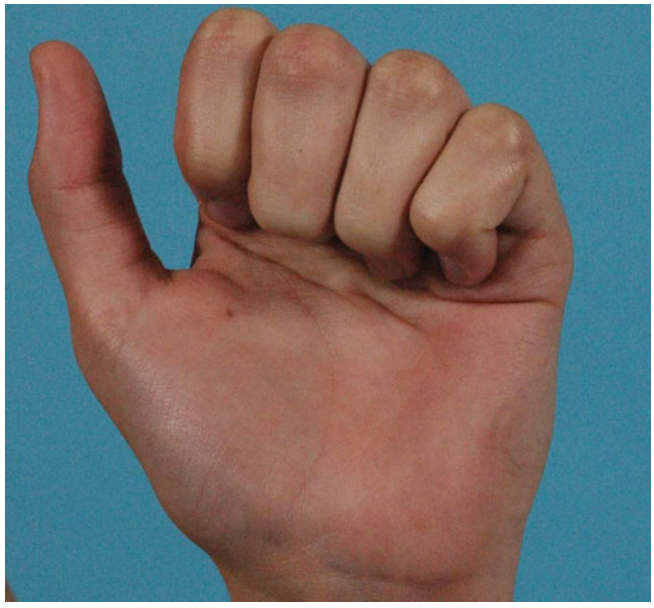

FIGURE 18-74 MCP, PIP and DIP flexion and extension.

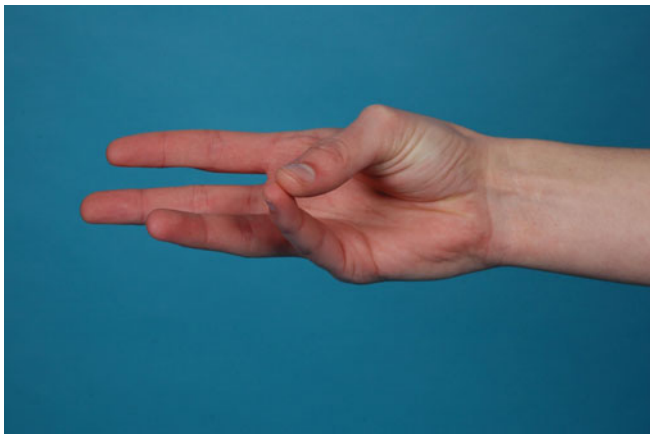

FIGURE 18-75 Thumb opposition.

and FDS may be performed.[169] Following the surgery the hand is immobilized with the wrist, MCP joints, and thumb in extension. At approximately 4 weeks, protective active motion exercises are introduced. These include MCP joint flexion and then PIP and DIP joint flexion with the MCP joint maintained in extension.[169]

- Active exercises of forearm pronation and supination.
- Active exercises of elbow flexion and extension

The AROM exercises are progressed to submaximal isometrics and muscle co-contractions. These early strengthening exercises are performed initially in the available pain-free ranges and, as pain subsides, are gradually progressed so that they are performed throughout the entire range.

Scar tissue management focuses on the control of stresses placed on healing tissues. Early active and passive motion provides controlled stress, encouraging optimal remodeling of scar tissue.[168] Methods to control scarring include the use of thermal agents, transverse friction massage (TFM) (see Chapter 11), mechanical vibration, compressive techniques, and splinting.

Splinting of the wrist and hand may be necessary. It is not within the scope of this text to provide comprehensive detail with regard to splinting. Entire texts are devoted to the subject.[170–173] However, splinting can often be an integral part of the rehabilitation program, and creative splinting can provide a useful adjunct to exercise. The general purposes of a splint are as follows[174,175]:

- ***Prevent or correct deformity or dysfunction.*** Maintain or re-establish normal tissue length, balance, and excursion.
- ***Immobilize/stabilize.*** To stabilize a mobile joint so the corrective exercise force can be directed to the stiff joint or adherent tendon.[169]
- ***Protect.*** Static splints have no moveable parts and maintain joints in one position to promote healing and minimize stress.
- ***Control/modify scar formation.***
- ***Substitute for dysfunctional tissue.***
- ***Provide exercise.*** *Dynamic splints* are used to provide active resistance in the direction opposite their line of pull to increase muscle strength, as well as to apply a corrective passive stretch to tendon adhesions and joint contractures.[169] *Drop-out* splints, which are commonly used with elbow flexion contractures, block joint motion in one direction but allow motion in another. Articulated splints contain at least two static components and are designed in such a way as to allow motion in one plane at a joint. *Static-progressive* splints involve the use of inelastic components to allow progressive changes in joint position as PROM changes without changing the structure of the splint. *Serial static* splints differ from static progressive splints in that they require the clinician to remold the splint to accommodate changes in range of motion.

Functional Phase

The functional phase of rehabilitation is usually initiated when normal wrist positions and co-contractions of the wrist flexors and extensors can be performed. The goals of the functional phase include the following:

- Attain full range of pain-free motion.
- Restore normal joint kinematics.
- Improve muscle strength to within normal limits.
- Improve neuromuscular control.
- Restore normal muscle force couple relationships.

The AROM exercises, initiated during the acute phase, are progressed until the patient demonstrates they have achieved the maximum range anticipated.

Normal joint kinematics are restored using joint mobilization techniques. Joint mobilization techniques refer to passive traction and/or gliding movements to joint surfaces that maintain or restore the joint play normally allowed by the capsule. The joint mobilization techniques for the forearm, wrist, and hand are described in "Therapeutic Techniques" at the end of this chapter.

Resistive exercises not only increase muscle strength and endurance, but also improve the ability of the patient to actively mobilize stiff joints.[169] Resistance exercises for the hand and wrist can be classified as either static (isometric) or dynamic (concentric, eccentric, or isokinetic). Strengthening of the muscles of the wrist and hand begins with specific exercises and progresses to exercises that involve the entire upper kinetic chain, including the trunk. Isometric exercises may be continued from the acute phase when the available range of motion remains restricted. Wherever possible, resistance exercises that strengthen functional muscle groups rather than individual muscles should be selected.[169] Specific exercises for the wrist and hand include the following:

- Resisted exercises into pronation (Fig. 18-76) and supination (Fig. 18-77).
- Hand and finger dexterity exercises including the nine-peg board (Fig. 18-78) or stroking exercises.
- Manually resisted exercises (Fig. 18-79). These are performed by the clinician initially, before becoming part of the patient's home exercise routine (Fig. 18-80).
- Resisted exercises can be performed using gripping with light resistive putty (Fig. 18-81) or a hand exerciser

FIGURE 18-76 Resisted pronation.

FIGURE 18-77 Resisted supination.

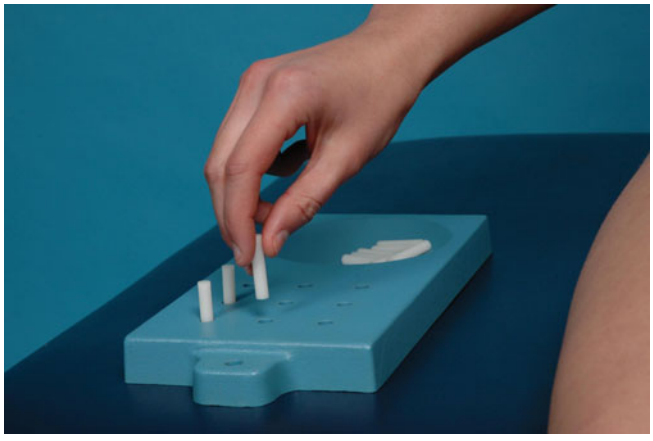

FIGURE 18-78 Nine-peg board.

(Fig. 18-82). Care must be taken with gripping or squeezing exercises because they typically restrict the use of the full range of motion.

- Resisted exercises can also be performed using elastic resistance (Fig. 18-83) or dumbbells (Fig. 18-84).
- Wrist extension should be done in pronation to work against gravity or in neutral forearm rotation to eliminate gravity. This exercise encourages the involvement of the ECRL, ECRB, and ECU. MCP flexion can be employed to eliminate any contribution from the ECU, thereby isolating the wrist musculature.
- Wrist flexion should be done in supination to work against gravity or in neutral forearm rotation to eliminate gravity. Wrist flexion works the FCU and FCR.

FIGURE 18-79 Manually resisted exercises.

FIGURE 18-80 Resistance using elastic bands.

FIGURE 18-81 Putty exercises.

FIGURE 18-82 Hand exerciser.

FIGURE 18-83 Resisted wrist flexion with elastic resistance.

- Proprioceptive neuromuscular facilitation patterns of the upper extremity are performed actively and then with resistance. These patterns incorporate the conjunct rotations involved with finger, hand, and wrist motions.

FIGURE 18-84 Resisted wrist extension with dumbbell.

- Wall push-ups encourage full wrist extension, while full push-ups require full, or close to full, wrist extension.
- ***Wrist flexion ball flips.*** Holding a small weighted ball, the patient leans forward over a treatment table so that the forearm is resting on the table but the hand and wrist is over the end, palm facing upward. The patient is asked to toss the ball in the air and then to catch it while keeping the elbow on the table.

The exercises for the other joints of the upper extremity are outlined in Chapters 16 and 17.

PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Rheumatoid Arthritis[176]

RA is a disease that affects the entire body and the whole person (see Chap. 5). It is a lifelong disease, which in the majority of people is only modified somewhat by intervention.[177] The cycle of stretching, healing, and scarring that occurs as a result of the inflammatory process seen in patients with RA causes significant damage to the soft tissues and periarticular structures.[178] As a consequence, these events may lead to pain, stiffness, joint damage, instability, and ultimately deformity. Many common hand and wrist deformities can be seen,[179] such as ulnar deviation of the MCP joints,[180] boutonnière deformity,[181] and swan-neck deformities of the digits.[182]

Ulnar Drift. The deformity of the ulnar drift and anterior (palmar) subluxation (Fig. 18-85A) is a result of a complex interaction of forces and damage to collateral ligaments and extensor mechanisms. Clinically, ulnar drift of the MCP articulations often precedes the wrist deformities.[23] The ulnar drift results in an imbalance that has the resultant effect of pulling the fingers into ulnar deviation, pronation, and

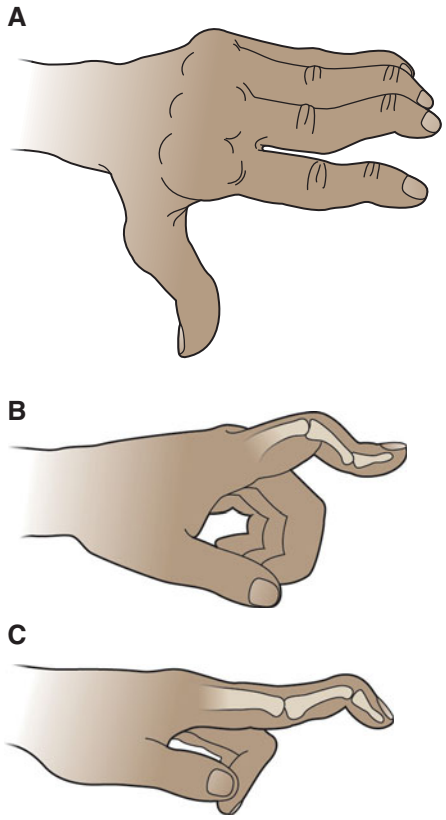

FIGURE 18-85 Finger deformities.

anterior (palmar) subluxation. The list of causes includes the following[179,183]:

- Subcollateral synovitis and weakening of the radial collateral ligament
- Distortion and attenuation of the sagittal fibers of the extensor hood
- A natural displacement of the extensor tendons to the ulnar side
- Radial deviation of the wrist
- Secondary contracture of the ulnar side intrinsic muscles
- Dysfunction of the radial side intrinsics
- Displacement of the flexor tendons to the ulnar side
- Appositional pinch (i.e., key pinch)
- Gravity
- The natural anatomic shape of the metacarpal head

Normally, in the flexed position, minimal lateral movement occurs at the MCP joint, but with increased laxity of the collateral ligaments, up to 45 degrees of lateral deviation occurs in this position.

Boutonnière Deformity. The boutonnière or buttonhole deformity (Fig. 18-85B) occurs when the common extensor tendon that inserts on the base of the middle phalanx is damaged. Damage to the central slip insertion requires extra effort to extend the joint, causing hyperextension at the DIP joint. The failure of the lateral bands to be connected to the central slip allows these bands to drift forward. Eventually they pass the axis of rotation of the PIP joint, and instead of extending this joint, they act as flexors while still hyperextending the distal joint. Such destruction also results in the loss of the influence of the interosseous muscles, ED longus, and lumbrical muscles on the PIP joints. Simultaneous with the loss of this muscle influence, the lateral bands of the extensor mechanism slide anteriorly. The realignment of the extensor mechanism, coupled with the loss of certain muscle influence, produces a deformity of extension of the MCP and DIP joints and flexion of the PIP joint. This is the classic boutonnière deformity.[182] The causes, namely synovitis, central slip rupture, and displaced lateral bands, are treatable by synovectomy,[184] repair, or reconstruction of the central slip and relocation of the lateral bands.

Other causes of boutonnière deformity include injuries caused by division, rupture, avulsion, or closed trauma to the common extensor tendon. The boutonnière deformity is the second most common closed tendon injury in sports.[26] In sports, the mechanism of injury is either a severe flexing force to the PIP joint or a direct blow to the posterior (dorsal) aspect of the PIP joint, which results in damage to the common extensor tendon. If traumatic in origin, this condition can be difficult to diagnose due to the degree of swelling, but if more than a 30-degree extension lag is present at the PIP joint, a boutonnière lesion should be suspected.[26]

The presence of a mobile correctable deformity requires little more than immobilizing the PIP in full extension for 6–8 weeks, with the DIP and MCP joints held free. Gentle AROM exercises can begin for flexion and extension of the PIP joint at 4–8 weeks, with the splint being reapplied between exercises. General strengthening usually begins at 10–12 weeks. For a return to competition an additional 2 months is required.[26]

Swan-Neck (Recurvatum) Deformity. The swan-neck deformity is characterized by a flexion deformity at the DIP and hyperextension of the PIP joint. This deformity is the least functional of all of the deformities that exist within the hand. Destruction of the oblique retinacular ligament of the extensor mechanism leads to posterior (dorsal) displacement of the lateral bands of the extensor mechanism. This rearrangement leads to an increased extensor force across the PIP joint with a resulting hyperextension of the PIP joint. The extended position of the PIP joint stretches the FDS and FDP tendons. The pull on the FDP tendon causes a passive flexion of the DIP joint. The resultant loss of function includes an inability to bring the tips of the fingers into grasp. The hypertrophy of rheumatoid synovitis displaces the tendon of the ECU forward. An alteration in posture at one joint leads to the reverse posture of the adjacent joint.[81] In addition to rheumatologic diseases, other etiologies include extensor terminal tendon injuries, spastic conditions, fractures to the middle phalanx that heal in hyperextension, and generalized ligamentous laxity.[182]

Clinical findings include a hyperextended PIP joint with a flexed DIP joint of the same digit (Fig. 18-85A).

The intervention for swan-neck deformity depends on the etiological status of the PIP joint and its related anatomic structures. The intervention for a swan-neck deformity with no loss of PIP joint flexion is usually conservative, with a Silver Ring splint used for the correction of the PIP hyperextension.[81]

Other deformities produced by RA

Radial Deviation of the CMC Block. This deformity is the result of the predominant action of the radial tendons (i.e., the FCR and the extensors carpi radialis longus and brevis), which radially deviate the CMC block. This deviation increases the angle between the radial border of the second metacarpal and the lower border for the distal radius, resulting in an important loss of muscular power in the flexors.[23,66]

The deviation of the wrist can involve an opposite deviation of the MCP joint, when the stabilizing elements of these joints (lateral ligament and volar plate) are weakened. The radial deviation of the CMC block may produce ulnar deviation of the MCP joints because of the interdependence of various articulations in the longitudinal chains.[23,185,186]

Effects of RA

The end result of the above-mentioned deformities is a reduction in the function of the hand and upper limb. Although humans are capable of significant compromise and adaptation, the loss of function that occurs with RA progressively accumulates to a point at which simple tasks become more difficult. The decreased excursion of tendons, weakness of muscles, and reduction of range of motion in joints multiplies the overall effects. Even when the muscle power is available, it may not be applied in the most effective direction. Joint laxity, which has been precipitated by synovitis and recurrent effusion, is progressively aggravated. Eventually the individual cannot cope with the resulting difficulties with doing activities of daily living. This is the characteristic end point of this progressive disease.

Interventions for RA of the Hand and Wrist

Because pain and instability of the wrist prevent much of the power from the forearm muscles from being transmitted from the wrist to the hand, some stabilization at the wrist level is necessary. The assessment of the thumb and finger problems involves careful evaluation of grasp and pinch. Based on the pathomechanics of the rheumatoid process, the following concepts form the foundation of any intervention to manage RA of the hand[187]:

1. Control the inflammation.
2. Focus on joint systems rather than isolated joints.
3. Consider the status of all tissues in the hand.
4. Consider the type of rheumatoid disease. The intervention is related to the type of rheumatoid disease:
    a. The type in which scarring outweighs the articular damage. Patients with stiff joints because of scarring do poorly after soft-tissue surgery. Patients in this group require aggressive and sustained therapy, often for 3–4 months.
    b. The type in which joint laxity and tissue laxity become difficult to stabilize after soft-tissue procedures. The patients in this group require careful intervention and control of the ROM and the direction of motion by the use of splints for many months after surgery.

The components of the intervention for patients with RA of the hand include the following:

1. ***Exercises.*** A combination of active exercises and isometric exercises are recommended to maintain muscle strength and improve range of motion. Range-of-motion exercises that encourage excursion of the long flexors are emphasized. The hand intrinsics are stretched by placing the MCP joints in extension and radial deviation while simultaneously flexing the PIP and DIP joints. Resistive exercises need to be introduced carefully due to the inflammatory nature of RA. Gentle squeezing exercises using a sponge in a tub of warm water are recommended. Bony and soft-tissue surgery will be less than successful in restoring function if there is residual severe imbalance in the forces acting across the joint.
2. ***Joint protection/energy conservation.*** Joint protection is the process of reducing internal and external stresses on the joints during functional activity and to help prevent poor use and abuse of the hand and wrist. Joint protection techniques include the following:
    a. Patient education to increase awareness of those activities that are stressful to the joints. In particular, tight and prolonged grasping should be avoided.
    b. The reduction of forces through the use of adaptive equipment and the avoidance of repetitive activities, positions of deformity, and the lifting of heavy weights. Many excellent self-help devices are available. Unless there is a reasonable use of the hand, any remaining imbalance will cause failure as shown in the secondary cycle of rheumatoid disease.
    c. The use of the larger/stronger and more proximal joints and muscles when available.
    d. The balance of rest and activity by planning ahead and using paced rests. Stress, rest, and sleep can have a significant effect on symptoms.
    e. The use of energy conservation techniques and labor-saving devices. Energy conservation involves sitting when able, organizing workspace and storage for accessibility, resting during activities when able, and using time savers such as prepared foods. Many different merchants offer adaptive equipments such as zipper pulls, kitchen utensils with enlarged handles, jar openers, and pens with a large grip.
    f. Elimination of some activities.
    g. Work simplification.
3. ***Splinting.*** Static splinting can be used to immobilize painful joints and prevent further deformity through positioning.
4. ***Pain management.*** The clinician should encourage the patient to investigate alternatives to pain medication, such as relaxation techniques, yoga, adopting a positive outlook, and the use of thermo- or cryotherapy.

TFCC Lesions

Injuries to the TFCC typically occur following a fall on the supinated outstretched wrist or as the result of chronic repetitive rotational loading.

Patients with lesions of the TFCC complain of medial wrist pain just distal to the ulna, which is increased with end-range forearm pronation/supination and with forceful gripping. Often there is a painful click during wrist motions. Tenderness is clearly localized to the posterior (dorsal) anatomic depression, which is immediately distal to the ulnar head.[188] Passive mobilization of the carpal condyle against the head of the ulna, with the wrist in passive or active ulnar deviation, will frequently elicit a painful crepitus or roughness, or more rarely an actual snap (McMurray test for the wrist). Passive supination combined with ulnar deviation can also reproduce the pain.

Initial radiographs are usually negative but can provide information as to whether an ulna-plus variance coexists with the triangular fibrocartilage tear (ulnocarpal impingement syndrome).[188] This condition is diagnosed on radiographs showing cystic or erosive changes in the ulnar head and along the proximal contour of the lunate.[189]

Injuries to the central, avascular portion of the disk are not amenable to spontaneous repair, whereas injuries to the vascularized periphery are.[188]

The conservative invention for a TFCC injury typically includes a long arm cast or splint fitted with the elbow in 90 degrees of flexion, and the forearm and wrist in ulnar deviation and extension for 6 weeks, if the TFCC is unstable.

While the wrist is in a cast or splint, the intervention should include proximal range-of-motion and strengthening exercises.

Active and active assisted exercises are initiated to the wrist and forearm after cast removal, with emphasis on flexion and extension initially, followed by pronation/supination, and radial/ulnar deviation. Two weeks after cast removal, assuming the patient is asymptomatic, progressive strengthening is initiated to the hand and wrist, taking care to prevent torsional loads to the wrist.

Osteoarthritis

Osteoarthritis (OA) is the most common joint disease (see Chap. 2). This condition can be primary or secondary, depending on the presence of a preexisting condition. While primary OA commonly involves the first CMC joint or sometimes the scaphotrapeziotrapezoid joint, it is uncommon in other parts of the joint.[188]

Secondary OA of the wrist attributable to an old trauma or infection is very common. In the case of malalignment of the scaphoid, degenerative arthritis will progress according to a very specific pattern that leads to an SLAC (scapholunate advanced collapse) wrist.[188] Degeneration occurs between the radius and the scaphoid and then between the lunate and the capitate. The radiolunate joint is almost never involved. Finally, a scapholunate diastasis develops and the capitate slides in between the lunate and the scaphoid.[190]

Patients with first CMC joint arthritis typically present with joint pain at the base of the thumb which is increased with use, restricted ROM in a capsular pattern, and joint crepitus.[188] First CMC arthritis is more common in women than men and is typically found in those 45 years and older.

Conservative intervention includes splinting, thermal modalities (moist heat or paraffin), and patient education.

Splinting. The splint should position the CMC joint in anterior (palmar) abduction to maximize the stability and anatomic alignment of the joint, with the IP joint free.[188]

Patient Education. The patient should be advised to

- minimize or avoid mechanical stresses including sustained pinching;
- avoid sleeping on the hands as this forces the thumb into adduction;
- use self-help devices such as jar lid openers and ergonomic scissors.

Gout

See Chapter 5.

Dupuytren Contracture (Palmar Fasciitis)

Population studies have shown that Dupuytren disease nearly always affects Caucasian races, particularly those of northern European descent.[191,192] The incidence increases with advancing age and it is exceedingly rare in children.[193] Men are 7–15 times more likely to have a clinical presentation requiring surgery than women, who tend to develop a more benign form of the disease that appears later in life.[194,195]

The etiology of Dupuytren disease is thought to be multifactorial. There is a higher incidence in the alcoholic population, the diabetic population, and the epileptic population.[195–197] Because of the association between smoking and microvascular changes in the hand, some believe that tobacco may also play a role in this disease.[195] Although not usually related to hand trauma, Dupuytren disease occasionally develops after significant hand injuries, including surgery.[198]

Dupuytren disease is an active cellular process in the fascia of the hand, which is characterized by the development of nodules in the palmar and digital fascia, which occur in specific locations along longitudinal tension lines.[191,195] The pathologic changes in the normal fascia result in the formation of tendon-like cords.[199–201] The characteritic contracture, which behaves similarly to the contracture and maturation of wound healing is caused by a thickening and shortening of the fascia.[195] The contractures form mainly at the MCP and PIP joint, and occasionally at the DIP joint.[202] The most commonly involved digit is the little finger, which is involved in approximately 70 percent of patients.

The diagnosis of Dupuytren disease in its early stages may be difficult and is based on the palpable nodule, characteristic skin changes, changes in the fascia, and progressive joint contracture. The skin changes are caused by a retraction of the overlying skin, resulting in dimples or pits.

Dupuytren disease can be classified into three biologic stages[200]:

- ***First stage.*** This proliferative stage is characterized by an intense production of myofibroblasts and the formation of nodules.
- ***Second stage.*** This involutional stage is represented by the alignment of the myofibroblasts along lines of tension.

- ***Third stage.*** During this residual stage, the tissue becomes mostly acellular and devoid of myofibroblasts, and only thick bands of collagen remain.[203]

The disease, which is usually bilateral, tends to be more severe in one hand, although there appears to be no association with hand dominance. Up to three rays may be involved in the more severely affected hand.

To date, conservative interventions have not yet proven to be clinically useful in the treatment of established contractures.[204] Some surgeons feel that any amount of PIP joint contracture warrants surgery, whereas others feel that 15 degrees or greater is an indication.[191,205] Surgery is the intervention of choice when the MCP joint contracts to 30 degrees and the deformity becomes a functional problem.[205]

Studies have shown that 50 percent of operative results depend on the postoperative management of effective splinting and exercise.[195,206] The intervention should be directed toward promoting wound healing, which in turn minimizes scarring and maximizes scar mobility so that hand function can be restored.[195]

Scar management and splinting are an important part of the postoperative management. The initial splint is positioned to provide slight MCP joint flexion of 10–20 degrees with PIP joint extension to allow maximal elongation of the wound.[195] Active, active assisted, and passive exercises are usually initiated immediately.

Wrist Sprains

The most common wrist sprain results from a downward force to the wrist exceeding its normal range of motion.[207] This forced movement of the joint is followed immediately by intense pain that subsides and then returns.[4]

Swelling typically occurs within 1–2 hours of the injury, with the degree of joint swelling indicating the severity of injury. With severe injuries, ecchymosis develops in 6–12 hours. Differential diagnosis includes a carpal fracture, particularly the scaphoid and lunate, traumatic instability, or a ligament tear.[208]

Conservative intervention depends on the severity of the sprain but likely includes some form of immobilization of the wristto avoid exacerbating the injury. Custom splints, which cover the palm and extend to about midforearm, are designed to allow for proper hand and wrist contouring while and to allow the fingers to move freely.[4] Cocking the wrist up about 10 degrees places the wrist in a position of rest.

Slight sprains typically remain splinted for 3–5 days. The splint is worn at all times except for removal for hygiene and exercise. More severe sprains take longer to recover, but should still be removed from the splint in 3–5 days to avoid stiffness.[4] Icing for 20–30 minutes, three to four times a day, concurrent with NSAIDs or aspirin can aid in reducing pain and swelling.

After splint removal, a rehabilitation program of AROM (wrist curls) should be started. Until the pain and swelling subside, wrist curls can be done in water to reduce muscle effort.[207] The clinician should consider taping the wrist to provide support and help decrease pain. The exercises are progressed to include a strengthening regime based on the hierarchy of strengthening exercises (see Chap. 12).

Perilunate Dislocation

A perilunate dislocation results from disruption of the scapholunate ligament, then extension of the injury to the capitolunate articulation and the lunotriquetral ligament.[209] Most carpal dislocations are of the perilunate variety with the lunate dislocating in an anterior (palmar) direction. This is accompanied by damage to both of the interosseous ligaments of the proximal row and possible injury to the median nerve.[9]

The usual mechanism of injury is hyperextension of the wrist. Physical examination is often limited, revealing swelling and a deformity, and the injury may be confused for a distal radius fracture. If the median nerve is involved, paresthesias or numbness in the median nerve distribution may be present. The dislocation is easily reduced if the intervention occurs soon after the injury. The reduction involves placing the wrist in extension and putting pressure on the lunate, after which the wrist is moved into flexion and immobilized.

Kienböck Disease

Kienböck disease is an aseptic necrosis, or osteonecrosis of the lunate. When the disease becomes advanced, carpal collapse, joint incongruity, and OA develop. The choice of treatment for patients with symptomatic Kienböck disease depends largely on the severity of the disease. Surgical intervention can include excision arthroplasty, limited intercarpal arthrodesis, revascularization, arthrodesis between the radius and the lunate, and vascular bundle implantation.[210] Conservative management of Kienböck disease involves immobilization in a short arm cast. Upon cast removal at 6–10 weeks, AROM exercises are initiated for the wrist, forearm, and thumb. Within 1–2 weeks following cast removal, PROM exercises are initiated. A wrist and thumb static splint is fitted with the wrist in neutral and the thumb midway between radial and anterior (palmar) abduction and is worn between exercise sessions and at night.

Intercarpal Instabilities

The integrity of the carpal relationship depends on the stability provided by both the interosseous ligaments and the midcarpal ligaments.[9] This relationship ensures that the carpal bones move as a unit. Conversely, disruption of this relationship allows abnormal independent motion of one or two carpal bones. Instability patterns are divided into those that are static and those that are dynamic. Static instability is the more severe of the two and usually involves a complete tear of one of the supporting ligaments or a fracture.[9] Dynamic instability patterns typically occur when the wrist is stressed. Carpal instability patterns that occur within the same row are classified as dissociative while those that occur across different rows are classified as nondissociative.

Dissociative. Two types of dissociative instability have been recognized[56]:

1. ***DISI (dorsal(posterior) intercalated segment instability).*** The most common dissociated instability is the scapholunate dissociation, in which the scapholunate angle is greater than 70 degrees when viewed on radiograph. Scapholunate instability usually follows a FOOSH injury where the primary forces are transferred through the wrist

in extension and ulnar deviation. As the scaphoid and lunate become disassociated, the lunate no longer follows the scaphoid into flexion, instead migrating with the triquetrum into a dorsal (posterior) angulation.[9] The patient with this type presents with difficulties and weakness with grasping and complains of chronic, vague wrist pain. The examination reveals tenderness over the scaphoid and/or lunate, laxity between the scaphoid and lunate, and a positive scaphoid-shift test.

2. ***VISI (ventral intercalated segment instability).*** The second most common dissociative instability is the lunatotriquetrum dissociation. Ventral refers to the ventral (anterior) tilt of the distal end of the lunate. The signs and symptoms for this instability are similar to those of the scapholunate instability, except for the location. In this type, the lunate remains tethered to the scaphoid by the interosseous ligament but not necessarily to the triquetrum.[9] During wrist motions, the lunate follows the scaphoid into a flexed posture, but the triquetrum does not. A scapholunate angle of less than 30 degrees indicates a VISI lesion.

Nondissociative. This is the most common dynamic instability of the wrist and usually results from an insufficiency of the posterior (dorsal) intercarpal ligaments. The nondissociative instability may not be symptomatic, and the patient may be able to sublux and reduce the joint at will.[9] A clunk can be felt to occur as the distal row jumps back into place at the extreme of ulnar deviation.[211]

Conservative intervention for carpal instabilities usually involves a trial period of cast immobilization. Surgery is reserved for chronic cases.

UCL Sprain of the Thumb

UCL injuries, also known as *gamekeeper's thumb*, and *skier's thumb*,[212] involve injury to the MCP joint of the thumb and are the most common ligament injury of the hand.[213]

The patient typically complains of pain or tenderness on the ulnar aspect of the MCP joint.

For the purposes of planning the intervention, these injuries can be divided into two categories:

- Grade I and II sprains, in which the majority of the ligament remains intact. The stability of the joint is tested in full extension and at 30 degrees of flexion, which stress the accessory collateral ligament and the UCL, respectively. An angulation of greater than 35 or 15 degrees greater than the uninvolved side indicates instability and the need for surgical intervention. Grade I and II tears are treated with immobilization in a thumb spica cast (a forearm-based splint fabricated from an anterior (palmar) or radial approach) for 3 weeks, with additional protective splinting for 2 weeks. Thumb spica splints are designed to immobilize the wrist, CMC, and MCP joints of the thumb, thereby permitting the radial wrist extensors and the proximal thumb to rest. Thumb spicas can be used for the intervention of a number of conditions including de Quervain disease and CMC arthritis.

When applying these splints, it is very important to ensure that the superficial radial nerve and the ulnar digital nerve of the thumb are not compromised. The splint is worn at all times except for removal for hygiene and exercise. AROM of flexion and extension begins at 3 weeks and progresses to strengthening exercises by 8 weeks, taking care not to apply any abduction stress to the MCP joint during the first 2–6 weeks.

- Grade III tears and displaced bony avulsions are treated with surgery and subsequent immobilization. If the ligament is completely torn, there is concern for a Stener lesion, in which the torn UCL protrudes beneath the adductor aponeurosis.[214] Postsurgical rehabilitation involves wearing a thumb spica splint for 3 weeks with an additional 2 weeks of splinting, except during the active flexion and extension exercises. Otherwise the exercise progression is the same as for the grade I and II sprains.
- Radial collateral sprains are classified and treated in a similar manner.

Ulnar Impaction Syndrome

The ulnar impaction syndrome can be defined as excessive impaction of the ulnar head against the TFCC and ulnar carpal bones. This results in a progressive degeneration of those structures.[215]

The patient with this syndrome typically presents with ulnar wrist pain and a limitation of motion. Upon physical examination, a combined motion of ulnar deviation and compression reproduces the pain (see "Special Tests").

The differential diagnosis includes ulnar impingement syndrome and arthrosis or incongruity of the DRUJ.[215]

It is important to remember that in the absence of obvious structural abnormalities, the ulnar impaction syndrome may result from daily activities that result in excessive intermittent loading of the ulnar carpal bones.

Conservative intervention includes the use of an ulnar gutter splint if there is evidence of wrist overloading.

Ganglia

Ganglia are thin-walled cysts containing mucoid hyaluronic acid that develop spontaneously over a joint capsule or tendon sheath. They are the most common soft-tissue tumor in the hand.[131,146] Common sites for ganglia are the anterior (volar) or posterior (dorsal) surfaces of the wrist and fingers.[4] Ganglia may not cause pain.[9] Frequently, as the ganglion begins to grow, the patient reports aching that is irritated by flexion and extension of the joint.[4]

At times, ganglia occur at other parts of the wrist, causing compression of the ulnar or median nerve.[4] When compression occurs, associated sensory symptoms in the digits or intrinsic muscle weakness may develop.[146] Upon examination, a ganglion is smooth, round, or multilobulated and tender with applied pressure.

For symptom relief, immobilization of the wrist through splinting is effective. This may cause the ganglion to shrink temporarily, although it is uncommon for the immobilization to be effective in resolving the ganglion.[146] Needle aspiration can resolve the ganglion. Occasionally, surgical excision is indicated for the patient with significant pain or cosmetic irritation (Table 18-19).

TABLE 18-19	Rehabilitation Protocol After Excision of Wrist Ganglion
Time Frame	**Intervention**
2 Wks	Remove the short arm splint and sutures Initiate active and active-assisted wrist extension and flexion Continue interval splint wear during the day between exercises and at night
2–4 Wks	Advance ROM exercises to resistive and gradual strengthening exercises Discontinue the splint at 4 wks
4–6 Wks	Allow normal activities to patient's tolerance
6 Wks	Allow full activity

Data from Brotzman SB, Calandruccio JH, Jupiter JB: Hand and wrist injuries. In: Brotzman SB, Wilk KE, eds. *Clinical Orthopaedic Rehabilitation*. Philadelphia, PA: Mosby, 2003:1–83.

Chondromalacia

Chondromalacia of the ulnar head is usually seen in young patients after a fall on the dorsiflexed wrist with the impact predominantly hypothenar, or repeated episodes of stressful pronation and supination (work or leisure activity).[188] The pain is localized to the posterior (dorsal) distal radioulnar area and manipulation of the ulnar head can elicit crepitation or a painful snap.[189]

Racquet Player's Pisiform

Racquet player's pisiform is a condition involving a minor subluxation of the pisiform, with occasional chondromalacia of the articular cartilage of the pisotriquetral joint.[16] The probable mechanism is a torsional stress upon the capsule of the pisotriquetral joint by the powerful and rapid pronation and supination movements at the wrist seen when wielding a racquet, particularly in badminton, racquetball, and squash players.

The typical clinical presentation is one of pain, disability, and swelling on the ulnar aspect of the wrist or proximal palm. The pain is reproduced with passive movement of the pisiform upon the triquetrum with the relaxed wrist flexed and ulnarly deviated.[16]

The typical intervention for this condition is surgical excision of the pisiform.[16]

PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION ASSOCIATED WITH LOCALIZED INFLAMMATION

Tendonitis and Tenosynovitis

Tendonitis is a term that clearly indicates an inflammation of the tendon or tendon–muscle attachment, whereas tenosynovitis involves an inflammation of the tendon sheath.

Overuse syndromes are a common cause of tendonitis, particularly in the "weekend warrior." As a rule, the tendons of the APL and EPB are involved. There are, however, some uncommon locations and types of tendonitis. There has been a marked increase in reports of the so-called repetitive strain injury of the upper extremity.[188] One of the difficulties in evaluating this disorder is the establishment of a diagnosis in the absence of objective physical findings or confirmatory diagnostic images or laboratory data. These issues become more complicated when insurers and attorneys ask clinicians to establish a causal relation between the job and the complaints.[216,217]

Tenosynovitis is frequently seen in inflammatory rheumatic diseases, diabetes mellitus, or hypothyroid conditions (Table 18-20).

Conservative intervention includes nonsteroidal medications, splinting, patient education on the neutral rest position for the wrist, activity modification, and the avoidance of exacerbating activities (e.g., forceful gripping and heavy lifting). A stretching and icing regimen is recommended for the wrist flexors or extensors depending on the diagnosis. Occasionally, a series of steroid injections may be warranted. Patients are typically considered for surgery when a tenosynovitis has persisted for a period of 3 months of conservative treatment.

DeQuervain Disease. De Quervain disease[218] is a progressive tenosynovitis or tenovaginitis, which involves the tendon sheaths of the first posterior (dorsal) compartment of the wrist, resulting in a thickening of the extensor retinaculum, a stenosing of the fibro-osseus canal, and an eventual entrapment and compression of the tendons. [219] Although originally thought of as an active inflammatory condition, recent histological studies have found the disorder to be characterized by degeneration and thickening of the tendon sheath.[220]

In most instances, the first posterior (dorsal) compartment is a single compartment, which contains the APL and the EPB tendons and their associated synovial sheaths. The APL and EPB tendons allow the thumb to flex, extend, and grip objects. Overuse, repetitive tasks which involve overexertion of the thumb, or radial and ulnar deviation of the wrist, and arthritis are the most common predisposing factors, as they cause the greatest stresses on the structures of the first posterior (dorsal) compartment.[79,121] Such activities include scraping wallpaper, painting, , hammering, fly fishing, knitting, and cutting with scissors[79,221–224]

Typically, patients report a gradual and insidious onset[79,121,225] of a dull ache over the radial aspect of the wrist made worse by such activities as turning doorknobs or keys.[4] Patients also may note a "creak" in the wrist as the tendon moves.

Examination of the wrist may reveal the following:

- A localized swelling and tenderness in the region of the radial styloid process[121,225] and wrist pain radiating proximally into the forearm and distally into the thumb.[121,225–227]
- Severe pain[121,225] with wrist ulnar deviation and thumb flexion and adduction.[123] A reproduction of the pain can also be reported with thumb extension and abduction.[228]

TABLE 18-20 Clinical Findings in Common Forms of Tenosynovitis

Tenosynovitis	Findings	Differential Diagnosis
Intersection syndrome	Edema, swelling, and crepitation in the intersection area; pain over the dorsum of the wrist that is exacerbated by wrist flexion and extension, unlike the pain of de Quervain tenosynovitis, which is exacerbated by radial and ulnar deviation; pain extends less radially than it does in de Quervain tenosynovitis	Wartenberg syndrome, de Quervain tenosynovitis
De Quervain	Pain along the radial aspect of the wrist that worsens with radial and ulnar wrist deviation; pain on performing Finkelstein maneuver is pathognomonic	Arthritis of the first carpometacarpal joint, scaphoid fracture and nonunion, radiocarpal arthritis, Wartenberg syndrome, intersection syndrome
Sixth posterior (dorsal) compartment	Pain over the ulnar dorsum of the wrist that is worsened by ulnar deviation and wrist extension; other planes of motion may also be painful; tenderness over the sixth posterior (dorsal) compartment; instability of the extensor carpi ulnaris is shown by having the patient circumduct the wrist while rotating the forearm from pronation to supination	Extensor carpi ulnaris instability, triangular fibrocartilage complex tears, lunotriquetral ligament tears, ulnocarpal abutment syndrome, distal radioulnar joint arthritis, traumatic rupture of the subsheath that normally stabilizes this tendon to the distal ulna
Flexor carpi radialis tunnel syndrome	Pain, swelling, and erythema around the anterior (palmar) radial aspect of the wrist at the flexor carpi radialis tunnel; pain exacerbated by resisted wrist flexion	Retinacular ganglion, scaphotrapezial arthritis, first carpometacarpal arthritis, scaphoid fracture/nonunion, radial carpal arthritis, injury to the anterior (palmar) cutaneous branch of the median nerve, Lindberg syndrome (tendon adhesions between the flexor pollicis longus and the flexor digitorum profundus)
Trigger finger	Pain on digital motion, with or without associated triggering or locking at the interphalangeal joint of the thumb or proximal interphalangeal joint of other fingers; may be crepitus or a nodular mass near the first annular pulley that moves with finger excursion	Connective tissue disease, partial tendon laceration, retained foreign body, retinacular ganglion, infection, extensor tendon subluxation

Data from Brotzman SB, Calandruccio JH, Jupiter JB: Hand and wrist injuries. In: Brotzman SB, Wilk KE, eds. *Clinical Orthopaedic Rehabilitation*. Philadelphia, PA: Mosby, 2003:1–83; Idler RS: Helping the patient who has wrist or hand tenosynovitis. *J Musculoskel Med* 14:62, 1997.

- Crepitus of the tendons moving through the extensor sheath.[123,229]
- Palpable thickening of the extensor sheath and of the tendons distal to the extensor tunnel.[230]
- A loss of abduction of the CMC joint of the thumb.
- A positive Finkelstein test (Fig. 18-54) (see "Special Tests").[121]

Although the diagnosis is mostly clinical, posteroanterior and lateral radiographs of the wrist can be obtained to rule out any bony pathology, such as a scaphoid fracture, radioscaphoid, or triscaphoid arthritis; and Kienböck disease.[4]

CLINICAL PEARL

Isolation of the EPB tendon in a separate compartment has been reported to contribute to the pathogenesis of de Quervain disease.[128]

The intervention can be conservative or surgical. Conservative intervention usually includes rest, modification of activities, splinting, and anti-inflammatory medication. In a study by Lane and colleagues[231] wrist splints and NSAIDs were found to be effective only in patients with minimal symptoms and no restrictions in daily activities. No added benefit has been found in using a combined injection and splinting approach.[232] If splinting is appropriate, a thumb spica splint is fabricated with the wrist in 15 degrees of extension, the thumb midway between anterior (palmar) and radial abduction, and the thumb MCP joint in 10 degrees of flexion. As the splint is supposed be worn all day, when fitting the splint it is important that the thumb is able to oppose the index and long finger to aid with hand function. Following the removal of the splint after approximately 3–6 weeks, ROM exercises are prescribed, with a gradual progression to strengthening.

Three case reports have been published that describe manual physical therapy treatment for de Quervain disease. In the first report, Backstrom[233] reported the complete resolution of symptoms in a patient with a 2-month history of de Quervain tenosynovitis by incorporating Mulligan mobilization with movement techniques (radial gliding of the proximal carpal row and ulnar gliding of the trapezium), capitate manipulation, CMC joint mobilizations, and TFM over the first posterior (dorsal) tunnel, into an overall treatment plan. The

second case report, by Anderson and Tichenor,[230] used an Australian (Maitland) approach consisting of central and unilateral cervical mobilizations, carpal bone mobilizations, cervical and upper extremity stretches, TFM to the APL and EPB tendon, and neural mobilizations. In this case report, the patient reported no wrist or hand pain following a 6-month treatment program. The third case report by Walker[78] used an impairment-based treatment approach for eight visits based on the examination findings of isolated radiocarpal, intercarpal, and CMC joint dysfunction. The treatments consisted of manual techniques and self-mobilizations applied to the radiocarpal, intercarpal, and CMC joints. At treatment completion, the patient achieved a pain-free state and nearly full function. These results were maintained at a long-term follow-up performed 10 months after treatment.[78]

The more invasive intervention begins with cortisone injections. If two to three injections do not give relief, surgical tendon sheath release is an option.[4]

Intersection Syndrome. Intersection syndrome is a tenosynovitis of the ECRL and ECRB (radial wrist extensors), where they cross under the APL and EPB.[217]Although similar to de Quervain, differentiation is made with the pain distribution. With the intersection syndrome, the pain is located over the distal forearm, 4–8 cm proximal to Lister's tubercle, approximately a hand's breadth proximal to the wrist joint..[217] posterior Symptoms are exacerbated by wrist flexion and extension and by resisted wrist extension.[234] The condition is common in rowers, weightlifters, and canoeists due to repetitive wrist flexion and extension.[126]

Intervention, in addition to NSAIDs, involves[217,235]

- splint immobilization of the wrist and thumb with the wrist in 15–20 degrees of extension;
- electrotherapeutic modalities including iontophoresis/phonophoresis;
- manual techniques including deep TFM followed by exercises for stretching and strengthening;
- patient education to emphasize the avoidance of any repetitive wrist flexion and extension in combination with a power grip.

EPL Tendonitis. This condition is rare except in RA, but it occurs when the EPL muscle extends into a tight third compartment.[236] Overuse (drummer boy palsy), direct trauma, forced wrist extension, and distal radius fractures may cause EPL tendonitis, which presents with the clinical signs and symptoms of decreased thumb flexion, pain, swelling, and crepitus at Lister's tubercle.[217]

EIP Syndrome. An increase in muscle size of the extensor indicis, caused by swelling or hypertrophy from repetitive exercise, may cause stenosis of the fourth posterior (dorsal) compartment and resultant tenosynovitis.[217]

A simple test of a resistance applied to active index finger extension while holding the wrist in a flexed position is a reliable provocative test.[237]

ECU Tendonitis. ECU tendonitis, a tenosynovitis of the sixth posterior (dorsal) compartment, usually presents as chronic dorsoulnar wrist pain, which is aggravated with forearm supination and ulnar deviation, which causes the tendon to sublux palmarly.[217,238]

FCU Tendonitis. The FCU is the most common wrist flexor tendon to become inflamed and is often associated with repetitive trauma and racquet sports.[16] The clinical signs and symptoms include pain and swelling localized just proximal to the pisiform, which is aggravated with wrist flexion and ulnar deviation.[217]

FCR Tendonitis. FCR tendonitis usually develops due to stenosis and tenosynovitis in the FCR fibro-osseous tunnel within the transverse metacarpal ligament. FCR tendonitis usually produces localized pain and swelling and painful deviation of the wrist.[217] FCR tendonitis frequently coexists with other conditions including fracture or arthritis around the CMC joint of the thumb.[217]

Digital Flexor Tendonitis and Trigger Digits. This condition is typically characterized by painful snapping or triggering of the fingers and thumb due to a disproportion between the flexor tendon and its tendon sheath. The condition invariably occurs at the metacarpal head level and at the A1 pulley (MCP joint pulley), with the result that the tendon is pulled through too narrow a canal.[217,239–241] The condition is more common in the fibrous flexor sheath of the thumb, ring, or middle finger.[242,243]

The etiology for this condition is unknown, although it is more common in patients with diabetes, young children, and menopausal women.[242,243] Trigger finger also commonly coexists with rheumatic changes of the hand and may be the earliest sign of RA.[244]

The base of the affected finger is often tender and is usually accompanied by the trigger phenomenon—pain on digital motion, with or without associated triggering or locking. As the condition progresses, it becomes very painful, and may result in limited or absent digital motion, especially in the PIP joint.[240] During excursion of the flexor tendon, the clinician may palpate crepitus or a moving nodular mass in the vicinity of, or slightly proximal to, the A1 pulley. The presence of swelling is most consistent with tenosynovitis that occurs secondary to connective tissue disease.

Conservative intervention involves the fitting of a hand-based MCP flexion block splint for the involved digit only, with the MCP joint only immobilized in full extension, for up to 6 weeks.[245] The purpose of this immobilization is to attempt to alter the mechanical forces on the proximal pulley system while encouraging maximal differential tendon gliding. Patient education plays an important role; the patient should be advised to eliminate any provocative movements such as repetitive grasping or the use of tools that apply pressure over the area.

Medical intervention usually involves one or a series of steroid injections,[246] with surgical release of the trigger finger reserved for those cases that do not respond to conservative measures.[217]

Tendon Ruptures

One of the main purposes of the hand is to grasp; therefore, the loss of flexor tendons imposes a catastrophic functional loss.[247] The purpose of a flexor tendon repair is to restore maximum active flexor tendon gliding to ensure effective finger joint motion.

Most flexor tendon ruptures occur silently after prolonged inflammatory tenosynovitis, although the causes can also be traumatic. When all nine flexor tendons to the digits have ruptured, little can be done. Single tendon ruptures are more common, and the FPL tendon is the most vulnerable to attrition rupture where it crosses the scaphotrapezial joint and where local synovitis can create a sharp spike of bone that abrades against this spur and ruptures during use. The FDP tendon to the index finger is also at risk from this bony spur.[248]

Tendon injuries are classified into five zones according to the level of injury. The zone within which the tendon is repaired dictates to some extent the intervention.

- ***Zone 1.*** This zone extends from the insertion of the FDP in the middle phalanx to that of the FDS in the base of the distal phalanx. Injuries at this level involve isolated lacerations of the FDS.
- ***Zone 2.*** This is the region in which both flexor tendons travel within the fibro-osseous tunnel from the A1 pulley to the FDP insertion. Usually, both flexor tendons are injured at this level.
- ***Zone 3.*** The area in the palm between the distal border of the carpal tunnel and the proximal border of the A1 pulley comprises zone 3. Common digital nerves and vessels, lumbrical muscles, and one or both flexor tendons may be injured in this region.
- ***Zone 4.*** This zone consists of that segment of the flexor tendons covered by the transverse carpal ligament. Injuries at this level involve median or ulnar nerves and tendons.
- ***Zone 5.*** The forearm from the musculotendinous junction of the extrinsic flexors to the proximal border of the transverse carpal ligament comprises zone 5. Interference with tendon gliding is less of a problem in this region.

There are a number of different procedures and rehabilitation protocols for flexor tendon repairs. In brief, the retracted ends of the tendon are retrieved either by hand and wrist positioning or with a surgical instrument. Although it is not within the scope of this text to discuss suturing techniques, it is important to mention that several suturing methods have been found to withstand an early active mobilization (EAM) protocol such as the one presented here. They include the Savage, Silfverskiold (modified Kirchmayer or modified Kessler),[249,250] Tang,[251] Robertson,[252] and cruciate[253] methods. In all of these methods, the anatomic relationship between the FDS and the FDP is maintained.

The rate of tendon healing following surgery depends on adequate nutrition (through vascular and synovial fluid perfusion), the part of the tendon affected, and the presence of the vinculum.

Early postoperative protected mobilization of repaired tendons has been popularly adopted as the postoperative treatment protocol after tendon repair.[254–260] Researchers have shown that early mobilization can prevent the formation of scar tissue without jeopardizing tendon healing. Several postsurgical protocols and modifications exist based on individual characteristics, the zone involved, the suture strength, and surgeon preferences. While it is not within the scope of this text to discuss all of the various types of protocols, it is important for the clinician to have an understanding of the concepts behind the two major types:[261]

- Early passive mobilization consists of passive flexion with active extension within the confines of a protective splint.[262] One of the original controlled motion protocols was developed by Kleinert and colleagues, who used a posterior ((dorsal) block splint with a rubber-band traction device and early active extension of the digit against the tension of the passive rubber-band flexion.[263] The block splint positioned the wrist in 40 degrees of flexion and the MCP joints in 40–60 degrees of flexion. In the 1970s, Duran and Houser[264] presented a controlled passive motion method that has become the basis for many of the early passive mobilization protocols used today. Various modified Duran protocols have since been developed.
- EAM consists of active flexion and extension of the involved finger within certain parameters of a protective splint.[262] In recent years, based on an improved understanding of connective tissue physiology and the success achieved with other types of surgical repairs, various active mobilization protocols have been attempted to obtain better function of repaired tendons.[257,258,265] It has been demonstrated that active mobilizations of the tendons are a more effective way to increase excursion and decrease adhesions of repaired tendons.[265–270] In addition, the tension added to the repaired tendon by active mobilization seems to help initiate proliferation of the teknocytes (tendon forming cells) and increase the rate of collagen synthesis of the repaired tendon, thereby enhancing the tendon healing process.[271,272] Considering the resistance of the sheath during tendon gliding and a decrease in suture strength during the initial weeks after repair, most investigators believe that sufficient suture strength is vital to the performance of gentle or moderate active finger motion.[249,252,253] The typical EAM protocol allows active flexion and extension of the involved fingers within the first 3–5 days by incorporating a concept known as *place and hold*, in which the involved finger is passively flexed to a certain position and the patient is then asked to hold it there through active contraction of that muscle.[262]

CLINICAL PEARL

Surgical repairs and treatment protocols can vary greatly, necessitating a high level of communication between the surgeon and the clinician.

Mallet Finger Deformity. Mallet finger deformity, one of the most common hand injuries sustained by the athletic population, is a traumatic disruption of the terminal tendon. This condition is especially common in the baseball catcher and the football receiver and results in a loss of active extension of the DIP joint.. The initial injury usually results from the delivery of a longitudinal force to the tip of the finger, which produces a sudden acute flexion force and a subsequent rupture of the extensor tendon just proximal to its insertion into the third phalanx or a fracture at the base of the distal phalanx.[26]

The physical examination reveals a flexion deformity of the DIP joint, which can be extended passively but not actively. This lack of active extension at the DIP joint is due to the zero tension being provided by the EDC, in addition to the resulting increased tone in the FDP.

The primary goal of treatment is to maximize function and range of motion of the involved DIP joint. Mallet deformities with an associated large fracture fragment are typically treated with 6 weeks of immobilization following open reduction and internal fixation (ORIF), usually with K-wires.[26] Closed reduction is used for other types, followed by 6 weeks of continuous posterior (dorsal) splinting of the DIP in 0 degrees of extension to 15 degrees of hyperextension.[26] The PIP joint should be free to move. If splinted, the splint is removed once a day while simultaneously holding the DIP joint in extension to allow air to reach the anterior (palmar) aspect of the middle and distal phalanx. Following the period of immobilization, the splint or fixators are removed and the terminal tendon is evaluated. If the tendon is unable to maintain extension of the DIP joint, a splint is reapplied and the tendon is retested periodically. Once the tendon has healed sufficiently to perform active extension of the DIP, AROM exercises to 20–35 degrees are initiated to the DIP joint. The clinician should continue to monitor for an extensor lag, and it is recommended that the patient continues to wear the splint between exercise sessions, at night, and when competing (as appropriate). Gentle progressive resistive exercises (PREs) using putty or a hand exerciser are initiated at week 8. Usually the splint is discontinued at 9 weeks if the DIP extension remains at 0–5 degrees and there is no extensor lag. Unrestricted use usually occurs after 12 weeks.

Rupture of the Terminal Phalangeal Flexor (Jersey Finger). A jersey finger rupture involves a rupture of the FDP tendon from its insertion in the distal phalanx. As there is no characteristic deformity associated with this type of rupture, this condition is often misdiagnosed as a sprained or " jammed" finger[26]

The injury commonly occurs in football when the flexed finger is caught in a jersey while the athlete is attempting to make a tackle, hence the term jersey finger. However, any forceful passive extension that is applied while the FDP muscle is contracting can cause this type of rupture. Although this condition can occur in any finger, the most commonly injured is the ring finger.[273]

Three types are recognized:

- In Type I, the tendon retracts into the palm with or without a bony fragment.
- Type II is the most common. The tendon retracts to the PIP joint and the long vinculum remains intact. As in type I, type II injuries may have a small bony avulsion.
- Type III injuries involve a large bony fragment.

To test the integrity of the tendon, the clinician isolates the FDP by holding the MCP and PIP joints of the affected finger in full extension and then asks the patient to attempt to flex the DIP. If the patient is able to flex the DIP, it is intact. If not, it is ruptured.

The intervention depends on the severity of the injury. If function is not seriously affected the condition is just monitored. However, if function is impacted, one option is surgical reattachment of the tendon, which requires a 12-week course of rehabilitation.

INTEGRATION OF PRACTICE PATTERNS 4F AND 5F

This includes conditions involving impaired joint mobility, motor function, muscle performance, and range of motion, or reflex integrity secondary to referred pain, spinal disorders, peripheral nerve entrapment, myofascial pain syndrome (MPS), and complex regional pain syndrome (CRPS).

Referred Pain

A number of structures can refer pain to the wrist and hand, and these include visceral structures, neurologic structures, and the more proximal joints (Chapter 5). The most common joints, which refer pain to the wrist and hand, include the cervical, thoracic, shoulder, and elbow joints.

Tumors

See Chapter 5.

Peripheral Nerve Entrapment

Peripheral nerve entrapments are common in this region and are typically associated with a history of pain or vague sensory disturbances.[274] Due to the vagueness of the signs and symptoms, nerve injuries are frequently overlooked as a source of acute, or more commonly chronic, symptomatology.[188] An early indicator of peripheral compression neuropathy may be the loss of vibration sensibility.[150] Nerve conduction studies may be performed, focusing on the sites of interest. Diabetes, with its associated neuropathies or cheiroarthropathy, may be an underlying cause of chronic wrist pain.[188]

Radial Nerve. The posterior interosseous nerve can be compressed as it enters the posterior (dorsal) wrist capsule by repetitive wrist extension maneuvers, inciting symptomatic inflammation.[275]

The major disability associated with radial nerve injury is weak wrist and finger extension, with the wrist and fingers adopting a position termed "wrist drop." The hand grip is weakened as a result of poor stabilization of the wrist and finger joints, and the patient typically demonstrates an inability to extend the thumb, proximal phalanges, wrist, and elbow, depending on the level. Supination of the forearm and adduction of the thumb are also affected. There is also decreased or impaired sensation on the posterior (dorsal) surface of the first interosseous space.

Wartenberg Syndrome. Wartenberg syndrome is a compression of the superficial sensory radial nerve. Inflammation of the tendons of the first posterior (dorsal) compartment can result in superficial radial neuritis. This results in pain, paresthesias, and numbness of the radial aspects of the hand and wrist.[276] In addition, the tendons of the brachioradialis and ECRL muscles can press on the nerve in a scissor-like fashion when the forearm is pronated, causing a proximal tethering on the distal segment of the nerve at the wrist.[277]

Wartenberg sign is described wherein the patient is asked to extend the fingers and abduction or clawing of the little finger occurs.[158]

Median Nerve Compression at the Wrist. CTS is a cause of chronic wrist pain and functional impairment of the hand. It results from an ischemic compression of the median nerve at the wrist as it passes through the carpal tunnel. Compression of the nerve in the carpal tunnel is compounded by an increase in synovial fluid pressure and tendon tension, which decreases the available volume.

Moersch[278] provided the first description of spontaneous median nerve compression and is credited with coining the term *carpal tunnel syndrome*.[279] The compression of the median nerve may result from a wide variety of factors that compromise the tunnel space such as fluid retention, which occurs during pregnancy,[280] infection,[281,282] and conditions such as renal dysfunction. In addition, several disease conditions, such as gout or pseudogout,[283] acromegaly, or amyotrophy[284] can also decrease the tunnel size. However, about half of the cases of CTS are related to repetitive and cumulative trauma in the workplace.[285,286] Forceful and repetitive contraction of the finger flexors can also provoke CTS.[287] Acute wrist trauma has also been associated with CTS. A FOOSH injury or other trauma can cause an anterior (palmar) subluxation of the lunate[288] or a distal radius fracture.[289,290] The degree of compression can be so great that profound neurologic deficit can rapidly follow, and if not treated appropriately, it can become permanent due to the decrease in capillary blood flow producing ischemia of the nerve.[291] A manipulative reduction should be carried out. If manipulation fails, the patient should be referred to a surgeon for immediate decompression.

Other causes include collagen disorders,[292,293] flexor tenosynovitis,[294]RA,[295] diabetes, hypothyroidism, and hemodialysis.[296] Less common causes include instances where the lumbrical muscles encroach within the tunnel during finger movements[297,298] or become hypertrophied.[299]

Although it occurs in all age groups, CTS more commonly occurs between the fourth and sixth decades. CTS is the most common compression neuropathy, with a prevalence of 9.2 percent in women and 0.6 percent in men.[300,301]

Carpal tunnel pressure appears to be an important factor in the pathophysiology of CTS, as increased pressure on the median nerve can produce short-term sensory and motor nerve conduction deficits and elicit symptoms of median nerve neuropathy.[291] Extreme wrist and finger postures can increase the tunnel pressure.[302] In addition, the angle of the MCP joint has been found to have a significant effect on carpal tunnel pressure during active wrist flexion and extension and radioulnar maneuvers. Motions performed in 0 degrees MCP flexion exhibit the highest pressures, followed by an MCP angle of 90 degrees.[303] This information should be considered in the design of splints for CTS patients. Fingertip loading has also been found to increase pressure in the carpal tunnel. [304]

The diagnosis of CTS is typically made after a review of the patient's history and physical examination.[147] The initial characteristic features of CTS include intermittent pain and paresthesias in the median nerve distribution of the hand (although the symptoms may radiate proximally into the forearm and arm), which progressively become more persistent as the condition progresses.[292,305–307] If the condition is allowed to progress, muscle weakness and paralysis can occur. The symptoms of CTS are typically worse at night due to the position of wrist flexion typically adopted during sleep and can be associated with morning stiffness.

Differential diagnosis for this condition includes cervical radiculitis,[308] thoracic outlet syndrome, pronator syndrome,[309] coronary artery ischemia, tendonitis, fibrositis, and wrist joint arthritis.[310,311] Cervical radiculopathy may be identified by the occurrence of proximal radiation of pain above the shoulder, paresthesias with coughing or sneezing, or a pattern of motor or sensory disturbances outside of the territory of the median nerve.[305] Ulnar neuropathy must be considered since no more than half of patients with CTS can reliably report the location of their paresthesias.[312] Thoracic outlet syndrome is occasionally a concern. Transient cerebral ischemia, not a rare occurrence, can be recognized by the absence of pain during an episode of numbness. Finally, when the symptoms persist following conservative or surgical intervention aimed to the site of the carpal tunnel, median nerve neuropathies proximal to the carpal tunnel should be suspected. Median nerve neuropathies can be due to diabetes, human immunodeficiency virus, nutritional deficiencies, and entrapment/compression of the nerve.[313] Median nerve compression proximal to the carpal tunnel may be divided into two major categories: pronator syndrome and anterior interosseus nerve syndrome (Chapter 17).[313]

The physical assessment focuses on an examination of the motor and sensory functions of the hand as compared to the uninvolved hand and includes Phalen test and Tinel sign.[141,305,314] A study[315] that examined the effect of upper extremity position on median nerve tension found the upper limb tension test for the median nerve to be specific.

Another study[316] described a maneuver that abolishes paresthesias in the carpal tunnel. The authors of this study suggest that this maneuver could be useful in the diagnosis of the syndrome, as well as providing a means of relieving symptoms and providing the basis for the design of a splint. With the involved hand positioned palm up, the clinician gently squeezes the distal metacarpal heads together.[316] If the basic maneuver does not relieve the symptoms, it may also be necessary to pronate the forearm while simultaneously stretching digits three and four. [316]

A number of medical tests can be used to help diagnose CTS. These include the median nerve conduction study (NCS) and EMG study. Median nerve conduction studies have been found to be normal in 5 percent of patients with symptoms.[146] The EMG study was found in one study[157] to confirm a diagnosis of CTS in only 61 percent of cases. However, radiculopathy due to disease of the cervical spine, diffuse peripheral neuropathy, or proximal median neuropathy can pose clinical questions that electrodiagnostic testing can settle.[305]

A carpal tunnel view radiograph may be the only view that shows abnormalities within the carpal tunnel. [29]

The conservative intervention for mild cases typically includes the use of splints, activity modification, diuretics, and NSAIDs.[317] The rationale for splints is based on observations that CTS symptoms improve with rest and worsen with activity.[318] However, prescription parameters for the type of

splint are not standardized,[319] with some advocating neutral positioning,[320] and some recommending 0–15 degrees of wrist extension. The length of time for wearing the splint is also undetermined, with some recommending day and night use,[321] while others instruct patients to wear the brace at night and during activities stressful to the wrist.[322] Still others recommend only night use.[320] Rigid splints have been found to be superior to flexible ones in controlling carpal tunnel pressure,[323] although the softer flexible ones enhance compliance in RA patients.[324]

Night splints appear to allow the wrist to rest fully, although one study found that night splints did not significantly reduce intracarpal pressure when compared to controls who did not wear them.[85] Splints during the day are helpful only if they do not interfere with normal activity. The positioning of the splint may be significant.

Yoga that focuses on upper body postures was found to be of benefit in one study,[325] although the sample size was small and the results were not conclusive.

Ergonomic modifications can help reduce the incidence of CTS and alleviate symptoms in the already symptomatic patient. Patient education is also important to avoid sustained pinching or gripping, repetitive wrist motions, and sustained positions of full wrist flexion.

Isolated tendon excursion exercises for the finger flexor tendons and nerve gliding of the median nerve exercises are performed. These include isolated tendon gliding of the FDS and FDP of each digit. The exercises are thought to have a positive effect by facilitating venous return or edema dispersion in the median nerve.[320]

Contrast baths can be used in 10-minute sessions to assist in the reduction of inflammation and edema.

Evaluation for surgical management is necessary for patients with atrophy of the thenar muscles, decreased sensation, and persistent symptoms that are intolerable despite conservative therapy.[296]

Ulnar Nerve. Entrapment of the ulnar nerve can occur at the elbow in the cubital tunnel (Chapter 17). Entrapment of the ulnar nerve at the wrist can occur at Guyon canal. The clinical features of an ulnar nerve entrapment at the wrist are described in chapter 3.

If ulnar neuropathy at Guyon canal is suspected, it is often helpful to evaluate the pisotriquetral joint and the hook of the hamate. Abnormalities may be present at either site, resulting in secondary ulnar neuropathy.[326] In addition, the clinician must ask the patient whether they have any medical history involving diabetes and peripheral neuropathies.

The intervention for ulnar nerve compression can be surgical or conservative depending on the severity. Indications for surgical intervention include preventing deformity and increasing functional use of the hand. Conservative intervention for mild compression involves the application of a protective splint and patient education to avoid positions and postures that could compromise the nerve.

Hand-Arm Vibration Syndrome

Vibration is a physical stressor to which many people are exposed at work, in the home, or in their social activities. Humans respond characteristically to certain critical vibration frequencies at which there is maximum energy transfer from source to receiver.[327]

Hand-arm vibration syndrome (HAVS) is frequently underdiagnosed and misdiagnosed as CTS since the two entities typically coexist.[328] HAVS is associated with occupations involving exposure to sources of vibration including air-compressed drilling, grinding, and electric drills and saws.[329]

The pathophysiology of HAVS is poorly understood, but chronic exposure to vibration may produce circulatory, neurologic–sensory–motor, and musculoskeletal disturbances. Khilberg[330] has studied the acute effects and symptoms of work with vibrating hand-held power tools. He found that workers using nonimpact tools (grinders) had a lower prevalence of elbow and shoulder symptoms than those using low-frequency impact tools (chipping hammers), but it did not differ in this respect from workers using high-frequency impact tools. Work with impact tools in general was associated with a higher prevalence of pain in the wrist than work with nonimpact tools.[327]

The diagnosis of HAVS is based on a history of HAV exposure and sensorineural or vascular signs and symptoms, which include the following[228]:

- Blanching white fingers (Raynaud phenomenon). This is the most common symptom, and it occurs on exposure to cold. Its extent and frequency of occurrence determines the severity of the vascular grading.[327]
- Episodic tingling and numbness. The numbness or tingling can be graded.
- Mild to severe sensory deficits.
- Swelling of the digits and forearm tissue.
- Trophic skin changes.

The intervention for HAVS includes maintaining central body temperature, avoiding exposure to cold and vibrating tools, job modification, and splinting at night.[228]

Myofascial Pain Syndrome

The most frequent cause of wrist, hand, and finger pain is myofascial referral from the forearm flexors and especially from the forearm extensors. Trigger points in these muscles increase tendon tension and therefore relative compression of the carpal joints, which causes cracking and crepitus at the wrist due to abnormal joint glide.[331] The patient often reports a sense of stiffness in the wrist and hand, and pain exacerbated with wrist and finger flexion, which stretches these muscles, and on full wrist extension, which shortens these muscles.[331]

Complex Regional Pain Syndrome

The term CRPS refers to a classification of disorders, which can occur even after minor injury to a limb and which is a major cause of disability.[332]

CRPS, originally termed *causalgia*, has since been referred to by a number of names including posttraumatic osteoporosis, Sudeck atrophy, transient osteoporosis, algoneurodystrophy, shoulder–hand syndrome, gardenalic rheumatism, neurotrophic rheumatism, reflex neurovascular dystrophy, and reflex sympathetic dystrophy (RSD).[333]

Two types of CRPS are recognized by the International Association for the Study of Pain:

- ***CRPS 1.*** This type refers to the pain syndrome, previously termed RSD, which involves a pain syndrome triggered by a noxious event that is not limited to a single peripheral nerve.
- ***CRPS 2.*** This type refers to the pain syndrome, previously termed causalgia, which involves a pain syndrome that involves direct partial or complete injury to a nerve or one of its major branches.

The signs and symptoms for both types include pain, edema, stiffness, skin temperature changes, and sweating.[334] More recently, it has been suggested that a third type may exist. This type is characterized by irreversible changes in the skin and bones, marked muscle atrophy, unyielding pain, and severely limited mobility of the affected area.

Type I CRPS. The pain of type I CRPS is classified as sympathetically maintained pain or sympathetically independent pain, where sympathetically maintained pain is characterized by an abnormal reaction of the sympathetic nervous system.[334]

The edema, which can be pitting or nonpitting, is often present throughout all stages of CRPS and may be the result of vasomotor instability coupled with a lack of motion.[333]

The stiffness is one of the components of CRPS 1 that increases with time and is due to increased fibrosis in the ligamentous structures and adhesion formation around the tendons.[333]

The reported incidence of CRPS 1 is 1–2 percent after various fractures,[335] 2–5 percent after peripheral nerve injury,[336] and 7–35 percent in prospective studies of Colles fracture.[337,281] In 10–26 percent of cases no precipitating factor can be found.[338,282] A number of psychological components have been proposed, including the following:

1. A significant period of stress, anxiety, or depression
2. Childhood experiences.
   a. Sexual abuse
   b. Physical abuse
   c. Emotional abuse
   d. Abandonment
   e. Family history of drug or alcohol abuse
3. Adult experiences
   a. Care provider for aging or ill parent(s) or other relative
   b. Problem children, parents, or siblings
   c. Unhappy marriage
   d. Alcoholism
   e. Grief
   f. Abuse of any type
4. A low self-esteem
5. A negative outlook on life

However, there has been no evidence to support such notions. Instead, it is thought that the emotional and behavioral changes noted are a result, rather than a cause, of the prolonged pain and disability.[339]

The diagnosis of CRPS is made from the physical examination and the patient's medical history, which may include past events of trauma, persistent pain, hyperalgesia, allodynia (perception of a nonpainful stimulus as painful), edema, and diminished function of the area.

The type of pain and its duration are perhaps the most important diagnostic signs. The pain is typically burning in nature and is of a much longer duration than would be expected from the injury.[339]

A number of other conditions need to be ruled out before establishing a diagnosis of CRPS 1, and these include, but are not limited to the following:

- Rheumatoid and septic arthritis
- Gout
- Disk herniation
- Peripheral neuropathy
- Peripheral nerve entrapment
- Peripheral vascular disease

Classically, CRPS 1 has been subdivided into three clinical phases[340,341]:

- An acute inflammatory phase that can last from 10 days to 2–3 months. The acute stage of CRPS lasts from 1 to 3 months. This stage is reversible if the patient is treated. The affected limb becomes flushed, warm, and dry because regional blood vessels are relaxed, and stimulation of the sweat glands is reduced.[334] The pain is diffuse, severe, and constant with a burning, throbbing, or aching quality. Edema and increased hair and nail growth can also occur. By the end of this stage, the limb turns cold, sweaty, and cyanotic from vasoconstriction caused by paradoxical sympathetic stimulation.[334]
- A phase of vasomotor instability that can last for several months. This is the dystrophic stage, which lasts another 3–6 months. Constricted blood vessels can cool limb temperature by nearly 10 degrees.[334] The area will be pale, mottled, edematous, and sweaty. Pain remains continuous, burning, or throbbing but is more severe.[334] Nails may crack or become brittle and heavily grooved. Limb movement is limited by muscle wasting and joint stiffness. Osteoporosis and contractures can develop.[334]
- A cold end phase. The atrophic stage is characterized by irreversible damage to muscles and joints. Over the next 2–3 months the bones atrophy and the joints become weak, stiff, or even ankylosed.[334] The pain lessens and may become spasmodic or breakthrough but is no longer mediated by the sympathetic nervous system.[334] The skin is cool and looks glossy and pale or cyanotic.

No prospective studies are available in which this staging is confirmed. However, a prospective study of 829 patients[333] indicated that the following:

- In its early phase, CRPS is characterized by regional inflammation and not of a disturbance of the sympathetic nervous system. The regional inflammation increases after muscular exercise.

- Tremor was found in 49 percent and muscular incoordination in 54 percent of patients.
- Sympathetic signs such as hyperhidrosis are infrequent.

These data support the concept of an exaggerated regional inflammatory response to injury or operation in CRPS.[333,342]

The most effective intervention for CRPS 1 is disputed. However, most agree that the intervention requires a team approach, in which the physical therapist plays a pivotal role and that the earlier the intervention is instituted, the better the prognosis. Immobilization and overprotecting the affected limb may produce or exacerbate demineralization, vasomotor changes, edema, and trophic changes.[343]

Physical therapy is the first line of intervention, whether it be the sole intervention or performed immediately following a nerve block.[339,344]

The most important rule is to minimize pain while employing physical therapy. When excessive pain is created, sympathetically mediated pain may worsen.[339] It is vital to not reinjure the region or aggravate the problem with aggressive physical rehabilitation.[345]

The patient's involved limb must be elevated as often as possible to counteract the vascular stasis and actively mobilized several times per day.[339,346]

Recovery from muscle dysfunction, swelling, and joint stiffness requires appropriate physical activity and exercise, and pressure and motion are necessary to maintain joint movement and prevent stiffening.[339] The progression should occur slowly and gently with strengthening, active assisted range-of-motion, and AROM exercises.

Weight-bearing exercises and active stress loading exercises should also be incorporated. Active stress loading exercises include scrubbing and carrying. Scrubbing is a form of closed kinetic chain exercise for the upper or lower extremity in which the patient in a variety of positions performs a scrubbing action on a firm surface. As its name suggests, carrying exercises for the upper extremity involve having the patient carry small objects in the hand on the affected side and gradually increasing the weight of the object. For the lower extremity stress loading can be achieved through weight bearing.

Sensory threshold techniques can be used. These include fluidotherapy, vibration desensitization, transcutaneous electrical nerve stimulation, contrast baths, and desensitization using light and heavy pressure of various textures over the sensitive area.

Topical capsaicin is helpful, as are NSAIDs.

INTEGRATION OF PRACTICE PATTERNS 4G AND 4I

This includes conditions that result in impaired joint mobility, motor function, muscle performance, and range of motion that are associated with fractures and bony or soft tissue surgical procedures.

Distal Radius Fractures

Fracture of the distal radius is the most common wrist injury for any age group. While the older patient usually sustains an extra-articular metaphyseal fracture, the younger patient tends to sustain the more complicated intra-articular fracture.[208] Physical examination reveals swelling of the wrist, possible gross deformity, limited range of motion, and point tenderness over the distal radius. Successful management of a distal radius fracture must take into account the integrity and function of the soft tissues, while restoring anatomic alignment of the bones. The clinician should avoid distracting or placing the wrist in a flexed position, so that the mechanical advantage of the extrinsic tendons is maintained, pressure in the carpal canal is not increased, any carpal ligament injury is not exacerbated, and stiffness is not encouraged. The rehabilitation after fracture of the distal radius is nearly uniform among the various fracture types outlined below. The more specific guidelines are listed after each fracture description.

Colles Fracture.[4] Colles fracture is a complete fracture of the distal radius with posterior (dorsal) displacement of the distal fragment. The typical mechanism of injury is a FOOSH. The fracture displacement and angulation are evident on the lateral film—the Colles fracture has the characteristic dorsiflexion or "silver fork" deformity. Radiographs of the AP view show the usual comminuted fracture.

Management of this fracture requires a precise reduction of the fracture in order to maintain the normal length of the radius. Although the method of reduction, as well as the position of immobilization, is quite variable, in most cases closed reduction and a cast are chosen. However, the more complicated cases may require open reduction and external fixations.[347] A common sequelae of this fracture is a loss of full rotation of the forearm.

Smith Fracture. A Smith fracture, sometimes called a reverse Colles fracture, is defined as a complete fracture of the distal radius with anterior (palmar) displacement of the distal fragment.[348] The usual mechanism for this type of fracture is a fall on the back of a flexed hand. Smith fractures are classified into three types[349]:

- ***Type I.*** This is described as a transverse fracture through the distal radial shaft.
- ***Type II.*** This is an oblique fracture through the distal shaft starting at the posterior (dorsal) articulating lip.
- ***Type III.*** This type (also referred to as a reverse Barton fracture) is an oblique fracture beginning more distally on the articular surface of the radius.

The typical management for a Smith fracture is with closed reduction and long arm casting in supination for 3 weeks, followed by 2–3 weeks in a short-arm cast.[348] However, because Types II and III are frequently unstable, they may require an ORIF.

Barton Fracture. A Barton fracture involves a posterior (dorsal) or anterior (volar) articular fracture of the distal radius resulting in a subluxation of the wrist.[348] This type of fracture usually results from some form of direct and aggressive injury to the wrist or from a sudden pronation of the distal forearm on a fixed wrist. A technique to reduce these dislocations under anesthesia has been described in the literature.[350] The technique involves applying traction to the wrist and then placing the patient's wrist in full supination, mid-extension, and ulnar deviation, which closes the diastasis by reducing the

scaphoid to its correct anatomic plane. An above-elbow cast is then applied for 4 weeks, followed by a forearm cast for a further 3 weeks with the wrist positioned in ulnar deviation. More complicated fractures may require an ORIF with 16 weeks being the average healing time.

Buckle Fracture. A buckle fracture is an incomplete, undisplaced fracture of the distal radius, which is commonly seen in children. Immobilization for 3–4 weeks in a short-arm cast or anterior (palmar) splint is adequate.[146] The possibility of abuse should be considered in the child with a fracture. Consultation with an orthopedist is advisable for fractures in the pediatric population.

The fracture is treated with a cast, external fixation, or ORIF. The fracture site is immobilized for 6 weeks if casted, 8 weeks with an external fixator, or 2 weeks if an ORIF with plate and screws is performed. If the fracture is nondisplaced, 2–6 weeks of rehabilitation is recommended, whereas displaced fractures typically require 8–12 weeks.

Conservative intervention usually begins while the fracture is immobilized and involves AROM of the shoulder in all planes, AROM of elbow flexion and extension, and finger flexion and extension. The finger exercises must include isolated MCP flexion, composite flexion (full fist), and intrinsic minus fisting (MCP extension with IP flexion). If a fixator or pins are present, pin site care should be performed.

Following the period of immobilization, extension and supination are commonly limited and need to be mobilized. AROM exercises of wrist flexion and extension and ulnar and radial deviation are initiated at this time. Wrist extension exercises are performed with the fingers flexed (especially at the MCP joints). The initiation of PROM occurs according to physician preference, either immediately or after 1–2 weeks.

Strengthening exercises are introduced as tolerated, using light weights and tubing. Putty can be used to increase grip strength if necessary.

Plyometrics and neuromuscular re-education exercises are next, followed by return to function or sports activities as appropriate.

Fractured Scaphoid

The scaphoid is the most commonly fractured carpal bone due to its location and is the only bone fractured in approximately 70 percent of all carpal fracture cases.[131,146,207,280] Most commonly, the injury results from a FOOSH with the wrist pronated. Although a fracture can occur in any part of the scaphoid, the common areas are at the waist and at the proximal pole.

Patients typically complain of posterior (dorsal) radial-sided wrist pain and have tenderness over the anatomic snuffbox. On physical examination, little swelling may be noted, although loss of the concavity of the anatomic snuffbox is frequently seen.[351] It may be good practice to treat all cases of wrist sprain that are accompanied with pain and swelling in the anatomic snuffbox as a scaphoid fracture until proven otherwise. Many investigators feel a reliable test for scaphoid injury is axial compression of the thumb along its longitudinal axis.[352,353] Described by Chen,[352] this test translates force directly across the scaphoid and should elicit pain if there is a fracture. Even with appropriate radiographs, fractures of the scaphoid can be difficult to visualize.[351] In cases in which there is a high clinical suspicion, a scaphoid view of the wrist is usually obtained. This is a clenched fist view with the wrist held in ulnar deviation. This view reduces the foreshortening of the scaphoid that occurs on a normal PA view and clearly displays the entire length of the scaphoid.[351] If plain radiographs are normal and clinical suspicion is high, MRI is warranted.

Accurate early diagnosis of scaphoid fracture is critical as the morbidity associated with a missed or delayed diagnosis is significant and can result in long-term pain, loss of mobility, and decreased function.[12] This degree of morbidity is related to the scant blood supply to the scaphoid, which results in a high incidence of delayed healing or nonunion, and the fact that scaphoid fractures are inherently unstable.

Conservative management of a scaphoid fracture remains controversial. For example, there is no agreement on the optimum position for immobilization. Current management is immobilization in a long-arm or short-arm thumb spica cast, with the wrist position and length of immobilization dependent on the location of the fracture:

- ***Proximal pole.*** Immobilization for 16–20 weeks in a long-arm or short-arm thumb spica, with the wrist positioned in slight extension and radial deviation.
- ***Central third.*** Immobilization for 6 weeks in a long-arm thumb spica, followed by a further 6 weeks in a short-arm thumb spica.
- ***Distal third.*** Immobilization for 6–8 weeks in a short-arm thumb spica.
- ***Tuberosity.*** Immobilization for 5–6 weeks in a long-arm or short-arm thumb spica.

For the patient with pain over the anatomic snuffbox but normal initial radiographs, application of a thumb spica cast for 3 weeks followed by repeat radiographs is indicated. If the radiographs remain normal but pain persists, a bone scan is the next step. If the bone scan is positive, management is continued as for an acute fracture. Chronic pain, loss of motion, and decreased strength from prolonged immobilization or early arthritis is common following a scaphoid fracture.

Following the removal of the splint, a capsular pattern of the wrist is usually evident. In addition, there will be a painful weakness of the thumb and/or wrist extension/radial deviation. AROM exercises for wrist flexion and extension, and radial and ulnar deviation are initiated as early as possible, with PROM to the same motions beginning after 2 weeks. A wrist and thumb immobilization splint is typically worn between exercises and at night for comfort and protection.

At about the same time as the PROM exercises are initiated, gentle strengthening exercises are introduced using 1- to 2-lb weights or putty. Over a period of several weeks, the exercise program is progressed to include weight-bearing activities, plyometrics, open- and closed-chain exercises, and neuromuscular reeducation, before finally progressing to functional and sport-specific exercises and activities as appropriate.

Because of the precarious nature of the blood supply and potential for movement at the fracture line, nonunion can occur in 8–10 percent of cases,[354,355] with the rate of nonunion varying with the actual fracture site (up to 20–30 percent of proximal third fractures and 10–20 percent of middle third

fractures, with distal third fractures being relatively rare).[351354,355]

SLAC wrist is a late complication of scaphoid fracture, scapholunate dissociation, Kienböck disease, fracture of the distal radius, Preiser disease, and deposition of crystals of calcium pyrophosphate dehydrate.[356] The SLAC wrist is thought to result from a loss of the stabilizing effect of the scaphoid, with the development of an arthrosis at the radioscaphoid articulation. When the injury has progressed to this state, proximal row carpectomy or wrist fusion is the only option for the hand surgeon.[357]

Carpal Boss

A carpal boss is a rounded bony prominence that presents between the base of second and third metacarpal and the trapezoid and capitate, resulting from repetitive forced extension of the wrist and subsequent irritation of soft tissues. The ECRL and ECRB are commonly involved. This prominence resembles a ganglion and is not necessarily pathologic, although it can cause pain and irritation of the local soft tissues.[358] Confirmation is through radiographs.

Conservative intervention includes a wrist immobilization splint with the wrist positioned in slight extension (10–15 degrees) to reduce tension on the radial wrist extensors.

Metacarpal Fractures

Injuries to the metacarpals are the result of either direct or indirect trauma, with nature and direction of the applied force determining the exact type of fracture or dislocation. Most metacarpal fractures occur in the active and working population, particularly adolescents and young adults.[359,360] Specific injury patterns that occur from commonly seen trauma are as follows:

- ***CMC injuries.*** Metacarpal base fractures and dislocations of the CMC joint commonly result from an axial load or other stress on the hand with the wrist flexed.[359,360] CMC joints, especially the central joints, are quite stable. The metacarpal bases are held in position by posterior (dorsal) and anterior (palmar) CMC ligaments, as well as by interosseous ligaments. CMC dislocations may occur with or without fracture. Fracture-dislocation of the fifth metacarpal base is a common intra-articular injury and has been dubbed the reverse Bennett fracture. A direct blow to the ulnar border of the hand tends to cause an extra-articular fifth metacarpal base fracture.
- ***Metacarpal shaft injuries.*** Metacarpal shaft fractures are typically produced by either axial loading,direct trauma, or torsional forces on the digits. Usually, the fractures are classified anatomically as transverse, oblique, or spiral.[359,360] The fracture pattern often denotes the mechanism of injury, with direct or axial injury leading to transverse or oblique fractures and torsion leading to spiral fracture.
- ***Metacarpal neck fractures.*** The most common metacarpal fractures usually result from striking a solid object with a clenched fist and thus are dubbed boxer fractures, although this injury almost never occurs during boxing. Fractures of the fifth metacarpal neck are among the most common fractures in the hand.[359,360]
- ***Metacarpal head injuries.*** Metacarpal head fractures, which are rare injuries, result from axial loading or direct trauma. Fractures of the metacarpal head are intra-articular and periarticular.[359,360] If displaced, metacarpal head fractures usually require ORIF.
- ***Avulsion fracture at the origin of the collateral ligaments.*** This type of fracture is caused by forced deviation of the flexed MCP joint.[359,360]
- ***MCP dislocations.*** Almost all MCP dislocations occur with the proximal phalanx displaced posterior (dorsal)ly on the metacarpal head, as there is no specific posterior (dorsal) restraint to the MCP joint other than the joint capsule and extensor mechanism.[359,360]

The management of a patient with a metacarpal fracture depends on a variety of factors including the location, degree of displacement, angulation, and rotation. In addition, the patient's age, occupation, general health, and concomitant injuries must also be considered. Most metacarpal injuries are managed by closed reduction and immobilization or sometimes controlled mobilization utilizing a posterior (dorsal) block splint. Specific indications are further described below.

- Impaction fractures of the metacarpal bases that are not significantly displaced can be treated with splinting, followed by early mobilization.
- CMC dislocations and fracture dislocations, especially when multiple, are unstable injuries. In the past, these fractures were managed by closed reduction and external immobilization, which frequently led to grip weakness and residual pain. The current literature supports closed reduction, if joint congruity can be obtained, but with the addition of internal fixation.
- Displaced fracture dislocations of the fourth and fifth metacarpals, which are accompanied by fracture of the posterior (dorsal) hamate, require ORIF. Reverse Bennett fractures frequently need K-wire stabilization to counteract the deforming forces. If little articular incongruity is present, this may be a closed procedure.

As the major complication of these fractures is adherence of soft tissues, the primary goals of rehabilitation, once bony healing has occurred, are to restore an optimized soft-tissue balance and glide to allow pain-free motion and strength while simultaneously protecting the healing tissues.

Finger Fractures

Fractures of the finger (phalangeal), which are more common than metacarpal or carpal fractures, represent approximately 45 percent of fractures of the hand and wrist.[361] Phalangeal fractures can be divided into base, shaft, and neck and head fractures. Conservative intervention for the more stable fractures involves closed reduction in as near normal alignment as possible with an appropriate cast or splint[362]:

Distal Phalanx Fractures

Tuft Fracture. This is the most common fracture of the fingers, frequently resulting from a crush injury. These fractures are often associated with injuries to the nail matrix.

Shaft Fracture. This type of fracture is either longitudinal or more commonly transverse in orientation. If displaced, this type of fracture is usually associated with an injury to the nail matrix.

Intra-articular Fracture. This fracture in adults usually involves either the volar or posterior (dorsal) lip at the end of the bone, whereas in children an epiphyseal separation also may occur.

Volar Lip Fracture. This type of fracture, also referred to as Jersey finger or sweater finger, is also a tendon avulsion injury where the FDP remains attached to the small fracture fragment.

Unstable displaced articular fractures require surgical intervention. Generally speaking, following a fracture of the distal phalanx, a protective splint is worn for 2–4 weeks until the fracture site is nontender. AROM begins at 2–4 weeks or earlier if the fracture is stable enough. PROM begins at 5–6 weeks. PREs normally begin at 7–8 weeks.

Fractures of the Proximal and Middle Phalanges

Shaft Fracture. The type of shaft fracture depends largely on the mechanism of injury. A direct blow frequently causes transverse fractures, whereas twisting injuries often cause spiral or oblique fractures.

The intervention for this type of fracture depends on the location and the severity:

Proximal Phalanx Fractures. Nondisplaced extra-articular fractures are splinted with buddy tape. AROM is initiated immediately, with PROM being initiated at 6–8 weeks. Nondisplaced intra-articular fractures are splinted in the intrinsic plus position for 2–3 weeks. AROM begins at 2–3 weeks, with PROM being initiated at 4–8 weeks. PREs normally begin at clinical union (8–12 weeks).

Middle Phalanx Fractures. If nondisplaced, these fractures are splinted in the intrinsic plus position for approximately 3 weeks. Buddy splinting, the taping of a neighboring finger to the involved finger, may also be an option. AROM is initiated when pain and edema subsides. PROM begins at 4–6 weeks, with PREs normally beginning at 6–8 weeks.

THERAPEUTIC TECHNIQUES

Myofascial Release

Carpal Tunnel Release. A number of myofascial techniques can be used to treat CTS

Opening the Canal. The patient is positioned in sitting or supine lying with their palms facing upward. The clinician applies pressure centrally from the posterior (dorsal) surface of the carpal bones simultaneously with pressure applied from the ventral edges of the carpal bones, using a three-point-opposing-pressure technique.[363]

Abductor Brevis Release. The patient is positioned in sitting or supine lying with their palm facing upward. The clinician grasps the thumb with one hand and pulls it back into hyperextension with abduction, while simultaneously performing the opening canal technique described above.[363]

Carpal Tunnel Stretch. The patient is positioned in sitting or supine lying with their palm facing upward. The clinician stabilizes the patient's wrist with one hand and simultaneously hyperextends the digits and wrist of the patient with the other hand.[363]

Techniques to Increase Joint Mobility

The majority of the joint mobility tests described in the tests and measures section can also be utilized as mobilization techniques. For each of the techniques, the patient is positioned in sitting with their forearm and wrist in a neutral position, with the clinician positioned to the side of the patient. The amplitude and the velocity of each of the techniques (i.e., grade) is varied according to the stage of healing and the irritability of the joint.

The clinician must be cognizant of the joints that are responsible for the individual motions that occur at the wrist and hand and which ones present with convex or concave joint surfaces in order to deliver the most specific technique.

- Supination–pronation occurs primarily at the ulnomeniscotriquetral joint and the proximal and inferior radioulnar joints.
- Wrist flexion occurs primarily at the radiocarpal joint (distal radius and the articulating surfaces of the navicular and lunate).
- Wrist extension occurs primarily at the midcarpal joints (articulating surface of the scaphoid, lunate, and triquetral bones proximally, and the trapezium, trapezoid, capitate, and hamate bones distally).

Passive Accessory Mobilizations

Distal Radioulnar Joint

Anterior–posterior Glide. The clinician glides the radius in an anterior direction to improve forearm pronation and in a posterior direction to improve forearm supination. The intensity of the technique (i.e., grade) is varied according to the irritability of the joint.

Radiocarpal

Posterior–anterior glide (Fig. 18-30). The posterior glide is used to improve the joint's ability to flex, whereas the anterior glide is used to improve the ability of the joint to extend.

Ulnar and radial glide (Fig. 18-31). The ulnar (medial) glide is used to improve the joint's ability to radially deviate, whereas the radial (lateral) glide is used to improve the ability of the joint to ulnarly deviate.

Ulnocarpal, Midcarpal, CMC, MCP, and IP Joints

Distraction. Using a pinch grip of the index finger and thumb of one hand, the clinician palpates and stabilizes the proximal bone of the joint being distracted. With a pinch grip of the index finger and thumb of the other hand, the clinician palpates and mobilizes the distal bone longitudinally (Fig. 18-36).

Posterior–Anterior Glide (Flexion/Extension). Using a pinch grip of the index finger and thumb of one hand, the clinician palpates and stabilizes the proximal bone of the joint being mobilized in a posterior (dorsal)–anterior (palmar) plane. With a pinch grip, the clinician glides the distal bone along the posterior (dorsal)–anterior (palmar) plane of the

corresponding joint. The appropriate conjunct rotation of the bone may be added. For example, to restore flexion at the radioscaphoid joint, the clinician rotates the scaphoid toward the center of the palm, while simultaneously gliding the scaphoid in a posterior (dorsal) direction.

The clinician can make the technique patient-assisted by flexing/extending the distal bone about the appropriate intra-articular axis to the limit of the physiologic range of motion. From this position, the patient is instructed to perform an isometric contraction against the clinician's equal resistance. The contraction is held for 3–5 seconds, following which the patient is instructed to completely relax. The new barrier of flexion/extension is localized and the mobilization repeated.

First CMC (Trapeziometacarpal) Joint

Posterior glide. This technique is used to improve range of motion into trapeziometacarpal joint abduction.

Anterior glide. This technique is used to improve range of motion into trapeziometacarpal joint adduction.

Medial–Lateral Glide (Abduction/Adduction). The medial glide technique is used to improve range of motion into trapeziometacarpal joint flexion. The lateral glide technique is used to improve range of motion into trapeziometacarpal joint extension.

The clinician can make the technique patient assisted by abducting/adducting the distal bone about the appropriate intra-articular axis to the limit of the physiologic range of motion. From this position, the patient is instructed to perform an isometric contraction against the clinician's equal resistance. The contraction is held for 3–5 seconds, following which the patient is instructed to completely relax. The new barrier of motion is localized and the mobilization repeated.

Intermetacarpal Loints. Using a pinch grip of the index finger and thumb of one hand, the clinician palpates and stabilizes one metacarpal. With the thumb and index finger of the other hand, the clinician mobilizes the neighboring metacarpal into an anterior or posterior glide, with the appropriate conjunct rotation

MCP Joints.

Posterior–Anterior Glide. A posterior glide is used to improve range of motion into extension for digits two through five, whereas an anterior glide is used to improve range of motion into flexion for digits two through five.

Ulnar (Medial)–Radial (Lateral) Glide. An ulnar glide is used to improve range of motion into ulnar deviation for digits two through five, whereas a radial glide is used to improve range of motion into radial deviation for digits two through five.

First MCP/IP Joint. A radial glide is used to improve trapeziometacarpal extension, while the ulnar glide is used to improve trapeziometacarpal flexion.

IP joints. The anterior glide can be used to improve the ability of the joint to move into flexion, whereas posterior glide can be used to improve the ability of the joint to move into extension.

High-Velocity, Low-Amplitude Thrusting

High-velocity thrust techniques can be used with any of the carpals. The following example describes the technique for a posteriorly (dorsally) displaced scaphoid:

FIGURE 18-86 High-velocity thrust technique to the scaphoid.

The patient is positioned in sitting with the forearm of their affected side resting on a table with the anterior (palmar) side facing down. The clinician sits or stands at right angles to the patient's affected side. The clinician grips the patient's scaphoid bone between their thumb and index finger (Fig. 18-86). The clinician reinforces this grip by placing the thumb and the index of the other hand on top of them. The patient's wrist is then passively extended to the end range. At the end of the available range, the scaphoid is thrusted anteriorly (ventrally) while passively extending the wrist slightly.

Transverse Friction Massage

Common Sheath of APL and EPB. Transverse friction can be applied to the common shared sheath of the APL and EPB (Fig. 18-87) or at the point where the tendons pass over the wrist extensors.

FIGURE 18-87 TFM to common shared sheath of the abductor pollicis longus and extensor pollicis.

Techniques to Increase Soft Tissue Extensibility

A number of techniques can be used to increase the extensibility of the soft tissues of the wrist, hand, and forearm. These include passive or AROM exercises that can be performed by the patient:

- Wrist flexion and extension
- Wrist ulnar and radial deviation
- Finger flexion and extension
- Finger adduction and abduction
- Thumb opposition, flexion, extension, abduction, and adduction

CASE STUDY

PAINFUL LEFT THUMB

HISTORY

History of Current Condition

A 23-year-old female patient complained of left thumb pain following a home do-it-yourself project that involved a lot of hammering of nails. The patient described a gradual onset of pain about 2 months ago and described the pain as burning located at the base of the left thumb. The patient also reported some swelling at the wrist. The patient attributed the pain to the hammering of nails as subsequent attempts to use the hammer reproduced the pain. Over time, the pain had worsened to the point where it hurt all of the time, even at night. The NSAIDs prescribed by the physician 2 weeks ago appeared to be helping.

Past History of Current Condition

No past history of left elbow, wrist, or hand pain.

Past Medical/Surgical History

Unremarkable except for removal of ganglion cysts from her right wrist/hand about 1 year ago.

Growth and Development

Right-hand dominant.

Medications

None, except for the prescribed NSAIDs.

Occupational/Employment/School

Office worker. College education.

Functional Status/Activity Level

The patient reported experiencing pain with vacuuming and lifting heavy pots and pans. The patient's goals were to decrease pain with activities of daily living.

Health Status (Self-Report)

In general good health, but pain interferes with gripping tasks at home and at work.

Questions

1. What are some of the more common diagnoses characterized by thumb pain?
2. What does the history of the gradual onset and of repetitive activity tell the clinician?
3. What findings do you expect to note in the physical examination in terms of palpation, resistive tests, and special tests?
4. What additional questions would you ask to help rule out referral of pain from the cervical spine or shoulder?
5. List the tests you would use to rule out the various diagnoses that you listed in question 1.
6. Does this presentation/history warrant an upper quarter scanning examination? Why or why not?

CASE STUDY

PAIN, WEAKNESS, AND NUMBNESS OF THE HAND

HISTORY

History of Current Condition

A 49-year-old female secretary complains of insidious onset of right hand numbness and pain, which began about 5 weeks previously. The symptoms are felt mainly in the right index finger, especially when working at her computer at work but also in her right thumb and middle finger after a day at work and at night. The symptoms are also reported to be worse during the night and early morning. The patient has also noted a slight decrease in her grip strength, which prompted her to see a MD, who prescribed PT, ibuprofen, vitamin B6, and a short course of diuretics. The patient denies any neck pain.

Past Medical/Surgical History

Unremarkable, including no history of previous symptoms or of diabetes mellitus reported by the patient.

Medications

800 mg of ibuprofen daily.

Other Tests and Measures

None. X-rays 1 year ago were unremarkable (per patient). Physician mentioned that further testing may be warranted (nerve conduction velocity, EMG).

Social Habits (Past and Present)

Smoker (1/2 pack per day).

Growth and Development

Right-hand dominant.

Occupational/Employment/School

Full-time secretary at local community hospital for last 6 years. Recently promoted which has meant an increase in computer work.

Functional Status/Activity Level

Symptoms interfering with work and at home with her needle craft. Symptoms also interfering with sleep approximately two times per night.

Questions

1. What are some of the more common diagnoses characterized by symptoms in this distribution?
2. What does the history of the gradual onset and of repetitive activity tell the clinician?
3. What findings do you expect to note in the physical examination in terms of palpation, resistive tests, and special tests?
4. What additional questions would you ask to help rule out referral of pain from the cervical and thoracic spine?
5. What additional questions would you ask to help rule out referral of pain from the shoulder or elbow?
6. List the tests you would use to rule out the various diagnoses that you listed in question 1.
7. Does this presentation/history warrant a scan? Why or why not?

REVIEW QUESTIONS*

1. Which two carpal bones does the radius articulate with?
2. Name the carpal bones in the distal row.
3. Which structures run through Guyon canal?
4. Which combination of symptoms indicates injury to the median nerve?
   a. The middle and index fingers lose the ability to flex and the thumb cannot adduct or extend.
   b. The ring and little fingers lose the ability to flex, and the little finger cannot abduct or oppose.
   c. The inability of the wrist and fingers to extend interferes with grasp.
   d. The middle and index fingers lose their ability to flex, and the thumb cannot oppose.
5. Finkelstein test is designed to assess involvement of which of the following contractile structures?
   a. EPL and APB muscles.
   b. EPB and APL muscles.
   c. Extensor pollicis longus and abductor pollicis longus muscles.
   d. EPB and APB muscles.

*Additional questions to test your understanding of this chapter can be found in the Online Learning Center for *Orthopaedic Assessment, Evaluation, and Intervention* at www.duttononline.net.

Hip CHAPTER 19

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joint, ligaments, muscles, and blood and nerve supply that comprise the hip joint complex.
2. Describe the biomechanics of the hip joint, including the open- and close-packed positions, normal and abnormal joint barriers, force couples, and the static and dynamic stabilizers of the joint.
3. Describe the purpose and components of the examination of the hip joint.
4. Perform a comprehensive examination of the hip joint, including palpation of the articular and soft tissue structures, specific passive mobility, passive articular mobility tests, and stability stress tests.
5. Evaluate the total examination data to establish a diagnosis.
6. Describe the relationship between muscle imbalance and functional performance of the hip.
7. Summarize the various causes of hip dysfunction.
8. Develop self-reliant intervention strategies based on clinical findings and established goals.
9. Develop a working hypothesis.
10. Describe and demonstrate intervention strategies and techniques based on clinical findings and established goals.
11. Evaluate the intervention effectiveness in order to progress or modify an intervention.
12. Plan an effective home program and instruct the patient in same.

OVERVIEW

The hip articulation is a ball-and-socket joint formed between the head of the femur and the acetabulum of the pelvic bone (Fig. 19-1). Structurally, the hip is suited for stability first, then mobility.[1] The primary function of the hip is to support the weight of the head, arms, and trunk during the static erect posture and during dynamic activities such as ambulation, running, and stair climbing.[2] In addition, the hip joint provides a pathway for the transmission of forces between the pelvis and the lower extremities. The hip joint is a marvel of physics, transmitting truly impressive loads, both tensile and compressive. For example, during walking, the hip supports 1.3–5.8 times the body weight, and 4.5–8 times the body weight while running.[3] Finally, the hip joint functions to provide a wide range of lower limb movement.

The hip joint is well designed to provide such an important service, provided that it is permitted to grow and develop normally.

Normal hip joint growth and development occur because of a genetically determined balance of growth of the acetabulum and the presence of a strategically located spherical femoral head.[4–8]

- Absence of a normal femoral head during growth, such as in developmental dysplasia of the hip (DDH), causes the acetabulum to have a flat shape.
- A deformed head stimulates the formation of a correspondingly deformed acetabulum if the deformation occurs at a young enough age.[4]

ANATOMY

Bony Anatomy

The os coxa (hip bone) initially begins life as three individual bones: the ilium, the ischium, and the pubis.

Ilium

The ilium (see Fig. 19-1) is the largest of these three bones. It is composed of a large fan-like wing (ala) and an inferiorly

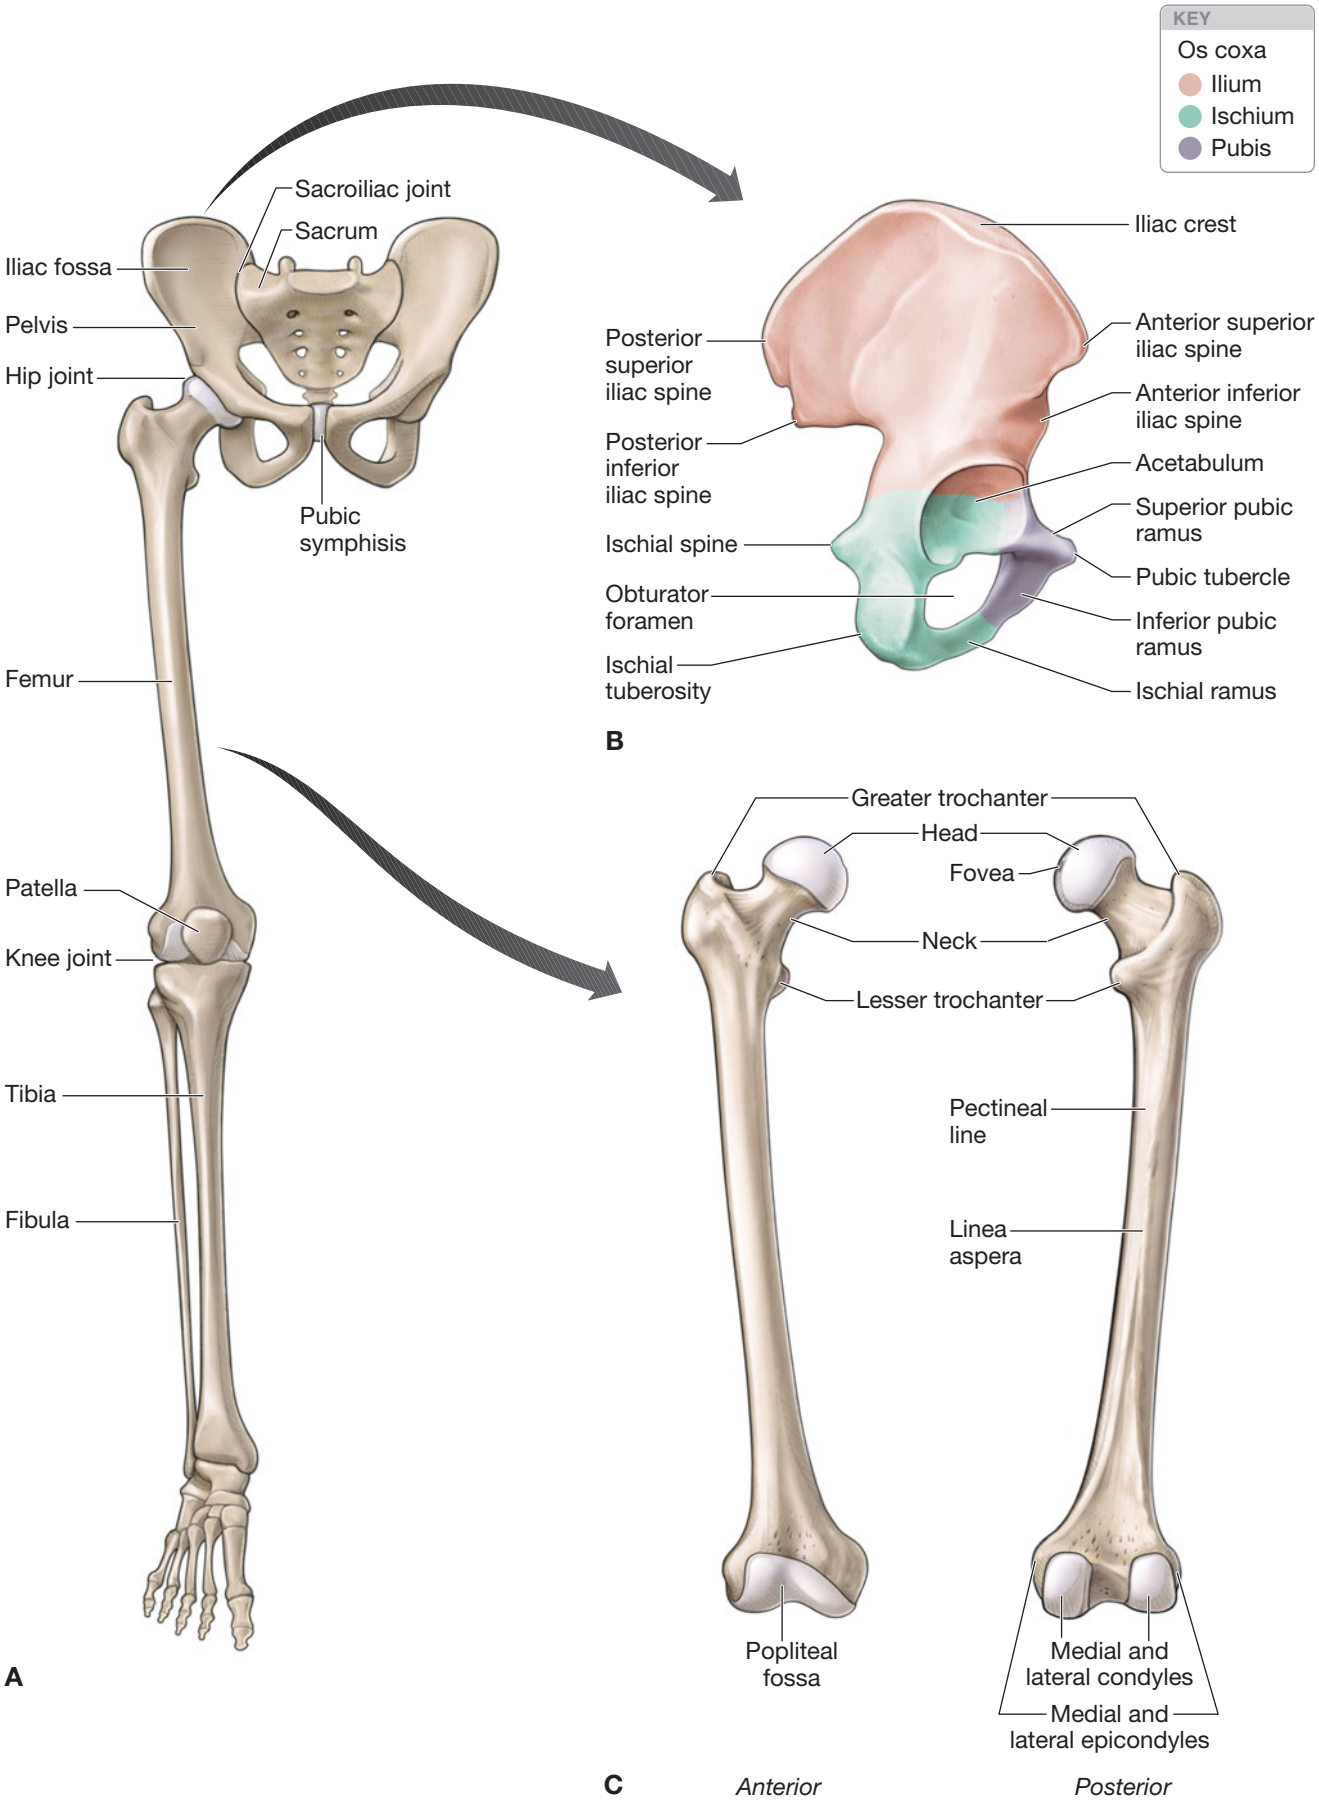

FIGURE 19-1 Bones of the lower extremity. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

positioned body. The body of the ilium forms the superior two-fifths of the acetabulum.

- The wing of the ilium spans superiorly from the posterior superior iliac spine (PSIS) to the anterior superior iliac spine (ASIS). The wing serves as the insertion for the gluteus minimus, medius, and maximus.
- The anterior surface of the ilium forms a fossa and serves as the proximal attachment of the iliacus muscle.

Ischium

The ischium (see Fig. 19-1) is composed of a body, which contributes to the acetabulum, and a ramus. The ischium forms the posterior two-fifths of the acetabulum. Together, the ischium and the ramus form the ischial tuberosity. The ischial tuberosity is an important landmark for palpation, as it serves as the attachment for several muscles (Table 19-1) and the sacrotuberous ligament. The ischial spine, located on the body of the ischium, serves as the attachment for the sacrospinous ligament.

Pubis

The pubis (see Fig. 19-1) is the smallest of the three bones and consists of a body and inferior and superior rami. The pubis forms the anterior fifth of the acetabulum.

Acetabulum

The ilium, ischium, and pubis fuse together within the acetabulum and form a deep-seated depression in the lateral pelvis, which allows for the proximal transmission of weight from the axial skeleton to the lower extremity.[9] The surface of the acetabulum faces laterally, inferiorly, and anteriorly (see Fig. 19-1). The superior and posterior margins of the acetabulum are reinforced with a compact cortical bone, which extends the peripheral brim of the fossa, enhancing the stability of the joint during weight-bearing from both flexed and extended positions.[9] While the majority of acetabular development is determined by the age of eight,[10–12] the depth of the acetabulum increases additionally at puberty, because of the development of three secondary centers of ossification.[4,5,13] Around the periphery of the acetabulum is a thickened collar of fibrocartilage known as the acetabular rim, or labrum (see "The Acetabular Labrum" section), that further deepens the concavity and grasps the head of the femur.[9] The transverse acetabular ligament is a fibrous tissue link spanning the inferior acetabular notch that connects the anteroinferior and posteroinferior horns of the semilunar surface of the acetabulum. The posterior aspect of the ligament attaches to the bone beneath the lunate surface, and the anterior aspect attaches to the labrum.[14] The transverse acetabular ligament contains no cartilage cells.[15] The function of this ligament in the hip is currently unknown.

The articular surface of the acetabulum is limited to an inverted horseshoe-shaped area covering the anterior, superior, and posterior margins.[9] This relatively small contact area, may contribute to the prevalence of hip degenerative joint disease in humans.[16] The articular surface is covered by a thickened layer of hyaline cartilage, which thins near the center of the joint, and is absent over the acetabular notch (see Fig. 19-1), the area occupied by the ligamentum teres and obturator artery. The diameter of the acetabulum is slightly less than that of the femoral head and results in an incongruous fit of the joint surfaces. This incongruity unloads the joint during partial weight-bearing (PWB), by allowing the femoral head to sublux laterally out of the cup, while in full weight-bearing, the femoral head is forced into the acetabulum.[9] In addition, elastic deformation of the acetabulum increases joint congruency of the two-joint surfaces in weight-bearing.[17] Finally, a strong vacuum contributes to the joint coaptation.[1] The position of maximum articular congruence corresponds to a quadriped position: 90 degrees flexed, slightly abducted, and externally rotated.

Femur

The femur is the strongest and the longest bone in the body. The proximal end of the femur consists of a head, a neck, and a greater and lesser trochanter (see Fig. 19-1). Approximately two-thirds of the femoral head is covered with a smooth layer of cartilage except for a depression, the fovea capitis, which serves as the attachment of the ligamentum teres.

The femoral head is composed of a trabecular bone core encased in a thin cortical bone shell. Both the trabecular framework of the head and its pliable hyaline cartilage covering contribute toward the shaping of the femoral head within the acetabulum during full weight-bearing.[9] The trabecular bone in the femoral neck and head is specially designed to withstand high loads because of the incorporation of both primary and secondary compressive and tensile patterns. However, within this trabecular system, there is a point of weakness called the Ward triangle, which is a common site of osteoporotic fracture.[18]

The neck of the femur is located between the shaft of the femur and its head. On the anterior surface of the femoral neck is the rough intertrochanteric line. The femoral neck serves to extend the weight-bearing forces lateral and inferior to the joint fulcrum. The intertrochanteric crest marks the posterior junction between the neck and the shaft of the femur. The greater trochanter serves as the insertion site for several muscles that act on the hip joint (Table 19-2). The lesser trochanter, located on the posteromedial junction of the neck and the shaft of the femur, is created from the pull of the iliopsoas muscle.

The head of the femur is angled anteriorly, superiorly, and medially. The femoral neck is externally rotated with respect to the shaft. The angle that the femoral neck makes with the

Gemellus superior	
Gemellus inferior	

acetabulum is called the angle of anteversion/declination (see "Biomechanics" section).

Joint Capsule

The joint capsule of the hip (Fig. 19-2), a substantial fibrous sleeve, attaches proximally to the pelvis just lateral to the acetabular labrum and extends laterally over the femoral head and neck to attach to the intertrochanteric line anteriorly. Posteriorly, the capsule attaches to the lateral one-third of the femoral neck allowing for the attachment of the obturator externus tendon in the posterior intertrochanteric fossa.[9] Both the articular cartilage and the joint capsule are thicker anterosuperiorly, where maximal stress and weight-bearing occurs, and thinnest posteroinferiorly. The joint capsule has three thickened regions that constitute the capsular ligaments. These anterior capsular thickenings include the iliofemoral ligament and the pubofemoral ligament.

- The iliofemoral ligament (Y ligament of Bigelow) (Fig. 19-2) consists of two parts: an inferior (medial) portion and a superior (lateral) portion. The iliofemoral ligament is the strongest ligament in the body. The ligament is oriented superior laterally and blends with the iliopsoas muscle. By limiting the range of hip extension, this ligament, with the assistance of the pubofemoral ligament, allows maintenance of the upright posture and reduces the need for contraction of the hip extensors in a balanced stance. Hip adduction tightens the superior portion of the iliofemoral ligament.
- The pubofemoral ligament (Fig. 19-2) blends with the inferior band of the iliofemoral, and with the pectineus muscle. The orientation of the pubofemoral ligament is more inferior-medial. Its fibers tighten in extension and abduction and reinforce the joint capsule along the medial surface.

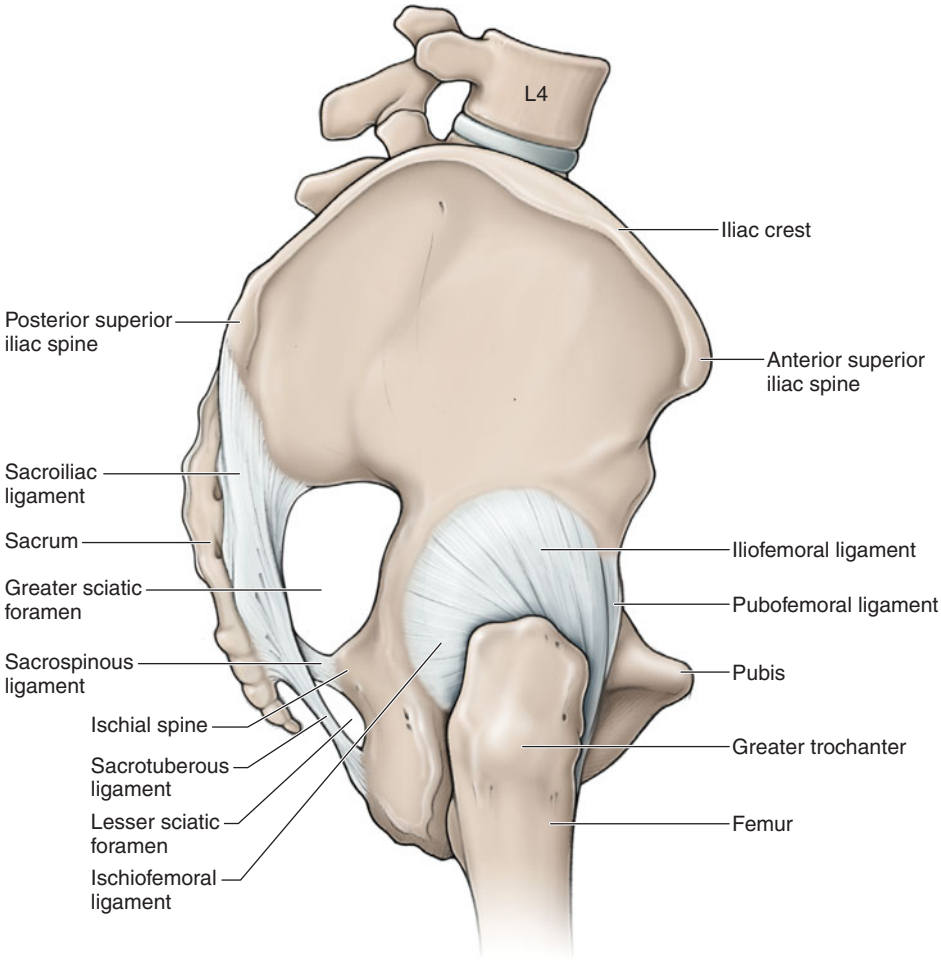

FIGURE 19-2 The hip joint capsule. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

The posterior thickening of the capsule accounts for the ischiofemoral ligament (Fig. 19-2), which winds posteriorly around the femur and attaches anteriorly, strengthening the capsule. This ligament, which tightens with internal rotation of the hip, is more commonly injured than the other hip ligaments.

All these capsular thickenings/ligaments are taut in hip extension, especially the inferior portion of the iliofemoral ligament. Conversely, all the ligaments are relaxed in hip flexion. In external rotation of the hip, the superior portion of the iliofemoral ligament and the pubofemoral ligament are both taut. Because of their inherent strength, the hip ligaments are only usually compromised with severe macrotrauma involving a fracture/dislocation of the hip.

The ligamentum teres, or capitis femoris ligament (Fig. 19-3), is a structure seen only in the hip joint.[9] This ligament spans the hip joint running from the acetabular notch to the fovis capitis of the femur, attaching the femoral head to the inferior acetabular rim. The ligament is entirely enclosed by synovial membrane, which forms a sheath around the ligament. Within this sheath, vessels and nerves pass to the femoral head, providing an important source of arterial blood from a tiny posterior branch of the internal iliac artery. This arterial supply is a significant source of blood to the femoral head in infants and children[19] but becomes less significant in adulthood, because of collateral circulation from the circumflex arteries (see "Vascular Supply" section) surrounding the femoral neck, although chronic interruption the blood supply of the femoral head has been associated with avascular necrosis and degenerative arthritis.[20]

The ligamentum teres tightens during adduction, flexion, and external rotation and, although it provides very little to stability, it can contribute to symptoms when injured.

The Acetabular Labrum

The acetabular labrum (Fig. 19-3) is a ring consisting of fibrocartilage and dense connective tissue[21] that encases the femoral head and is attached to the acetabular margin. The acetabular labrum of the hip, to a large extent, is analogous to the meniscus of the knee (see Chap. 20) and the labrum of the glenohumeral joint (see Chap. 16) in that it enhances joint stability, decreases the forces transmitted to the articular cartilage,[22,23] and provides proprioceptive feedback.[22,23] The majority of the acetabular labrum is thought to be avascular. However, cadaver studies have shown blood vessels entering primarily the peripheral part of the labrum, with penetration only into the outer one-third of the substance of the labrum.[21] Nerve-endings and sensory end organs in the superficial layers of the labrum participate in nociceptive and proprioceptive mechanisms.[17,24] The osseous acetabulum in the hip provides substantial static stability to the hip joint.[24] Deepening of the socket that is provided by the labrum would, therefore, appear to be less important at the hip. Some research does indicate,

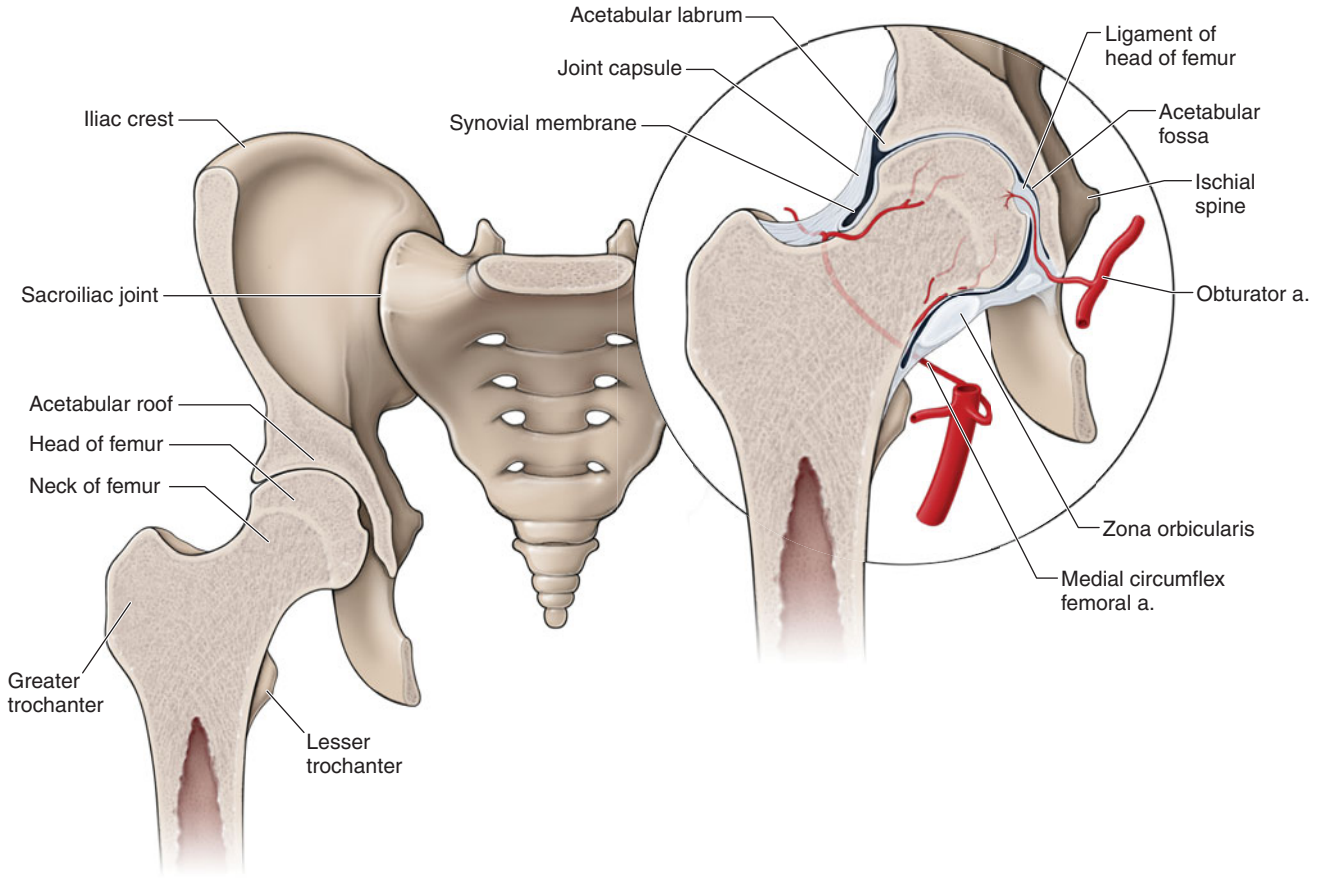

FIGURE 19-3 The hip joint. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

however, that the labrum may enhance stability by providing negative intra-articular pressure in the hip joint.[25] Another study, by Konrath et al.,[17] examined the role of the acetabular labrum in load transmission in a biomechanical study. The distribution of contact area and pressure between the acetabulum and the femoral head was measured in cadaver hips before and after removal of the acetabular labrum. No appreciable changes with regard to contact area, load, and mean pressure were noted after removal of the labrum.[17]

Another proposed function of the labrum is to improve the mobility of the hip by providing an elastic alternative to the bony rim.[17] The labrum, which varies greatly in form and thickness, has a triangular cross section: an internal articular surface, an external surface contacting the joint capsule, and a basal surface attached to the acetabular bone and transverse ligaments.[15] Most of the labrum is composed of thick, type I collagen fiber bundles principally arranged parallel to the acetabular rim, with some fibers scattered throughout this layer running obliquely to the predominant fiber orientation.[26] The normal microvasculature of the acetabular labrum consists of a group of small vessels located in the substance of the labrum traveling circumferentially around the labrum at its attachment site on the outer surface of the bony acetabular extension.[27] In addition, the labrum is surrounded by highly vascularized synovium that is present in the capsular recess.[27]

Muscles

The hip joint is surrounded by a wide variety of muscles that accelerate, decelerate, and stabilize the hip joint. Indeed 21 muscles cross the hip, providing both tri-planar movement and stability between the femur and the acetabulum.[28] Consequently, abnormal performance of the muscles of the hip may alter the distribution of forces across the joint articular surfaces, potentially causing, or at least predisposing, degenerative changes in the articular cartilage, bone, and surrounding connective tissues.[28] The origin, insertion, and innervation of these muscles are outlined in Table 19-3. Since the hip joint is able to move through a wide range of motion (ROM), a muscle's line of pull may be altered with changing hip position, which makes describing a muscle's action difficult. For example, the orientation of the gluteus medius allows it to work as an internal rotator in hip flexion yet as a weak external rotator in hip extension.[29] Similarly, the tensor fascia latae (TFL) is a hip abductor and flexor, depending upon the hip position, while being a weak internal rotator in all positions.[30] The hip muscles and their respective actions are outlined in Table 19-3 and Table 19-4.

Iliopsoas

The iliopsoas muscle, formed by the iliacus and psoas major muscles (see Fig. 19-4), is the most powerful hip flexor, while also functioning as a weak adductor and external rotator of the hip. The iliopsoas attaches to the hip joint capsule, thereby giving it some support. Since the muscle spans both the axial and appendicular components of the skeleton, it also functions as a trunk flexor, and affords an important element to the vertical stability of the lumbar spine, especially when the hip is in full extension and passive tension is greatest in the muscle.[28,31] Theoretically, a sufficiently strong and isolated bilateral contraction of any hip flexor muscle will either rotate the femur toward the pelvis, the pelvis (and possibly the trunk) toward the femur, or both actions simultaneously.[28]

Gluteus Maximus

The gluteus maximus (Fig. 19-5) is the largest and most important hip extensor. It is also an important external rotator of the hip. The larger, superficial portion of this muscle inserts at the proximal part of the ITB, while the deep portion inserts into the gluteal tuberosity of the femur. The inferior gluteal nerve, which innervates the muscle, is located on the deep portion.

The gluteus maximus is normally active only when the hip is in flexion, as during stair climbing or cycling, or when extension of the hip is resisted.[32]

Gluteus Medius

The gluteus medius (Fig. 19-5) is critical for balancing the pelvis in the frontal plane during one leg stance,[33] which accounts for approximately 60% of the gait cycle (see Chap. 6).[34] During one leg stance, approximately 3 times the body weight is transmitted to the hip joint with two-thirds of that being generated by the hip-abductor mechanism.[34] In addition to its role as a stabilizer, the gluteus medius also functions as a decelerator of hip adduction.

Because of its shape, the gluteus medius is known as the deltoid of the hip. The muscle can be divided into two functional parts: an anterior portion and a posterior portion. The anterior portion works to flex, abduct, and internally rotate the hip. The posterior portion extends and externally rotates the hip. On the deep surface of this muscle is located the superior gluteal nerve and the superior and inferior gluteal vessels.

Gluteus Minimus

The gluteus minimus (Fig. 19-6), the major internal rotator of the femur, is a relatively thin muscle situated between the gluteus medius muscle and the external surface of the ilium. It receives support from the TFL, semitendinosus, semimembranosus, and gluteus medius.[32] The gluteus minimus also abducts the thigh, as well as helping the gluteus medius with pelvic support.

Piriformis

The piriformis (Fig. 19-6) is an external rotator of the hip at less than 60 degrees of hip flexion. At 90 degrees of hip flexion, the piriformis reverses its muscle action, becoming an internal rotator and abductor of the hip.[35] Because of its close association with the sciatic nerve, the piriformis can be a common source of buttock and leg pain.[36–39]

Rectus Femoris

The rectus femoris muscle (Fig. 19-7), one of the four quadriceps muscles (see Chap. 20), is a two-joint muscle that arises from two tendons: one, the anterior or straight, from the anterior inferior iliac spine (AIIS); the other, the posterior or reflected, from a groove above the brim of the

TABLE 19-3 Origin, Insertion, and Innervation of Muscles Acting Across the Hip Joint

Muscle	Origin	Insertion	Innervation
Adductor brevis	External aspect of the body and inferior ramus of the pubis	The line from the greater trochanter of the linea aspera of the femur	Obturator nerve
Adductor longus	In angle between pubic crest and symphysis	The middle third of the linea aspera of the femur	Obturator nerve
Adductor magnus	Inferior ramus of pubis, ramus of ischium, and the inferolateral aspect of the ischial tuberosity	To the linea aspera and adductor tubercle of the femur	Obturator nerve and tibial portion of the sciatic nerve
Biceps femoris	Long head arises from the sacrotuberous ligament and posterior aspect of the ischial tuberosity. Short head does not act across the hip	On the lateral aspect of the head of the fibula, the lateral condyle of the tibial tuberosity, the lateral collateral ligament, and the deep fascia of the leg	Tibial portion of the sciatic nerve, S1
Gemelli (superior and inferior)	Superior–posterior (dorsal) surface of the spine of the ischium and inferior-upper part of the tuberosity of the ischium	Superior- and inferior-medial surface of the greater trochanter	Sacral plexus
Gluteus maximus	Posterior gluteal line of the ilium, iliac crest, aponeurosis of the erector spinae, posterior (dorsal) surface of the lower part of the sacrum, side of the coccyx, sacrotuberous ligament, and intermuscular fascia	Iliotibial tract of the fascia latae and gluteal tuberosity of the femur	Inferior gluteal nerve
Gluteus medius	Outer surface of the ilium between the iliac crest and the posterior gluteal line, anterior gluteal line, and fascia	Lateral surface of the greater trochanter	Superior gluteal nerve
Gluteus minimus	Outer surface of the ilium between the anterior and inferior gluteal lines, and the margin of the greater sciatic notch	On the anterior surface of the greater trochanter	Superior gluteal nerve
Gracilis	The body and inferior ramus of the pubis	The superior medial surface of the proximal tibia, just proximal to the tendon of the semitendinosus	Obturator nerve
Iliacus	Superior two-thirds of the iliac fossa and upper surface of the lateral part of the sacrum	Fibers converge with tendon of the psoas major to lesser trochanter	Femoral nerve
Obturator externus	Rami of the pubis, ramus of the ischium, and medial two-thirds of the outer surface of the obturator membrane	Trochanteric fossa of the femur	Obturator nerve
Obturator internus	Internal surface of the anterolateral wall of the pelvis and obturator membrane	Medial surface of the greater trochanter	Sacral plexus
Pectineus	Pectineal line	Along a line extending from the lesser trochanter to the linea aspera	Femoral or obturator or accessory obturator nerves
Piriformis	Pelvic surface of the sacrum, gluteal surface of the ilium, capsule of the sacroiliac joint, and sacrotuberous ligament	Upper border of the greater trochanter of femur	Sacral plexus
Psoas major	Transverse processes of all the lumbar vertebrae bodies and intervertebral disks of the lumbar vertebrae	Lesser trochanter of the femur	Lumbar plexus
Quadratus femoris	Ischial body next to the ischial tuberosity	Quadrate tubercle on femur	Nerve to quadratus femoris
Rectus femoris	By two heads, from the anterior–inferior iliac spine, and a reflected head from the groove above the acetabulum	Upper border of the patella	Femoral nerve
Sartorius	Anterior–superior iliac spine and notch below it	Upper part of the medial surface of the tibia in front of the gracilis	Femoral nerve
Semimembranosus	Ischial tuberosity	The posterior-medial aspect of the medial condyle of the tibia	Tibial nerve
Semitendinosus	Ischial tuberosity	Upper part of the medial surface of the tibia behind the attachment of the sartonus and below that of the gracilis	Tibial nerve
Tensor fascia latae	Anterior part of outer lip of the iliac crest and the lateral surface of the anterior–superior iliac spine	Iliotibial tract	Superior gluteal nerve

TABLE 19-4 Hip Actions and Muscles if in Anatomic Position

Hip Action	Prime Movers	Assistant Movers
Flexors	Iliopsoas Sartorius Tensor fascia latae Rectus femoris Pectineus Adductor longus	Adductor brevis Gracilis Gluteus minimus (anterior fibers)
Extensors	Gluteus maximus Semitendinosus Semimembranosus Biceps femoris (long head) Adductor Magnus (posterior head)	Gluteus medius (middle and posterior fibers) Adductor magnus (anterior head)
Abductors	Gluteus medius (all fibers) Gluteus minimus (all fibers) Tensor fascia latae	Sartorius Rectus femoris Piriformis
Adductors	Adductor magnus (anterior and posterior heads) Adductor longus Adductor brevis Gracilis Pectineus	Biceps femoris (long head) Gluteus maximus (posterior fibers) Quadratus lumborum Obturator externus
External rotators	Gluteus maximus Gemellus inferior Gemellus superior Obturator internus Quadratus femoris Piriformis (at less than 60 degrees hip flexion)	Gluteus medius (posterior fibers) Gluteus minimus (posterior fibers Biceps femoris (long head) Sartorius Obturator externus
Internal rotators	Not applicable	Semitendinosus Semimembranosus Gracilis Piriformis (at 90 degrees hip flexion) Gluteus medius (anterior fibers) Adductor longus Adductor brevis Pectineus Adductor Magnus (posterior head) Gluteus minimus (anterior fibers) Tensor fascia latae

Data from Anderson LC: The anatomy and biomechanics of the hip joint. *J Back Musculoskeletal Rehabil* 4:145–153, 1994; and Neumann DA: Kinesiology of the hip: a focus on muscular actions. *J Orthop Sports Phys Ther* 40:82–94, 2010.

acetabulum. The rectus femoris combines movements of flexion at the hip and extension at the knee. It functions more effectively as a hip flexor when the knee is flexed, as when a person kicks a ball.[32]

Obturator Internus

The obturator internus (Fig. 19-6) is normally an external rotator of the hip and an internal rotator of the ilium but becomes an abductor of the hip at 90 degrees of hip flexion.[40]

Obturator Externus

The obturator externus (Fig. 19-6), named for its location external to the pelvis, is an adductor and external rotator of the hip.[15]

Gemelli

The superior and inferior gemelli muscles (Fig. 19-6) are considered extensions of the obturator internus tendon. The superior gemellus is the smaller of the two. Both the gemelli function as minor external rotators of the hip.[15]

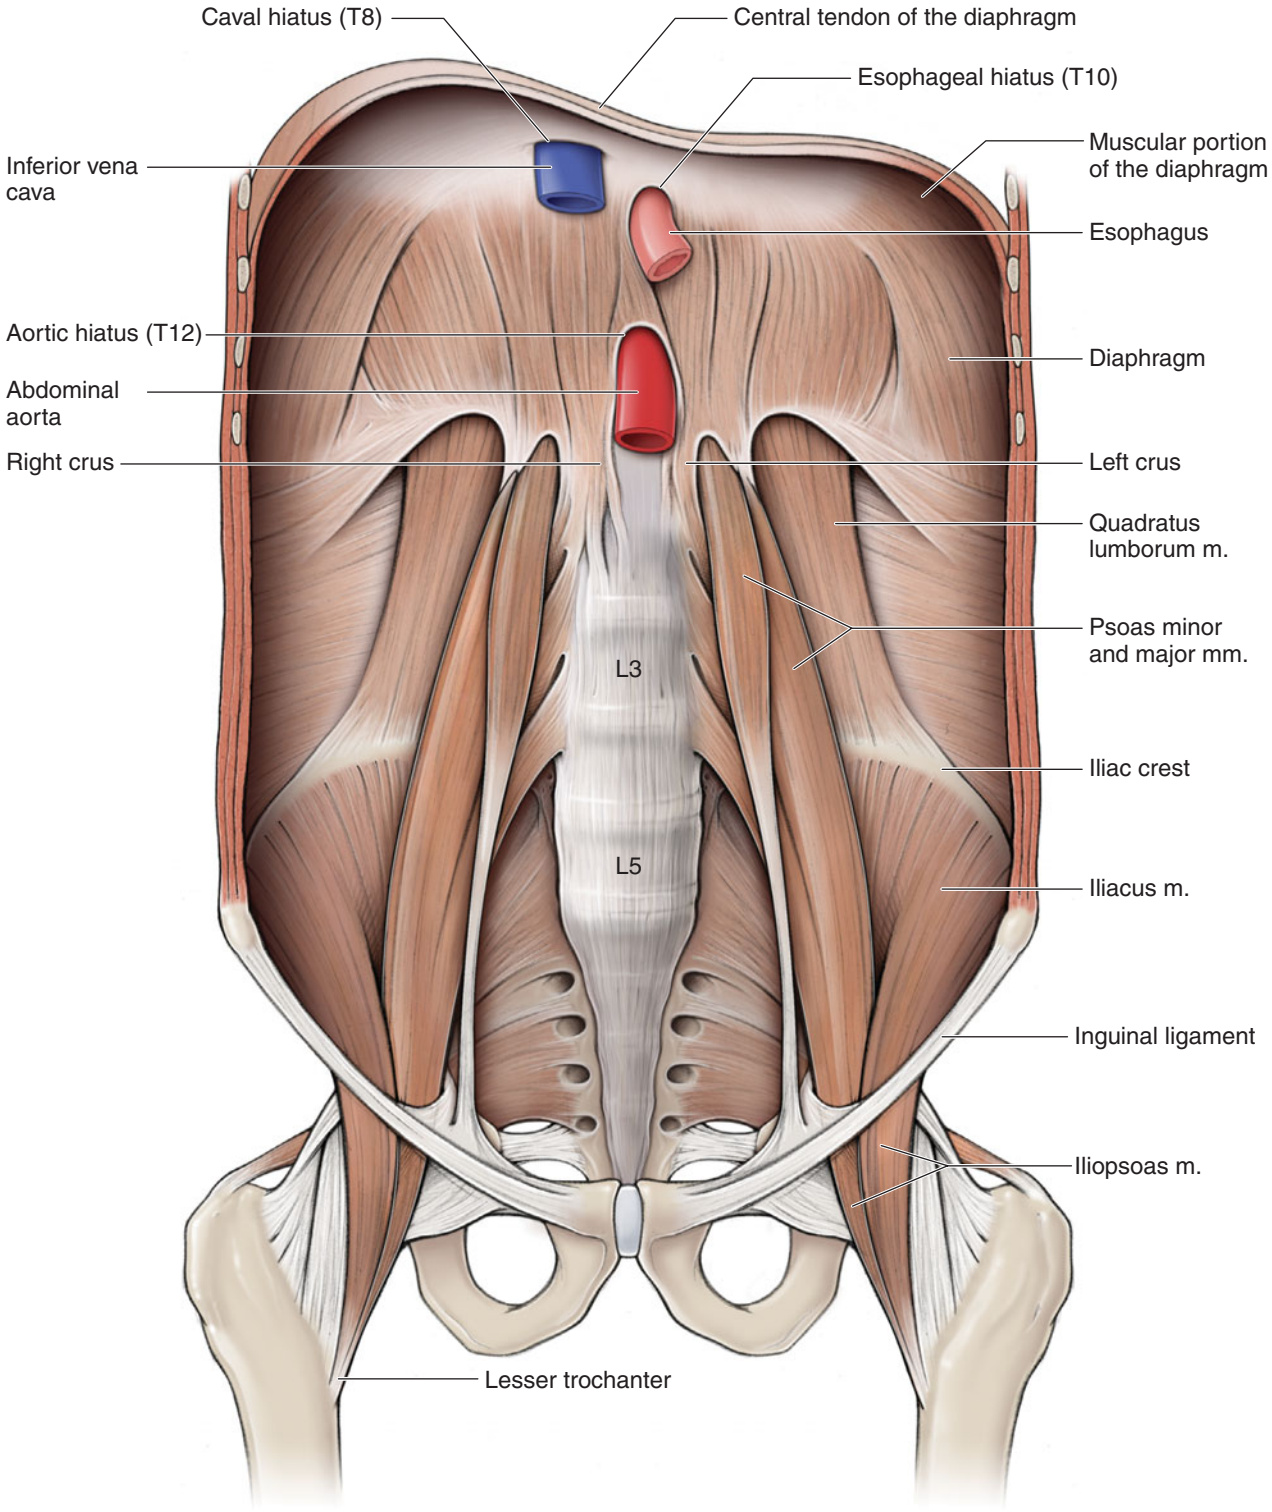

FIGURE 19-4 Muscles of the anterior hip. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Quadratus Femoris

The quadratus femoris muscle (Fig. 19-6), another external rotator of the hip, is a flat, quadrilateral muscle, located between the inferior gemellus and the superior aspect of the adductor magnus. The quadratus femoris and the inferior gemellus share the same innervation (L4–L5).[15] The obturator internus and superior gemellus also share the same innervation (L5–S1).[15]

CLINICAL PEARL

In a manner, generally, similar to the infraspinatus and teres minor at the glenohumeral joint, the short external rotators of the hip provide an important element of mechanical stability to the hip articulation[34] Interestingly, the popular posterior surgical approach to a total hip arthroplasty (THA), used by some surgeons, necessarily cuts through at least

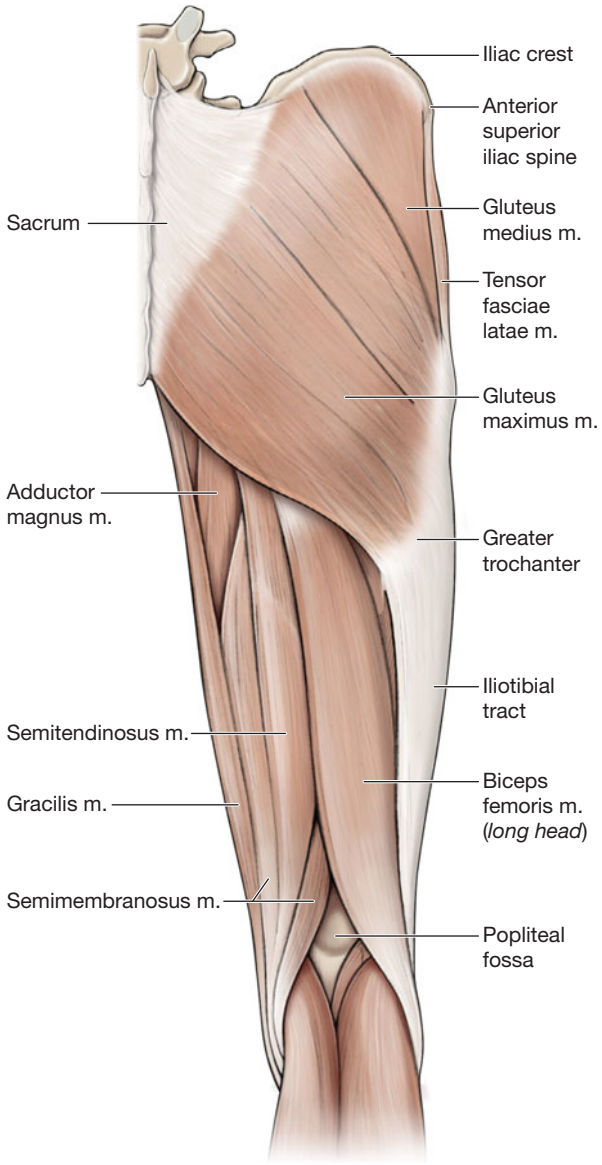

FIGURE 19-5 Superficial muscles of the posterior hip. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

part of the hip's posterior capsule, potentially disrupting several of the short external rotators tendons.[28] Studies have reported a significant reduction in the incidence of posterior hip dislocation when the surgeon carefully repairs the posterior capsule and external rotator tendons.[28,41,42]

Pectineus

The pectineus (see Fig. 19-7) is an adductor, flexor, and internal rotator of the hip. Like the iliopsoas, the pectineus attaches to and supports the joint capsule of the hip.

Tensor Fascia Latae

The TFL (see Fig. 19-5) envelops the muscles of the thigh. The TFL counteracts the backward pull of the gluteus maximus on the iliotibial band (ITB). The TFL also flexes, abducts, and externally rotates the hip. The trochanteric bursa is found deep to this muscle, as it passes over the greater trochanter (see later).[43] The attachment of the TFL via the ITB to the anterolateral tibia provides a flexion moment in knee flexion and an extension moment in knee extension.[2]

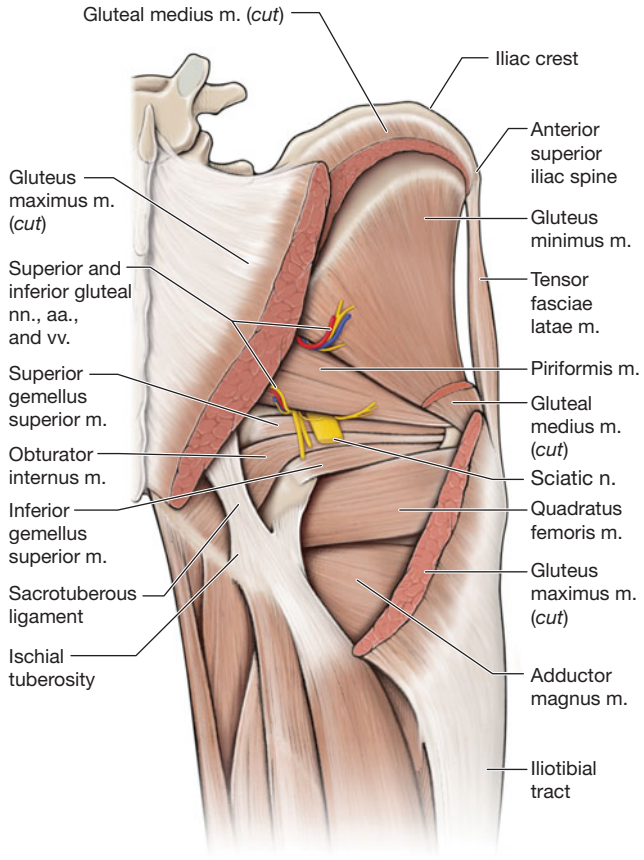

FIGURE 19-6 Deeper muscles of the posterior hip. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Sartorius

The sartorius muscle (see Fig. 19-7) is the longest muscle in the body. The sartorius is responsible for flexion, abduction, and external rotation of the hip, and some degree of knee flexion.[44]

Hamstrings

The hamstrings muscle group consists of the biceps femoris, the semimembranosus, and the semitendinosus.

Biceps Femoris. The biceps femoris (see Fig. 19-8) arises by way of a long and short head. Only the long head acts on the hip. The long head is active during conditions that require lower amounts of force, such as decelerating the limb at the end of the swing phase and during forceful hip extension.[45] The biceps femoris extends the hip, flexes the knee, and externally rotates the tibia. The biceps femoris (53%) is the most commonly strained muscle of the hamstring complex. The anatomy of the biceps femoris may help to explain its higher rate of injury. Firstly, it has a long and a short head, both with separate nerve supplies. This dual innervation may lead to asynchronous stimulation of the two heads. Mistimed contraction of the different parts of the muscle group may mean a reduced capacity to generate effective tension to control the imposed loads of the muscle. There may also be

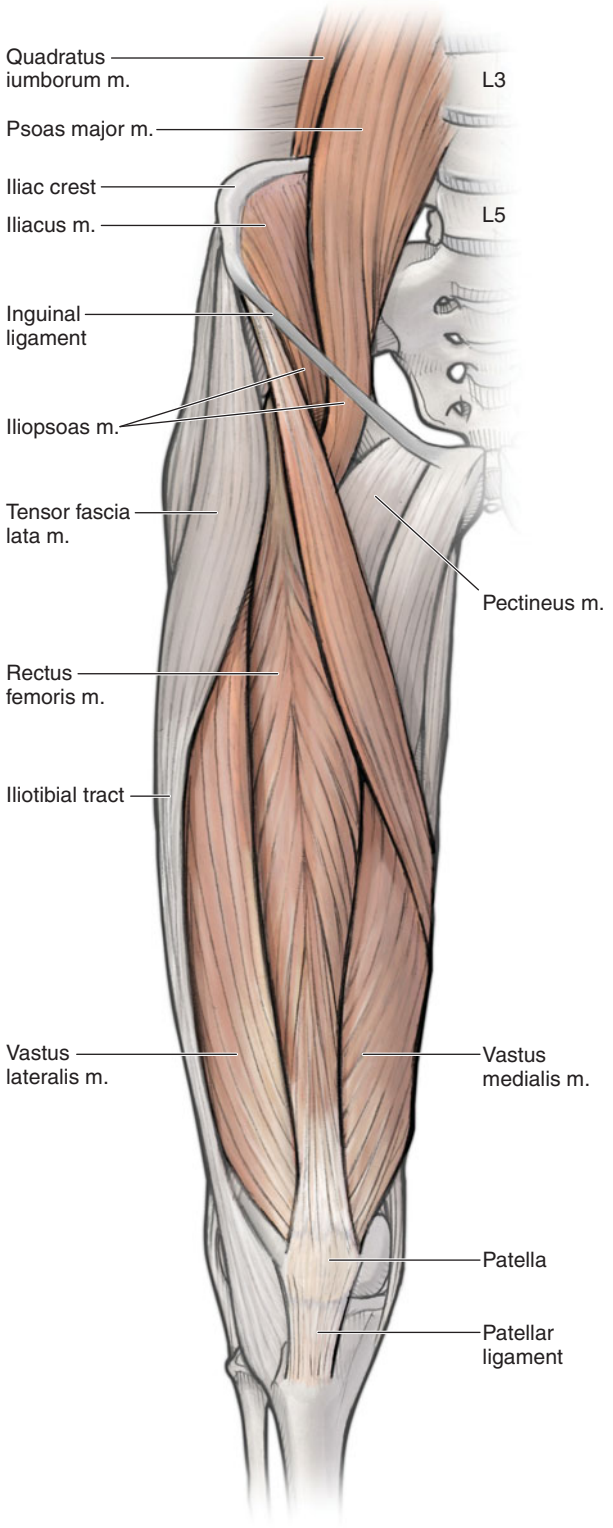

FIGURE 19-7 Muscles of the anterior hip and thigh. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

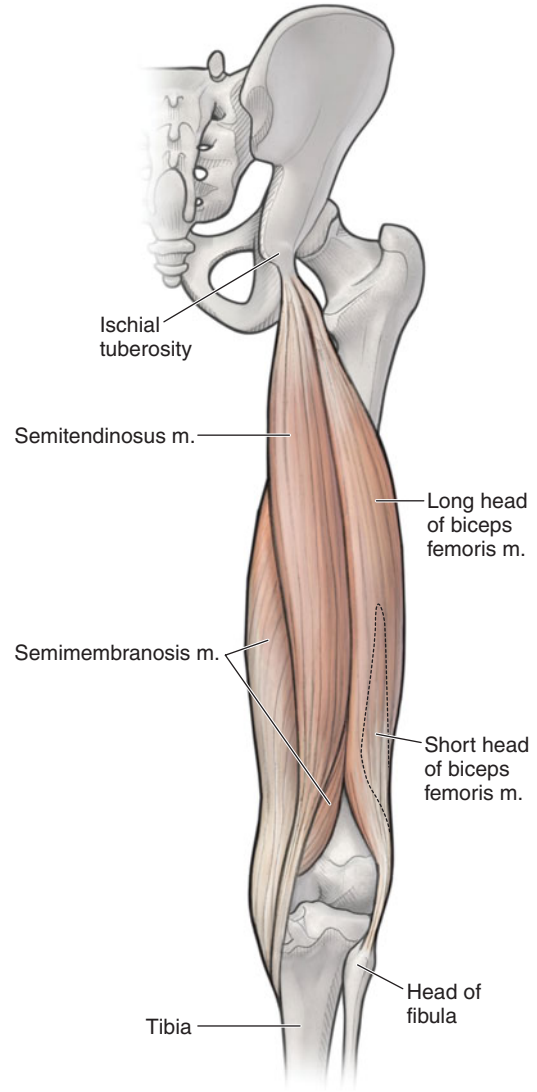

FIGURE 19-8 The hamstrings. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

anatomical variations in the attachments of biceps femoris, which may predispose certain people to injury. Burkett suggested that an extensive femoral attachment of the short head of the biceps femoris with an overlying strength deficit predisposes to hamstring strain. The long head of the biceps femoris originates from the lower part of the sacrotuberous ligament; therefore, it could be argued that the biceps femoris has a triarticular function and is, therefore, more predisposed to injury than the other hamstring muscles. The insertion of the biceps femoris into the head of the fibula may also be a predisposing factor to injury. A previous knee or ankle injury resulting in alteration in the movement of the superior tibiofibular joint may affect the biomechanics of the biceps femoris, although this notion is speculative. However, incomplete knee excursion caused by meniscal damage may lead to excessive loading of the biceps femoris.[46] The biceps femoris acts as an external rotator of the semiflexed knee and the extended hip. Given the rotational demands of many sports, this function may also predispose the biceps femoris to injury.

Semimembranosus. The semimembranosus (see Fig. 19-8) gains its name from its membranous origin at the ischial tuberosity.

Semitendinosus. The semitendinosus (see Fig. 19-8) arises from the ischial tuberosity and inserts as part of the pes

anserinus on the superior and medial aspect of the tibia, and deep fascia of the leg.

All three muscles of the hamstring complex (except for the short head of the biceps) work with the posterior adductor magnus and the gluteus maximus to extend the hip. The hamstrings also flex the knee and weakly adduct the hip. The long head of the biceps femoris helps with external rotation of the thigh and leg; the more medial semimembranosus and semitendinosus muscles assist with internal rotation of the thigh and leg. When the hamstrings contract, their forces are exerted at both the hip and knee joints simultaneously; functionally, however, they can actively mobilize only one of the two joints at any one time. Compared to walking and jogging, running is a stressful activity for the hamstrings and increases the high demands on their tendon attachments, especially during eccentric contractions. During running, the hamstrings have three main functions:

1. They decelerate knee extension at the end of the forward swing phase of the gait cycle. Through an eccentric contraction, the hamstrings decelerate the forward momentum (i.e., leg swing) at approximately 30 degrees short of full knee extension. This action helps provide dynamic stabilization to the weight-bearing knee.
2. At foot strike, the hamstrings elongate to facilitate hip extension through an eccentric contraction, thus further stabilizing the leg for weight-bearing.
3. The hamstrings assist the gastrocnemius in paradoxically extending the knee during the takeoff phase of the running cycle.

Hip Adductors

The adductors of the hip (Fig. 19-9) are found on the medial aspect of the joint.

Adductor Magnus. The adductor magnus is the most powerful adductor, and it is active to varying degrees in all hip motions except abduction. The posterior portion of the adductor magnus is sometimes considered functionally as a hamstring because of its anatomic alignment. Because of its size, the adductor magnus is less likely to be injured than the other hip adductors.[47]

Adductor Longus. The adductor longus is the most prominent muscle of the adductors during resisted adduction, and forms the medial border of the femoral triangle. The adductor

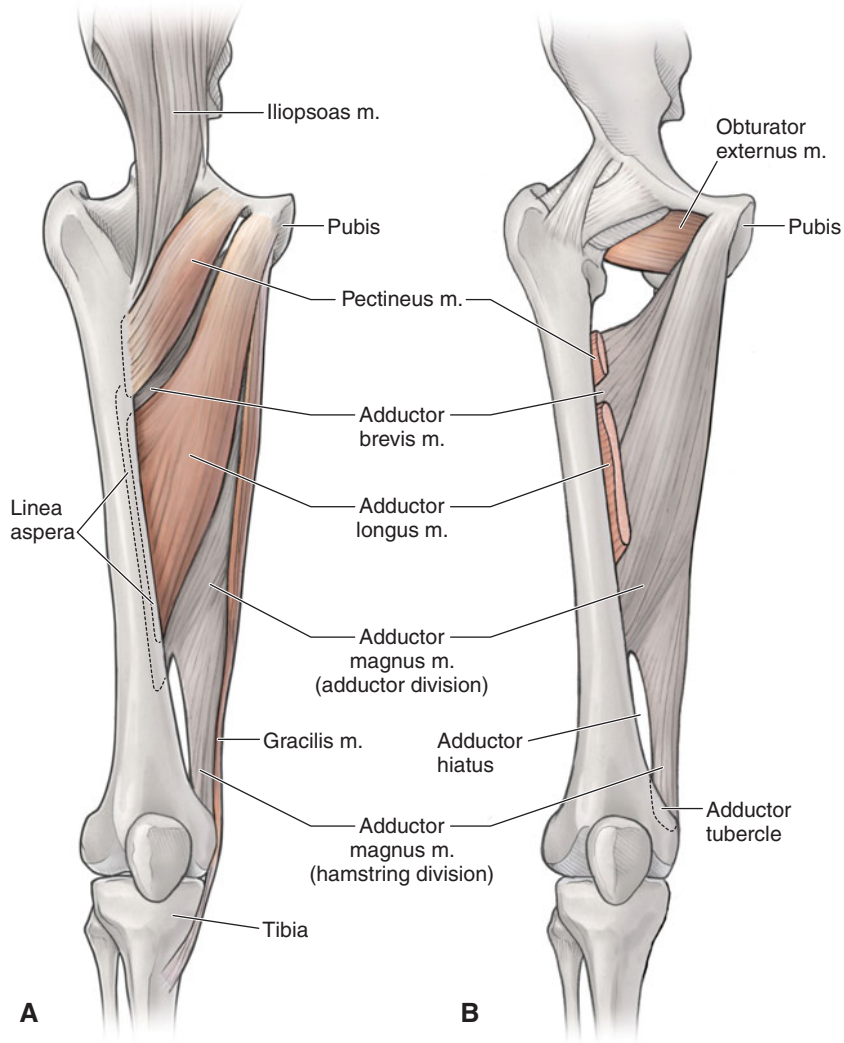

FIGURE 19-9 The hip adductors. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

longus also assists with external rotation, in extension, and internal rotation in other positions. The adductor longus is the most commonly strained adductor muscle.[48]

Gracilis. The gracilis (see Fig. 19-9), the longest of the hip adductors, is also the most superficial and medial of the hip adductor muscles. The gracilis functions to adduct and flex the thigh and flex and internally rotate the leg.

The other adductors of the hip include the adductor brevis, obturator externus, and the pectineus muscles. The main action of this muscle group is to adduct the thigh in the open kinetic chain and stabilize the lower extremity to perturbation in the closed kinetic chain. Each individual muscle can also provide assistance in femoral flexion and rotation.[49]

Bursa

There are more than a dozen bursae in this region.[50] The more clinically significant ones are described below.

Iliopsoas Bursa

Many names have been used to describe the iliopsoas bursa (IPB), including the iliopsoas, iliopectineal, iliac, iliofemoral, and subpsoas bursa.[51] The IPB is the largest and most constant bursa about the hip, present in 98% of normal adult individuals, usually bilaterally.[52] The IPB is situated deep to the iliopsoas tendon and serves to cushion the tendon from the structures on the anterior aspect of the hip joint capsule. Its dimensions may be up to 7 cm in length and 4 cm in width.[52] Anatomic boundaries of the bursa include the iliopsoas muscle anteriorly, the pectineal eminence and the hip joint capsule posteriorly, the iliofemoral ligament laterally, and the acetabular labrum medially.[53]

In 15% of patients, the IPB communicates with the hip joint via a 1-mm-to-3-cm point of relative capsular thinning between the iliofemoral and pubofemoral ligaments.[18,51] While this connection may occur on a congenital basis,[51] this number rises to 30–40% in patients with hip joint pathology.[54]

As with other bursae, the IPB can become inflamed and distended. Inflammation and distension of this bursa are most commonly associated with rheumatoid arthritis, but it is also seen in association with athletic activity, overuse and impingement syndromes, osteoarthrosis, pigmented villonodular synovitis, synovial chondromatosis, infection, pseudogout, metastatic bone disease, and, in rare cases, after THA (see "Interventions" section).[55]

Trochanteric Bursa

Three bursae are consistently present at the greater trochanter, two major bursae and one minor bursa. The two clinically significant trochanteric bursae are the subgluteus medius bursa, and the more superficial subgluteus maximus bursa:

- Subgluteus medius bursa: located at the superoposterior tip of the greater trochanter and functions to prevent friction between the gluteus medius muscle and the greater trochanter and also between the gluteus medius and gluteus minimus muscles.
- Subgluteus maximus bursa: located between the greater trochanter and the fibers of the gluteus maximus and tensor fascia lata muscles as they blend into the ITB

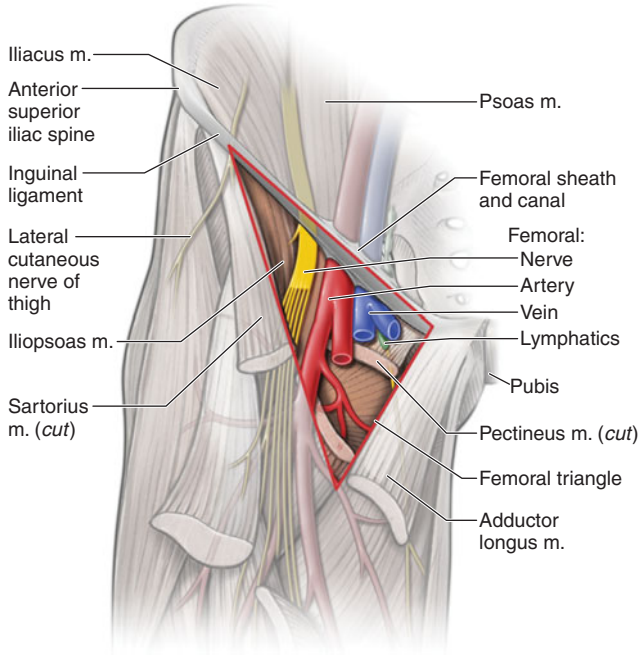

FIGURE 19-10 The femoral triangle. (Reproduced, with permission, from Morton, DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

Ischiogluteal Bursa

The ischiogluteal bursa is located between the ischium and the gluteus maximus muscle. It can be painfully squeezed between the ischial tuberosity and the hard surface of a chair during sitting, producing an ischial bursitis. This condition is often referred to as *weaver's bottom*.

Femoral Triangle

For topographic reasons, it is important to have an understanding of the anatomy of the femoral triangle. The femoral triangle is defined superiorly by the inguinal ligament, medially by the adductor longus, and laterally by the sartorius (Fig. 19-10). The floor of the triangle is formed by portions of the iliopsoas on the lateral side and by the pectineus on the medial side (Fig. 19-10). A number of neurovascular structures pass through this triangle. These include (from medial to lateral) the femoral vein, artery, and nerve (Fig. 19-10). Thus, the clinician should use caution when palpating in this area or applying soft tissue techniques.

Neurology

The posterior gluteal region receives cutaneous innervation by way of the subcostal nerve; the iliohypogastric nerve; the posterior (dorsal) rami of L1, L2, and L3; and the posterior (dorsal) primary rami (cluneal nerves) of S1, S2, and S3 (Figs. 19-11, and 19-12A).[56]

The anterior region of the hip has its cutaneous supply divided around the inguinal ligament. The area superior to the ligament is supplied by the iliohypogastric nerve. The area inferior to the ligament is supplied by the subcostal nerve, the femoral branch of the genitofemoral nerve, and the ilioinguinal nerve (see Chap. 3).[56]

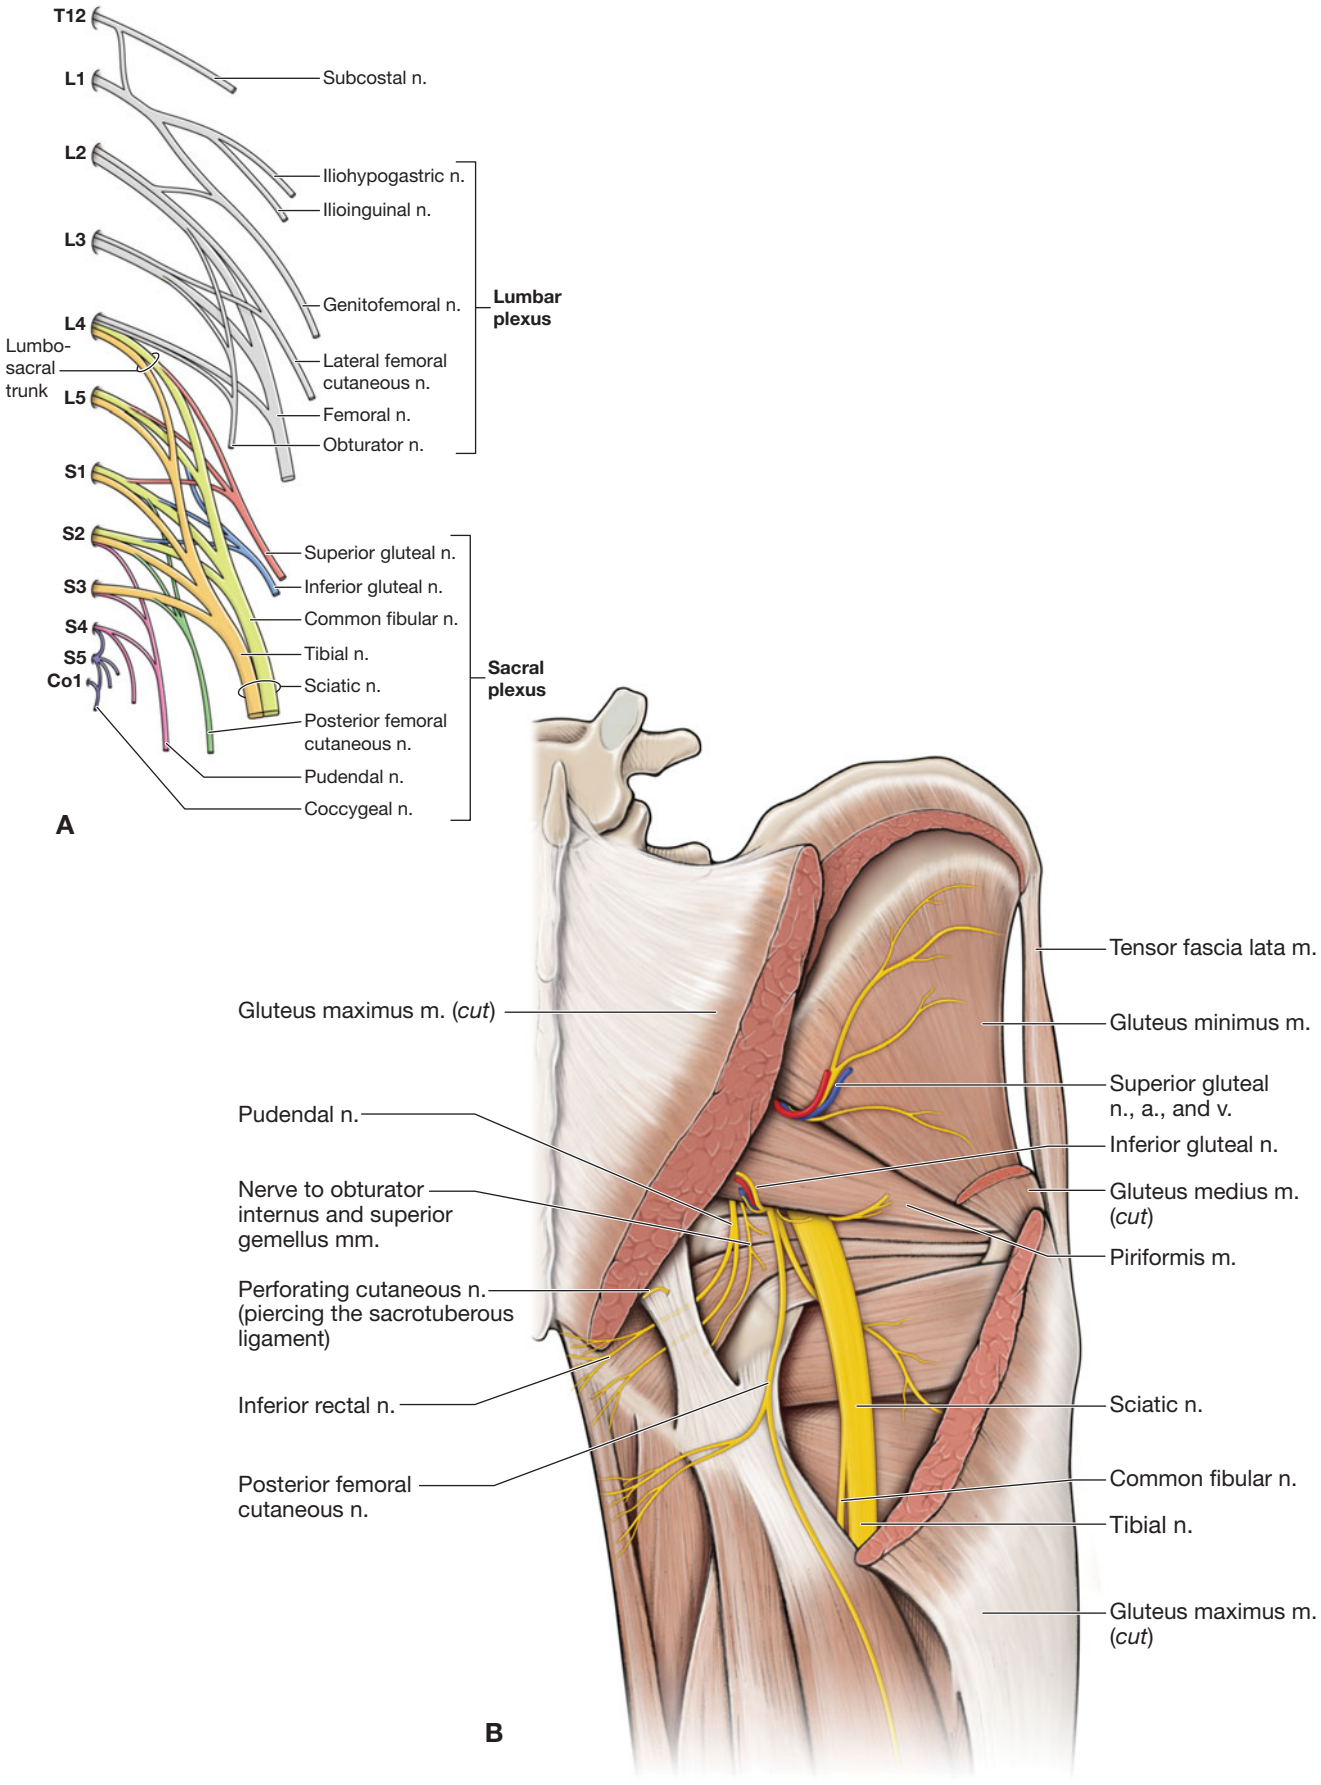

FIGURE 19-11 Neurology and vasculature of the posterior hip. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

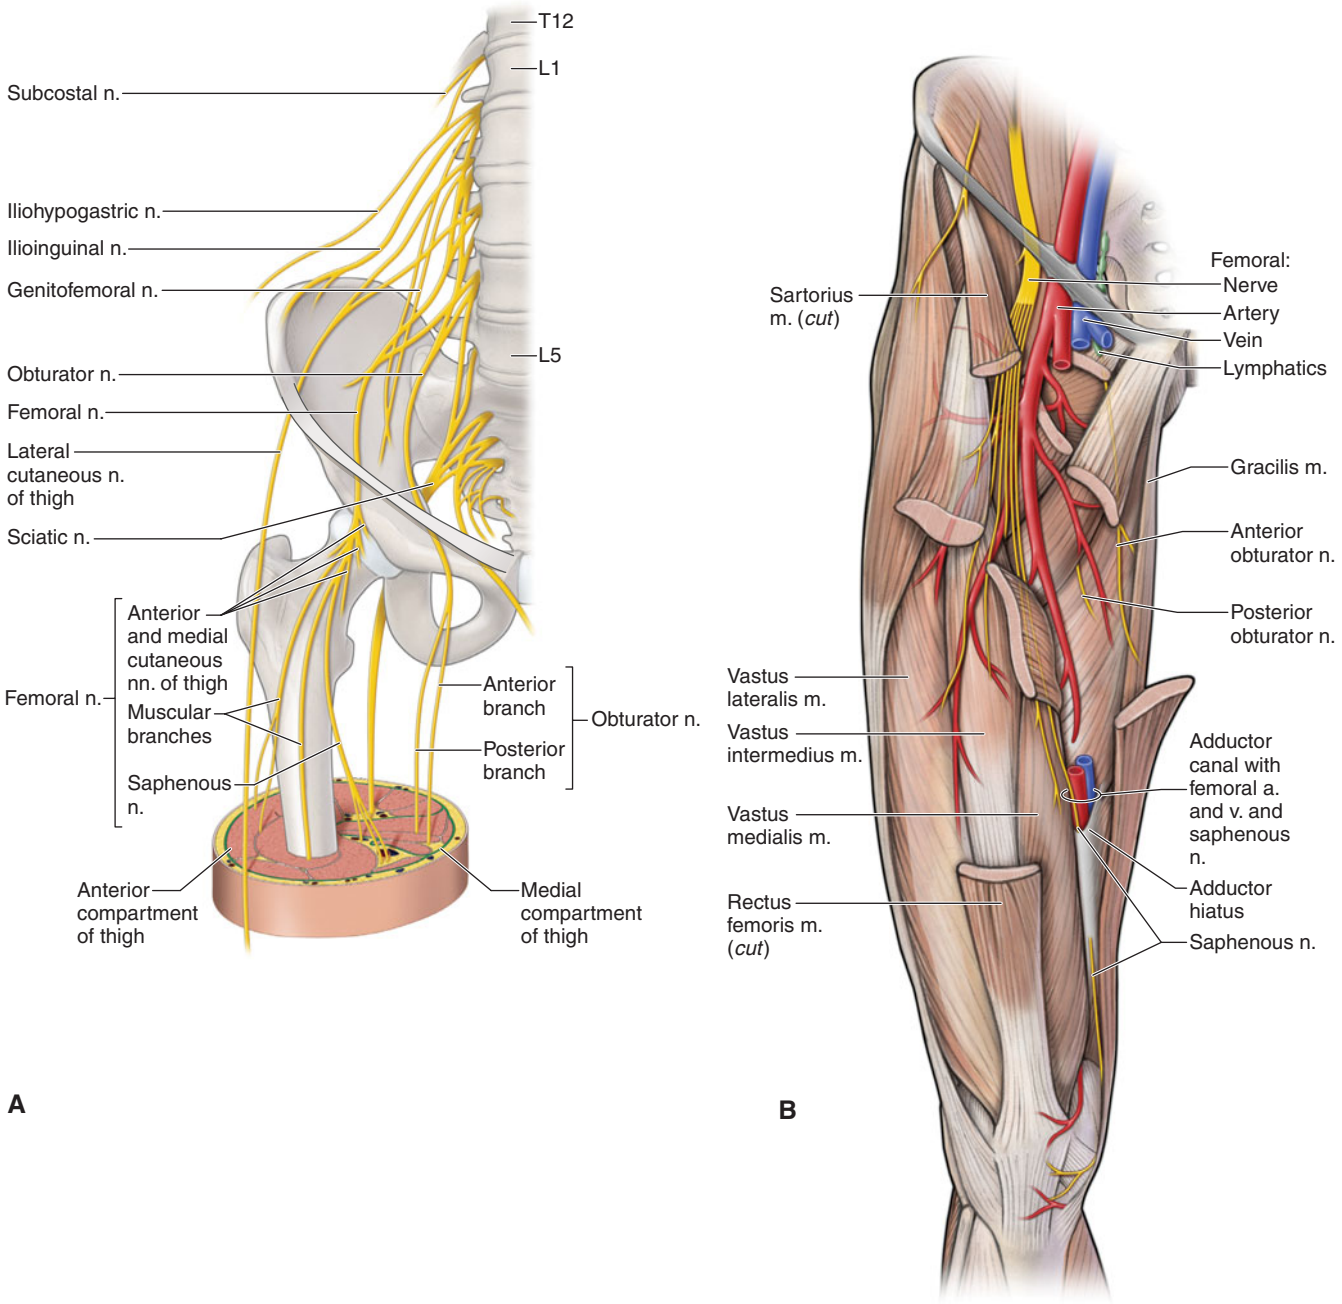

FIGURE 19-12 Neurology and vasculature of the anterior hip. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

The nerves of the muscles that cross the hip joint (femoral, obturator, superior gluteal, and the nerve to the quadratus femoris) also supply the joint capsule and the joint. Therefore, pain referred from the hip joint may be felt anywhere in the thigh, leg, or foot.

Vascular Supply

The internal iliac artery becomes the femoral artery (Figs. 19-12B and 19-13), as it passes underneath the inguinal ligament. The femoral artery forms two branches. The anterior portion of the femoral neck and the anterior portion of the capsule of the hip joint are supplied by the lateral femoral circumflex artery. The medial femoral circumflex artery (MFCA) perforates and supplies the posterior hip joint capsule and the synovium.[56] The deep branch of the MFCA gives rise to two to four superior retinacular vessels and, occasionally, to inferior retinacular vessels.[57,58]

Most of the femoral head, comprising its upper one-half or upper two-thirds, is supplied by the obturator artery and a terminal branch of the MFCA (Fig 19-3).[20] The inferior epiphyseal artery, a branch of the lateral circumflex artery, contributes to the vascularization of the lower area of the femoral head. The supply to the femoral head from the ligamentum teres artery is extremely variable.[59] The blood supply to the weight-bearing portion of the head of the femur is derived from the MFCA.[60]

Two other branches are formed from the internal iliac artery: the inferior and superior gluteal arteries. These arteries supply the superior portion of the capsule and the gluteus maximus muscle.

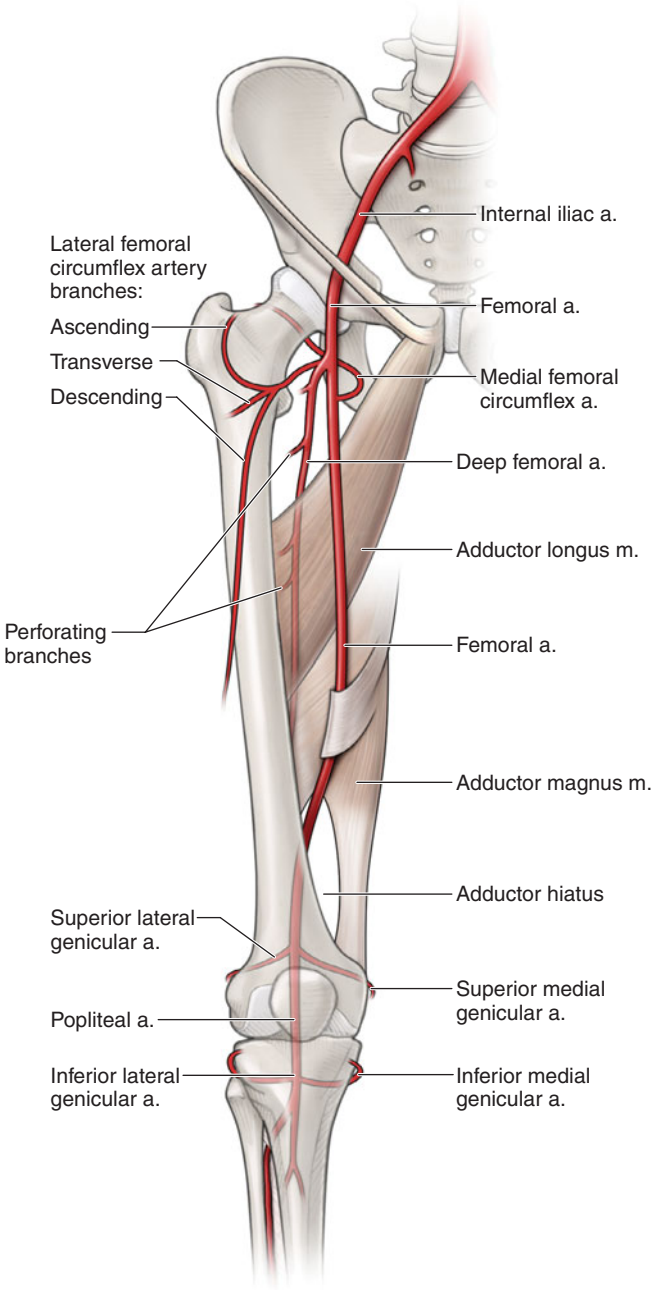

FIGURE 19-13 Vasculature of the hip and thigh. (Reproduced, with permission, from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

BIOMECHANICS

The hip joint, classified as an unmodified ovoid joint, has three degrees of freedom, which permits motion in three planes: sagittal (flexion and extension around a transverse axis), frontal (abduction and adduction around an antero-posterior axis), and transverse (internal and external rotation around a vertical axis) (Fig. 19-14). All three of these axes pass through the center of the femoral head.

Active range of motion (AROM) of the hip is variable. Hip flexion averages 110–120 degrees, extension 10–15 degrees, abduction 30–50 degrees, and adduction 25–30 degrees. Hip external rotation averages 40–60 degrees and internal rotation averages 30–40 degrees (Table 19-5). Motions about the hip joint can occur independently; however, the extremes of motion require motion at the pelvis.[61]

CLINICAL PEARL

End-range hip flexion is associated with a posterior rotation of the ilium bone. The end range of hip extension is associated with an anterior rotation of the ilium. Hip abduction/adduction are associated with an upward/downward tilting of the pelvis (see Table 19-6).

The structure and design of the hip allows for both mobility and stability. The stability is particularly important for weight-bearing and ambulation. In the human body, the center of gravity is located at the second sacral vertebral level, several segments above and medial to the femoral head. Control of the body mass from such a distant fulcrum requires the generation of significant counterbalance forces as well as the ability of the joint to sustain both high compression and tensile strains.[62]

Quantitative and qualitative analysis of the generation of compressive forces at the hip and the muscular mechanisms during weight-bearing have been thoroughly documented.[63–70] During walking, the hip extensors have a vital, stabilizing role at the onset of each stride. As body weight is dropped onto the forward limb, the extensor muscles contract sharply to preserve upright stance by resisting the forward fall of the pelvis and the trunk.[71] The hip's flexed position, before attaining the passive stability provided by full extension in midstance, creates the demand (see Chap. 6). In a standing position, weakness of the hip extensors causes the pelvis to fall forward.[71]

The relationship between the proximal femur, the greater trochanter, and the overall femoral neck width is affected by muscle pull and the forces transmitted across the hip joint. In addition, normal joint nutrition, circulation, and muscle tone during development play an important role.[4,72–74]

In the anatomic position, the orientation of the femoral head causes the contact force between the femur and the acetabulum to be high in the anterosuperior region of the joint.[75] Since the anterior aspect of the femoral head is somewhat exposed in this position, the joint has more flexibility in flexion than extension.[76]

The femoral neck is subjected to shearing and torsional strains because of its oblique orientation to the shaft of the femur.[9] Downward forces act to displace the femoral head inferiorly and to bend the femoral neck downward. To counter these forces, the femoral neck has developed a unique system of obliquely oriented trabeculae that traverse the head and the neck.[9] The angle between the femoral shaft and the neck is called the collum/inclination angle (Fig. 19-15). This angle is approximately 125–130 degrees (Fig. 19-15)[35] but can vary with body types. In a tall person, the collum *angle* is larger. The opposite is true with a shorter individual. The collum angle has an important influence on the hips. An increase in the collum angle causes the femoral head to be directed more superiorly in the acetabulum and is known as coxa valga (Fig. 19-15). Coxa valga has the following effects at the hip joint:

- It alters the orientation of the joint reaction force (JRF) from the normal vertical direction to one that is almost parallel to the femoral shaft.[77,78] This lateral shift of the JRF reduces the

External rotation

available weight-bearing surface, resulting in an increase in stress applied across joint surfaces not specialized to sustain such loads.

- The moment arm of the hip abductors is shortened, placing these muscles in a position of mechanical disadvantage.[78]

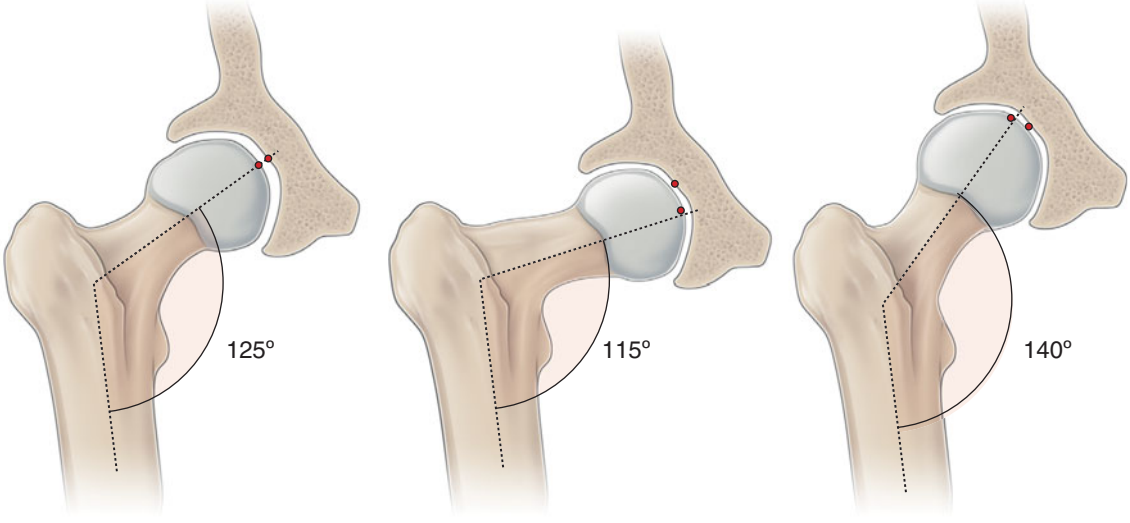

FIGURE 19-15 Angle of inclination and coxa vara/valga.

This causes the abductors to contract more vigorously to stabilize the pelvis, producing an increase in the JRF.[76]

- It increases the overall length of the lower extremity, impacting other components in the kinetic chain. For example, coxa valga decreases the normal physiologic angle at the knee, which places an increased mechanical stress on the medial aspect of the knee joint and more tensile stress on the lateral aspect of the joint.

If the collum angle is reduced, resulting in a more horizontal orientation of the femoral neck, it is known as coxa vara (Fig. 19-15). This position increases the downward shear forces on the femoral head and the tensile stretching forces through the superior trabecular bone along the lateral portion of the neck.[9] In coxa vara, the joint compression forces are significantly reduced as the greater trochanter is displaced lateral and superior, which increases the effective angle of pull and the lever arm of the hip abductors.[79] While the reduced compressive forces generated across the joint surfaces serve to decrease the incidence of articular cartilage damage, the increase in shearing and torsional forces at the femoral head/neck junction significantly increases the incidence of damage to the epiphyseal plate.[9]

Femoral alignment in the transverse plane also influences the mechanics of the hip joint. The *torsion angle* of the femur describes the relative rotation that exists between the shaft and the neck of the femur. Normally, as viewed from above, the femoral neck projects on average 5–15 degrees anterior to a mediolateral axis to the femoral condyles. An anterior orientation of the femoral neck to the transverse axis of the femoral condyles, is known as anteversion (Fig. 19-16), or a reverse orientation known as retroversion.[76,80,81] The normal range for femoral alignment in the transverse plane in adults is 5 degrees of anteversion (Fig. 19-16).[81,82] Typically, an infant is born with about 30 degrees of femoral anteversion.[83,84] This angle usually decreases to 15 degrees by 6 years of age because of bone growth and increased muscle activity. Subjects with excessive anteversion usually have more hip internal rotation ROM than external rotation, and gravitate to the typical "frog-sitting" posture as a position of comfort. There is also associated in-toeing while weight-bearing.[76]

Excessive anteversion directs the femoral head toward the anterior aspect of the acetabulum when the femoral condyles are aligned in their normal orientation. Some studies have supported the hypothesis that a persistent increase in femoral anteversion predisposes to osteoarthritis (OA) of the hip,[79,85–88] and knee,[89–91] although other studies have refuted this.[92–94]

The most stable position of the hip is the normal standing position: hip extension, slight abduction, and slight internal rotation.[15,70,95] The commonly cited open-packed (resting) positions of the hip are between 10 and 30 degrees of flexion, 10–30 degrees of abduction, and 0–5 degrees of external rotation.

When body weight is evenly distributed across both legs during upright standing, the forces acting on the hip joint are equivalent to half the partial weight made up of the trunk, head, and upper extremities.[96] Were this partial body weight to represent 60% of total body mass, then each hip would be compressed by a force equal to 30% of the total body weight. In a single-limb support, however, shifts in the center of gravity away from the supporting limb dramatically change the equilibrium forces necessary to maintain balance and create a state of disequilibrium. This state of disequilibrium requires the generation of compensatory forces by the hip musculature, in order to maintain balance. The hip joint is the fulcrum for all of the forces. Depending on the length of the moment arm created by the abductor muscles, the added force of the hip abductors acting on the hip joint can increase the pressures translated across the joint to levels exceeding three times body weight.[96]

During ambulation, these compressive joint forces are further multiplied by ground reaction forces and inertial forces related to acceleration and deceleration of the lower limb. Because of muscle tension, compression on the hip is approximately the same as body weight during the swing phase.[97]

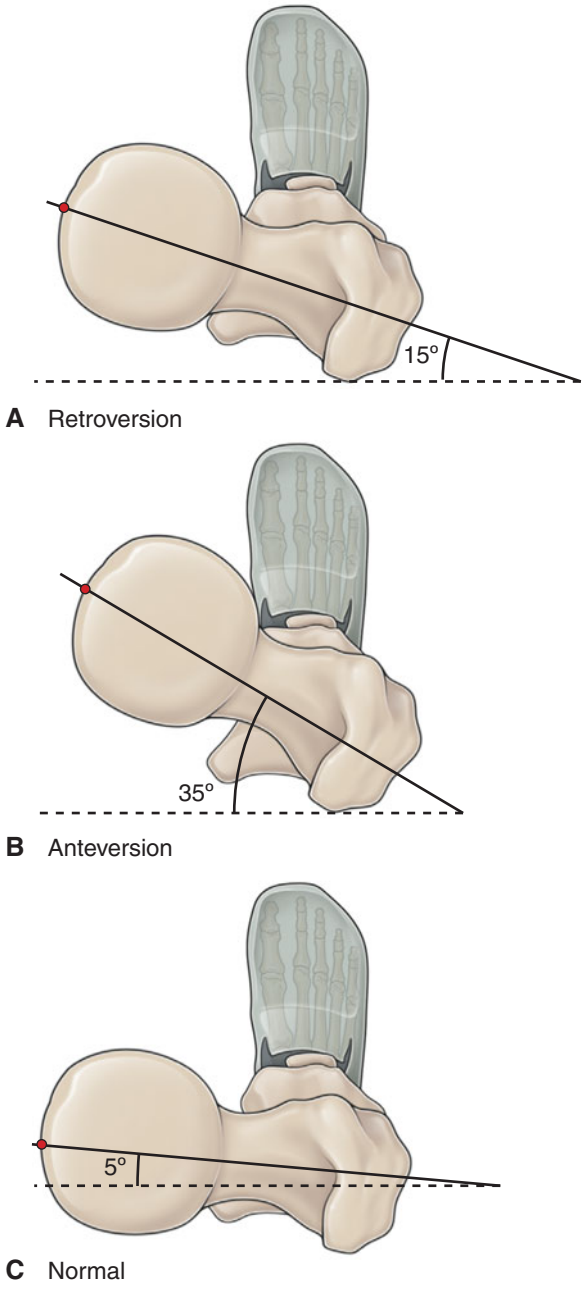

FIGURE 19-16 Angle of torsion: Anteversion and retroversion.

However, during the support phase, peak joint forces can range from 300 to 400% of body weight at normal walking speed, to 550% of body weight during fast walking and jogging, and as high as 870% of body weight during stumbling.[32,98] Stair climbing and descending increase the loads on the hip by approximately 10% and 20%, respectively.[32,99] When pain accompanies degeneration of the hip joint articulation, the body compensates by attempting to reduce the forces generated across the articular surfaces. Since the contribution of body mass cannot be changed, the patient attempts to reduce joint pressures by shifting the upper trunk over the supporting limb during the stance phase. While this maneuver decreases the joint compression forces, the energy expended by laterally bending the trunk during stance significantly increases the energy cost of gait. For a patient with a painful hip, the use of a cane or crutch in the hand contralateral to the involved hip can be used to substantially reduce the excessive trunk motion and to decrease pressure on the hip joint.[2]

CLINICAL PEARL

Rapid flexion of the hip is generally associated with abdominal muscle activation that slightly precedes the activation of the hip flexor muscles.[100] This anticipatory activation may reflect a feedforward mechanism intended to stabilize the lumbopelvic region by increasing intra-abdominal pressure and increasing the tension in the thoracolumbar fascia.[101,102] Without sufficient stabilization of the pelvis by the abdominal muscles, a strong contraction of the hip flexor muscles may inadvertently tilt the pelvis anteriorly, thereby accentuating the lumbar lordosis, which may contribute to low back (LB) pain in some individuals.[28]

Bending forward at the waist requires a coordinated sequence of movements between the lumbar spine, pelvis, and hips. As the head and the upper trunk initiate flexion, the pelvis shifts posteriorly to maintain the center of gravity over the base of support. The trunk continues to forward bend, being eccentrically controlled by the extensor muscles of the spine, until approximately 45 degrees at which point the posterior ligaments of the spine become taut, and the facets of the zygapophyseal joints approximate. Once all of the vertebral segments are at the end of the range and stabilized by the posterior ligaments and facets, the pelvis begins to rotate forward (anterior pelvic tilt), being controlled eccentrically by the gluteus maximus and hamstring muscles. The pelvis continues to rotate forward until the full length of the muscles is reached. The return to the upright position begins with the hip extensor muscles rotating the pelvis posteriorly through reverse muscle action, then the back extensor muscles extending the spine from the lumbar region upward.

The hip extensor muscles, as a group, produce the greatest torque across the hip of any of the muscle groups.[103] This extensor torque is often used to rapidly accelerate the body upward and forward from a position of hip flexion, such as when pushing off into a sprint, arising from a deep squat, or climbing a very steep hill.[28] Furthermore, with the hip

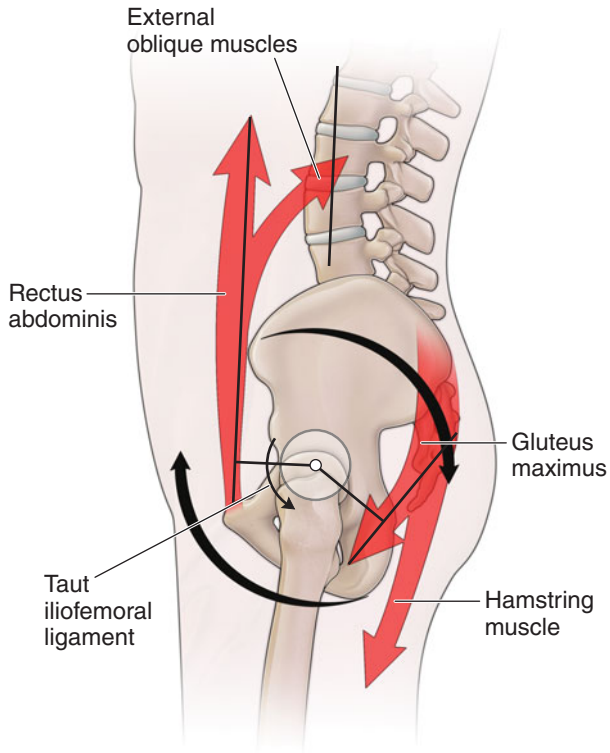

FIGURE 19-17 Force couples at the hip.

markedly flexed, many of the adductor muscles produce an extensor torque, thereby assisting the primary hip extensors.[104] With the trunk held relatively stationary, contraction of the hip extensors and abdominal muscles (with the exception of the transversus abdominis) functions as a force couple to posteriorly tilt the pelvis (Fig. 19-17).[28] Assuming the trunk remains upright during this action, the lumbar spine must flex slightly, thereby reducing its natural lordotic posture.[28]

The functional potential of the entire external rotator muscle group at the hip is most fully recognized while performing pelvic and trunk rotation activities while bearing weight over one limb. With the right femur held relatively fixed, contraction of the external rotators would rotate the pelvis and the attached trunk to the left. This action of planting the limb and cutting to the opposite side is a natural way to abruptly change direction while running.[28] The gluteus maximus appears uniquely designed to perform this action as, with the right limb securely planted, a strong contraction of the gluteus maximus would, in theory, generate a very effective extension and external rotation torque about the right hip, helping to provide the necessary thrust to the combined-cutting and propulsion action.[28]

In sharp contrast to the external rotators, no muscle with any potential to internally rotate the hip lies even close to the horizontal plane in the anatomic position, making it difficult to assign any muscle as a primary internal rotator of the hip.[28,105] Since the overall orientation of the internal rotator muscles is positioned closer to the vertical and horizontal position, these muscles possess a far greater biomechanical potential to generate torque in the sagittal and frontal planes than in the horizontal plane.[28]

The adductors of the hip are found on the medial aspect of the joint. The primary function of this muscle group is to create an adduction torque bringing the lower extremity toward the midline.[106] This adduction torque can also bring the pubis symphysis region of the pelvis closer to the femur.[106] From the anatomic position, the adductors are also considered hip flexor muscles.

The most frequent demands placed on the hip abductors occur while walking during the single-limb support phase of walking.[28] The external (gravitational) abduction torque about the hip dramatically increases within the frontal plane as soon as the contralateral limb leaves the ground.[107] The hip abductors respond by generating an abduction torque about the stance hip that stabilizes the pelvis relative to the femur.[107] In addition, the hip abductors can hike the hip when working concentrically, and can lower the pelvis when working eccentrically.

According to Cyriax,[108,109] the capsular pattern of the hip is a marked limitation of flexion, abduction, and internal rotation. Kaltenborn[95] considers the capsular pattern of the hip to be extension more limited than flexion, internal rotation more limited than external rotation, and abduction more limited than adduction. Klassbo and colleagues[110] performed a theory-testing, observational, cross-sectional, and descriptive study involving 168 patients (mean age 61.7 years, range 36–90 years), of whom 50 had no hip OA, 77 had unilateral hip OA, and 41 had bilateral OA, based on radiological reports. The purpose of the study was to arrange and describe passive range of motion (PROM) patterns and to count the number of hips presenting with Cyriax's or Kaltenborn's capsular patterns. One examiner tested PROM bilaterally, using a goniometer and a standardized protocol. PROM limitations were calculated by comparing norms from the symptom-free hips ($n = 100$) in the study, from Kaltenborn, and, in patients with unilateral hip OA ($n = 77$), from the non-OA hip. The limitations were arranged by size in PROM patterns. The patterns and the numbers of hips with patterns corresponding to Cyriax's and Kaltenborn's capsular patterns were counted. Between 68 and 138 PROM patterns were identified by the use of different PROM norms for defining limitations. The results from this study showed that few OA hips showed Cyriax's capsular pattern and none demonstrated Kaltenborn's capsular pattern. In addition, it was concluded that it is impossible to anticipate radiological evidence of hip OA from the multitude of PROM patterns. A more useful determination can be made by assessing hip ROM in all planes and, if three planes of motion or more are restricted, OA is likely present.[111]

EXAMINATION

Although injuries of the hip are not as common as injuries to the knee or shoulder, they can create diagnostic and therapeutic challenges, and diseases of the hip can be very disabling. The common pathologies and the interventions for the hip joint are detailed after the examination. Table 19-7 outlines the clinical findings, differential diagnosis, and intervention strategies of some hip conditions, and Table 19-8 describes some of the physical findings for some of the more common causes of hip and thigh pain. An understanding of the pathology and the clinical findings is obviously necessary. Identifying the primary source of the pain is essential if one hopes to provide long-lasting relief of the symptoms. Acute presentations usually have a clear and identifiable cause, whereas in chronic conditions the true etiology may not be as obvious. For example, a protracted hip joint disorder can result in compensations that can develop secondary dysfunctions, which in turn may lead to symptoms such as trochanteric bursitis or chronic gluteal discomfort. As mention of the various pathologies occurs with reference to the examination and vice versa, the reader is encouraged to switch between the two.

CLINICAL PEARL

One study demonstrated that the clinical assessment of the hip can be 98% reliable at detecting the presence of the hip joint problem; although the exam may be poor at defining the exact nature of the intra-articular disorder.[112] However, as many structures can refer pain to the hip and groin region, the symptoms are often both confusing to the patient and challenging to the clinician. For example, hip joint disease may coexist with lumbar spine disease.

History

The importance of history taking cannot be overemphasized as the potential causes of hip pain are numerous (Table 19-9). The history should determine the onset of the symptoms, the mechanism of injury, if any, and the patient's chief complaint. A medical screening questionnaire for the pelvis, hip, and thigh is provided in Table 19-10. It is important for the clinician to determine:

Patient Age. The patient's age may help in the diagnosis. OA of the hip is diagnosed most often in patients over 60 years of age, although it can occur earlier.

Pain Location. The location of the pain can provide the clinician with some useful information (Table 19-12). Complaints of hip or groin pain, morning stiffness, stiffness after sitting, and hip pain with weight-bearing are suggestive of joint involvement, such as OA. It is important to identify patients with symptomatic OA correctly and to exclude conditions that may be mistaken for or coexist with OA.[113,114] Periarticular pain that is not reproduced by passive motion and direct joint palpation suggests an alternate etiology such as bursitis, tendinitis, or periostitis. Groin pain can result from local and referred sources. One of the more common causes of groin pain in the older patient is OA of the hip. However, OA of the hip may also cause pain behind the greater trochanter, anterior thigh, and knee because of the various nerves that cross the hip.[115]

Lateral and posterior hip (buttock) and thigh pain may be referred from the lumbar spine.

Distribution of Symptoms. The distribution of painful joints is helpful to distinguish OA from other types of arthritis because MCP, wrist, elbow, ankle, and shoulder arthritis are unlikely locations for OA except after trauma.

Symptom Fluctuations. The time of day that appears to change the pain for better or worse can provide some clues.

TABLE 19-7 History, Clinical Findings, Differential Diagnosis, and Intervention Strategies of Some Hip Conditions

Diagnosis	Medical Findings	Intervention	Whether to Refer
Legg–Calvé–Perthes disease	Insidious onset (1–3 months) of limp with hip or knee pain	Limited hip abduction, flexion, and internal rotation	Juvenile arthritis and other inflammatory conditions of the hip
Slipped capital femoral epiphysis	Acute (<1 month) or chronic (up to 6 months) presentation; pain may be referred to knee or anterior thigh	Pain and limited internal rotation, leg more comfortable in external rotation; chronic presentation may have leg length discrepancy	Muscle strain and avulsion fracture
Avulsion fracture	Sudden, violent muscle contraction; may hear or feel a "pop"	Pain on passive stretch and active contraction of involved muscle; pain on palpation of involved apophysis	Muscle strain and slipped capital femoral epiphysis
Hip pointer	Direct trauma to iliac crest	Tenderness over iliac crest; may have pain on ambulation and active abduction of hip	Contusion and fracture
Contusion	Direct trauma to soft tissue	Pain on palpation and motion and ecchymosis	Hip pointer, fracture, and myositis ossificans
Myositis ossificans	Contusion with hematoma approximately 2–4 wks earlier	Pain on palpation; firm mass may be palpable	Contusion, soft tissue tumors, and callus formation from prior fracture
Femoral neck stress fracture	Persistent groin discomfort increasing with activity, history of endurance exercise, and female athlete triad (eating disorder, amenorrhea, and osteoporosis)	ROM may be painful, pain on palpation of greater trochanter	Trochanteric bursitis, osteoid osteoma, and muscle strain
Osteoid osteoma	Vague hip pain present at night and increased with activities	Restricted motion and quadriceps atrophy	Femoral neck stress fracture and trochanteric bursitis
Iliotibial band syndrome	Lateral hip, thigh, or knee pain; snapping as iliotibial band passes over the greater trochanter	Positive Ober test	Trochanteric bursitis
Trochanteric bursitis	Pain over greater trochanter on palpation; pain during transitions from standing to lying down to standing	Pain on palpation of greater trochanter	Iliotibial band syndrome and femoral neck stress fracture
Avascular necrosis of the femoral head	Dull ache or throbbing pain in groin, lateral hip, or buttock; history of prolonged steroid use; prior fracture; and slipped femoral capital epiphysis	Pain on ambulation, abduction, and internal and external rotation	Early degenerative joint disease
Piriformis syndrome	Dull posterior pain, may radiate down the leg mimicking radicular symptoms, and history of track competition or prolonged sitting	Pain on active external rotation, passive internal rotation of hip, and palpation of sciatic notch	Nerve root compression and stress fractures
Iliopsoas bursitis	Pain and snapping in medial groin or thigh	Reproduce symptoms with active and passive flexion/extension of hip	Avulsion fracture
Meralgia paresthetica	Pain or paresthesia of anterior or lateral groin and thigh	Abnormal distribution of lateral cutaneous nerve of the thigh on sensory examination	Other causes of peripheral neuropathy
Degenerative arthritis	Progressive pain and stiffness	Reduction in internal rotation early, in all motion later, and pain on ambulation	Inflammatory arthritis

(Continued)

TABLE 19-7 History, Clinical Findings, Differential Diagnosis, and Intervention Strategies of Some Hip Conditions *(Continued)*

Diagnosis	Medical Findings	Intervention	Whether to Refer
Legg–Calvé–Perthes disease	Normal CBC and ESR; plain films positive (early with changes in the epiphysis, later with flattening of the femoral head)	Maintain ROM, and follow position of femoral head in relation to acetabulum radiographically	Orthopaedic surgery if unresolved
Slipped capital femoral epiphysis	Plain films show widening of epiphysis early, later slippage of femur under epiphysis	Non–weight-bearing, and surgical pinning	Urgent orthopaedic surgery with acute, large slips
Avulsion fracture	Plain films; if these are negative, CT or MRI	Rehabilitation program of progressive increase in ROM and strengthening	Orthopaedic surgery of >2-cm displacement
Hip pointer	Plain films if suspect fracture	Rest, ice, NSAIDs, local steroid, and anesthetic injection for severe pain; gradual return to activities with protection of site	PT appropriate
Contusion	Plain films negative	Rest, ice, compression, static stretch, and NSAIDs	PT appropriate
Myositis ossificans	Radiograph or ultrasound examination reveals typical calcified, intramuscular hematoma	Ice, stretching of involved structure, NSAIDs; surgical resection after 1 year if conservative treatment fails	PT appropriate; orthopaedic surgery if resection needed
Femoral neck stress fracture	Plain films may show cortical defects in femoral neck (superior or inferior surface); bone scan, MRI, and CT may also be used if plain films are negative and diagnosis is suspected	Inferior surface fracture; no weight-bearing until evidence of healing (usually 2–4 wks) with gradual return to activities; superior surface fracture: ORIF	Orthopaedic surgery for ORIF
Osteoid osteoma	Plain films; if these are negative and symptoms persist, MRI or CT	Surgical roemoval if unresponsive to medical therapy with aspirin or NSAIDs	Orthopaedic surgery
Iliotibial band syndrome		Modification of activity, footwear; stretching program, ice massage, and NSAIDs	PT appropriate
Trochanteric bursitis	Plain films, bone scan, and MRI negative for bony involvement	Ice, NSAIDs, stretching of iliotibial band, protection from direct trauma, and steroid injection	PT appropriate
Avascular necrosis of the femoral head	Plain films and MRI	Protected weight-bearing, exercises to maximize soft tissue function (strength and support), and total hip replacement	PT trial appropriate; orthopaedic surgery
Piriformis syndrome	EMG studies may be helpful; MRI of lumbar spine, if nerve root compression is suspected	Stretching, NSAIDs, relative rest, and correction of offending activity	PT appropriate
Iliopsoas bursitis	Plain films are negative	Iliopsoas stretching and steroid injection	PT appropriate
Meralgia paresthetica	Nerve conduction velocity testing may be helpful	Avoid external compression of nerve (clothing, equipment, and pannus)	—
Degenerative arthritis	Plain films help with diagnosis and prognosis	Maximizing support and strength of soft tissues, ice, NSAIDs, modification of activities, cane, and total hip replacement	PT trial appropriate; orthopaedic surgery

CBC, complete blood count; CT, computed tomography; EMG, electromyelography; ESR, erythrocyte sedimentation rate; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs; ORIF, open reduction with internal fixation; PT, physical therapy; ROM, range of motion.
Data from Adkins SB, Figler RA: Hip pain in athletes. *Am Fam Phys* 61:2109–2118, 2000.

TABLE 19-8 Physical Findings in Some of the More Common Causes of Hip and Thigh Pain

Condition	Description of Findings
Osteoarthritis of the hip	Tenderness over the anterior hip capsule Pain reproduced by passive rotation of the hip Restricted range of motion (rotation is usually first affected) Pain reproduced by Stinchfield's test (see "Special Tests" section) Abductor limp (more severe cases) Functional leg length discrepancy (if abduction contracture has developed)
Meralgia paresthetica	Altered sensation over the anterolateral thigh Symptoms reproduced by pressure or percussion just medial to the anterior–superior iliac spine
Piriformis tendinitis	Tenderness to deep palpation near the hook of the greater trochanter. Pain reproduced by piriformis stretch
Gluteus medius tendinitis	Tenderness just proximal to the greater trochanter Pain reproduced by resisted abduction of the hip
Trochanteric bursitis	Tenderness over the lateral aspect of the greater trochanter Popping or crepitation felt with flexion–extension of the hip (occasionally) Tight iliotibial tract revealed by Ober test (variable)—see "Special Tests" section
Quadriceps strain or contusion	Tenderness and swelling of the involved area of the quadriceps Weakness of quadriceps contraction Restriction of knee flexion, especially when the hip is extended Palpable divot in the quadriceps (more severe strains) Warmth and firmness in quadriceps (impending myositis ossificans)
Hamstring strain	Localized tenderness and swelling at the site of injury Ecchymosis (frequently) Restricted knee extension and straight-leg raising Palpable divot in the injured hamstring (more severe injuries) Abnormal tripod sign

Data from: Martell JM, Reider B: Pelvis, hip and thigh. In: Reider B, ed. *The Orthopaedic Physical Examination*. Philadelphia, PA: WB Saunders, 1999:159–199.

Hip joint pathology is usually associated with stiffness of the hip in the morning on arising. Such pathologies include

- OA of the hip joint;
- rheumatoid arthritis of the hip joint; prolonged morning stiffness (greater than 1 hour) should raise suspicion for this type of inflammatory arthritis;
- avascular necrosis of the femoral head.

Motion Restrictions. The first two motions that are diminished in hip OA are usually hip internal rotation and hip flexion, although as previously discussed, this can vary significantly.[116] A significant decrease or loss of motor function will always necessitate imaging studies to rule out an avulsion fracture, and/or nerve injury (see Chap. 7).

Mechanism of Injury. Patients who present with acute macrotrauma (e.g., falls and motor vehicle accidents) and who report having difficulty moving the hip or bearing weight require radiographs to rule out a fracture and/or dislocation. Falls on the outside of the hip are a common cause of trochanteric bursitis or contusion of the iliac crest (hip pointer). Such an injury may also involve the abdominal and/or gluteal muscles at their attachment sites. When the abdominal muscles are involved, patients may complain of pain with deep inspiration or have difficulty with trunk rotation.[117] Macrotraumatic forces applied along the femur such as those that occur with dashboard injuries and falls on the knee can result in damage to the articular cartilage, an acetabular labrum tear, a pelvic fracture, or a hip subluxation. An immediate loss of movement following direct trauma to this area usually indicates the presence of a hip or pelvic fracture, or a dislocation. Posterior contusions to the gluteus maximus and sciatic nerve can occur from a direct blow to the buttock.[117] In such cases, the patient may complain of pain in the buttocks and of pain, numbness, and/or tingling radiating down the course of the sciatic nerve. Both the athlete and nutritionally compromised individual are at risk of pelvic rami or femoral neck stress fractures. Anterior blows to the thigh can produce quadriceps contusions. These contusions can also result in myositis ossificans. The femoral nerve is fairly well protected and not usually injured. Acute muscle strains in the hip and thigh region, especially of the hamstrings, are usually seen in the athletic individual, most often occurring following a

TABLE 19-9 Potential Causes of Hip Pain

Type of Pain/Structure Involved	Cause
Articular cartilage	Chondral lesion
	Osteoarthritis
Childhood disorders	Congenital dysplasia
	Legg–Calvé–Perthes disease
	Slipped capital femoral epiphysis
Inflammation	Trochanteric bursitis
	Psoas bursitis
	Tendinitis
	Toxic synovitis
Infection	Septic arthritis
	Osteomyelitis
Labral tear	
Neoplasm	
Neurologic	Local nerve entrapment
Overuse	Stress fractures of the femur
	Muscle strains
	Inguinal hernia
	Femoral hernia
Referred	Lumbar disk pathology
	Lumbar spine-degenerative joint disease
	Athletic pubalgia
	Radiculopathy
	Piriformis syndrome
	Sacroiliac joint pathology
	Genitourinary tract pathology
	Abdominal wall pathology
Systemic	Rheumatoid arthritis
	Crohn's disease
	Psoriasis
	Reiter's syndrome
	Systemic lupus erythematosus
Trauma	Soft tissue contusion
	Fractures of the femoral head
	Dislocation of the femoral head
	Avulsion injury
	Myositis ossificans
Vascular	Avascular necrosis
	Osteonecrosis

Data from Martin RL, Enseki KR, Draovitch P, et al.: Acetabular labral tears of the hip: Examination and diagnostic challenges. *J Orthop Sports Phys Ther* 36:503–515, 2006.

short sprint, jump kick, fall, or collision.[117] Quadriceps strains, usually involving the rectus femoris, occur in sprinters and kickers. The most frequently strained adductors are the longus and magnus, while hamstring injuries usually involve the biceps femoris.[118–120]

CLINICAL PEARL

Ironically, in general, a history of a significant traumatic event is a good prognostic indicator of a potentially correctable problem,[121] whereas arthritis is an indicator of poor long-term outcomes.[122]

If the patient is unable to recall a specific mechanism, the clinician should suspect a systemic (see "Systems Review" section and Chap. 5) or biomechanical cause. The hip is a region that is prone to overuse injuries. Walking or running can aggravate trochanteric bursitis, ITB friction syndrome, hamstring and adductor strains, or a femoral neck stress fracture. Pain with bursitis is frequently referred along the course of the muscle it underlies and nearby neurologic structures.[117] Obturator internus bursitis can refer pain to the back and buttock or along the course of the sciatic nerve. Subtrochanteric bursitis commonly refers pain to the LB, lateral thigh, knee, and hip.[117] Iliopectineal bursitis can refer pain along the course of the femoral nerve and anterior thigh. Ischiogluteal bursitis can refer pain along the posterior femoral cutaneous or sciatic nerve.[117]

Behavior of Symptoms. Reports of twinges of pain with weight-bearing activities may indicate the presence of a loose body within the joint. Noises in and around the joint can result from many causes so are not particularly diagnostic. One of the more common causes for clicking is a "snapping" hip, especially if the snapping consistently occurs at approximately 45 degrees of hip flexion. This type of snapping hip is thought to be because of the iliopsoas tendon riding over the greater trochanter or anterior acetabulum. The other types of snapping hip are described in the "Interventions" section. If pain is associated with the clicking, it requires further investigation.

CLINICAL PEARL

Mechanical symptoms such as locking, catching, popping, or ones that are sharp stabbing in nature are better prognostic indicators of a correctable problem.[123]

Aggravating or Relieving Factors. Information must be gathered with regard to the activities or positions that appear to aggravate or lessen the symptoms. For example, prolonged sitting on a hard surface may aggravate the ischial bursa, whereas buttock pain with prolonged sitting on a soft surface is more likely to be the result of a lumbar disk lesion. Rising from a seated position can be especially painful and the patient may experience an accompanying catching or sharp stabbing sensation. Entering and exiting an automobile is often difficult, because the hip is in a flexed position along with twisting maneuvers. As the hip is a weight-bearing joint and weight-bearing tends to aggravate articular pathologies, it is very important to gather information concerning the role of weight-bearing in painful activities, particularly whether the patient has pain at rest as well as during weight-bearing, or whether specific weight-bearing activities (e.g., stair climbing and walking) are the cause of increased pain.

TABLE 19-10 Medical Screening Questionnaire for the Pelvis, Hip, and Thigh Region

	Yes	No
Have you recently had a trauma, such as a fall?		
Have you ever had a medical practitioner tell you that you have osteoporosis?		
Have you ever had a medical practitioner tell you that you have a problem with the blood circulation in your hips?		
Are you currently taking steroids or have you been on prolonged steroid therapy?		
Do you have a history of cancer or has a member of your immediate family (i.e., parents or siblings) ever been diagnosed with cancer?		
Have you recently lost weight even though you have not been attempting to eat less or exercise more?		
Have you had a recent change in your bowel functioning such as black stools or blood in your rectum?		
Have you had diarrhea or constipation that has lasted for more than a few days?		
Do you have groin, hip, or thigh aching pain that increases with physical activity, such as walking or running?		

Data from DuVall RE, Godges J: Introduction to physical therapy differential diagnosis: The clinical utility of subjective examination. In: Wilmarth MA, ed. *Medical Screening for the Physical Therapist. Orthopaedic Section Independent Study Course 14.1.1.* La Crosse, WI: Orthopaedic Section, APTA, Inc, 2003:1–44.

Questions about work environment, athletic participation, and other daily and recreational activities help the clinician identify risk factors for cumulative trauma that might not be apparent to the patient.[117] Activities and positions that aggravate and alleviate symptoms should be identified (Table 19-11).

The hip and pelvic areas are also common sites for pain referral (Table 19-12). The differential diagnosis of hip pain is described in Chapter 5. To help determine the symptom distribution, a pain diagram should be completed by the patient (see Chap. 4). Following its completion, the patient should be encouraged to describe the type of symptoms experienced for each of the areas highlighted on the diagram, as well as the motions or positions that increase or decrease the symptoms. Since the lumbar spine can refer symptoms to the hip region, the clinician should always rule out involvement of the lumbar spine before a hip problem is suspected. The most common source of referred pain from the LB includes both neurogenic (nerve root compression) and spondylogenic (facet or sacroiliac joint) causes. Brown and colleagues[124] identified a limp, groin pain, and limited hip internal rotation as signs that significantly predicted a hip problem rather than a lumbar problem.

Finally, the clinician should determine the impact that the patients' condition has on their activities of daily living (ADL).

Systems Review

Referred pain to the hip is common and should be considered in the absence of acute trauma or when symptoms do not clearly originate from the hip. Pain may be referred to the hip region from a number of neuromusculoskeletal sources (see Chap. 5). In addition to those already mentioned, these can include

- pubic symphysis dysfunction;
- sacroiliac joint dysfunction;

TABLE 19-11 Subjective Reports and Possible Diagnoses

Subjective Report	Possible Diagnosis
Pain that is usually worse with sitting on hard surfaces, cycling, and prolonged standing	Ischiogluteal bursitis
Pain with squatting, lying on the involved side, climbing stairs, and walking	Subtrochanteric bursitis
A clicking or popping sound that occurs during running and dancing activities	Snapping hip syndrome
Pain with prolonged sitting, trunk flexion, and coughing/sneezing	Lumbar disk herniation
Pain with activities that involve lumbar extension	Spinal stenosis, spondylolisthesis, or facet syndrome
Pain at night unrelated to movement	Malignancy
Pain with walking, which is relieved with cessation of the activity	Vascular claudication
Pain that appears to be affected by the weather	Arthritic condition or fibromyalgia syndrome
Progressive loss of or change in motor, bowel, bladder, or sexual function	Myelopathy, conus medullaris syndrome, or cauda equinus syndrome

Data from Feinberg JH: Hip pain: Differential diagnosis. *J Back Musculoskeletal Rehabil* 4:154–173, 1994.

TABLE 19-12 Differential Diagnosis for Pain in the Hip or Buttock Area

Pain Distribution	Potential Cause	Pain Distribution	Potential Cause
Groin area	Stress fractures of the pelvis and femur	Groin and inner thigh region	Transient synovitis
	Crystal-induced synovitis (gout)		Infection
	An inguinal/femoral hernia		Loosened prosthesis
	Muscle calcification		Inflamed lymph nodes
	Hip adductor strain		Lower abdominal muscle strain
	Iliopectineal bursitis		Referred pain from viscera or spinal nerve
	Iliopsoas strain or avulsion fracture of the lesser	Pubic area	Sprain of pubic symphysis
	Trochanter	Lateral buttock area	Osteitis pubis
	Arthritis of the hip	Anterior and lateral thigh	Abdominal muscle strain
	Hip arthrosis	Medial thigh	Bladder infection
	Femoral neck fracture	Anterior–superior iliac spine	Trochanteric bursitis
	Osteonecrosis of the femoral head	Iliac crest	Tendinitis of abductors or external rotators
	Pubic symphysis dysfunction:		Apophysitis of greater trochanter
	► Osteitis pubis		Referred pain from mid or lower lumbar spine
	► Osteomyelitis pubis		Thrombosis of gluteal arteries
	► Pyogenic arthritis		Strain of quadriceps
	► Pubic fracture		Meralgia paresthetica
	► Pubic osteolysis		Entrapment of femoral nerve
	► Postpartum symphyseal pain		Thrombosis of femoral artery or great saphenous vein
	Sacroiliac joint lesion		Stress fracture of femur
	Tumor		Referred pain from hip or mid-lumbar spine
	Ureteral stone		Strain of adductor muscles
	Hernia		Entrapment of obturator nerve
	Inflammatory synovitis (e.g., rheumatoid arthritis, ankylosing spondylitis, and systemic lupus erythematosus)		Referred pain from hip or knee
	Subluxation		Apophysitis or sartorius or rectus femoris
	Dislocation		Strain of gluteal, oblique abdominals, tensor fascia, latae, and quadratus lumborum
			Entrapment of iliohypogastric nerve
			Referred pain from upper lumbar spine

Data from Beattie P: The hip. In: Malone TR, McPoil T, Nitz A, eds. *Orthopaedic and Sports Physical Therapy*, 3rd ed. St. Louis, MO: CV Mosby 1996:506.

- lumbar and low thoracic disk-degenerative disease;
- lumbar stenosis with neurogenic claudication;
- peripheral nerve entrapments (lateral cutaneous nerve of the thigh);
- myofascial pain syndrome;
- spondyloarthropathy.

Complaints associated with referred pain include

- thigh pain, knee pain, and leg pain with or without hip pain, which may be indicative of lumbar radiculopathy;
- pain that is decreased with walking up stairs, which may indicate the presence of lumbar spine stenosis.

Referred pain is often related to posture and positioning. Other conditions that can refer symptoms to the pelvis, hip, and thigh region in an adult include cancer, pathological fractures of the femoral neck, and osteonecrosis of the femoral head (avascular necrosis). In the child, pain and loss of range at the hip joint should always alert the clinician to the possibility of transient synovitis, Legg–Calvé–Perthes disease, or a slipped femoral capital epiphysis (Table 19-13).

The Cyriax lower quarter scanning examination can be used to screen for the presence of upper or lower motor neuron lesions or the referral of symptoms from the spine (see Chap. 4). Key muscle testing is used to test for neurologic weakness. (see also "Active, Passive, and Resistive Tests" section).

TABLE 19-13 Red Flags for the Pelvis, Hip, and Thigh Region

Condition	Red Flags
Colon cancer	Age over 50 yr Bowel disturbances (e.g., rectal bleeding or black stools) Unexplained weight loss History of colon cancer in immediate family Pain unchanged by positions or movement
Pathological fractures of the femoral neck	Older women (>70 yr) with hip, groin, or thigh pain History of a fall from a standing position Severe, constant pain that is worse with movement A shortened and externally rotated lower extremity
Osteonecrosis of the femoral head (avascular necrosis)	History of long-term corticosteroid use (e.g., in patients with rheumatoid arthritis, systemic lupus erythematosus, or asthma) History of avascular necrosis of the contralateral hip Trauma

Data from: DuVall RE, Godges J: Introduction to physical therapy differential diagnosis: The clinical utility of subjective examination. In: Wilmarth MA, ed. *Medical Screening for the Physical Therapist. Orthopaedic Section Independent Study Course 14.1.1.* La Crosse, WI: Orthopaedic Section, APTA, Inc., 2003:1–44.

Trigger points in patients with myofascial pain syndrome can cause both localized and referred symptoms that often closely resemble the referral patterns of a radiculopathy.[117]

Evidence of intense inflammation on examination suggests infectious or microcrystalline processes such as gout or pseudogout. Weight loss, fatigue, fever, and loss of appetite should be sought out, because these are clues to a systemic illness such as polymyalgia rheumatica, rheumatoid arthritis, lupus, or sepsis.

Examples of viscerogenic referred pain (see Chap. 5) include renal calculi (pain radiates into the groin), ovarian cysts or an ectopic pregnancy (pain radiating into the back or hip, or along the course of the sciatic nerve when there is direct compression), and diverticulitis or inguinal hernias (pain radiating across the abdomen or back or into the groin).[117]

Referred pain to the buttock can be a form of vasculogenic pain (see Chap. 5) and occurs in patients who have vascular claudication from stenosis of the distal aorta or common iliac vessels.[117]

If, following the history and systems review, the clinician is concerned with any signs or symptoms of a visceral, vascular, or systemic disorder, the patient should be referred to the appropriate health-care professional.

Tests and Measures

The hip can be one of the more challenging joints to examine. Unlike the knee or ankle, the joint is not readily palpable, and one must rely on a number of provocative tests and maneuvers to identify intra-articular or bony abnormalities.[117] Even many of the soft tissue structures are difficult to manually identify but can usually be isolated with proper clinical skills.

Observation

The most important aspect of inspection is stance (standing and sitting) and gait. The patient is observed from the front, back, and sides for general alignment of the hip, pelvis, spine, and lower extremities (see Chap. 6). While standing, a slightly flexed position of the involved hip and the ipsilateral knee is a common finding associated with hip pathology. In the seated position, slouching or listing to the uninvolved side avoids extremes of flexion. An antalgic gait may or may not be present depending on the severity of the symptoms.

The clinician observes the hip region, noting any scars, anatomical abnormalities, muscle atrophy, bruising, swelling, etc.

- A localized soft tissue mass or swelling may indicate a bursitis, an acute muscle contusion or tear with a hematoma, an avulsion fracture, myositis ossificans, a tumor, infection, or deep vein thrombosis.[117]
- Asymmetric muscle atrophy is usually an indication of a radiculopathy or peripheral neuropathy, but can also be seen with a tendon rupture.
- An ecchymosis may be seen with contusions, muscle tear, fracture, and patients with a bleeding diathesis.[117]
- Vesicular skin lesions that have a dermatomal distribution may be found in cases of herpes zoster. Café au lait spots greater than 3 cm and greater than six in number are characteristic of neurofibromatosis.
- Skin rashes may be because of secondary psoariatic arthritis, drug reactions, or one of the collagen vascular diseases.
- Obvious joint or bony deformity should raise suspicion of a fracture or dislocation.

Both pain and musculotendinous dysfunction can produce movement and postural dysfunctions at the hip joint.[125] According to Kendall,[126] the ideal alignment of the pelvis is indicated when the ASIS is on the same vertical plane as the symphysis pubis. The degree of pelvic tilt, which is measured as the angle between the horizontal plane and a line connecting the ASIS with the PSIS, varies from 5 to 12 degrees in normal individuals.[127] Both a low ASIS in women and a structurally

flat back in men can cause structural variations in pelvic alignment, which can be misinterpreted as acquired postural impairments.[125] According to Sahrmann, all of the following are necessary to indicate the presence of a postural impairment of the hip[125]:

- An increase or decrease in the depth of the normal lumbar curve.
- A marked deviation from the horizontal line between the ASIS and PSIS.
- An increase or decrease in the hip joint angle in the anterior–posterior plane, with neutral knee joint alignment.

The following should be examined[125]:

- The glutei should be symmetrical and well rounded, not hanging loosely. The pelvic crossed syndrome (see Chap. 6) demonstrates weakness and inhibition of the glutei muscles.[128] This syndrome can be easily identified by having the patient perform a partial bridge with single leg support. This maneuver results in cramping of the hamstrings within a few seconds if the pelvic crossed syndrome is present. Atrophy of one buttock cheek compared with the other side may also indicate a superior or inferior gluteal nerve palsy. A balling-up of the gluteal muscle typically indicates a grade III tear of the gluteal muscles. Buttock swelling occurs with the "sign of the buttock."[108]

CLINICAL PEARL

The pelvic crossed syndrome is exhibited by adaptively shortened hip flexors and hamstrings, and inhibited glutei muscles and lumbar erector spinae.

- Swelling over the greater trochanter could indicate trochanteric bursitis.
- Adaptive shortening of the short hip adductors is indicated by a distinct bulk in the muscles of the upper third of the thigh.[128]
- The bulk of the TFL should not be distinct. A visible groove passing down the lateral aspect of the thigh may indicate that the TFL is overused, and both it and the ITB are adaptively shortened.[128]

The architecture and position of the hip joint and lower extremity is observed.

- In acute arthritis and gross osteoarthrosis, the hip joint is usually held in flexion and external rotation. This may be compensated for by an anterior tilt of the pelvis, together with an increased lordosis of the lumbar spine.
- Excessive external rotation of the leg, accompanied with toeing-out, occurs in extreme femoral neck retroversion, or a slipped femoral epiphysis.
- Increased hip flexion in standing can result from weakness or excessive lengthening of the external oblique or rectus abdominis muscles. Increased hip flexion may also be because of a hip flexion contracture.
- Increased hip extension in relaxed standing is indicative of a swayback posture. This is characterized by a posterior pelvic tilt and hyperextension of the knees, and results in a stretch on the anterior joint capsule of the hip and stress on the iliopsoas muscle and tendon.
- Lateral asymmetry in relaxed standing is characterized by a high iliac crest on one side. The difference in height between the two crests must be greater than one-half inch to have clinical significance. Lateral asymmetry may indicate a positive Trendelenburg sign (see "Special Tests" section), which indicates hip-abductor weakness.

Observation of the lower components of the kinetic chain includes

- the degree of genu varum/valgus (see Chap. 20);
- the degree of tibial torsion (see Chap. 20);
- the amount of calcaneal inversion/eversion (see Chap. 21).

Gait. Analysis of both the stance and swing phases of gait is essential (see Chap. 6). Determinants of the stance-phase of gait involve interaction between the pelvis and hip and distal limb joints (knee and ankle)[129,130] The clinician should note whether[70]

- the patient is using an assistive device. If they are, is it fitted at the correct height and do they use it correctly?
- there is a lack of hip motion, particularly extension. A lack of hip extension can have an impact on gait (see Chap. 6).
- there is a lateral horizontal shift of the pelvis and trunk over the stance leg during the swing phase. This may indicate a positive Trendelenburg sign (see "Special Tests" section). Activation of the abductor mechanism on weight-bearing is necessary to stabilize the hip and pelvis and prevent excessive lateral tilting of the pelvis to the contralateral side during the swing phase.
- the ankle alignment is neutral. Increased ankle pronation increases the degree of hip internal rotation which can place greater stress on hip rotators. This can be especially traumatic to those hip rotators that cross bony prominences, increasing the risk of bursitis; conversely, supination causes greater external rotation.

Strong activation of the hip extensors (with the abductors) is necessary at initial contact into early stance, from 30 degrees initial flexion to approximately 10 degrees of extension at terminal stance.[129] If the hip flexors are short or stiff in relation to the abdominal muscles, there may be an exaggeration in the anterior pelvic tilt and increased lumbar extension during this phase.[125]

Joint Loading Tests. Pain on weight-bearing is a common complaint in some patients with hip joint pathology, including rheumatoid arthritis and OA.[70] Depending on the capability of the patient, the following weight-bearing tests may produce pain:

- ***High step.*** The patient places one foot on a chair and then leans onto it (Fig. 19-18). This maneuver flexes the raised hip and extends the other. The test is repeated on the other side. This test gives the clinician an indication as to the range of flexion and extension at the hip.
- ***Unilateral standing.*** The patient stands on one leg (Fig. 19-19). An inability to maintain the pelvis in a horizontal position during unilateral standing is called a positive Trendelenburg (see "Special Tests" section).

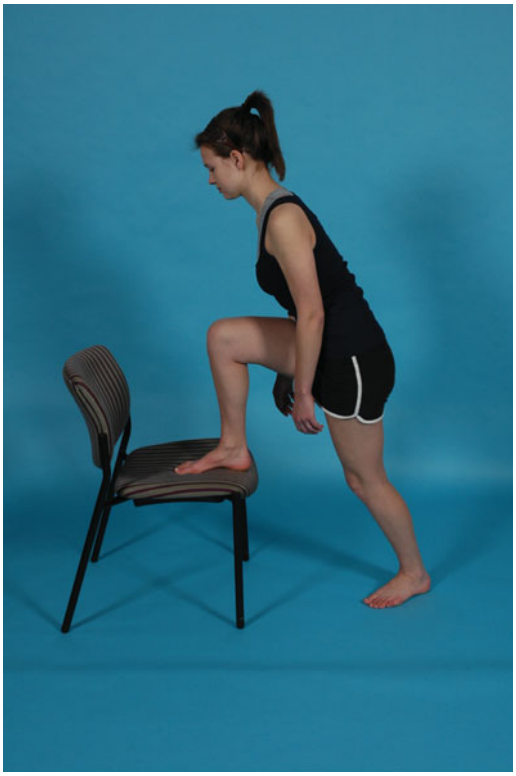

FIGURE 19-18 High step.

Palpation

The palpatory exam is done to identify both anatomic abnormalities and potential sources of symptoms other than from the hip joint itself. Given the location of the hip joint, palpation is usually unrevealing as far as any specific areas of discomfort related to an intra-articular source of hip symptoms. A palpable mass following acute trauma that is not well defined usually indicates a muscle tear, a muscle spasm, or hematoma.[117] A mass that developed 2–3 weeks after the initial injury and is warm and erythematous may be the first indication of myositis ossificans. A bursitis usually presents with some localized swelling, warmth, and erythema, and no history of acute trauma. Trigger points are usually identified as discrete nodules or bands within muscle tissue. There is no associated swelling and no warmth or erythema. Postural or bony malalignment can increase the risk of both acute traumatic and overuse injuries. The anatomic relationships of the joints of the lower extremity should be compared, looking for valgus and varus deformities, pes cavus or planus, spine mobility, hip anteversion, pelvic asymmetry, and leg length discrepancies (see Chap. 29).[117]

Hoppenfeld[131] advocates an approach to palpation that is organized by region. Under this system, the palpation of bony structures occurs separately from the palpation of the soft tissues. While this may be helpful to the clinician, time constraints often dictate that the two are examined concurrently.

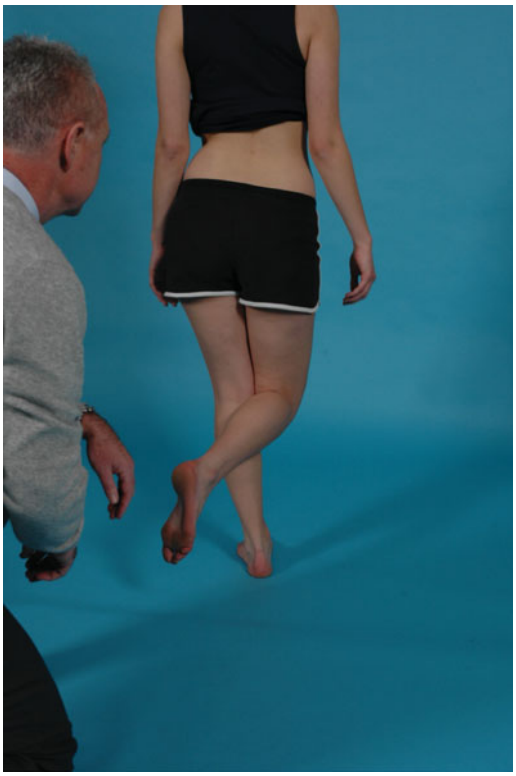

FIGURE 19-19 Trendelenburg sign indicating weakness of the left hip abductors.

CLINICAL PEARL

The following are useful landmarks to use when locating the hip joint center of rotation[18]:

- The midpoint between the ASIS and pubic symphysis, lies over the femoral pulse.
- The superior tip of the greater trochanter is in line with the center of rotation.

Anterior Aspect of Hip and Groin

Anterior–Superior Iliac Spine. The anterior iliac spine serves as the origin for the sartorius muscle and the TFL. Both can be located by flexing and abducting the patient's hip, which produces a groove that resembles an inverted **V** close to the ASIS. The lateral side of the inverted **V** is formed by the TFL, while the medial side is formed by the tendon of the sartorius.

Anterior–Inferior Iliac Spine. The anterior–inferior iliac spine can be palpated in the space formed by the sartorius and the TFL, during passive flexion of the hip in the space known as the *lateral femoral triangle*. The lateral cutaneous nerve of the thigh passes through this triangle. Compression of this nerve produces a condition called *meralgia paresthetica* (see Chap. 5). The AIIS serves as the origin for the rectus femoris tendon.

Pubic Tubercle. The pubic tubercle is located by finding the groin crease and then traveling in an inferomedial direction, or by following the tendon of the adductor longus proximally. In males, the spermatic cord runs directly over the tubercle and can be tender to palpation in normal individuals. Inguinal hernias are usually found superior and medial to the tubercle, while femoral hernias are located lateral to the tubercle.

Adductor Magnus. The adductor magnus is palpable in a small triangle in the distal thigh, posterior to the gracilis muscle and anterior to the semimembranosus.

Rectus Femoris. The rectus femoris has its origin at the AIIS, which is located just distal to the ASIS, between the TFL and sartorius.

Iliopsoas Bursa. At the iliopectineal eminence, the iliopsoas muscle makes an angle of about 30 degrees in a posterolateral direction. To palpate this bursa, the patient is positioned in supine, with the hip being positioned in approximately 40 degrees of flexion and external rotation, and resting on a pillow. At the proximal end of the femur, the clinician palpates the adductor tubercle and then moves to the ASIS. From there, the clinician proceeds to the inguinal ligament, under the fold of the external oblique, and into the femoral triangle. The psoas bursa is located under the floor of the triangle, close to the pubic ramus.

Femoral Triangle. The femoral artery lies superficial and medial to the iliopsoas muscle and is easily located by palpation of the pulse. The femoral nerve is the most lateral structure in the femoral triangle. To examine the femoral triangle, the patient is positioned in supine and, if it is possible for the patient to do this, the heel of the leg is placed upon the opposite knee. This places the patient in a position of flexion–abduction and external rotation.

Inguinal Ligament. The inguinal ligament is located in the fold of the groin, running from the ASIS to the pubic tubercle. It can be located by using transverse palpation.

Adductor Longus. Together with the gracilis, the adductor longus forms the medial border of the femoral triangle. The gracilis is located medial and posterior to the adductor longus. The adductor longus is best viewed during resisted adduction, when it forms a cord-like structure just distal to the pubic tubercle, before crossing under the sartorius. It is often tender in dancers, cheerleaders, and others who perform strenuous activities requiring abduction at the hip.

Lateral Aspect of the Hip. The patient is positioned in side lying.

Iliac Crest. The iliac crest is easy to locate. The cluneal nerves are superficial structures and can be located just superior to the crest.

Greater Trochanter. The superior border of the greater trochanter represents the transverse axis of hip, and when the leg is abducted, an obvious depression appears above the greater trochanter. The gluteus medius inserts into the upper portion of the trochanter and can be palpated on the lateral aspect.[132]

Palpation of the greater trochanter is also used to assess the angle of anteversion and retroversion using the Craig test (see "Special Tests" section).

Lesser Trochanter. The lesser trochanter, covered as it is with the iliopsoas and adductor magnus, is very difficult to palpate directly, but it can be located on the posterior aspect if the hip is placed in extension and internal rotation, and the palpation is performed deeply lateral to the ischial tuberosity.

Piriformis Attachment. The origin of the piriformis can be found on the medial aspect of the superior point of the greater trochanter. Moving inferiorly from this point and the quadratus femoris located on the quadrate tubercle, the following tendon insertions can be palpated: superior gemellus, obturator internus, and inferior gemellus.

Psoas. The insertion for the psoas is located on the inferior aspect of the greater trochanter and can be found by placing the patient's hip in maximum internal rotation. Once the superior aspect of the greater trochanter is located, the clinician moves in a posterior/medial/inferior direction to locate the inferior aspect of the greater trochanter.

Subtrochanteric Bursa. The subtrochanteric bursa cannot be palpated directly. However, it can be tested by positioning the patient's leg in hyperadduction. At this point, the patient is asked to abduct the hip isometrically against the clinician's resistance. The contraction of the hip abductors compresses the bursa and may cause pain if the bursa is inflamed.

Posterior Aspect of the Hip. The patient is positioned in side lying or prone.

Quadratus Lumborum. Palpation of the quadratus lumborum is best accomplished with the patient in side lying, with the arm abducted overhead to open the space between the iliac crest and the 12th rib.

Ischial Tuberosity. A number of structures have their attachments on the ischial tuberosity. These include the ischial bursa, the semimembranosus tendon, the sacrotuberous ligament, the biceps femoris and semitendinosus tendons, and the tendons of the quadratus femoris, adductor magnus, and inferior gemellus. The ischial tuberosity is best palpated in the side lying position with the hip flexed to 90 degrees (see Chap. 29). This position moves the gluteus maximus upward, permitting direct palpation at the tuberosity. The *ischial bursa* is located on the inferior and medial aspect of the ischial tuberosity. A diagnosis of ischial bursitis is usually based on a history of pain with sitting on a hard surface and finding tenderness with palpation of the ischial tuberosity.

Sciatic Nerve. One of the most important structures to palpate in this area is the sciatic nerve. It can be located for palpation at a point halfway between the greater trochanter and ischial tuberosity. Tenderness of this nerve can be produced by a piriformis muscle spasm or by direct trauma.

Active, Passive, and Resistive Tests

The clinical procedures for performing ROM measurements vary, and disagreement exists about the accuracy of visual estimates compared to goniometer measurements. A study by Holm and colleagues[133] comprising 25 patients (6 M, 19 F; mean age 68.5 years, range 46–76 years) with osteoarthrosis of the hip, verified both clinically and radiologically, examined the reliability of goniometric measurements and visual estimates of hip ROM. Hip ROM measurements (abduction VIDEO, adduction VIDEO, extension VIDEO, flexion VIDEO, and internal VIDEO/external rotation VIDEO) were recorded by four different teams on the same day and were repeated 1 week later. Teams 1, 2, and 3 consisted of physiotherapists using standardized goniometric measurements. Team 4 involved an experienced orthopaedic surgeon making the assessments from visual estimates only. With the exception of abduction ($p = 0.03$), there were no significant differences between the measurements recorded on the first and second occasions for the same teams. The coefficient of variance was 5.5% for flexion (lowest) and 26.1% for extension (highest). Reproducibility was best for flexion. There was also high reliability when all the arcs of motion were summed up (abduction + adduction + extension + flexion + internal/external rotation). With the exception of internal rotation, there were highly significant differences between the teams when two people performed the measurements compared to the values measured by a single individual.

Concordance, expressed as the standardized agreement index, between visual estimates made by one individual (the orthopaedic surgeon) and goniometric measurements made by two experienced physiotherapists, was 0.77–0.83, which indicates good agreement.

Bierma-Zeinstra and colleagues[134] performed a study to compare the reliability of measurements of hip motions obtained with two instruments, an electronic inclinometer and a two-arm goniometer, and to investigate whether the two instruments, and different body positions, produce the same measurement data. Maximal active and passive hip movements were measured simultaneously with both instruments, in nine subjects during 10 consecutive measurements at short intervals. The results from the study demonstrated the following[134]:

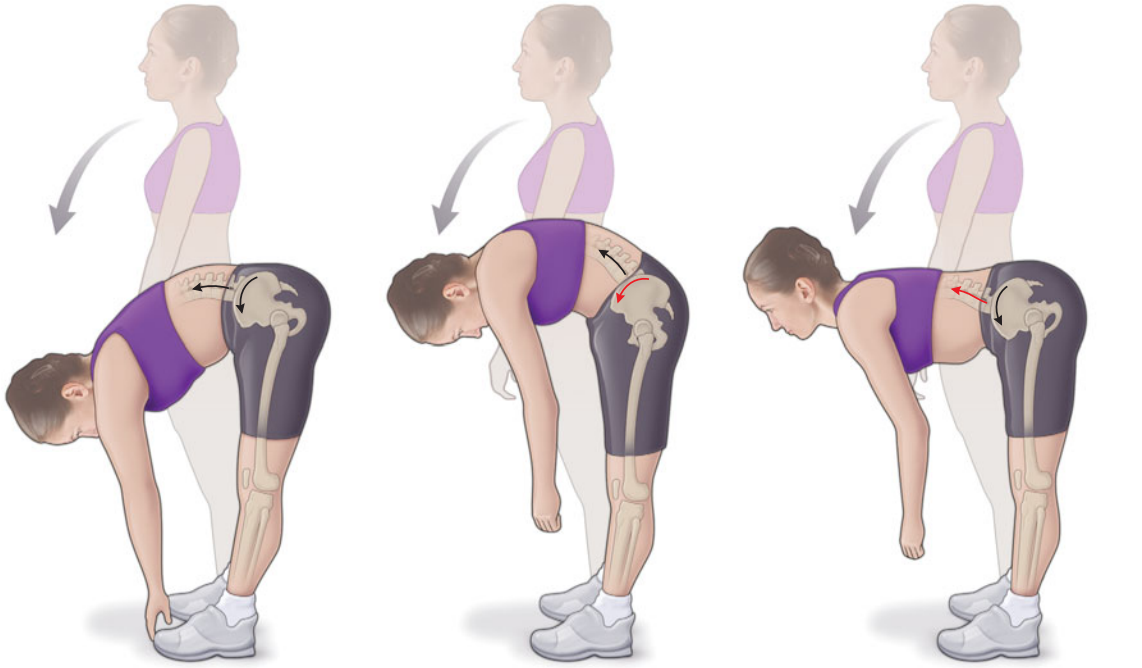
- The intraobserver variability was lower with the inclinometer in measurements of passive hip rotations.
- The two instruments showed equal intraobserver variability for hip movements in general.
- The inclinometer showed lower interobserver variability in the measurements of active internal rotation.
- More rotational movement was measured with the two-arm goniometer and more extension and flexion with the inclinometer. Also, more rotational movement was found in the prone position compared to the sitting and supine positions.

The study concluded that the inclinometer is more reliable in measurements of hip rotation; for hip movements, in general, the two-arm goniometer is just as accurate when used by only one observer; and the two instruments, and some positions, are not interchangeable during consecutive measurements.[134]

During the examination of the ROM, the clinician should note which portions of the ROM are pain free and which portion causes the patient to feel pain. An assessment of the lumbopelvic rhythm can alert the clinician to the primary area of a particular limitation. During normal forward bending, the patient should be able to touch their toes without bending the knees and with a flattening of the lordosis (Fig. 19-20). However, if the hamstrings are adaptively shortened, toe touching, cannot be accomplished even with a flattening of the lordosis. If the tightness is located in the LB, as the patient bends forward, no flattening of the lordosis occurs, and the patient is unable to touch the toes even with good hamstring flexibility.

The capsular pattern of the hip appears variable and is an unreliable method for determining the presence of OA when used alone,[110] Twinges of pain with active motions may indicate the presence of a loose body within the joint. At the end of available AROM, passive overpressure is applied to determine the end-feel. The normal ranges and end-feels for the various hip motions are outlined in Table 19-5. Abnormal end-feels common in the hip include a firm capsular end-feel before expected end range; empty end-feel from severe pain, as in the sign of the buttock; and bony block in cases of advanced OA.[18] Horizontal abduction and adduction of the femur occur when the hip is in 90 degrees of flexion. Since these actions require the simultaneous, coordinated actions of several muscles, they can be used to assess the overall strength of the hip muscles.

Resisted testing of the muscles that cross the hip joint (Table 19-4) is performed to provide the clinician with information



A Normal lumbar and hip flexion

B Limited hip flexion and excessive lumbar flexion

C Limited lumbar flexion and excessive hip flexion

FIGURE 19-20 Lumbopelvic rhythm.

about the integrity of the neuromuscular unit, and to highlight the presence of muscle strains (see "Systems Review" section).[131]

If the history indicates that repetitive motions or sustained positions cause the symptoms, the clinician should have the patient reproduce these motions or positions.[135]

CLINICAL PEARL

In the child, pain and loss of range at the hip joint should always alert the clinician to the possibility of transient synovitis, Legg–Calvé–Perthes disease, or a slipped femoral capital epiphysis (see Chap. 30).

In addition to reports of pain and overall ROM, the clinician also notes information about weakness, joint end-feel, palpation of the moving joint, and muscle tightness.

Flexion. The six muscles primarily responsible for hip flexion are the iliacus, psoas major, pectineus, rectus femoris, sartorius, and TFL (Table 19-4). The primary hip flexor is the iliopsoas muscle.

Hip flexion motion can be tested in sitting or supine, first with the knee flexed (Fig. 19-21) and then with the knee extended. With the hip flexed, the ROM should be approximately 110–120 degrees. More hip flexion should be available with the knee flexed.

Resisted tests are then performed.

- To test the strength of the iliopsoas, the patient is seated with the thigh raised off the bed and resistance is applied by the clinician **VIDEO**.
- The action of the sartorius muscle, which flexes, abducts, and externally rotates the hip, is tested by asking the patient to bring the plantar aspect of the foot toward the opposite knee **VIDEO**. The clinician applies resistance at the medial malleolus and at the lateral aspect of the thigh to resist flexion, abduction, and external rotation.

A painless weakness of hip flexion is rarely a good sign. Although it may indicate a disk protrusion at the L1 or L2 level, these protrusions are not common. A more likely scenario is compression of the nerves by a neurofibroma or a metastatic invasion. Pain with the active motion or resisted tests should prompt the clinician to examine the contractile tissues individually. Passive stretching can also produce pain in a contractile structure.

FIGURE 19-21 Hip flexion with knee flexed.

FIGURE 19-22 Hip extension.

Extension. The primary hip extensor is the gluteus maximus (Table 19-4). The hamstrings also serve as hip extensors. Hip extension also involves assistance from the adductor magnus, gluteus medius and minimus, and indirect assistance from the abdominals and the erector spinae.[136]

The patient is positioned in prone or over the end of a table. As the clinician monitors motion at the pelvis to ensure the lumbar spine does not extend, the patient is asked to lift the thigh toward the ceiling (Fig. 19-22). With a normal recruitment pattern, the order of firing should be gluteus maximus, opposite erector spinae, and then the ipsilateral erector spinae and hamstrings.[128] Poor recruitment patterns are demonstrated as follows:

1. An initial activation of the hamstrings and erector spinae with a delayed contraction of the gluteus maximus. The biceps femoris has a tendency to become shortened and overactive, resulting in delayed activation of the gluteus maximus.[137]
2. The erector spinae initiate the movement with a delayed activity of the gluteus maximus. This would lead to little, if any, extension of the hip joint, as the leg lift would be achieved by an anterior pelvic tilt and a hyperextension of the lumbar spine. This is a very poor movement pattern.

The normal ROM for hip extension is approximately 10–15 degrees. Reduced hip extension with the knee flexed can be the result of a number of reasons, including

- adaptive shortening of the iliopsoas, characterized by an increased lumbar lordosis, an externally rotated lower extremity, and a noticeable groove in the ITB in standing[138];
- a hip flexion contracture.

As before, the pelvis is monitored, and the patient is asked to raise the thigh off the table. The strength of the gluteus maximus is tested with the knee flexed (Fig. 19-23) **VIDEO**. The role of the hamstrings at the hip can be tested with the knee extended. By observing the patient's shoulder during this test, the recruitment pattern can be analyzed.

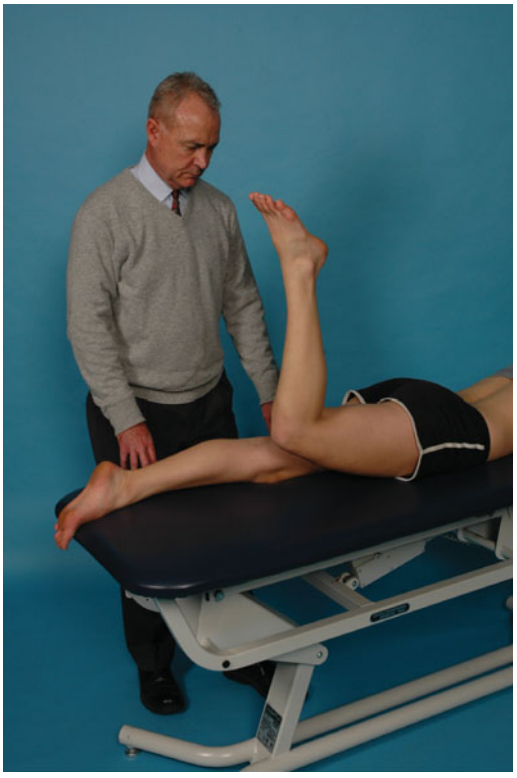


FIGURE 19-23 Hip extension with knee flexed.

The opposite shoulder should be seen to rise off the bed. With the abnormal pattern, the same shoulder rises off the bed. Patients who use this abnormal recruitment pattern will often have well-developed thoracic musculature on the posterior aspect and, as a result, develop problems at the thoracolumbar junction.[128]

Resistance is then applied by the clinician. A strong and painful finding with resisted hip extension may indicate a grade I muscle strain of the gluteus maximus or hamstrings. It may also indicate a gluteal bursitis or a lumbosacral strain. The strength of the medial and lateral hamstrings is also tested using resisted knee flexion, with the patient positioned in prone (see Chap. 20).

CLINICAL PEARL

Although hip extensor strength in the elderly has been identified as the primary predictor of walking ability, physical performance and balance, assessment of hip extensor strength in this population is commonly overlooked, as the presence of pain, contractures, and reduced mobility often limits the ability of the elderly patient with hip or spine impairment to adopt the prone position.[71] In these situations, the clinician should modify the testing position to accommodate the patient (e.g., have the patient lean over a table).

Abduction/Adduction. Hip adduction (Fig. 19-24) and abduction (Fig. 19-25) ROM can be tested in supine or sidelying making sure that both ASIS are level, and the legs are perpendicular to a line joining the ASIS.

FIGURE 19-24 Hip adduction ROM using anti-gravity position.

Abduction. The clinician monitors the ipsilateral ASIS, and the patient is asked to abduct the leg. The abduction motion is stopped when the ASIS is felt to move. The prime movers for this movement are the gluteus medius/minimus and the TFL. The quadratus lumborum functions as the stabilizer of the pelvis. The strength of the gluteus medius and minimus can be tested against gravity in the sidelying position **VIDEO**. The patient is asked to perform hip abduction of the uppermost leg without any flexion or external rotation occurring (Fig. 19-25). The clinician applies resistance to the distal thigh.

The correct sequence of firing for hip abduction in side lying should be gluteus medius, followed by the quadratus lumborum and TFL after approximately 15 degrees of hip abduction. Altered patterning demonstrates the following:

1. External rotation of the leg during the upward movement, indicating an initiation and dominance of the movement by the TFL, accompanied by a weakness of the gluteus medius/minimus. The TFL has a tendency to become shortened and overactive.[137]
2. Full external rotation of the leg occurs during the leg lift, indicating a substitution of hip flexion and iliopsoas activity for the true abduction movement. If the piriformis is shortened and overactive, the external rotation of the leg is reinforced.[137]

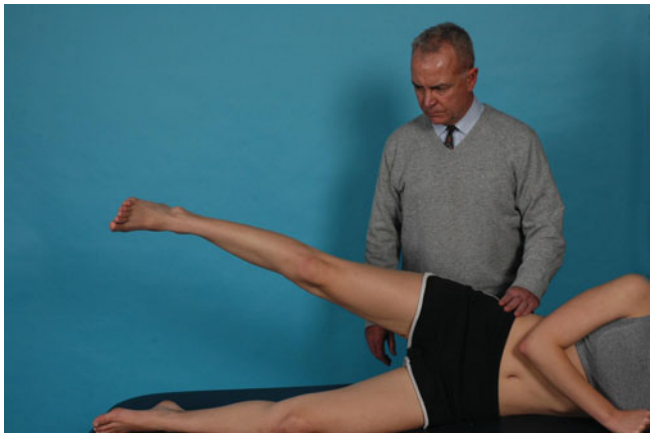

FIGURE 19-25 Hip abduction ROM.

3. A lateral pelvic tilt at the initiation of movement, indicating that the quadratus lumborum, which has a tendency to become shortened and overactive, is both stabilizing the pelvis and initiating the movement.[137] This is indicative of a very poor movement pattern.

Adduction. Hip adduction is tested with the patient supine and with the uninvolved leg adducted over the other leg or held in flexion (Fig. 19-24). As before, the ASIS is monitored for motion, indicating the end of range for adduction. The primary hip adductor is the adductor longus. Adaptive shortening of the hip adductors can theoretically result in inhibition of the gluteus medius, a decrease in frontal stability, ITB tendinitis, and anterior knee pain. Pain can be referred from the hip adductors into the anterolateral hip, groin, medial thigh, the anterior knee, and medial tibia. Pain in these regions with passive abduction, or active adduction, may indicate a strain of one of the adductors. The cause of the pain can be differentiated between the two-joint gracilis and the other hip adductors (longus, brevis, and pectineus) in the following manner. The patient is positioned in supine, with the tested leg over the edge of the table, monitored by the clinician. The clinician places the involved hip into the fully abducted position and the knee is flexed (Fig. 19-26). If no pain is reproduced with this maneuver, the patient is asked to extend the knee (Fig. 19-27), thereby bringing in the gracilis and implicating it if the pain is now reproduced. This can be confirmed with resisted hip adduction and knee flexion. If the other adductors are implicated, this can be confirmed with resisted adduction (longus and brevis) or resisted hip adduction and hip flexion (pectineus).

The strength of the hip-adductor muscle group can also be tested in side lying **VIDEO**, by flexing the uninvolved leg over the tested leg or by supporting the upper leg and then applying resistance. This position also stretches the hip abductors and can be a source of pain in the case of an ITB syndrome.

A strong and painful finding with resisted adduction is usually the result of an adductor longus lesion, whereas a painless weakness with resisted abduction is often found in a palsy of the fifth lumbar root because of a disk herniation of the same level.

FIGURE 19-26 Differentiating hip-adductor muscles—knee flexed.

FIGURE 19-27 Differentiating hip-adductor muscles—knee extended.

Internal and External Rotation. Although a number of muscles contribute to external rotation of the femur (see Table 19-4), six muscles function solely as external rotators.[32] These are the piriformis, gemellus superior, gemellus inferior, obturator internus, obturator externus, and quadratus femoris. Normal ROM for hip external rotation is approximately 40–60 degrees. Excessive external rotation of the hip may indicate hip retroversion.

The major internal rotator of the femur is the gluteus minimus, assisted by the gluteus medius, TFL, semitendinosus, and semimembranosus. The internal rotators of the femur are estimated to be only approximately one-third the strength of the external rotators.[96] Normal ROM for hip internal rotation is approximately 30–40 degrees. Excessive internal rotation of the hip may indicate hip anteversion.

If an asymmetry exists between the two positions such that more ROM is available in the prone position compared with supine, a muscle restriction is likely present.[139] When the asymmetry of internal rotation ROM is much greater than the external rotation range in both the hip flexed and hip extended positions, structural anteversion may be present.[139] If retroversion is present, the range of external rotation is greater than the range of internal rotation in both the flexed and extended positions of the hip.[139]

To assess the ROM of the hip rotators, the patient is positioned in supine, with the leg in 90 degrees of hip flexion and 90 degrees of knee flexion. Hip IR (Fig. 19-28) and ER (Fig. 19-29) is then assessed. Alternatively, the patient can be positioned in prone, with the knee flexed to 90 degrees and the hip in neutral. Once the ROM measurements have been established, the strength of the internal rotators **VIDEO** and external rotators **VIDEO** is then assessed.

Functional Assessment

In addition to gait analysis, the function of the hip can be assessed through observation during functional activities such as sit to stand, or through use of a self-report measure, which allow a patient to rate his or her capacity to perform ADL. Table 19-14 outlines a functional assessment tool for the hip.

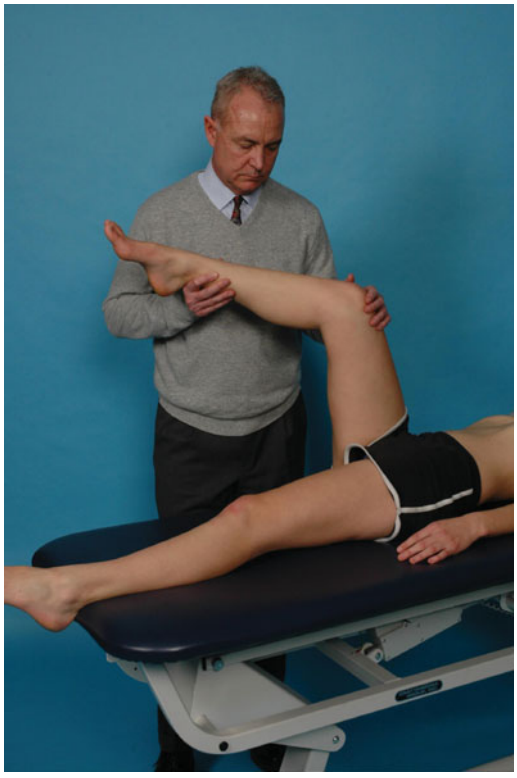

FIGURE 19-28 Supine hip IR.

The Harris Hip Rating Scale (Table 19-15) is the most commonly used functional outcome assessment for the hip and can be used to assess patient status following the onset of traumatic arthritis, and a variety of hip disorders.

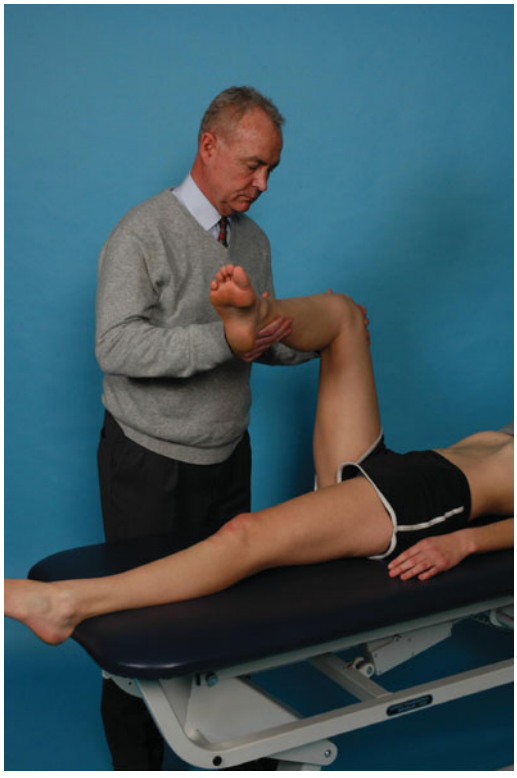

FIGURE 19-29 Supine hip ER.

Examination of Movement Patterns

Some of the movement patterns were assessed in the "Active, Passive, and Resistive Tests" section. One further test is described here.

Trunk Curl Up. This test assesses the patient's ability to sit up from a supine position and the relationship between the abdominal and iliopsoas muscles. The patient is positioned

TABLE 19-14 Functional Tests of the Hip

Starting Position	Action	Functional Test
Standing	Hip flexion: lift foot onto an 8-inch/20-cm step and return	5–6 repetitions: functional 3–4 repetitions: functionally fair 1–2 repetitions: functionally poor Zero repetitions: nonfunctional
Standing	Hip extension: sit in a chair and return to standing	5–6 repetitions: functional 3–4 repetitions: functionally fair 1–2 repetitions: functionally poor Zero repetitions: nonfunctional
Standing	Hip abductors: lift leg to the articular surfaces balance on one leg while keeping pelvis level	Hold 1–1.5 min: functional Hold 30–59 s: functionally fair Hold 1–29 s: functionally poor Cannot hold: nonfunctional
Standing	Hip adductors: walk sideways 6 m	6–8 m one way: functional 3–6 m one way: functionally fair 1–3 m one way: functionally poor 0 m: nonfunctional
Standing	Hip internal rotation: test leg off floor (holding onto object for balance if necessary), internally rotate non–weight-bearing hip	10–12 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor Zero repetitions: nonfunctional
Standing, facing closed door	Hip external rotation: test leg off floor (holding onto object for balance if necessary), externally rotate non–weight-bearing hip	10–12 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor Zero repetitions: nonfunctional

Comments:

Data from Harris WH: Traumatic arthritis of the hip after dislocation and acetabular fractures. Treatment by mold arthroplasty: An end-result study using a new method of result evaluation. *J Bone Joint Surg* 51:737–755, 1969.

in supine with the hips and knees flexed, both feet flat on the bed.

The patient is then asked to perform a sit-up while actively plantar flexing their ankles, thus removing the effect of the iliopsoas.[136] The patient progressively flexes the spine, starting at the cervical region, until the lumbar region is flexed. As soon as the iliopsoas becomes involved in the motion, the patient's feet will lift from the bed. Normally, the patient should be able to curl up so that the thoracic and lumbar spines are clear of the bed before the feet lift. A patient in excellent condition can complete a full sit-up without the feet lifting from the bed.

Passive Accessory Movements

Because of the extreme congruency of the joint partners at the hip joint, this is a difficult area to assess with any degree of accuracy, especially as the glides that occur are very slight. Unless otherwise indicated, the patient is positioned supine with the hip in its resting position. The clinician can wrap a belt around the patient's pelvis and the treatment table to help stabilize the pelvis.

Distraction. A joint distraction can be used to assess for pain and any hypomobility at the hip joint. The patient's thigh is grasped by the clinician as proximal as possible, and a distraction force is applied along the line of the femoral neck (see Fig. 19-30).

Leg Traction. The clinician grasps the patient's ankle and applies a longitudinal force along the length of the leg (Fig. 19-31).

Posterior Glide. The clinician stands on the medial side of the patient's thigh. A belt can be placed around the clinician's shoulder and under the patient's thigh, to help hold the weight of the lower extremity. The clinician places one hand on the distal thigh of the patient and the other hand on the anterior surface of the patient's proximal thigh (Fig. 19-32). Keeping the elbows extended and flexing the knees, the clinician applies a force through the patient's hip in a posterior direction (Fig. 19-32).

FIGURE 19-31 Leg traction for hip.

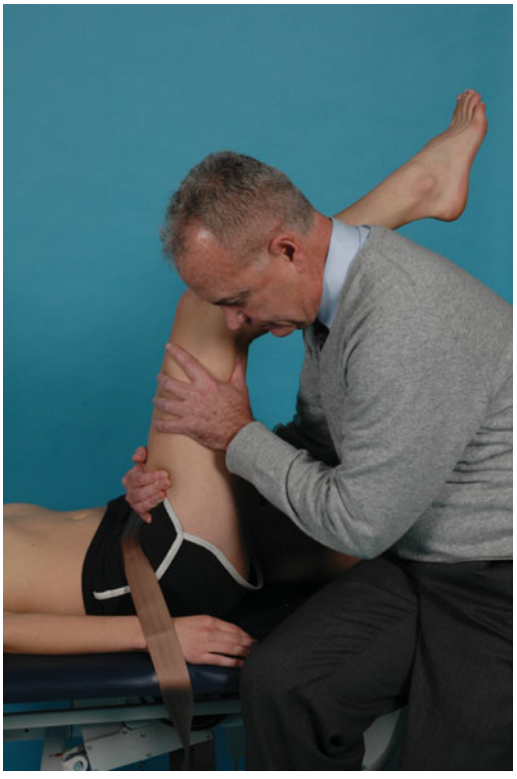

FIGURE 19-30 Hip joint distraction.

FIGURE 19-32 Posterior glide of the hip.

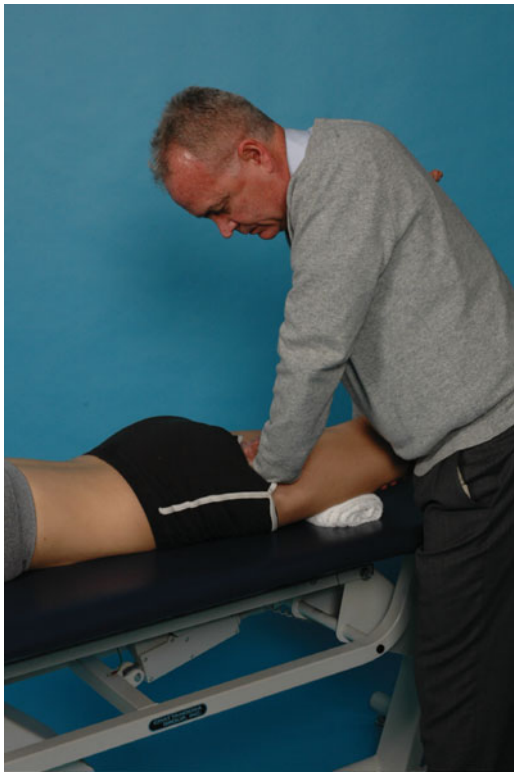

FIGURE 19-33 Anterior glide of the hip.

FIGURE 19-34 Inferior glide of the hip.

Anterior Glide. The patient is positioned prone, with the trunk resting on the table, their thigh over the edge, and the opposite foot supported (Fig. 19-33). The clinician stands on the lateral side of the patient's thigh. A belt can be placed around the clinician's shoulder and under the patients thigh to help hold the weight of the lower extremity. Using one hand, the clinician grasps the patient's lower leg. The other hand of the clinician is placed posteriorly on the proximal thigh of the patient, just below the buttock (Fig. 19-33). Keeping the elbows extended and flexing the knees, the clinician applies a force through the proximal hand in an anterior direction.

Inferior Glide. The patient is positioned with the hip and knee each flexed to 90 degrees and the lower leg placed against the clinician's shoulder. The clinician grasps the anterior aspect of the proximal femur as far proximally as possible with one hand. An inferior glide is imparted using the hands, while simultaneously rocking the patient's thigh into flexion (Fig. 19-34).

Neurological Tests

For sensation testing, the clinician should be aware of the dermatomal pattern as well as the areas supplied by the peripheral nerves (inferior femoral cutaneous nerve, lateral cutaneous nerve of the thigh, and posterior femoral cutaneous nerve).

Paresthesia or anesthesia is not commonly found in the buttock, hip, or groin region because of the degree of dermatome overlap. However, paresthesia in the "saddle" region should be considered indicative of a sign of cauda equina compression.

Special Tests

Special tests are merely confirmatory tests and should not be used alone to form a diagnosis. The results from these tests are used in conjunction with the other clinical findings to help guide the clinician. To assure accuracy with these tests, both sides should be tested for comparison.

Quadrant (Scour) Test. The quadrant or scour test is a dynamic test of the inner and outer quadrants of the hip joint surface.[140]

The patient is positioned in supine, close to the edge of the bed, with their hip flexed and foot resting on the bed. The clinician places one hand over the top of the patient's knee. The patient's hip is placed in 90 degrees of flexion, with the knee being allowed to flex comfortably. From this point, the clinician adducts the hip to the point at which the patient's pelvis begins to lift off the bed, to assess the inner quadrant (Fig. 19-35). At the end range of flexion and adduction, a compression force is applied through the knee along the longitudinal axis of the femur. From this point, the clinician moves the hip into a position of flexion and abduction to examine the outer quadrant. Throughout the entire movement, the femur is held midway between internal and external rotation, and the movement at the hip joint should follow the smooth arc of a circle. An abnormal finding is resistance, apprehension, or pain felt anywhere during the arc. The pain can result from compression of, or stress to, a number of structures including[140]

- the articular surfaces of the hip joint;
- the labrum;
- the hip joint capsule;
- the insertion of the TFL and the sartorius;

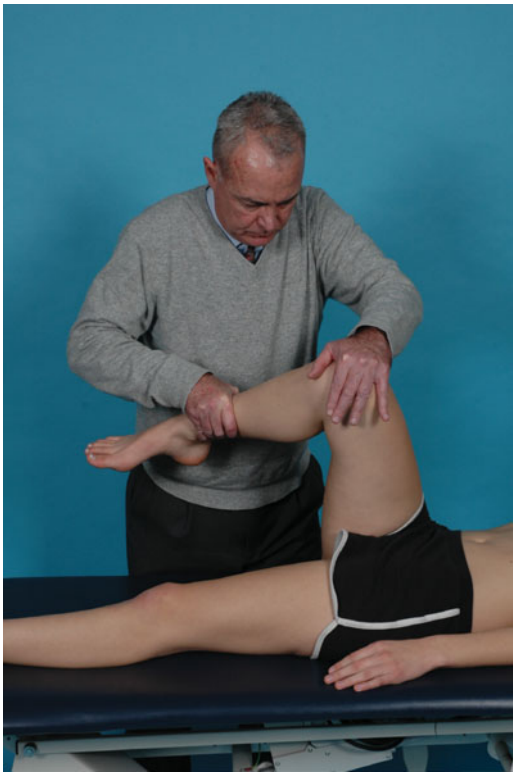

FIGURE 19-35 Scour test.

- the iliopsoas muscle;
- the IPB and neurovascular bundle;
- the insertion of the pectineus;
- the insertion of the adductor longus;
- the femoral neck.

The resistance may be caused by capsular tightness, an adhesion, a myofascial restriction, or a loss of joint congruity. Given all of the possible diagnoses, extreme care must be taken when interpreting the results from this test. Of the various studies that have looked at the Scour test, most have had poor study designs. Given the wide range of possible diagnoses with a positive finding, and the variety of patients this test is used with, bias is likely to result.

FABER or Patrick's Test. The FABER (flexion, abduction, external rotation) test (Fig. 19-36) is a screening test for hip, lumbar, or sacroiliac joint dysfunction, or an iliopsoas spasm (see Chap. 29).

SI Provocation Tests. A number of tests can be used to examine the sacroiliac joint (see Chap. 29).

In addition to the provocative tests, the passive motions of the hip can be examined with the innominate stabilized. The hip motions and their respective innominate motions in parenthesis are outlined in Table 19-6.

Craig Test. The Craig test is used to assess femoral anteversion/retroversion. The patient is positioned in prone with the knee flexed to 90 degrees. The clinician rotates the hip through the full ranges of hip internal and external rotation, while palpating the greater trochanter and determining the point in the range at which the greater trochanter is the most prominent laterally. If at this point the angle is greater than 8–15 degrees in the direction of internal rotation, when measured from the vertical and long axis of the tibia, the femur is considered to be in anteversion.[80,87,139,141]

FIGURE 19-36 FABER test.

One study[141] showed this test to be accurate to within 4 degrees of intraoperative measurements, for the assessment of femoral anteversion/retroversion, and was more accurate than radiographic measurement techniques.

Flexion–Adduction Test. This test is used as a screening test for early hip dysplasia.[142] The patient is positioned in supine, and the hip is passively flexed to 90 degrees and in neutral rotation while maintaining the contact of the patient's pelvis to the bed. From this position, the clinician monitors the pelvis and the hip is passively adducted (Fig. 19-37). The resultant end-feel, restriction, discomfort, or pain is noted and

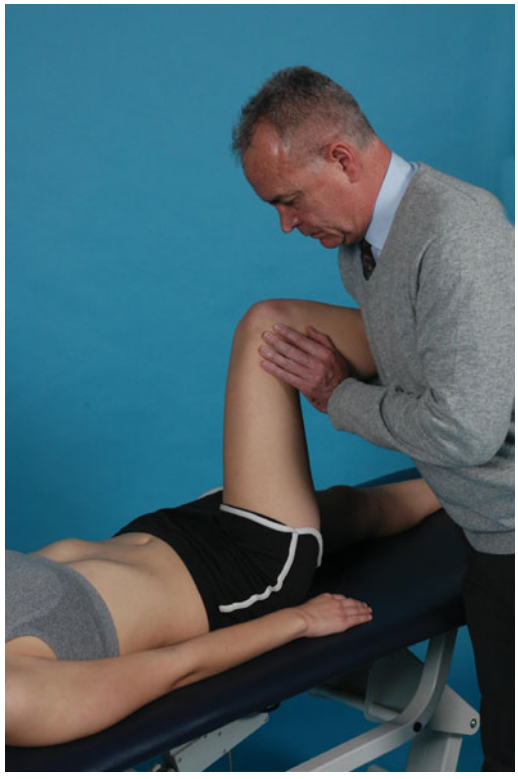

FIGURE 19-37 Flexion–Adduction test.

FIGURE 19-38 Supine Plank test.

compared with the normal side. A positive test for an early sign of hip dysplasia is the inability to adduct the flexed hip past midline toward the opposite hip. Although Woods and Macnicol[142] found the sensitivity to be 100% with this test, the test was performed on adolescents and demonstrated many design flaws.

Supine Plank Test. This test is used to detect hamstring weakness or injury. The patient is positioned in supine, resting on his or her arms and heels. The patient is asked to elevate the pelvis while maintaining their body weight on the arms and heels (Fig. 19-38). The patient is then asked to alternately lift one leg at a time. The test is positive for weakness if pelvic collapse or rotation occurs, or for injury if pain occurs at the ischial origin or in the hamstring musculature.

Trendelenburg Sign. The Trendelenburg sign indicates weakness of the gluteus medius muscle during unilateral weight-bearing. This position produces a strong contraction of the gluteus medius, which is powerfully assisted by the gluteus minimus and TFL, in order to keep the pelvis horizontal. For example, when the body weight is supported by the left foot (Fig. 19-19), the left hip abductors contract both isometrically and eccentrically to prevent the right side of the pelvis from being pulled downward by gravity.

The clinician crouches or kneels behind the patient so that the eyes are level with the patient's pelvis, and ensures that the patient does not lean to one side during the testing. The patient is asked to stand on one limb for approximately 30 seconds, and the clinician notes whether the pelvis remains level. If the hip remains level, the test is considered negative. A positive Trendelenburg sign is indicated if during unilateral weight-bearing the pelvis drops toward the the side of the unsupported limb (Fig. 19-19). A number of dysfunctions can produce the Trendelenburg sign. These include superior gluteal nerve palsy, lumbar disk herniation, weakness or tear of the gluteus medius, and advanced degeneration of the hip. Thus, if used in isolation, this test has little diagnostic value.

Pelvic Drop Test.[92] The patient is asked to place one foot on a 20-cm (8-inch) stool or step and to stand up straight. The patient then lowers the non–weight-bearing leg to the floor (Fig. 19-39). On lowering the leg, there should be no arm abduction, anterior or pelvic motion, trunk flexion, or any hip

FIGURE 19-39 Pelvic Drop test.

adduction or internal rotation occuring at the weight-bearing hip. These compensations are indications of weak external rotators or an unstable hip.

Piriformis Compression of the Sciatic Nerve.[117] Piriformis compression of the sciatic nerve can be reproduced by maximally stretching the piriformis muscle. The patient lies supine with both legs flat on the exam table. The clinician raises one leg, and positions it in maximum flexion of the hip and knee. The hip is then internally rotated and fully adducted (Fig. 19-40). Pain radiating down the leg constitutes a positive test for piriformis syndrome.

Stinchfield's Test. Stinchfield's test is designed to help determine the source of a patient's back, buttock, groin, and/or leg pain. The patient is positioned in supine and asked to lift their leg, without bending the knee, to about 30 degrees. If this maneuver does not reproduce any pain, the clinician applies pressure downward on the patient's raised leg, in an attempt to extend the flexed hip, while the patient resists the force (Fig. 19-41). Pain produced either with or without resistance is assessed for location. If the pain is felt in the groin or anterior thigh, it is considered to arise from the hip; if from the buttock or lumbar spine, the sacroiliac joint or lumbar spine is the likely source. Stinchfield's test should not be confused with the straight-leg raise test used to detect neuromeningeal problems (see Chap. 11). Stinchfield's test is not dependent on the range obtained but rather on the location of symptoms. The only manner in which the two diagnoses could be confused is if a lumbar lesion was producing a restriction of the SLR at or below 30 degrees, but other signs and symptoms would help differentiate between the two. Unfortunately, Stinchfield's test has not been subjected to

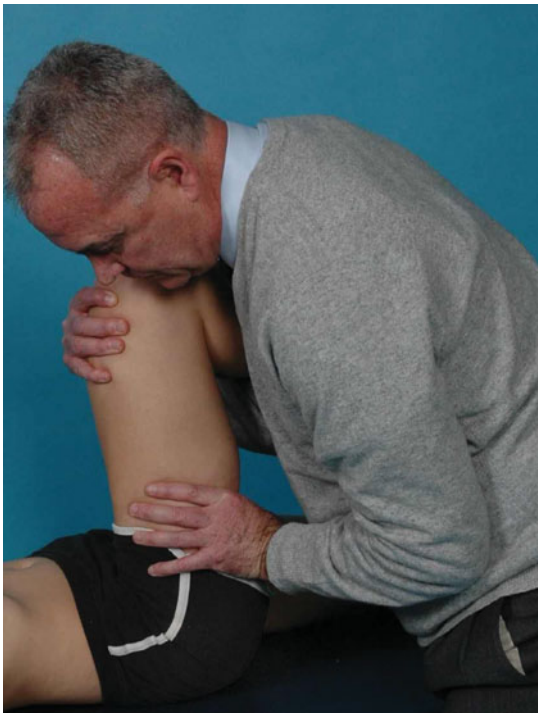

FIGURE 19-40 Piriformis Stretch.

criteria validity research, so no sensitivity or specificity numbers are available.

Auscultatory Patellar-Pubic Percussion Test.[143–145] The ausculatory patellar-pubic percussion test is used when there is a suspicion of occult hip fracture. The patient is positioned in supine, and the clinician places the head of a stethoscope over the pubic symphysis. With the lower extremities extended and positioned symmetrically, the clinician taps (percusses) each patella with a finger or reflex hammer and compares the generated sound (Fig. 19-42). The percussion note should have symmetrical quality and intensity of sound. Any bony disruption along the conduction path (femur) will result in a diminished or muffled sound intensity of a duller quality. Reliability and validity of the technique has been demonstrated.[143] Tiru and colleagues[146] noted a positive predictive value of 0.98, sensitivity of 0.96, and specificity of 0.76. Although the study design was not without fault, the test does appear to have diagnostic value as a screening tool and as a diagnostic tool. Thus, a positive patellar-pubic percussion test should prompt a referral for diagnostic imaging.[143]

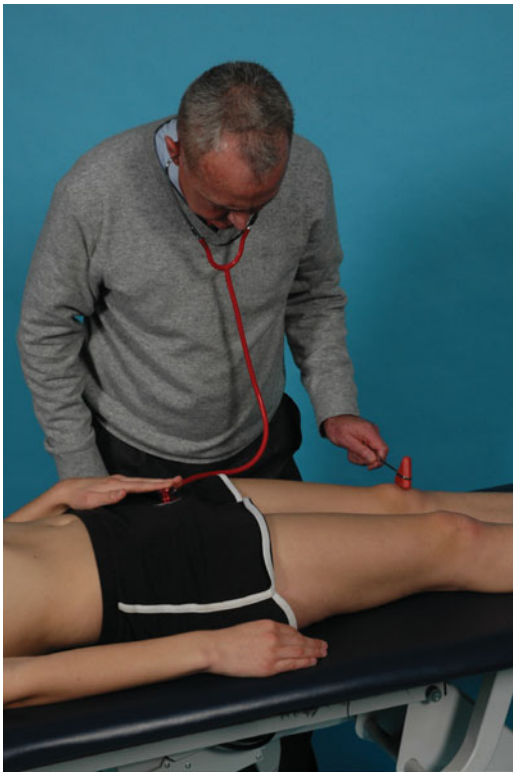

FIGURE 19-42 Auscultatory Patellar-Pubic Percussion test.

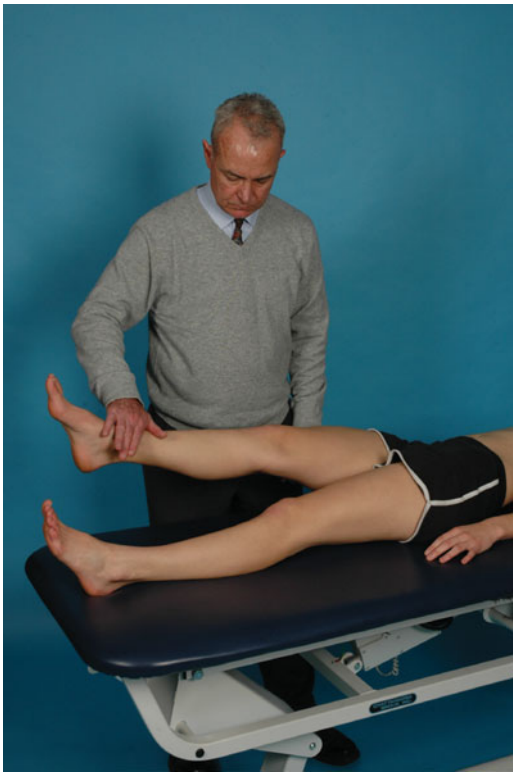

FIGURE 19-41 Stinchfield's test.

Muscle Length Tests

Restrictions in motion limit functional capacity, decrease muscle strength (by adversely affecting the muscle length–tension relationship), and can have an adverse effect on muscle and joint biomechanics.

Thomas Test and Modified Thomas Test. The original Thomas test was designed to test the flexibility of the iliopsoas complex but has since been modified and expanded to assess a number of other soft tissue structures. Neither the original test nor the suggested variations have ever been substantiated for reliability, sensitivity, or specificity.

The original test involves positioning the patient in supine, with one knee being held to the chest at the point where the lumbar spine is felt to flex (Fig. 19-43). The clinician assesses whether the thigh of the extended leg maintains full contact with the surface of the bed. If the thigh is raised off the surface

FIGURE 19-43 Thomas test demonstrating adaptive shortening.

of the table, the test is positive. A positive test indicates a decrease in flexibility in the rectus femoris or iliopsoas muscles or both. One of the limitations of this test is that it merely determines the amount of hip extension possible at any given degree of pelvic flexion.[147] Another problem is that there are better methods of measuring the flexibility of the iliopsoas complex. For example, positioning the patient in prone, stabilizing the pelvis, and then extending the thigh. The precise point at which the pelvis begins to rise marks the end of the hip motion and the beginning of pelvic and spine motion.

A modified version of this test is commonly used to help eliminate the effect of the lumbar curve. For the modified version, the patient is positioned in sitting at the end of the bed. From this position, the patient is asked to lie back, while bringing both knees against the chest. Once in this position, the patient is asked to perform a posterior pelvic tilt. While the contralateral hip is held in maximum hip flexion by the patient's hands, the tested limb is lowered over the end of the bed toward the floor (Fig. 19-44). If normal, the thigh should be parallel with the bed, in neutral rotation, and neither abducted nor adducted, with the lower leg being perpendicular to the thigh and in neutral rotation. There should be 100–110 degrees of knee flexion present with the thigh in line with the table.

If the thigh is raised compared to the table, a decrease in the flexibility of the iliopsoas muscle complex should be suspected. If the rectus femoris is adaptively shortened, the amount of knee extension should increase with the application of overpressure into hip extension.[136] If the decrease in flexibility lies with the iliopsoas, attempts to correct the hip position should result in an increase in the external rotation of the thigh.[136]

The application of overpressure into knee flexion can also be used. If the increase in knee flexion produces an increase in hip flexion (the thigh rises higher off the bed), the rectus femoris is implicated, whereas if the overpressure produces no change in the degree of hip flexion, the iliopsoas is implicated.

This test can also be used to assess the flexibility of the TFL, if the hip of the tested leg is maximally adducted while monitoring the ipsilateral ASIS for motion. There should be 20 degrees of hip adduction available.

Two things must be remembered when interpreting the results of this test:

FIGURE 19-44 Modified Thomas test.

- The criteria are arbitrary and have been shown to vary between genders and limb dominance and to depend on the types and the levels of activity undertaken by the individual.[148]
- The apparent tightness might simply be normal tissue tension, producing a deviation of the leg because of an increased flexibility of the antagonists.

As always, the cause of the asymmetry must be found (or at least looked for) and addressed.

Ely's Test. This is a test designed to assess the flexibility of the rectus femoris. The patient is positioned in prone and the knee is passively flexed by the clinician (Fig. 19-45). If the rectus is tight, the hip flexes on the same side and the pelvis is observed to anteriorly rotate early in the range of knee flexion. The other side is tested for comparison. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Ober Test. The Ober test is used extensively to evaluate the flexibility of the ITB and TFL (see Thomas test).[149] The patient is placed in the side lying position, and with the hip extended and abducted and the knee flexed to 90 degrees, the proximal part of the tested leg is released and allowed to drop passively (Fig. 19-46). The test is considered positive when the leg fails to lower. However, there have been some doubts expressed as to the reliability of the Ober test as a measure for ITB tightness and to date, no diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.[150]

Modified Ober Test. The modified Ober test is performed in the same fashion as the Ober test except that the knee of the

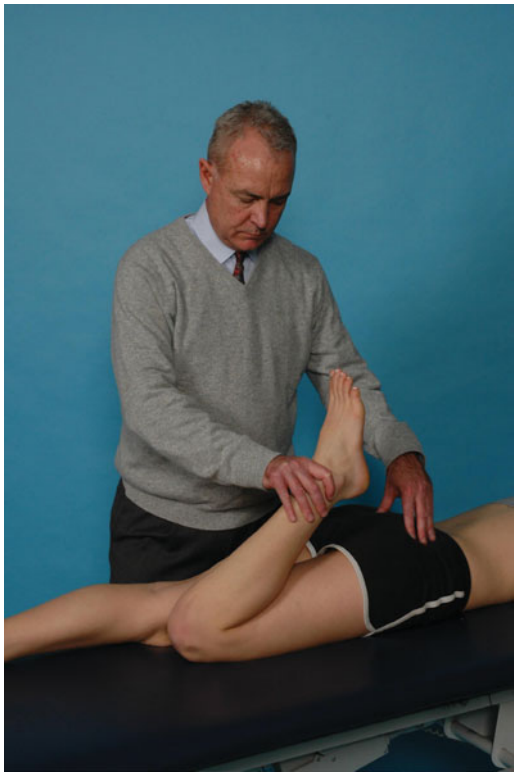

FIGURE 19-45 Ely's test.

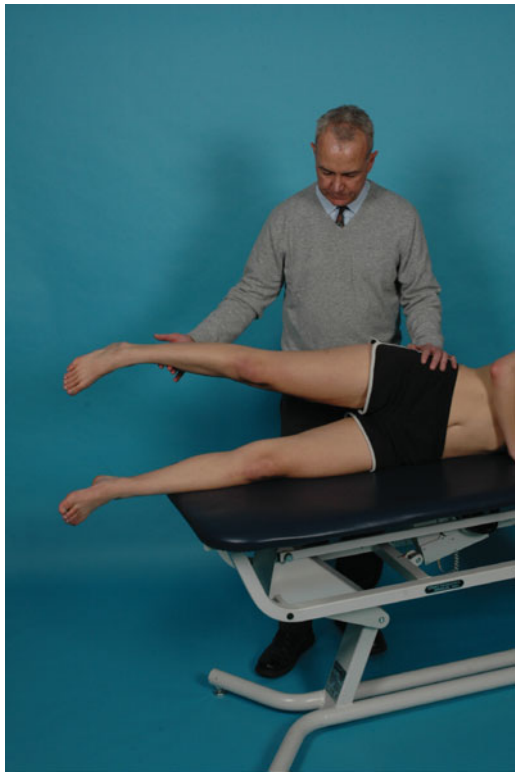

FIGURE 19-47 Modified Ober test.

tested leg is extended (Fig. 19-47).[151] A study by Reese and Bandy[151] was performed to determine the intrarater reliability of the Ober test and the modified Ober test for the assessment of IT band flexibility using an inclinometer to measure the hip adduction angle and to determine if a difference existed between the measurements of IT band flexibility between the Ober and the modified Ober test. Sixty-one subjects, with a mean age of 24.2 (SD = 4.3) years, were measured during two measurement sessions over 2 consecutive days.[151] During each measurement session, subjects were positioned on their left side and, with an inclinometer at the lateral epicondyle of the femur, hip adduction was measured during the Ober test (knee at 90 degrees of flexion) and the modified Ober test (knee extended).[151] If the limb was horizontal, it was considered to be at 0 degrees, if below horizontal (adducted), it was recorded as a positive number, and if above horizontal (abducted), it was recorded as a negative number. The ICC values calculated for the intrarater reliability of the repeated measurement were 0.90 for the Ober test and 0.91 for the modified Ober test.[151] Results of the dependent *t* test indicated a significantly greater ROM of the hip in adduction using the modified Ober test as compared to the Ober test.[151] The study concluded that the use of an inclinometer to measure hip adduction using both the Ober test and the modified Ober test appears to be a reliable method for the measurement of IT band flexibility, and the technique is quite easy to use.[151] However, given that the modified Ober test allows significantly greater hip adduction ROM than the Ober test, the two examination procedures should not be used interchangeably as a measurement of IT band flexibility.[151]

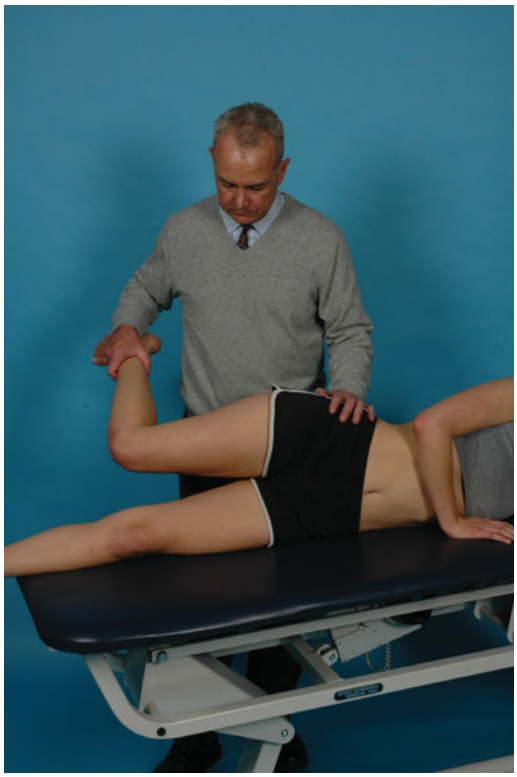

FIGURE 19-46 Ober test.

Straight-Leg Raise Test for Hamstring Length. The patient is positioned in supine with the legs staright and together resting on the table. The clinician stands on the side of the leg to be tested and grasps the patient's ankle with one hand, while visually monitoring, or palpating the patient's opposite ASIS. With the patient's knee extended, the clinician lifts the

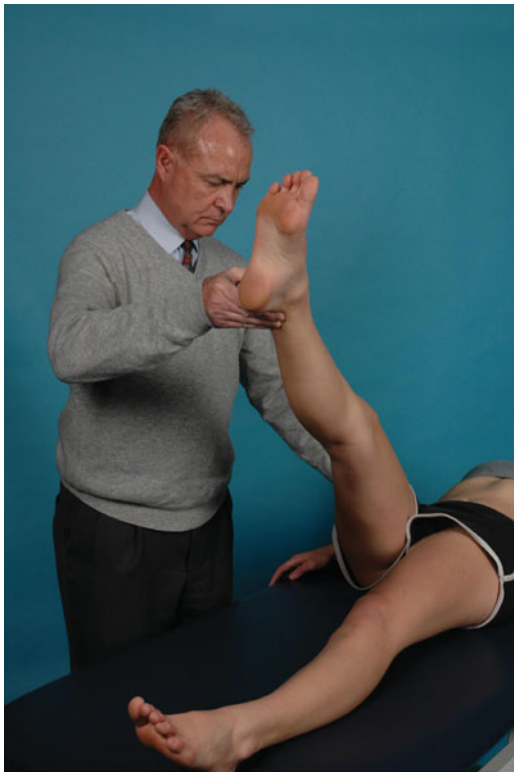

FIGURE 19-48 Straight-Leg Raise test for Hamstring Length.

FIGURE 19-49 Straight-Leg Raise test with ankle dorsiflexion.

patient's leg, flexing it at the hip until motion is detected at the opposite ASIS (Fig. 19-48). The angle of hip flexion from the table is measured. The clinician returns the leg to the table and repeats the maneuver from the other side of the table with the other leg. The hamstrings are considered shortened if a straight leg cannot be raised to an angle of 80 degrees from the horizontal, while maintaining the other leg straight.[128] Any limitation of flexion is interpreted as being caused by adaptively shortened hamstring muscles.

This straight-leg raise test may also be used as a screen for adverse neural tension, particularly of the sciatic nerve (see Chap. 11), and to differentiate between a hamstring lesion and a sciatic nerve lesion by adding ankle dorsiflexion (Fig. 19-49)—adding dorsiflexion places tension through the sciatic nerve but does not alter hamstring length.

90–90 Straight-Leg Raise. Hamstring length can also be assessed with the patient positioned in supine and the tested leg flexed at the hip and knee to 90 degrees. From this position, the patient is asked to extend the knee of the involved side without extending the hip (Fig. 19-50). A measurement of knee motion is taken at the first resistance barrier.

Piriformis. The FAIR (flexion, adduction, and internal rotation) test is designed to detect compression of the sciatic nerve by the piriformis. The patient is positioned in side lying or supine with the involved extremity by the clinician. Holding the patient's knee, the clinician brings the involved extremity into a position of hip flexion, adduction, and internal rotation (Fig. 19-51). If pain is elicited at a point corresponding to the intersection of the sciatic nerve and the piriformis during this test, the result is considered positive.[152,153] The FAIR test has been demonstrated to have a

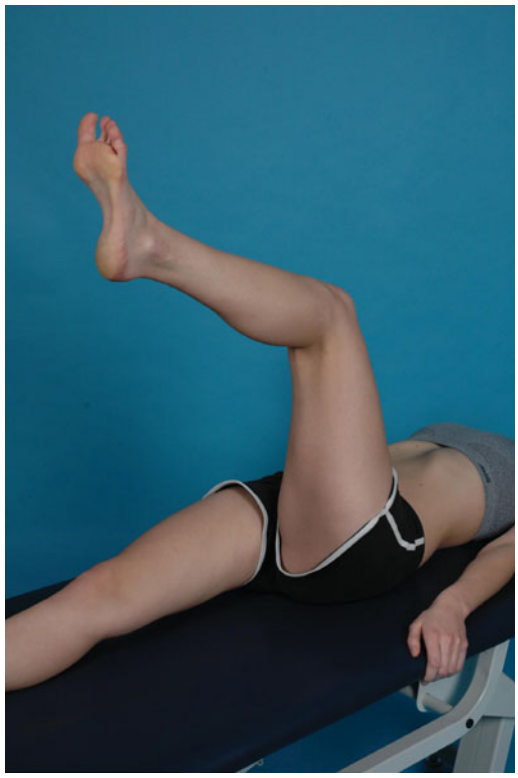

FIGURE 19-50 90–90 Straight-Leg Raise.

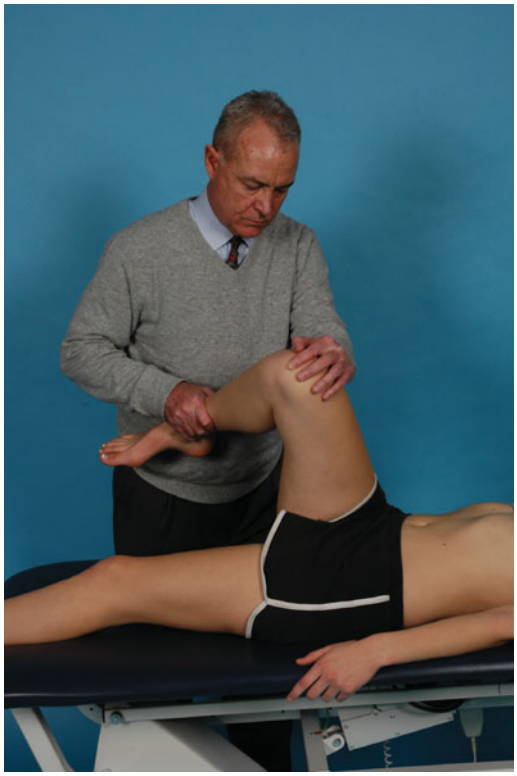

FIGURE 19-51 FAIR test.

sensitivity of 0.88, a specificity of 0.83, a + LR of 5.2, and a –LR of 0.14.[152,154]

Leg Length Discrepancy. The tests used to detect the presence of a leg length discrepancy are described in Chapter 29.

Fulcrum Test. The fulcrum test[155] is used to test for the presence of a stress fracture of the femoral shaft. The patient is positioned in sitting, with their knees bent over the edge of the bed and feet dangling. The clinician positions his or her arm under the thigh to be tested and moves it proximal to distal, as gentle pressure is applied on the thigh with the clinician's hand (Fig. 19-52). A positive test is when the patient reports sharp pain or expresses apprehension when the fulcrum arm is placed under the fracture site. The fulcrum test has not been subjected to criteria validity research, so no sensitivity or specificity numbers are available.

FIGURE 19-52 Fulcrum test.

Diagnostic Imaging

The standard radiographic views of the hip include anteroposterior views and axial or frog leg views (see Chap. 7).

INTERVENTION STRATEGIES

The hip joint and surrounding tissues are prone to a number of common conditions, including joint dysfunction, soft tissue injuries, impingement syndromes, and muscle imbalances of strength and flexibility. Also, because of the high potential of symptom referral from other regions to this area, any intervention for the hip joint must take the entire lower kinetic chain (lumbar spine, pelvis, and lower extremities) into consideration.

The techniques to increase joint mobility and soft tissue extensibility are described in the "Therapeutic Techniques" section.

Acute Phase

During the acute phase, the principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication) are applied as appropriate. Elevation of the hip joint is usually not applicable or possible. The goals of the acute phase include

- protection of the injury site;
- restoration of pain-free ROM in the entire kinetic chain;
- improvement of patient comfort by decreasing pain and inflammation;
- retardation of muscle atrophy;
- minimization of the detrimental effects of immobilization and activity restriction[156–161];
- maintenance of general fitness;
- independence with home exercise program.

The promotion and progression of healing ususally involves a decrease in weight-bearing with rest and/or modification of activities, or through use of an assistive device. Assistive devices are often used to offset the load through the hip joint and to promote a symmetric gait pattern.[70,162] The use of a walker for maximum functional ambulation and safety may be required for some patients, particularly those with poor balance.[70]

The use of shoes with specially made cushion heels may further aid in diminishing the pain associated with weight-bearing.

According to patient tolerance, the clinician should also attempt to remove any other stresses to the hip joint such as joint restrictions in the lumbar spine or sacroiliac joint, and any muscle imbalances.

The approach during this phase may depend on the specific tissue involved:

- Contractile tissue lesions are treated with rest, gentle friction massage, submaximal isometric exercises (glut sets, quad

sets, ham sets), pain-free range-of-motion exercises (heel slides, supine hip abduction/adduction), and with appropriate modalities. Whenever possible, active exercises are performed within a functional context.

- Articular lesions are best treated by placing the joint in the open-packed position (flexion, abduction, and external rotation) and with grade I and II joint mobilizations.

A progressive stretching program is initiated for those muscles that are prone to adaptive shortening (the hip flexors, short hip adductors, sartorius, piriformis, rectus femoris, hamstrings, TFL, and ITB), and those that are prone to be weak or inhibited (glutei muscles and the lumbar erector spina. Initially, the stretches can be performed using the milder techniques of postisometric relaxation techniques and myofascial release before progressing to other techniques (see "Techniques" section) as symptoms subside. The stretch positions used are those that are used for testing muscle length. Self-stretching is taught to the patient at the earliest opportunity.

Balance and coordination retraining activities are usually performed in some form of weight-bearing (sitting then standing), provided that there are no contraindications (pain or instability) to weight-bearing.[70] Simultaneous contraction of hip extensors and abductors in weight-bearing is the normal co-activation pattern used in early stance-phase of gait.[70,129] Once the patient is able to weight bear, these exercises are initially performed with double limb support (Fig. 19-53) and then progressed to single leg support as the patient progresses (Fig. 19-54). Once the static weight-bearing exercises can be performed, sit–stand transfers and gait activities are introduced. Functional exercises such as sit–stand–sit require simultaneous activation of hip muscles coordinated with other trunk and limb patterns normally used to accomplish the activity.[70] Gait-training procedures[163,164] during this phase involve the use of manual contacts at the pelvis to guide and stretch, and to apply joint approximation or resistance to help promote the development of appropriate patterns of neuromuscular control.

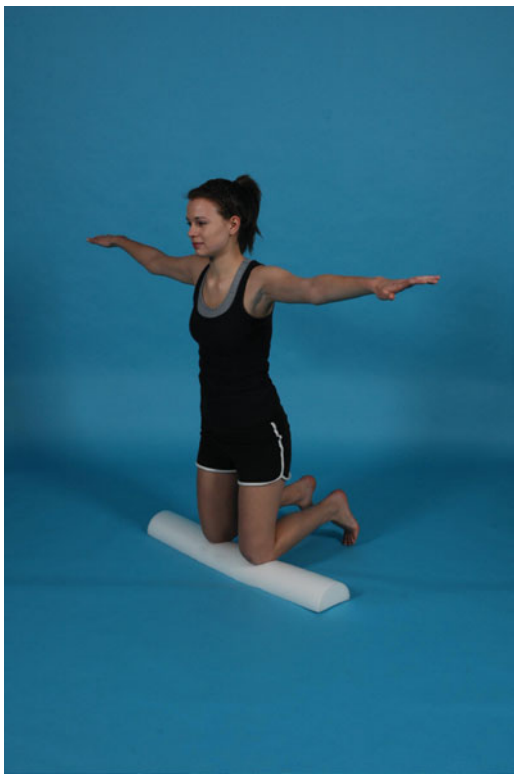

FIGURE 19-53 Weight shifting on fitter.

FIGURE 19-54 Unilateral balancing.

The essential components of normal swing-phase gait[129,164] to develop are

- posterior rotation of the pelvis during swing-phase flexion of the hip;
- a pelvic dip (drop) of no more than approximately 5 degrees on the side of swing limb;
- flexion of the hip to a maximum of 30 degrees (activation of hip flexors) with simultaneous knee flexion and dorsiflexion.

While standing, active hip flexion with adduction, combined with knee flexion, and dorsiflexion simulates the normal swing phase of gait, and promotes balance control in weight-bearing on the contralateral stance leg.[70] A multi-hip machine can be introduced as the hip muscles become stronger.

Cardiovascular fitness can be maintained during this phase using an upper body ergometer. If tolerated, a stationary bicycle can be used.

Functional Phase

Once there is no pain, and when the ROM is equal to that of the uninvolved limb, the patient progresses to the functional stage. The patient should also be able to perform normal walking and

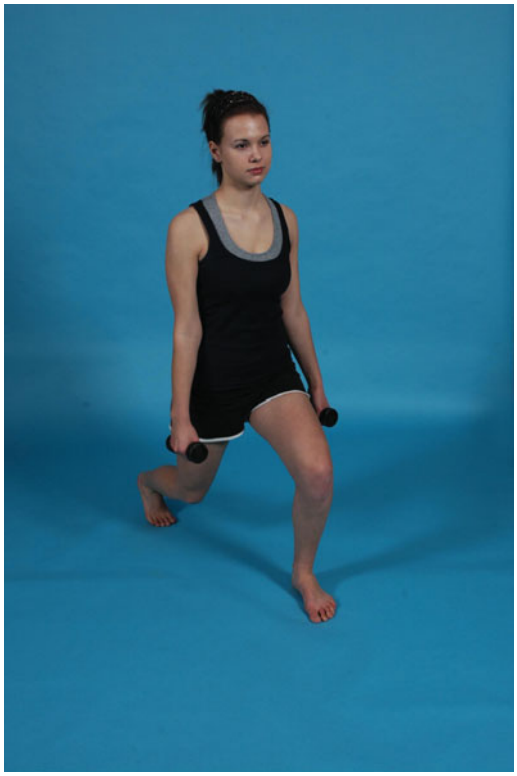

FIGURE 19-55 Lunge.

FIGURE 19-57 Hip circumduction.

daily activities without pain. The goals of the functional phase include

- restoring normal joint kinematics;
- improving muscle strength to within normal limits;
- improving neuromuscular control;
- restoring normal muscle force couple relationships.
- Return to normal function or athletic performance as appropriate

The following exercises are recommended during this phase:

- Quadruped exercises incorporating rocking forward and backward. These exercises help to stretch the joint capsule and apply joint compression.
- Lunging (Fig. 19-55) **VIDEO**, squatting (Fig. 19-56) **VIDEO**, and hip circumduction (Fig. 19-57). These exercises increase functional ROM and strength while simultaneously stretching the capsule.
- Open-chain exercises using cuff weights or tubing may be used to develop strength and endurance of all of the hip musculature **VIDEO** (Fig. 19-58). The exercises are initially performed using concentric contractions and then advanced to eccentric contractions using a variety of speeds and resistance.
- Bridging. Bridging utilizes body weight as a resistance force to the hip extensors and abductors.[70] A variety of bridging exercises exist, from the traditional, where the patient lies supine with the hips and knees flexed and the feet resting on the table and then raises the trunk until it is parallel with the thighs, (Fig. 19-59), **VIDEO** to the more difficult unilateral bridging exercises (Fig. 19-60) **VIDEO**. Manually applied resistance can be superimposed on the pelvis or thighs to generate maximal muscular tension in the contracting muscles.

FIGURE 19-58 Hip abduction with T-band.

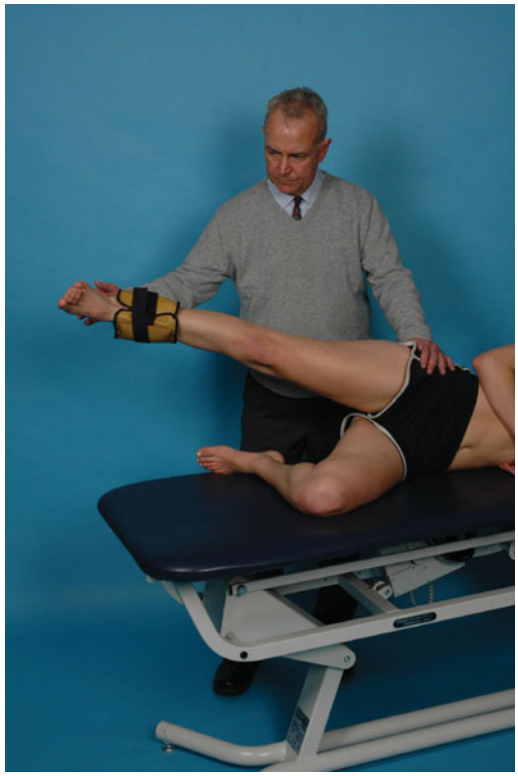

FIGURE 19-61 Gluteus medius strengthening.

FIGURE 19-59 Bridging.

FIGURE 19-60 Unilateral bridging.

- Strengthening of the gluteus medius muscle is often an important component of the hip rehabilitation program. The gluteus medius can be strengthened in side lying, with the upper leg in slight hip extension and external rotation **VIDEO** (Fig. 19-61), the pelvic rise and drop exercise (Fig. 19-62), which also strengthens the quadratus lumborum, stool rotations (Fig. 19-63) and the clam shell exercise progression (Figs. 19-64 through 19-67).
- Strengthening of the hamstrings, including supine bent knee bridge walk-outs (Fig. 19-68 and Fig. 19-69), the supine single-leg chair bridge (Fig. 19-70 and Fig. 19-71), unilateral good mornings with rotations (Fig. 19-72 and Fig. 19-73), lunges with torso rotations (Fig. 19-74), hamstring lowers (Fig. 19-75), and grapevine stepping (Fig. 19-76). The grapevine stepping exercise, using the right leg as an example, is performed by asking the patient to stand with the feet together. The patient is then asked to take one step to the right, and then using the left leg to step behind and slightly to the right of the right foot, thereby crossing the left leg behind the right leg. The left foot should be pointed toward the right heel, but not directly behind it (Fig 19-76). The patient is then asked to take a step to the right with the right foot, and then to move the left foot so that the feet are together again. The routine is then repeated. The exercise is then performed moving to the left.
- The stationary bicycle can be used to increase lower extremity strength, endurance, and range during repetitive reciprocal movements of the lower extremities.[70] Electromyographic (EMG) analysis of lower limb muscles during pedaling has shown that the highest peak of activity

FIGURE 19-62 Pelvic rise and drop exercise.

for the gluteus maximus and biceps femoris muscles (as hip extensors) occurs during the pedal downstroke.[165] Stationary bicycling has also been found to be as effective for increasing ROM at the hip joint as static stretching.[166] The stationary bicycle is a convenient mode of exercise for home use; however, the use of vigorous protocols should be carefully monitored for cardiac effects, especially in light of the fact that both blood pressure and heart rates have been found to increase markedly during this type of exercise.[70,167]

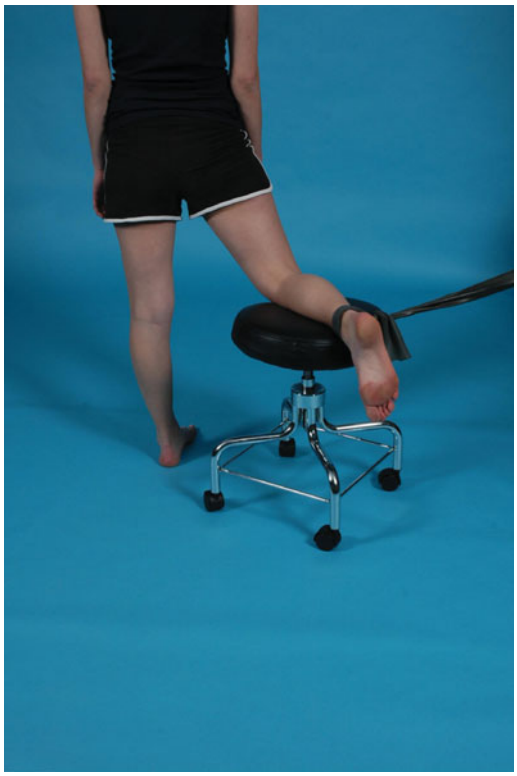

FIGURE 19-63 Stool rotations.

FIGURE 19-64 Clam shell progression.

FIGURE 19-65 Clam shell progression.

FIGURE 19-66 Clam shell progression.

- Pool walking, swimming, and kicking may also be incorporated if available.

FIGURE 19-67 Clam shell progression.

FIGURE 19-69 Supine bent knee bridge walk-outs—end position.

Neuromuscular reeducation exercises for the hip are prescribed to emphasize specific movement patterns and sequencing of muscle contractions. These exercises demand a high level of control and coordination.[168–171] Ambulation activities can be used initially, progressing to more difficult unilateral extremity exercises.

Task-oriented exercise programs (work hardening) should be instituted for the patient who intends to resume

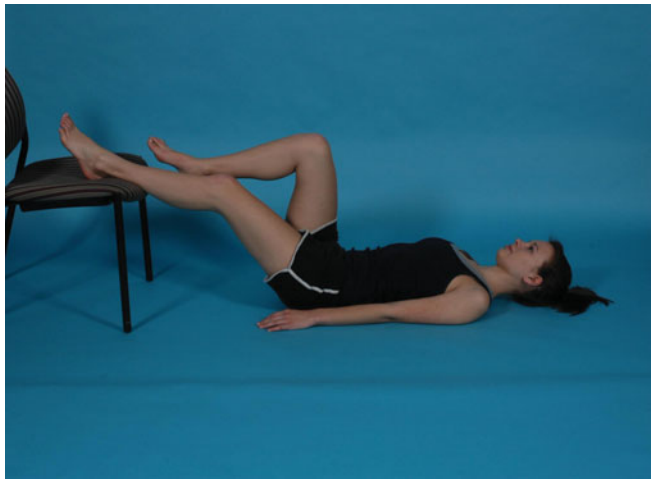

FIGURE 19-70 Supine single-leg chair bridge—start position.

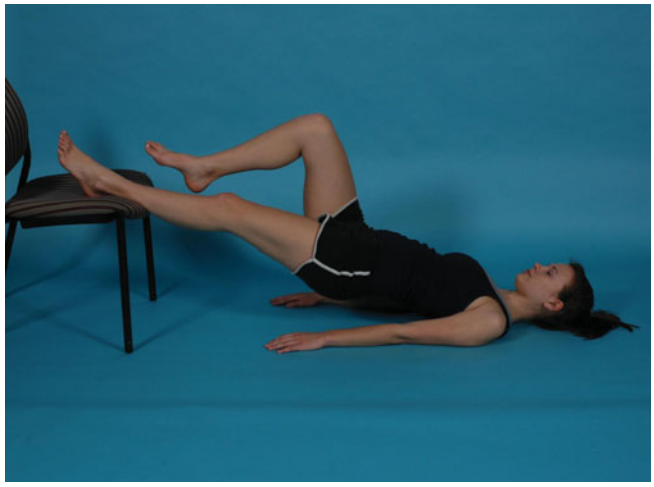

FIGURE 19-71 Supine single-leg chair bridge—end position.

a type of employment that requires a predetermined level of work performance. A more aggressive protocol needs to be adopted for the returning athlete. These exercise programs attempt to incorporate activities that simulate the actual circumstances and patterns of contraction used in the sport.[70,172] Examples of two such protocols are outlined in Tables 19-16 and 19-17.

Practice Pattern 4A: Primary Prevention/Risk Factor Reduction for Skeletal Demineralization

Idiopathic transient osteoporosis of the hip

Osteoporosis is the most prevalent bone disease among the aging population, and osteoporotic hip fractures account for substantial morbidity, mortality, and health-care costs.[173] Two types of osteoporosis are distinguished on the basis of age of presentation[174] and differing rates of loss of cortical or trabecular bone.[175] Type I is characterized by vertebral fractures in postmenopausal women at about the age of 65 years; type II may occur in both sexes at about 75 years of age and produces mainly osteoporotic hip fractures.[175]

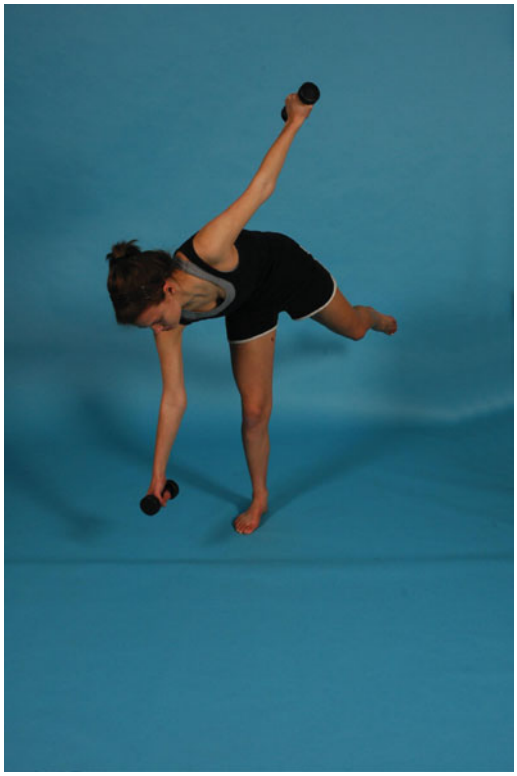

FIGURE 19-72 Unilateral good mornings with rotations.

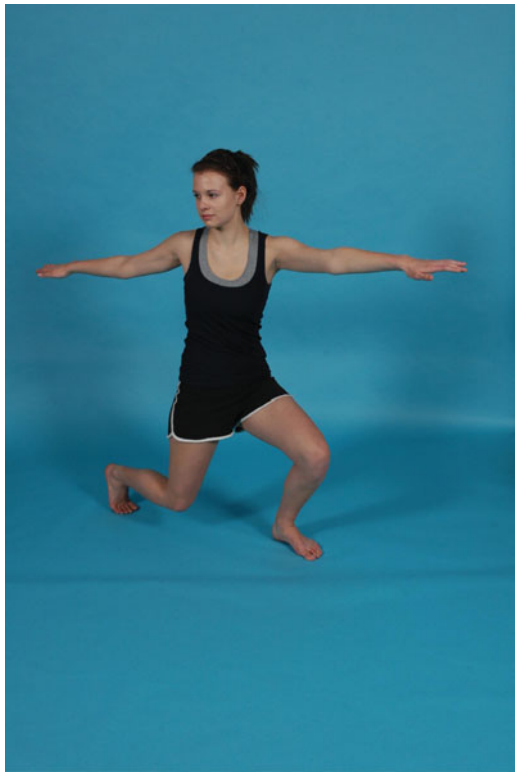

FIGURE 19-74 Lunge with torso rotations.

Men with osteoporosis of the hip are likely to have an underlying metabolic abnormality contributing to bone loss. The most common etiologies in men are hypogonadism, alcohol and corticosteroid use, anticonvulsant use, malabsorption syndromes, hyperthyroidism, and neoplasias.[176] Many factors have been cited for women, including decreased bone mass with an accelerated loss after menopause, parity, smoking, alcohol consumption, various medications, and diet. Although the reasons are unclear, in male patients either hip may be involved, whereas in women, the left hip is involved much more frequently.[177]

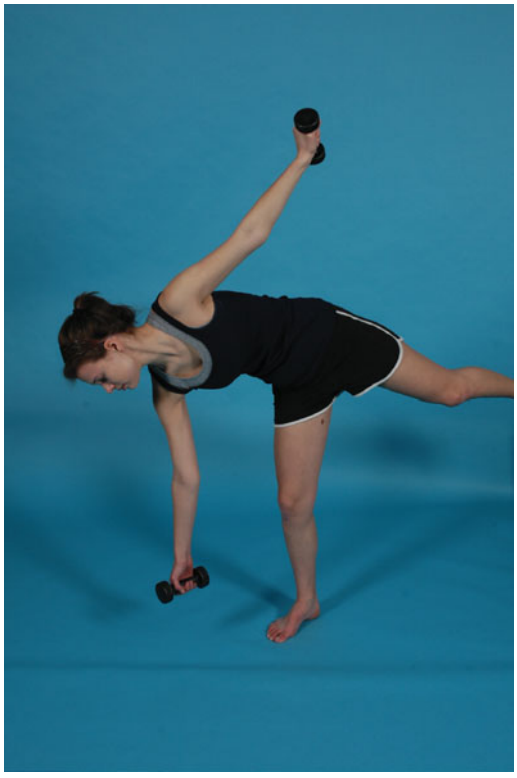

FIGURE 19-73 Unilateral good mornings with rotations.

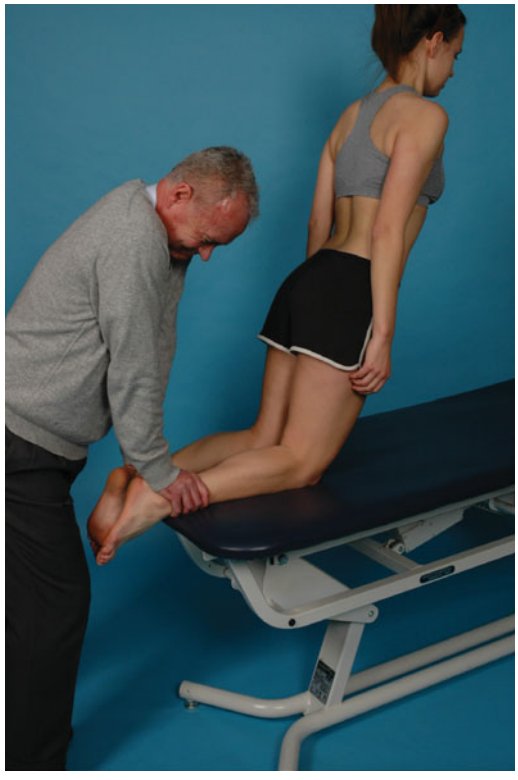

FIGURE 19-75 Hamstring lowers.

FIGURE 19-76 Grapevine stepping.

Hip pain begins spontaneously, without an antecedent history of trauma. The condition is aggravated by weight-bearing. The symptoms may become severe enough to result in a limp. The clinical findings are self-limiting and resolve in 2–6 months without permanent sequelae.[177] Biopsy of the synovium reveals normal findings or slight (mild, minimal, or equivocal) chronic inflammation.[178]

Radiographic findings are characteristic and become apparent within weeks or months of the onset of clinical findings. Osteoporosis is not usually found in the acetabulum but may be seen in the femoral neck. Progressive and marked osteoporosis of the femoral head is identified on plain radiographs.[178] The joint space is normal and the femoral subchondral bone is usually intact.

The differential diagnosis includes avascular necrosis, OA, septic arthritis, and rheumatoid arthritis.[178] The intervention for osteoporosis is discussed in Chapter 5.

Practice Pattern 4D: Impaired Joint Mobility, Motor Function, Muscle Performance, and ROM Associated with Connective Tissue Dysfunction

Osteoarthritis

OA involves a focal loss of articular cartilage with variable reaction of the subchondral bone. The prevalence of hip OA ranges from 7 to 25% in adults aged 55 years and older in the

TABLE 19-16 Return to Sport for Runners Following Soft Tissue Injury

Aerobic capacity and endurance

Cycling

- Incorporating appropriate warm-up and cool-down intervals, cardiovascular conditioning may be performed on stationary bicycle as symptoms permit or regular
- Attention to proper bike fit is important, as hip and back pain may result from improper biking biomechanics.
- If biking has not been used as a cross-training method in the past, an appropriate base building period is necessary:
- 3–5 min warm-up at 70–90 rpm, at 55–65% of age-estimated maximum heart rate.
- 10–15 min at 80–90 rpm, at 70–75% of age-estimated maximum heart rate, building this phase at no more than 3–5 min per session, as symptoms and cardiovascular condition permit.
- 3–5 min cool-down at 70 rpm, at 55–65% of age-estimated maximum heart rate.

Aqua jogging

- Deep-water jogging has been shown to be an effective mode of cross-training for runners, with good specificity of carryover.
- Use of a flotation device (Wet Vest) will enhance the comfort of beginners.
- Appropriate warm-up and cool-down intervals should be incorporated, as well as a base building period if this is an unfamiliar activity.

Running

As soon as symptoms permit, a return to running should be initiated. This should consist of level-ground or treadmill running at first, at a speed that brings the heart rate no higher than 60% of age-estimated maximum (warm-up pace), for durations that do not exacerbate symptoms (generally less than 15 min). As symptoms permit, duration (mileage) should be increased by no more than 10% per week. Once a substantial base of mileage has been built with no return of symptoms, the addition of speed-specific training may be incorporated. This may consist of "fartlek" (short bursts of acceleration within a longer run) or "tempo" (runs of longer duration at or near race pace), or it may be more regimented intervals using a track and stopwatch.

- For marathoners, the distance covered on any interval may range from 400 m at 10K race pace to 3–5 miles at marathon race pace.
- For shorter-distance runners, the intervals would be relatively shorter. For example, a 10K racer may do intervals of 100–400 m at 5K-race pace and 400 m up to 2 miles at 10K-race pace.

Speed-specific intervals should be performed no more than once per week initially and should be pursued cautiously. Total speedwork distance should make up no more than 10% of total weekly mileage.

Additional strengthening may be obtained with the incorporation of hill repeats.

(Continued)

TABLE 19-16 Return to Sport for Runners Following Soft Tissue Injury *(Contiinued)*

Specific hill training should be performed no more than twice per week and pursued cautiously.

- Monitoring of heart rate will assist in avoiding excessive speed on the uphill.
- Maintaining proper form on the downhill will reduce risk of impact injuries.
- To avoid overuse injury, periodization of mileage, terrain, interval training, proper footwear, etc., is crucial. For example, the following beginning marathon training schedule demonstrates good periodization of intensity, duration, and terrain:
  - Sun: 10 miles at 70% of age-estimated maximum heart rate on rolling trails.
  - Mon: 3 miles at 70% of age-estimated maximum heart rate on rolling hills.
  - Tues: 6 miles at 70% of age-estimated maximum heart rate on rolling hills.
  - Wed: Off or alternate form of training (e.g., swimming and biking)
  - Thurs: 5 miles, consisting of 1-mile warm-up, 2–3 miles of interval work at 80–85% of age-estimated maximum heart rate, and 1-mile cool-down (track).
  - Fri: 3 miles at 70% of age-estimated maximum heart rate on flat pavement.
  - Sat: Off or alternate form of training.

Balance/proprioceptive re-education

Balance/reach drills

The following exercises are performed at three to five sets of 10–15 reaches:

- Unilateral stance balancing, reaching one or both arms in various directions to maximum distance, avoiding use of other leg for counterbalance. Additional challenges can be added by holding a light weight or medicine ball or by using resistive tubing.
- Anterior reach: the anterior reach stimulates hamstrings, soleus, gastrocnemius, and hip/back extensors (depending on height of reach).
- Posterior overhead reach: the posterior overhead reach stimulates the gluteals, quadriceps, and hip/back extensors.
- Rotational reach to side: this reaching exercise stimulates the gluteals, quadriceps, trunk stabilizers, hip abductors, and abdominals.

Strengthening

Open-kinetic chain exercises

The following exercises are performed using weight machines, cuff weights, or resistive tubing, at three to five sets of 15–18 repetitions:

- Hip flexion
- Hip extension
- Hip abduction
- Hip adduction

Closed-kinetic chain functional exercises

The following exercises are performed: three to five sets of 15–18 repetitions, observing for deterioration of proper form because of fatigue.

Squats. Progression is made from mini-squats to deeper squats as symptoms permit, with additional challenges from additional weight.

Lunges. Progression is made from straight anterior/posterior and lateral lunges to rotational lunges as appropriate, increasing distance lunged or using additional weight as appropriate.

Step-ups/step-downs. Variations are made with step height and direction of step (lateral, anterior, posterior, or rotational) as appropriate, with additional challenges of increasing distance from step or use of additional weight as appropriate.

Flexibility

Flexibility exercises

These exercises are performed once the athlete has warmed up, for example after walking at least 3–5 min, or after a warm shower or bath. Emphasis should be on proper technique and form. The stretch should be held for at least 15–30 s.

The patient performs three to five repetitions of each stretch on both sides on a regular basis.

- Gastrocnemius/soleus
- Hamstrings
- Quadriceps
- Gluteals
- Psoas

Data from Schunk C, Reed K: *Clinical Practice Guidelines*. Gaithersburg, MD: Aspen, 2000.

TABLE 19-17 Return to Sport Following Osteitis Pubis

Phase I

1. Static adduction against soccer ball placed between feet when lying supine; each adduction is held for 30 s and is repeated 10 times.
2. Abdominal sit-ups performed both in straight direction and in oblique direction. The patient performs five sets to fatigue.
3. Combined abdominal sit-up and hip flexion (crunch). The patient starts from supine position and with a soccer/basketball placed between knees. The patient performs five sets to fatigue.
4. Balance training on wobble board for 5 min.
5. One-foot exercises on sliding board, with parallel feet as well as with a 90-degree angle between feet. Five sets of 1-min continuous work are performed with each leg, and in both positions.

Phase II (from third week)

1. Leg abduction and adduction exercises in side lying. The patient performs five series of 10 repetitions of each exercise.
2. Low-back extension exercises while in prone over the end of treatment table. The patient performs five series of 10 repetitions.
3. One-leg weight-pulling abduction/adduction standing. The patient performs five series of 10 repetitions of the exercise for each leg.
4. Abdominal sit-ups both in straightforward direction and in oblique direction. The patient performs five sets to fatigue.
5. One-leg coordination exercise, flexing and extending knee and swinging arms in same rhythm (cross-country skiing on one leg). The patient performs five sets of 10 repetitions for each leg.
6. Skating movements on sliding board. This is performed five times for 1-min continuous work.

Data from Holmich P, Uhrskou P, Ulnits L, et al: Effectiveness of active physical training as treatment for long-standing adductor-related groin pain in athletes: Randomised trial. *Lancet* 353:439–443, 1999.

white European population.[179] Studies of the natural history of hip OA clearly demonstrate heterogeneity of disease progression, and the lack of a universal agreement as to the definition of progression of hip OA. Most define progression by radiological features such as loss of joint space, osteophytes, and sclerosis.[180,181] However, the demonstration of a correlation between radiographic features and clinical symptoms is not easy in OA: factors differentiating symptomatic OA from asymptomatic disease are unknown.[182] The two clinical sequelae of OA are joint pain and functional impairment.

Hip OA usually begins insidiously, although in a few cases it may start abruptly. The development of OA at any joint site depends on a generalized predisposition to the condition and abnormalities of biomechanical loading, which act at specific joints.[183] Individual risk factors, which may be associated with a generalized vulnerability to the disorder, include family history, obesity, and hypermobility of the joint.[182] Those that reflect local biomechanical insults include minor trauma to an already diseased joint, abnormalities of joint shape, and physical activity.[182]

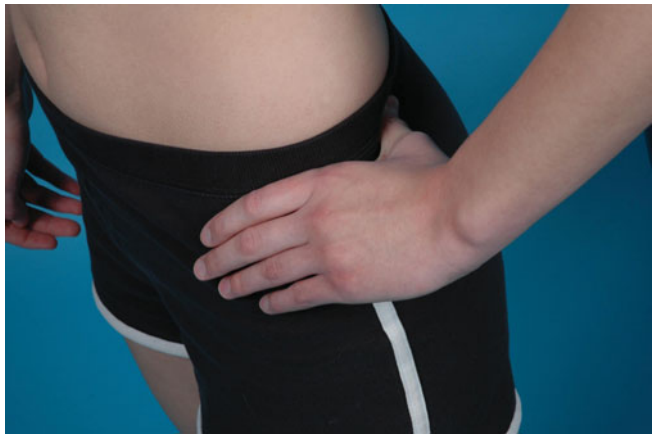

FIGURE 19-77 The C sign.

The pain of hip OA can vary greatly in both its site and its nature, sometimes making early diagnosis difficult.[184] The pain may be felt in the buttock, groin, thigh, or knee and varies in character from a dull ache to sharp and stabbing. The C sign (Fig. 19-77) may be encountered when asking the patient describe the location of the pain—the patient will cup the hand above the greater trochanter with the thumb posterior and the fingers gripping deep into the anterior groin when describing deep interior hip pain.[185] The discomfort associated with hip OA is generally related to activity and the bouts of pain can last for several hours.[184] Stiffness of the hip is usual, particularly after inactivity, and can be the presenting feature. As the disease progresses, the patient experiences difficulty in climbing stairs with the involved leg and may have difficulty in donning socks or stockings.[186] In advanced cases of the disease, the patient may complain of severe pain that is present at night or during rest, and there is a marked decline in the participation of recreational activities.

Early physical signs include restriction of internal rotation and abduction or flexion of the affected hip, with pain at the end of the range.[184] Birrell et a1.[111] notes that as the number of restricted planes of hip motion increases, the specificity, or ruling in of the diagnosis of hip OA, increases. As specificity increases, sensitivity, or the ruling out of a diagnosis of hip OA, decreases in those patients with mild-to-moderate and severe OA of the hip.[111,116] This trade-off, where sensitivity decreases while specificity increases, is common with sensitivity and specificity.[116] The diagnostic value of decreased ROM in the hip is best when present in two or three planes of motion (positive likelihood ratio of 2.5–5), as compared to just one plane of motion (positive likelihood ratio of 1.9).[111,116]

A diagnosis of hip OA can usually be confirmed by radiography; joint space width of 2.5 mm or less indicates substantial loss of cartilage in the hip joint, and osteophytes, subchondral bone sclerosis, or cysts are usually present.[184] As mentioned, though, radiographs can be misleading because of the relative insensitivity of the their findings with clinical signs and symptoms. Two separate studies by Bierma-Zeinstra et al.[187] and Altman et al.[188] examined the relationship between patients with clinical signs and symptoms of hip OA and radiographic findings. The clinical diagnosis of early hip

OA according to Bierma-Zeinstra et al.[187] includes such variables as decreased external rotation, no pain aggravation with sitting, and over 60 years of age. The criteria from the Altman et al. study included hip internal rotation less than 15 degrees and an age of over 50 years. Diagnostic measurement properties, like sensitivity, specificity, and likelihood ratios, are probabilistic statistics; consequently, false-positive and false-negative results will always be potentially possible.[116]

The narrowing of the joint space associated with OA could potentially slacken the supporting ligaments, rendering them less effective and producing changes in proprioceptive input. Indeed, OA of the hip has been associated with deficits in a patient's proprioception and balance.[189,190] The joint space narrowing may also result in a relative decrease in the length of the muscles that cross the hip joint, which could feasibly result in a mechanical disadvantage of the muscles that act on the hip joint. In addition, OA of the hip can have many manifestations in neighboring joints, particularly the lumbar spine and the foot. This is likely because the joint stiffness associated with the disease diminishes the amount of rotation available at the hip, forcing the lumbar spine and foot to compensate for this loss.

Systematic reviews have concluded that exercise reduces the pain and disability associated with hip OA. Weigl et al.[191] demonstrated that strengthening exercises, flexibility, relaxation, and endurance training decreased pain and improved physical function in patients with OA.[116] van Baar and colleagues[192] showed that exercise improved function and reduced pain in patients with hip OA, but later found that the beneficial effect of exercise declined over time.[116,193] Research on the use of manual physical therapy in the treatment of hip OA is limited. Hoeksma and colleagues,[194] in a randomized clinical trial comparing the effectiveness of two different therapy programs in a group of patients with hip OA, demonstrated the superiority of manual physical therapy plus exercise over exercise alone for improving pain and ROM. MacDonald and colleagues,[195] in a case series describing the outcomes of individual patients with hip OA treated with manual physical therapy and exercise reported that all patients exhibited reductions in pain and increases in PROM, as well as a clinically meaningful improvement in function. The inherent limitations of the case series, however, do not allow for the identification of a cause-and-effect relationship. Further research, including randomized clinical trials, is necessary to uncover the exact effect of manual physical therapy and exercise in the treatment of hip OA.[195]

Based on the above research, the intervention goals for hip OA include relieving symptoms, minimizing disability, and reducing the risk of disease progression.[184] Intervention in the earlier stages includes:

- Patient education and empowerment through advice about what patients can do for themselves. Patients are often frightened that use of the hip will "wear out" an already damaged joint and feel they need "permission" to use it.[184] Evidence suggests that the involved joint will benefit from regular loading to help maintain its integrity.
- Modalities for muscle relaxation, pain relief, and anti-inflammation.
- Modification of ADL and self-care. Patients need to learn an appropriate balance and intersperse periods of activity with rest, as prolonged or heavy activity involving the diseased hip may cause further damage.[196]
- It is important to maintain a full range of hip movement, if possible. In addition to specific exercises for hip ROM, recreations such as swimming or cycling may help. Contact sports and activities such as jogging, which can cause repetitive high impact loading of the hip, are probably best avoided.[196]
- Diet and weight. There is no evidence for the involvement of any dietary factor in the etiopathogenesis of hip OA.[184] However, it is possible that obesity may accelerate progression or cause more pain. A reduction in weight can significantly improve a patient's symptoms, increase mobility, and improve health status.[197]
- Many people with arthritis of the spine or legs are more comfortable wearing trainers or other shoes with good shock-absorbing properties than they are in regular footwear. Sorbithane and other shock-absorbing insoles, which are available in sports and shoe shops, may be helpful.[184]
- A simple walking stick can make a big difference, reducing loading on a hip by 20–30%, but attention must be given to its length, characteristics, and use. In most cases, it will be most beneficial if it is held on the uninvolved side of the body and that it comes to the top of the pelvis and has a good ferrule and comfortable handle.[184]

The patient should be advised

- to engage in adequate warm-ups before exercising;
- to pay attention and respect the limitations of their body and not exercise if in discomfort;
- not to use medication to cover up pain from exercising.

Other measures include:

- manual techniques to mobilize the joint and passive stretches of the capsule, particularly distractive techniques.[195] Following these techniques, a fairly vigorous stretching program into flexion, abduction, and external rotation should be initiated. The FABER position, or cross-legged sitting, is ideal for this. Stretching the hip joint capsule involves maintaining the stretch for as long as an hour.
- strengthening exercises for the trunk stabilizers and the major muscle groups of the hip region, especially the gluteus medius.

The surgical intervention for advanced OA of the hip is addressed later in the chapter.

Rheumatoid arthritis

Rheumatoid arthritis is a systemic, inflammatory, and chronic disorder of unknown etiology, which is characterized with periods of exacerbation and remission, and which eventually result in destruction of the joint surfaces and progressive disability.[186]

In the early phases of the disease, systemic manifestations such as malaise, weight loss, and ability fatigue are seen.[186] The

patient typically experiences vague pain and stiffness in the hip, especially when arising from bed in the morning. With time, the stiffness and pain becomes more severe and persistent and is accompanied by protective muscle spasms. Eventually, a hip flexion contracture develops.

Conservative intervention involves pharmacologic management and active exercises of the hip within the limits of pain to preserve joint motion and maintain good muscle tone.[186] The activity modifications outlined for OA of the hip are also advocated during periods of remission. The patient is instructed on joint protection skills and to take frequent breaks.

Ankylosing spondylitis

Ankylosing spondylitis (AS), also known as Marie–Strümpell disease or rheumatoid spondylitis, is a form of inflammatory arthritis, usually characterized by initial involvement of the sacroiliac joints, later involvement of the spinal joints, and occasional involvement of the hip joints and other joints of the body (refer to Chap. 5).[186] The patient is usually between 15 and 40 years, and AS affects one to three per 1000 people. Although males and females are affected evenly, mild courses of AS are more common in the latter.[198] Clinical findings in the hip may include an early capsular pattern of motion restriction.

An exercise program is particularly important for these patients to maintain functional outcomes (see Chap. 5).[199] The goal of exercise therapy is to maintain the mobility of the involved joints for as long as possible and to prevent stiffening. A strict regime of daily exercises, which include positioning and spinal extension exercises, breathing exercises, and exercises for the peripheral joints must be followed. Several times a day, the patient should lie prone for 5 minutes to help maintain hip and spinal extension, and they should be encouraged to sleep on a hard mattress and avoid side lying. Swimming is the best routine sport.

Avascular necrosis of the femoral head

Avascular necrosis of the femoral head is a condition in which there is progressive ischemia and secondary death of osteocytes or bone cells of the femoral head, resulting in the collapsing of bone of the femoral head and the later development of degenerative arthritis.[186] Avascular necrosis of the femoral head is described in more detail in Chapter 5.

Acetabular labral tear

Labral tears of the hip are more common than previously thought.[18] In the last 15 years, there have been numerous studies on the location and anatomical features of acetabular labral tears, including cadaver, arthroscopic, and MRI studies.[200] In studies of people with a tear of the labrum, researchers have attributed the injury to a variety of causes.[201] Direct trauma, sporting activities, and certain movements of the hip including torsional or twisting movements have been cited to cause labral tears.[201] However, a large percentage of labral tears are not associated with any known specific event or cause. Two common types of mechanisms have been recognized:

1. A young person with a twisting injury to the hip, usually an external rotation force in a hyperextended position.
2. An older person with a history of hip and/or acetabular dysplasia, or the result of repeated pivoting and twisting.

Acetabular labral tears represent the most common cause for mechanical hip symptoms—in a recent study, they were found to be the cause of groin pain in more than 20% of athletes presenting with groin pain.[202]

Labral tears can be classified according to location, etiology, and type[203]:

- ***Location.*** With respect to location, tears can be anterior, posterior, or superior (lateral), although anterior and anterosuperior tears appear to be the most common.[203] Anterior labral tears are also common in patients with degenerative hip disease or acetabular dysplasia. The most likely reason for the prevalence of anterior labral tears is that this region is subjected to higher forces or greater stresses than other regions of the labrum.[201] Because of the anterior orientation of both the acetabulum and the femoral head, the femoral head has the least bony constraint anteriorly and relies instead on the labrum, joint capsule, and ligaments for stability.[201]
- ***Etiology.*** With respect to etiology, tears can be degenerative, dysplastic, traumatic, or idiopathic. Degenerative tears can also be seen in association with inflammatory arthropathies.
- ***Type.*** Labral tears have been classified into four types: radial flap (the most common type), radial fibrillated, longitudinal peripheral, and abnormally mobile.[204] Seldes et al.[27] classified acetabular labral tears into type 1 and type 2 on the basis of their anatomical and histological features.
  - Type 1 tears consist of detachment of the labrum from the articular cartilage surface. These tears tend to occur at the transition zone between the fibrocartilaginous labrum and the articular hyaline cartilage.[27] They are perpendicular to the articular surface and, in some cases, extend to the subchondral bone.
  - Type 2 tears consist of one or more cleavage planes of variable depth within the substance of the labrum.[27]

Both types of tears are associated with chondrocyte proliferation and hyalinization of the labral fibrocartilage along the edges of the defect. All labral tears are associated with increased microvascularity within the substance of the labrum at the base of the tear adjacent to the labrum's attachment to bone.[26] Osteophyte formation is also sometimes seen within the labral tears.

Diagnosis can be made on the basis of the history and physical examination. However, it must be remembered that labral tears can have a variety of clinical presentations associated with a wide degree of clinical findings.[26]

- ***History.*** Since a labral lesion produces a decrease of pressure within the joint and causes an increase in the laxity of that joint, symptoms of a labral tear are usually mechanical: buckling, twinges, locking, instability, and painful clicking. There may or may not be a history of trauma. In the presence of a recalled incident, the trauma can vary from severe to very mild.[26] The injury is usually caused by the hip joint being stressed while in rotation. The pain is mainly in the anterior groin (most commonly) but can be in the thigh and/or medial knee, trochanteric, or buttock region.[26] It can have an acute onset or be gradual, and it is common for it to be sharp with a clicking, snapping, catching, or locking sensation.[26] Activities that involve

forced adduction of the hip joint in association with rotation in either direction tend to aggravate the pain.[26]

- ***Physical examination.*** On examination, ROM of the hip may not be limited, but there may be pain at the extremes.[26] There is little information regarding the sensitivity, specificity, or likelihood ratios associated with a single clinical test or a cluster of tests in diagnosing a labral tear.[204] Generally speaking, the combined movement of flexion and rotation causes pain in the groin. More precisely, the specific maneuvers that may cause pain in the groin include:[205]
  - flexion, adduction, and internal rotation of the hip joint (impingement test/scour test) while it is held in at least 90 degrees of flexion and at least 15 degrees of abduction—positive with anterior—superior tears, anterior labral tears, and iliopsoas tendinitis;
  - passive hyperextension, abduction, and external rotation (with posterior tears), with the patient lying supine at the edge of the table; a positive finding with this test is apprehension or exquisite pain and suggests anterior hip instability, an anterior labral tear, or posteroinferior impingement;
  - resisted straight-leg raise test;
  - flexion of the hip with external rotation and full abduction, followed by extension, abduction, and internal rotation (anterior tears)[206];
  - extension, abduction, and external rotation brought to a flexed, adducted, and internally rotated position (posterior tears).[206]

In general, the clinician should suspect an acetabular labral tear when a patient has the following combination of signs and symptoms:

- no restrictions in ROM
- normal radiographs
- complaints of a long duration involving anterior hip or groin pain and clicking
- pain with passive hip flexion combined with adduction and internal rotation
- pain with an active straight-leg raise[201]

The diagnosis is typically confirmed with arthrography, MRI with intravenous or intra-articular administration of contrast medium, or arthroscopy.[17]

The appropriate physical therapy intervention for a patient with an acetabular labral tear has yet to be established.[201] Conservative intervention has traditionally included bed rest with or without traction, followed by a period of protected weight-bearing and use of nonsteroidal anti-inflammatory medication. Lewis and Sahrmann[201] recommend the use of key elements of the examination to develop a plan of intervention (Table 19-18). Operative treatment consists of arthrotomy or arthroscopy with resection of the entire labrum or the portion of the labrum that is torn. Postoperatively, the protocol can be divided into three phases[202,206,207]:

Phase 1 (days 1–7):

- Weight-bearing to tolerance with crutches.
- Isometric quadriceps, gluteal sets.
- AROM in all planes of motion.
- Closed-chain bridging, weight shifts, and balancing exercise.
- Open-chain standing abduction, adduction, flexion, and extension with no resistance.
- Avoidance of straight-leg raise exercises.

Phase 2 (weeks 2–3):

- Progress off crutches and normalize gait.
- Progress ROM exercises to gradual end-range stretch within tolerance.
- Stationary bike, if tolerated.
- Open-chain above the knee-resistive theraband or light pulley exercises.

Phase 3 (weeks 4–6):

- Continue flexibility exercises.
- Progress resisted strengthening and closed-chain exercises.
- Functional activities introduced as tolerated.

Femoral acetabular impingement

Femoral acetabular impingement (FAI) occurs when there is decreased joint clearance between the femur and the acetabulum.[204] Two types of FAI have been described: cam and pincer.

- Cam. Cam impingement occurs when the femoral head has an abnormally large radius, with a loss of the normal spherical junction between the femoral head and the neck. This deformity causes abnormal contact between the femur and the acetabulum, particularly when hip flexion is combined with adduction, and internal rotation. The cam impingement has been implicated in the etiology of anteriosuperior labral and chondral lesions.
- Pincer. The pincer type of impingement is caused by an abnormal acetabulum with increased overcoverage. This overcoverage can be general (coxa profunda) or local anterior (acetabular retroversion).

Pincer impingements are thought to be more common in middle-aged women participating in athletics, while cam impingements are more common in young athletic males.

Loose bodies

In advanced cases of OA, the hip joint becomes susceptible to loose bodies of cartilage or bone within the joint. If the loose body is large enough, it will cause a distraction in the joint, which will produce muscle inhibition and problems with gait and weight-bearing.

The patient typically reports sudden leg pain twinges with weight-bearing and periodic giving way of the leg. Clinical findings include a springy end-feel in the hip during passive hip extension (the close-packed position of the joint), which is often painless.

Confirmation and intervention usually involves arthroscopic techniques to identify and then remove the loose body.

The limping child

Examination and evaluation of the pediatric hip is very difficult because of the many changes the joint undergoes

TABLE 19-18 Conservative Intervention for Acetabular Labral Tears Based on Examination Findings

Examination	Intervention
Positions and movement tests	Standing alignment, particularly noting the presence of hip hyperextension, as evident in the hyperextension or pelvic posterior tilt, or both In a sitting position, femoral motions accompanying the extension Precision of both active and passive hip flexions In the prone position, the pattern of hip extension as an indication of the relative participation of the hamstring and gluteus maximus muscles Effect of passive knee flexion on femoral motion in the prone position Pattern and range of hip rotation in prone and sitting positions; this assessment includes asymmetric ranges, suggesting the presence of femoral anteversion or retroversion In the quadruped position, the alignment of the hip joint and the presence of symptoms both while in the position and when rocking backward toward the heels
Muscle strength (force-generating capacity of muscle) and pattern of control	Hip abductor, gluteus maximus, iliopsoas, and deep external rotator muscles when not painful; the deep external rotator muscles are best tested with the hip flexed
Muscle length and stiffness	Medial and lateral hamstring muscles
Gait assessment	Particularly noting a lack of appropriate knee flexion at heel strike and early stance phase, prolonged foot flat during stance, and knee hyperextension that causes hip hyperextension Walking with the hip in external rotation as an improper correction of femoral anteversion
Modification of functional activities	Avoid sitting ▶ with knees lower than hips; ▶ with legs crossed or sitting on legs so that the hip is rotated; ▶ on the edge of deceit and contracting hip flexor muscles; ▶ with pressure on the femur, which can cause forces into the hip joint; instead, the pressure should be on the ischial tuberosity. When getting up from a chair that is behind a desk or out of the car, patients should avoid pushing or rotating the pelvis on a loaded femur. When walking on a treadmill, patients must be careful not to let the moving tread contribute to excessive hip hyperextension. Patients should avoid weight training of quadriceps femoris and hamstring muscles and avoid any exercises causing hip hyperextension

Data from Lewis CL, Sahrmann SA: Acetabular labral tears. *Phys Ther* 86:110–121, 2006.

throughout development. With infants, myelomeningocele (spina bifida), arthrogryposis, and development dysplasia of the hip (DDH) are the major concerns. Hip conditions to consider in children include the potentially serious diseases: bone or joint sepsis, primary or metastatic tumors of the bone, Legg–Calvé–Perthes disease, and slipped femoral capital epiphysis (see Chap. 30). A more benign cause for the limp is "irritable hip"/transient synovitis. A proportion of limping children will have a preceding history of injury, but often this is absent. The main concerns are not to miss serious pathology and to begin appropriate management for the underlying condition.

The watershed age for prognosis of pediatric hip conditions is 8 years old. This is the age when most acetabular development is complete.[4] In children younger than 8 years of age, deformities in the femoral head as a result of a disease process such as Perthes disease or osteonecrosis secondary to the intervention of DDH may be accommodated for by secondary changes in acetabular development.[4] After 8 years of age, accommodation of acetabular shape to a deformed femoral head may not be possible.

The flexion–adduction test (see "Special Tests") can provide an early indication of underlying hip disease, often before any noticeable or measurable change in abduction, internal rotation, or total flexion arc.[142]

It is often the first quadrantric movement to be restricted.[208,209]

Transient Synovitis. This is the most common cause of hip pain and of limp in preschool and early grade school-age children. Transient synovitis is also known as toxic synovitis, irritable hip, and observation hip. The child usually presents with a limp of acute onset, with no history of an inciting episode. There is usually unilateral pain at the hip, knee, or thigh and the child may refuse to move the involved leg in any direction because of pain. If ROM can be examined, it is usually limited in abduction and internal rotation, although with gentle, slow ROM it is possible to obtain full passive range of the hip. The intervention for transient synovitis is decreased

weight-bearing for 1–2 weeks, along with nonsteroidal anti-inflammatory drugs (NSAIDs). The condition should be self-limiting unless there is a more serious condition such as septic arthritis or juvenile rheumatoid arthritis present.[210]

Integration of Practice Patterns 4C and 4D: Impaired Joint Mobility, Motor Function, Muscle Performance, and ROM Associated with Muscle Performance Because of Impaired Muscle Performance and Connective Tissue Dysfunction

Snapping hip (Coxa saltans)

Multiple etiologies for snapping hip (coxa saltans) exist. The etiologies are categorized as internal, external, or intraarticular.[211,212]

1. The internal type has been attributed to
   a. the iliopsoas snapping over structures just deep to it, namely the femoral head, proximal lesser trochanter, pectineus fascia, and iliopectineal eminence, which produces a snapping in the anterior groin region[213–216];
   b. stenosing tenosynovitis of the iliopsoas insertion.[217]
2. The external causes include snapping of the ITB or gluteus maximus over the greater trochanter.[213,215,216,218–220] This condition is more common in females with a wide pelvis and prominent trochanters and is exacerbated with running on banked surfaces.[221]
3. The intra-articular causes have included synovial chondromatosis, loose bodies, fracture fragments, and labral tears.[222–224] Snapping of the iliofemoral ligament over the anterior femoral head has also been described,[214,225,226] as has snapping of the long head of biceps origin over the ischium.[227]

When no cause can be identified, as in most patients, the condition is classified as a myopathy of idiopathic origin.

Particular areas of attention during the examination include observation of genu recurvatum, leg length, knee flexion contracture, overpronation of the foot, hip flexion contracture, and the amount of internal or external rotation of the lower extremity during static standing.

The intervention is based on etiology. If an imbalance of the TFL or iliopsoas is producing the symptoms, the intervention is focused on reconditioning and prevention. This includes increasing the flexibility of the soft tissues, and the correction of any strength imbalances. For example, if the flexibilty of the ITB is decreased, the emphasis is on stretching the ITB.

Flexion contracture

A flexion contracture at the hip is a common occurrence. Hip flexion contractures can result from

- adaptive shortening of the iliopsoas muscle or rectus femoris muscles;
- contracture of the anterior hip capsuloligamentous complex.

These changes to the soft tissue and connective tissues around the hip can result from OA, injury, or sustained postures involving hip flexion.

The resulting anterior rotation of the pelvis shifts the weight-bearing of the hip to a thinner region of hyaline cartilage, in both the femur and the acetabulum, and places the hip extensors in a state of low-level tension.[18]

Flexion contractures can be diagnosed using the Thomas test (see "Special Tests").

The intervention for the contracture is based on the cause. Adaptive shortening of the contractile tissues may be addressed using muscle energy, passive stretching, and myofascial techniques. Stretching of the capsuloligamentous complex is accomplished by grade III distraction mobilizations and by prolonged stretching.

Movement impairment syndromes of the hip

Three of the movement impairment syndromes detailed by Sahrmann in her excellent book, *Movement Impairment Syndromes*,[125] are described. The intervention for these syndromes focuses on the correction of muscle imbalances. The adaptively shortened structures are stretched and the weak muscles are strengthened.

Femoral Anterior Glide Syndrome. The characteristic findings for this condition result from an insufficient posterior glide of the femoral head during hip flexion. Typically, the patient complains of groin pain, particularly during hip flexion, gait, and running. The consequences of this syndrome are

- stretching of the anterior joint capsule and tightening of the posterior structures resulting in excessive hip extension ROM;
- an increase or decrease in the length of the hip external rotators;
- a decreased posterior glide of the femoral head;
- a decrease in length of the TFL on the involved side;
- weakness and lengthening of the iliopsoas on the involved side;
- dominance of hamstring activity over gluteus maximus activity, both of which are shortened.

Hip Extension with Knee Extension Syndrome. The characteristic findings for this condition result from an insufficient participation of the gluteus maximus during hip extension or the quadriceps during knee extension. Typically, the patient complains of pain at the hamstring insertion site on the ischial tuberosity and along the muscle belly, particularly during resisted hip extension, knee flexion, or both. The consequences of this syndrome are

- a decrease in hip flexion because of the hypertrophy of the hamstrings;
- dominance of hamstring activity over gluteus maximus activity;
- weakness of the gluteus maximus and hip external rotators;
- a decrease in the length of the hamstrings;
- an increase in the frequency of hamstring strains.

Femoral Accessory Motion Hypermobility. The characteristic findings for this condition result from early degenerative changes and increased compression at the hip joint

because of stretching forces on the rectus femoris and hamstrings. Typically, the patient complains of pain deep in the hip joint and anterior groin that may extend along the medial and the anterior thigh, particularly during gait. The consequences of this syndrome are

- a slight antalgic gait;
- internal rotation of the hip during single-leg stance;
- external rotation of the hip with passive knee flexion in prone;
- medial rotation of the femur with knee extension in sitting;
- stiffer rectus femoris and hamstrings as compared to the iliopsoas and intrinsic hip internal rotators;
- anterior hip joint pain with FABER test.

Practice Pattern 4E: Impaired Joint Mobility, Motor Function, Muscle Performance, and ROM Associated with Localized Inflammation

In addition to those conditions producing impaired ROM, motor function, and muscle performance attributed to inflammation, practice pattern E includes conditions that cause pain and muscle guarding without the presence of structural changes. Such conditions include

- sprains of the hip ligaments;
- strains of the hip muscles;
- internal derangements of the hip joint;
- periarticular syndromes: tendinitis, bursitis, capsulitis, and tenosynovitis;
- pubalgia.

Overuse injuries of the hip result from repetitive microtrauma that leads to inflammation and local tissue damage in the form of cellular and extracellular degeneration. This tissue damage can be cumulative, resulting in myositis, bursitis, joint synovitis, cartilaginous degeneration, stress fractures, and neuropraxic or axonal nerve injury. Successful intervention requires a correct identification of the injury.

Hip joint sprains

The classic history of a hip joint sprain is a vigorous twisting of the lower extremity or trunk.[228] Clinical findings include an inability to circumduct the leg because of pain.[229]

Conservative intervention includes an ACE wrap hip spica. Crutches are used for partial weight-bearing ambulation. The crutch walking continues until the patient is able to ambulate without pain.[230] The patient is progressed to strengthening and flexibility exercises, and the functional tests of hopping, sprinting, running backward, cutting, and pivoting in the athlete must be satisfactorily passed prior to return of play.[228]

Muscle strains

First- and second-degree muscle strains are frequent injuries in sports activities.[70] The adductors, iliopsoas, rectus abdominis, gluteus medius, and hamstrings muscles are commonly involved.

Gluteus Medius/Gluteus Minimus. Tendinosis and tears of the gluteus medius and gluteus minimus were a common finding in an MRI study of patients presenting with buttock, lateral hip, or groin pain.[231] Gluteus medius syndrome is manifested by tenderness to palpation of the gluteus medius muscle, which can be triggered by sudden falls, prolonged weight-bearing on one extremity for long periods, activity overuse, or sporting injuries. Most commonly, this condition is observed in middle-aged women who have embarked upon a vigorous walking program, or who have started working out at a health club. Patients may present with pain that is transient and worsening over a time period, a Trendelenburg gait, a leg-length discrepancy and weakness. These symptoms also affect runners, as there is tilting of the pelvis with running. Hip-abduction strengthening should be avoided in the initial stages of gluteus medius syndrome because it only provokes tendinitis. As the acute stage resolves, hip-abductor strengthening is important and is best achieved in the aquatic environment.

Adductor. The hip-adductor muscles, especially the adductor longus and magnus are the most frequent cause of muscle-induced groin region pain.[48,232] Adductor strains have been known to cause long-standing problems.[233]

There are a number of causative factors for an adductor strain, including fatigue or an abduction overload.[234] Laboratory studies have shown that strengthening exercises can protect these muscles from injury.[235]

Adductor strains are associated with running, jumping, and twisting activities, particularly when external rotation of the affected leg is an added part of the activity.[229] Soccer players with a history of forceful kicking are particularly vulnerable to an adductor strain. In fact, the incidence of groin pain among male soccer players is 10–18% per year.[236–238] Adductor muscle strains are also commonly encountered in ice hockey.[239–241] These sports require a strong eccentric contraction of the adductor musculature during competition.[242,243] Risk factors associated with adductor strains include an imbalance between strength and flexibility,[244] and an imbalance between adductor and abductor strength.[243]

The signs and symptoms that are easily recognizable[245]:

- Pain on palpation of the adductor tendons or their insertion on the pubic bone, or both
- Twinging or stabbing pain in the groin area associated with quick starts and stops
- Edema or ecchymosis several days postinjury
- Pain with passive abduction or manual resistance to hip adduction when tested in different degrees of hip flexion (0 degrees [gracilis], 45 degrees [adductor longus and brevis], and 90 degrees [if combined with adduction, pectineus])
- A possible palpable defect in severe ruptures accompanied by muscle guarding

Groin strains are graded as a first-degree strain if there is pain, a minimal loss of strength and minimal restriction of motion; second degree if there is compromise to the strength of the muscle, but not including complete loss of strength and function; and third degree if there is complete disruption of the muscle tendon units, including complete loss of function of the muscle.[246] The differential diagnosis includes abdominal muscle strains, inguinal hernia, osteitis pubis, piriformis syndrome, and referred pain from the hip joint (osteoarthrosis), rectum, or lumbar spine.

Conservative intervention involves the principles of PRICEMEM in the acute stage (see Chap. 8). This is followed by heat applications, hip-adductor isometrics, and gentle stretching during the subacute phase, progressing to a graded resistive program for the adductors, including concentric and eccentric exercises, PNF diagonal motions to promote balance strength and flexibility around the joint, and then a gradual return to full activity. As part of the rehabilitation program, any imbalance between the adductors, abductors, and the abdominals needs to be addressed. In addition, the clinician should examine the patient's technique in their required activity, as poor technique can overload and fatigue the adductors.

Sports Hernia. A sports hernia occurs when weakening of the muscles or tendons of the lower abdominal wall occur but there is no palpable hernia. The symptoms of a sports hernia are characterized by pain during sports movements, particularly twisting and turning during single-limb stance. The pain usually radiates to the adductor muscle region, although it is often difficult for patients to pinpoint. Any exertion that increases intra-abdominal pressure, such as coughing or sneezing can cause pain. Currently, no clinical special test exists with a high degree of specificity to diagnosis this condition so the diagnosis is based on the patient's history and clinical signs when all other causes are ruled out. Conservative treatment usually involves a short period of rest followed by an exercise program focusing on abdominal strengthening. If the conservative approach fails, surgical repair is required.

Iliotibial Band Friction Syndrome. An iliotibial band friction syndrome (ITBFS) can manifest itself at the hip and at the knee (see Chap. 20). At the hip, an ITB contracture can lead to trochanteric bursitis by increasing compression and friction of the sub gluteus maximus bursa between the ITB and the greater trochanter.[34] The classic test for ITB contracture is the Ober test. A comprehensive approach of soft tissue mobilization and hold/relax stretching of the ITB, rectus femoris, and iliopsoas is necessary to decrease the stresses on the bursa.

Iliopsoas. With the exception of the adductors and hamstrings, the iliopsoas is one of the most frequently strained muscles of this region.[247] The mechanism of injury is forced extension of the hip while it is being actively flexed. Clinical findings include

- complaints of pain with attempts at acceleration and high-stepping activities;
- increased pain with resisted hip flexion, adduction, and external rotation.[228]

Conservative intervention involves rest, ice, and compression during the acute phase, progressing to prone lying, heat, a graded resistive exercise program, and specific instructions on proper warm-up and cool-down. Recovery from this condition can be lengthy, and recurrences are frequent.

Quadriceps. Strains of the quadriceps most commonly occur during sports involving sprinting, jumping, or kicking. The rectus femoris is the most commonly involved. Typically, the patient complains of local pain and tenderness in the anterior thigh, which may be gradual in onset or sudden during an explosive muscle contraction. Grade I strains result in pain with resisted testing and with passive stretching. Grade II strains cause significant pain with resisted testing and with passive and unopposed active stretching. Complete tears of the rectus feminists are rare and are usually associated with a palpable defect. During the initial period following injury, the principles of PRICEMEM are applied. Pain-free stretching and soft-tissue mobilization are instituted early to preserve ROM. Straight-leg raises are initiated in the supine position and are progressed to long sitting. Short arc quad sets in pain-free ranges are progressed to full range as tolerated. Closed-kinetic-chain exercises at sub-maximal weight are initiated using short arcs before being progressed to full range. Both concentric and eccentric exercises are performed. Attention must be given to hip flexor and hamstring strength and flexibility to ensure correct muscular balance.

Rectus Abdominis. Rectus abdominis strains usually occur when the muscle is strongly contracting, as it is being moved into a stretched and lengthened position. These strains are common in such sports as tennis, wrestling, pole vaulting, weight lifting, and soccer. Abdominal strains are primarily the result of inadequate abdominal strength and/or incorrect technique.[228] As it may be difficult to differentiate this condition from an inflammation of one of the internal abdominal organs, a physician should be consulted whenever there is any doubt.[247]

These are difficult injuries to heal. Although mild strains may only take 2–3 weeks to heal, premature return to play can create large muscle ruptures, leading to hernia formation in the abdominal wall.[228]

Conservative intervention is the same as for other muscle strains and involves rest, ice, and compression during the acute phase, progressing to heat and gentle stretching, a graded resistive exercise program, and specific instructions on proper warm-up and cool-down. Training and retraining of the rectus abdominis should include half sit-ups, done slowly with the knees bent, to eliminate compensation by the iliopsoas.[228,247]

Hamstrings. The hamstrings are the most commonly strained muscles of the hip,[229] with the biceps femoris being the most commonly injured hamstring. Hamstring tears are typically partial rather than complete, and usually occur during the eccentric phase of muscle usage, when the muscle develops tension as it lengthens. These running related hamstring injuries typically occur along and intramuscular tendon, or aponeurosis, and the adjacent muscle fibers.[248] Another type of hamstring injury, which involves the semimembranosus and its proximal free tendon, can occur during activities such as kicks that involve simultaneous hip flexion and knee extension.[249] This type of injury tends to require a prolonged recovery before an individual is able to return to his or her preinjury level of performance.[250]

A hamstring strain has a varied list of contributing factors including[230]:

- ***Previous hamstring injury.*** There is a strong correlation between a history of prior hamstring injury and recurrence. This is likely because of the fact that the initial injury results in a loss of extensibility and a loss of eccentric strength.

- ***Degenerative joint disease of the lumbar spine.*** LB pain and injury result in restricted ROM and decreased hamstring extensibility. In addition, research has demonstrated that LB pain decreases proprioception and neuromuscular control of the lower extremities.
- ***Advancing age.*** It is not clear why injuries to soft tissues served by the L5 and S1 nerves, which supply the hamstring and calf muscles, have such a strong correlation with advancing age, whereas there is little or no correlation between age and the soft tissue injuries with an L2–4 nerve supply. One could summize that the lumbar nerve roots of L5 and S1 are more likely to be affected by age-related spinal degeneration than the nerve supply of the quadriceps muscles (L2, L3, and L4).[251]
- ***Anterior pelvic tilt.*** A common finding is anterior tilt of the innominate bones on the injured side that increases tension in the hamstrings and causes a relative lengthened position of their origin and insertion. This altered pelvic position can also contribute to decreased hamstring strength. Cibulka et al.[252] researched manipulative treatment to correct an anterior innominate position in patients who had hamstring injuries. After only one treatment, isokinetic hamstring peak torque increased by 21.5% when compared with controls.[252] However, functional improvement from this torque increase was not addressed. One of the reasons cited for the significantly increased incidence in hamstring injuries in athletes of black origin is because they tend to have an increased anteriorly tilted pelvis.
- ***Leg length inequality.*** The shorter leg can develop overly tight hamstrings.
- ***Anatomical arrangement.*** Being a biarticular muscle group means that the hamstrings are more susceptible to adaptive shortening[253] and can also be subjected to large length changes. Everyday movements, such as walking, squatting, and sitting, flexion of the hip and knee occur together, with opposing effects on hamstring length. In contrast, the knee is extended and the hip is flexed in running and kicking, which places the hamstrings at longer lengths thereby increasing the risk of muscle tears. Antagonists to prime movers, muscles that are used to control or resist motion, are also at a greater risk of injury than the prime movers themselves. While decelerating the body, these muscles contract while rapidly lengthening. Therefore, they are performing "eccentric contractions."
- ***Poor posture.*** For example, Janda's lower crossed syndrome, which is associated with adaptive shortening of the hip flexors and the erector spinae, weak/inhibited gluteal and abdominal muscles, an increased anterior pelvic tilt and a hyperlordosis of the spine.
- ***Muscle imbalance.*** Muscle balance is a term used to describe the relationship between either:
  - Agonist to antagonist muscle groups. The hamstrings are directly antagonistic to the quadriceps during the first 160–165 degrees of leg extension but assume a paradoxical extensor action concurrent with initial contact.
  - The relationship of agonist muscle groups between limbs (inhibited gluteus maximus).
  - Eccentric to concentric muscle ratios.
  - The strength ratios between the hamstrings and trunk stabilizers.
- ***Decreased flexibility.*** Although there is little to no evidence to support this theory, decreased flexibility of the hamstrings has long been cited as the primary cause of hamstring injuries. In fact, the evidence has demonstrated that there is no correlation between passive hip flexion measurements and hamstring injuries provided that the minimum range is between 85 and 90 degrees. However, a differentiation must be made between active flexibility (the absolute range of movement in a joint or series of joints that is attainable in a momentary effort) and passive flexibility (the ability to assume and maintain extended positions) as research has shown that active flexibility is more closely related to sports achievement than is passive flexibility.

CLINICAL PEARL

Jonhagen and colleagues[254] found decreased flexibility and lower eccentric hamstring torques in runners who sustained a hamstring strain when compared with uninjured subjects matched for age and speed.

- ***Hamstring strength.*** The relationship between strength and the potential for a hamstring injury is not made clear in the studies available. Many authors have commented on the limitations of isokinetic testing and the specificity of the types of training. Few studies have reported on the relationship between concentric and eccentric strengths and the frequency of hamstring injury, but those that have suggested that poor eccentric strength in the hamstring muscle group might be a causative factor in hamstring strains. Kibler[255] stated that sports- or activity-specific testing is more appropriate for evaluating an athlete. Zachazewski[256] commented that for a test to have a predictive value it must incorporate some of the dynamic characteristics specific to that sport. Lephart et al.[257] states that low peak torque values are not necessarily related to functional capacity.
- ***Precipitating activity.*** Most hamstring injuries occur during running at the end of the swing phase or at foot strike when the hamstrings are working to decelerate the limb, while also controlling extension of the knee. At this point the greatest muscle–tendon stretch is incurred by the biceps femoris, which may contribute to its tendency to be more often injured than the other two hamstring muscles during high-speed running.[248] With the forceful flexion of the hip and extension of the knee during the swing phase of sprinting, the hamstring muscle groups are put under extremely high loads in a lengthened position where they must change from functioning eccentrically, to decelerate knee extension in the late swing, to concentrically, becoming an active extensor of

the hip joint. It has been proposed that this rapid changeover from eccentric to concentric function of the hamstring is when the muscle is most vulnerable to injury. Kujala et al.[46] also suggested that, during this swing phase, the hamstrings are placed under extremely high loads in an elongated position.

- ***Inadequate warm-up.*** Although most clinicians prescribe warm-up and stretching to help reduce the incidence of muscle strains, the evidence supporting this idea is weak and largely based on retrospective studies.[258]
- ***Fatigue.*** In a study of professional soccer players, nearly half (47%) of the hamstring injuries sustained during matches occurred during the last third of the first and second halves of the match. Kyrolainen et al.[259] looked at the recruitment pattern of leg muscles during different running speeds. The greatest changes in muscle activity pattern were observed in the biceps femoris muscles as the speed increased from a slow jog to maximum speed. Pinniger et al[260] found that, when footballers became fatigued during sprinting, there was earlier activation of the biceps femoris and semitendinosus muscles. Asynchrony may be because of local muscle fatigue and/or neural fatigue as a result of "irritation or damage along the path of the nerve supplying the muscle." General fatigue secondary to poor sleep patterns, stress, or suboptimal nutrition could result in central nervous system fatigue.
- ***Poor coordination.*** Many hamstring strains occur during the last part of the swing phase or at heel strike, during which time the hamstrings work maximally eccentrically to decelerate the leg.

Other unsubstantiated predisposing factors include cleat design, playing surface, level of hydration, adverse neural tension, experience of the coach, and hormonal levels (abnormally low resting levels of testosterone and unfavorable testosterone/cortisol ratio during recuperation after exercise).[46,119,261–263]

It is likely that a combination of the aforementioned factors play a role in hamstring injuries. Some of these factors are modifiable, others are not. The modifiable factors include muscle imbalances between flexibility and strength, overall conditioning, and playing surface.

Clinical findings associated with hamstring injury include:

- patient reports of a distinctive mechanism of injury with immediate pain during sprinting or while decelerating quickly.[228] In acute cases, the patient may report a "pop" or tearing sensation.
- tenderness elicited with passive stretching of the hamstrings.
- posterior thigh pain, often near the buttock, which is worsened with resisted knee flexion.
- tenderness to palpation, which is generally located at the muscle origin at the ischial tuberosity but may also be present in the muscle belly and distal insertions.

Hamstring strains can be graded according to findings:[228]

- Grade I: gait appears normal but there is pain with extreme range of a straight-leg raise.
- Grade II: antalgic gait or gait with a flexed knee. Resisted knee flexion and hip extension are both painful and weak.
- Grade III: usually requires the use of crutches for ambulation. In severe cases, ecchymosis, hemorrhage, and a muscle defect may be visible several days postinjury.

The differential diagnosis for posterior thigh pain includes neoplasms, overt lumbar disk protrusions with definite signs of nerve root impingement, ischial tuberosity apophysitis, or an avulsion fracture. Examination of the lumbar spine is important, because muscle injury may be related to referred pain with subsequent muscle inhibition and weakness.[264]

No consensus exists for rehabilitation of the hamstring muscles after strain. Despite differences in injury mechanisms and recovery time, current examination and rehabilitation approaches generally do not consider injury location (i.e., proximal free tendon injuries versus intramuscular tendon and adjacent muscle fibers) as part of the clinical decision making process. [249] Since in noninjured subjects, the performance of controlled eccentric strength training exercises has been shown to facilitate a shift in peak force development to longer muscle–tendon lengths,[265] eccentric exercises have been advocated in the rehabilitation of hamstring injuries.[266] A recent prospective investigation determined through isokinetic testing that a strength imbalance ($\geq$20% bilateral deficit) between the eccentric hamstrings (30 degrees per second) and concentric quadriceps (240 degrees per second) resulted in a four-fold increase in risk ratio of hamstring injury (risk ratio, 4.66; 95% confidence interval: 2.01–10.8) compared to a normal strength profile.[267]

A number of eccentric strengthening protocols have been proposed that include such exercises as hamstring lowers, and the use of Yo-Yo^{TM} flywheel ergometry. Although these protocols appear to decrease the severity of an initial injury, they tend to have an increased participant dropout rate because of the occurrence of muscle soreness and delayed onset muscle soreness (DOMS).[261,268,269]

As with all strains, the rehabilitation protocol is based on the stage of healing. Patients with a grade I strain can usually continue activities as much as possible. A grade II strain typically requires 5–21 days for rehabilitation, whereas a patient with a grade III strain may require 3–12 weeks of rehabilitation.

The protocol outlined in Table 19-19 is recommended. Muscle imbalances of strength and flexibility are addressed with proper techniques to stretch and strengthen the hamstrings. Exercises to enhance eccentric loading include the supine bent knee bridge walk out (Fig. 19-68), the supine single-limb chair bridge (Fig. 19-70), unilateral good mornings with rotations (Fig. 19-72), and increasing intensities of grapevine stepping (Fig. 19-76).

Finally, when appropriate, the biomechanical factors, including excessive anterior tilt of the pelvis, lumbar spine and sacroiliac joint dysfunction (trunk stabilization exercises) and leg length discrepancies, should be addressed and corrected.

TABLE 19-19 Rehabilitation Protocol for Hamstring Injury

Phase	Protocol
I (acute): 1–7 days	Rest, ice, compression, and elevation to control hemorrhaging and minimize inflammation and pain. Nonsteroidal anti-inflammatory drugs are an almost universally accepted treatment, and the only controversial aspect to their use is the appropriate timing of administration. The most common recommendation in the literature is short-term use (3–7 d), starting immediately after the injury. However, theoretically it would be beneficial to delay the treatment until 2–4 d after the injury, because they interfere with chemotaxis of cells, which is necessary for the repair and remodeling of regenerating muscle. Early motion exercise is theoretically important to prevent or decrease adhesion within the connective tissue. Active knee flexion and extension exercises could be performed during the treatment with ice. It is important that the exercises are pain free to prevent further injury during the rehabilitation.
II (subacute): day 3 to 3 wks	Begins when the signs of inflammation (swelling, heat, redness, and pain) begin to resolve. In this phase, it is important to continue muscle action to prevent atrophy and promote healing. Regular concentric strength exercises can begin in this phase when the athlete has achieved full range of motion without pain. The common recommendation in this stage is multiple joint angle, submaximal isometric contraction. If the athlete experiences pain, the intensity should be decreased. In this phase, other activities can be initiated to maintain cardiovascular fitness. This could be stationary bike riding, swimming, or other controlled resistance activities.
III (remodeling); 1–6 wks	To avoid the hamstring muscle becoming less flexible after the injury, hamstring stretching can begin in the third phase. Eccentric strengthening can begin (see text).
IV (functional): 2 wks to 6 months	The goal in this phase is return to sport without reinjury. This is achieved by increasing hamstring strength and flexibility to the normal values for the individual athlete. Simultaneously, pain-free running activities are increased from jogging at low intensity to running and finally sprinting. Pain-free participation in sports-specific activities is the best indicator of readiness to return to play.
V (return to competition): 3 wks to 6 months	When the athlete has returned to competition, the goal is to avoid reinjury. The focus should, therefore, be on maintaining stretching and strengthening.

Data from Clanton TO, Coupe KJ: Hamstring strains in athletes: Diagnosis and treatment. *J Am Acad Orthop Surg* 6:237–248, 1998.

CLINICAL PEARL

Rehabilitation of hamstring strains using progressive agility and trunk stabilizing exercises has been found to be more effective than a program emphasizing isolated hamstring stretching and strengthening.[270] An athlete should not be permitted to return to full participation in sports until flexibility and strength ratios have been restored, and before plyometric and functional exercises are able to be performed pain free.[228,230]

Tendinitis

Rectus Femoris. Rectus femoris tendinitis is typically sports-related, resulting from acute or chronic overuse. The pain is usually located at the origin (ASIS), or just distal to it. The patient often complains of groin pain during sprinting or lifting the knee. In most cases, the cause is adaptive shortening of the rectus. Intervention involves stretching and transverse friction massage (TFM).

Iliopsoas. Tendinitis of the iliopsoas complex almost always involves an overstretching of the muscle belly. The patient complains of groin pain, which can radiate into the anterior thigh. Resisted hip flexion and external rotation are often painful. In addition, passive hip flexion or passive hip extension/internal rotation are painful. The involved site is almost always just distal to the inguinal ligament, and just medial to the sartorius muscle. Conservative intervention involves TFM and stretching.

Quadriceps contusion

The term *charley horse* is synonymous with a contusion of the quadriceps muscle. These contusions are quite common and can vary in their degree of discomfort. They are usually because of a direct blow to the anterior thigh, with the vastus lateralis and intermedius being the most frequently involved.

The patient usually describes a specific mechanism and complains of a dull aching pain over the thigh. Clinical findings include

- palpable tenderness over the anterior lateral aspect of the thigh;
- variable swelling; extreme swelling should alert the clinician to the possibility of an injury to major vessels;

- pain increased with knee flexion, which is sometimes accompanied by spasm;
- a palpable hematoma on occasion.

Quadriceps contusions can be graded according to functional loss[271]:

- ***Grade I.*** In a mild contusion, the patient has localized tenderness with no alteration of gait. Knee motion can be performed without pain up to at least 90 degrees of flexion.
- ***Grade II.*** In a moderate contusion, the patient displays swelling and a tender muscle mass. Knee flexion motion is restricted to less than 90 degrees and an antalgic gait is present. The patient is unable to climb stairs or arise from a chair without considerable discomfort.
- ***Grade III.*** In a severe contusion, the patient cannot bend their knee beyond approximately 45 degrees. The patient is unable to walk unaided. Marked tenderness and swelling are present.

Conservative intervention involves a gradual progression of ROM and strengthening exercises.

Hip pointer

A hip pointer is a subcutaneous contusion of the iliac crest resulting from a direct blow, usually at or near the ASIS. The contusion is graded from I to III, depending on the extent of damage. Grade I hip pointers functionally limit the patient for about 5–14 days, while grade II and III hip pointers can functionally limit the patient for 14–21 days.

Usually, the patient reports point tenderness over the ASIS. The pain is increased with passive hip extension, resisted hip flexion, external rotation and abduction, active trunk motions, and with such activities as laughing, coughing, or sneezing.[228]

Early intervention within 2–4 hours is critical to avoid severe pain and limited trunk motion. The early intervention includes ice, compression, rest, and anti-inflammatory measures. Early motion exercises, which emphasize trunk side flexion to the side opposite the injury, should be initiated as tolerated and can be accompanied with transcutaneous electrical nerve stimulation (TENS). As the symptoms subside, gentle-graded stretching exercises are added in addition to trunk-strengthening exercises. Especially effective exercises include long sitting, straight-leg raises with the hip externally rotated, as well as the PNF diagonal flexion adduction, external rotation to extension, abduction, and internal rotation.

Prophylactic prevention of the injury with adequate padding of the iliac crest using materials such as high-density foam and orthoplast is recommended.

Pubalgia

Pubalgia is a collective term for all disorders that cause chronic pain in the region of the pubic tubercle and the structures attached to the pubic bone (inguinal region), including osteitis pubis, a chronic inflammatory and overuse condition of the pubic symphysis and adjacent ischial rami. A number of abnormalities in joints and muscles around the groin may increase the mechanical stress placed on the pubic region:

- limited hip ROM;
- increased adductor muscle tone;
- increased rectus abdominis tone;
- iliopsoas muscle shortening, often associated with hypomobility of the upper lumbar spine;
- lumbar spine/SIJ dysfunction;
- decreased lumbopelvic stability.

Pubalgia typically results from a sports injury. It usually results from a single-leg movement, where the weight-bearing leg is rotated as the other leg performs a movement such as kicking, or during activities such as sprinting and pivoting. During this kind of motion, small shearing movements occur in the pubic symphysis. The condition is rarely found in women—this may be because of variations in pelvic anatomy between men and women and strength differences or participation levels between genders.

Pubalgia typically presents as lower abdominal pain with exertion, minimal to no pain at rest, and increased pain with activities that involve resisted hip adduction. After the initial pain, the pain disappears when the patient is warmed up, only to return, often more intensely, after the activity. Eventually, the pain will increase with exertion and only slightly diminish with rest.

In most cases, the pain is unilateral at onset, with progression to bilateral pain in about 40% of cases.[272] Examination findings include the following:

- Pain may be elicited with passive hip flexion, when combined with hip adduction, or with passive abduction with a straight or bent knee. However, in some cases, ROM may appear normal.
- Point tenderness at the pubic tubercles, rectus abdominis insertion, adductor origin, and inferior pubic rami.
- Pain is intensified with sit-ups and resisted hip adduction.

Groin pain is a common complaint and can be ascribed to various disorders (see Table 19-20 and Table 19-21), necessitating a thorough knowledge of differential diagnosis. Palpation of the relevant structures should help in locating the cause, as will resistive testing of the various muscles.

Once the diagnosis has been established, the conservative intervention should be causal:

- A period of relative rest and anti-inflammatory medications.
- TFM can be applied locally.
- Ultrasound, electrical stimulation, thermotherapy, and cryotherapy as appropriate.
- Stretching as tolerated to the muscles surrounding the injured area:
  - The short and long adductors.
  - Hip flexors (iliopsoas and rectus femoris).
  - Hip internal rotators.
  - Abdominals.
  - Gluteal muscles.
- Strengthening of the same muscle groups. The strengthening exercises are performed isometrically initially, and then concentrically and eccentrically, and finally isokinetically as appropriate.
- Core stability training. A particularly effective form of core strengthening for athletic pubalgia, developed by Alex

TABLE 19-20 Differentiation of Hip Pathologies

Factor	Congenital Hip Dislocation	Septic Arthritis	Legg–Calvé–Perthes Disease	Transient Synovitis	Slipped Femoral Capital Epiphysis	Avascular Necrosis	Degenerative Joint Disease	Fracture
Age	Birth	Less than 2 yr; rare in adults	2–13 yr	2–12 yr	Males 10–17 yr; females 8–15 yr	30–50 yr	40 yr	Older adults
Incidence	Female > male; left > right; blacks < whites		Male > female; rare in blacks; 15% bilateral	Male > female; unilateral	Male > female; blacks > whites	Male > female	Female > male	Female > male
Observation	Short limb, associated with torticollis	Irritable child; motionless hip; prominent greater trochanter; mild illness	Short limb; high greater trochanter; quad atrophy; adductor spasm	Decreased flexion, abduction, and external rotation; thigh atrophy; and muscle spasm	Short limb, obese, quadriceps atrophy, and adductor spasm		Frequently obese, joint crepitus, and atrophy of gluteal muscles	Ecchymosis; may be swelling; short limb
Position	Flexed and abducted	Flexed, abducted, and externally rotated			Flexed, abducted, and externally rotated			External rotation
Pain		Mild pain with palpation and passive motion; often referred to knee	Gradual onset; aching in hip, thigh, and knee	Acute: severe pain in knee; moderate: pain in thigh and knee; tenderness over hip	Vague pain in knee, suprapatellar area, thigh, and hip; pain in extreme motion	50% sharp pain and 50% insidious and intermittent pain in extreme ends of range	Insidious onset and pain with fall in barometric pressure	Severe pain in groin area
History	May be breech birth	Steroid therapy; fever	20–25% familial, low birth weight, and growth delay	Low-grade fever	May be trauma		May be prolonged trauma and faulty body mechanics	May be trauma and fall
Range of motion	Limited abduction	Decreased (capsular pattern)	Limited abduction and extension	Decreased flexion, limited extension, and internal rotation	Limited internal rotation, abduction, and flexion; increased external adductor spasm	Decreased range of motion	Decreased motion, external and internal rotation, and extreme flexion	Limited
Special tests	Galeazzi's sign, Ortolani's sign, and Barlow's sign;	Joint aspiration						
Gait		Refuses to walk	Antalgic gait after activity	Refuses to walk and antalgic limp	Acute: antalgic; chronic: Trendelenberg external rotation	Coxalgic limp	Limp	
Radiologic findings	Upward and lateral displacement and delayed development of acetabulum	CT scan: localized abscess; increased separation of ossification	In stages: increased density, fragmentation, and flattening of epiphysis center	Normal at first, widened medial joint space	Displacement of upper femoral epiphysis, especially in frog position	Flattening followed by collapse of femoral head	Increased bone density, osteophytes, and subarticular cysts; degenerated articular cartilage	Fracture line and possible displacement; short femoral neck

Data from Richardson JK, Iglarsh ZA: *The Hip, Clinical Orthopaedic Physical Therapy*. Philadelphia, PA: WB Saunders, 1994:367–368.

TABLE 19-21 Differential Diagnosis for Common Causes of Hip Pain

Condition	Patient Age (yr)	Mechanism of Injury/Onset	Area of Symptoms	Symptoms Aggravated by	Observation
Trochanteric bursitis	15–45	Direct trauma Microtrauma	Lateral aspect of hip/thigh	Lying on involved side	Unremarkable
Groin strain	20–40	Sudden overload	Anteromedial thigh Medial thigh	Running	Possible bruising around medial thigh
Hamstring muscle tear	15–45	Sudden overload	Buttock and posterior thigh	Running	Possible bruising around posterior thigh
Piriformis syndrome	25–55	Gradual	Buttock and posterior thigh Back of leg	Prolonged sitting	Unremarkable
Hip OA	50+	Gradual	Anterior thigh Anteromedial thigh	Weight-bearing	Possible atrophy of thigh muscles Altered gait
Iliotibial band syndrome	25–55	Overuse	Lateral aspect of thigh Lateral aspect of knee		Unremarkable
Psoas bursitis	20–40	Overuse	Anteromedial thigh		Unremarkable
Lumbar/thoracic disk pathology	20–50	Gradual Sudden overload	Varies according to spinal nerve root involved but occurs in dermatomal distribution	Lumbar/thoracic flexion (bending/sitting) Activities that increase intrathecal pressure	May have associated deviation of trunk

OA, osteoarthritis; AROM, active range of motion; ER, external rotation; SLR, straight-leg raise; IR, internal rotation; PROM, passive range of motion.

AROM	PROM	Resisted	Tenderness with Palpation
Painful hip abduction with rotation	Pain at end-range hip ER Pain with hip ER with abduction	Pain with resisted hip abduction Pain with resisted hip IR	Lateral thigh over greater trochanter
Hip extension only limited movement	Pain at end-range hip extension Pain at end-range hip abduction	Pain with resisted hip adduction	Proximal medial thigh
Hip ER limited and painful	Pain at end-range hip flexion		
SLR limited and painful	Pain at end-range hip extension Pain with passive SLR	Pain with resisted hip extension Pain with resisted knee flexion	Posterior thigh
SLR limited and painful	Pain at end-range hip ER Pain with passive SLR	Pain with resisted hip ER	Buttock
Limited hip IR and extension	Pain at end-range hip IR	Weak hip abduction	Anterior hip
Painful hip IR	All movements feel stiff	General weakness of hip muscles	
Painful hip extension			
Pain on moving from knee extension to flexion	Pain at end-range hip ER with abduction	All resistive tests negative	Lateral epicondyle of femur Lateral aspect of knee
Hip extension with only limited movement	Pain at end-range hip extension	Pain with resisted hip flexion	Anterior hip
Increased symptoms with trunk flexion	Symptoms invariably increased with passive SLR	Fatigable weakness of associated myotome	Possible tenderness over involved spinal segment
Increased symptoms with hip flexion with knee extended (SLR)			

McKechnie, uses diagonal elastic tubing resistance between the upper and lower extremities. These exercises combine a contraction of the pelvic floor and transversus abdominis muscles while performing activities such as squats (Fig. 19-56), lunges (Fig. 19-55), and sport-specific movements.

- Proprioception training.

Effective warm-ups and preparation before the sporting activity can play an important preventative role.

In cases of failed conservative intervention, which is common, surgical intervention (pelvic floor repair) or cessation from the offending activity becomes the patient's only choice.[272] Post-surgical rehabilitation uses many of the same exercises and modalities as in the traditional rehabilitation program outlined above.

Bursitis

Trochanteric/Subtrochanteric. Trochanteric bursitis is the shared name given to inflammation of any one of the three trochanteric bursae. It has been suggested that trochanteric bursitis should be considered as a clinical diagnosis rather than an anatomical diagnosis, because it cannot be distinguished from gluteal tendinitis by signs and symptoms alone.[34] Trochanteric bursitis is the second most frequent cause of lateral hip pain, with a peak incidence occurring between 40 and 60 years of age,[50] and is more common in arthritic conditions and fibromyalgia and leg length discrepancy.[34,273] It is also more common in females than males (2–4:1 ratio).[34]

The bursae can become inflamed through either friction or direct trauma, such as a fall on the side of the hip.

The history may reveal complaints of aching lateral thigh, groin, and gluteal pain, especially when lying on the involved side.[274] Although the pain is typically local to the hip region, it can radiate distally to the knee and the lower leg.

Objectively, the clinical findings include

- the reproduction of pain with palpation or with stretching of the ITB across the trochanter with hip adduction or the extremes of internal or external hip rotation[275];
- that resisted abduction, extension, or external rotation of the hip are also painful;
- that there is often associated tightness of the hip adductors, which cause the patient's feet to cross the midline, resulting in increased stress on the trochanteric bursa.

Differential diagnosis should include[43,276]

- tendopathy of the gluteus medius or maximus muscles, with or without calcification;
- inguinal and femoral hernia;
- an irritation of the L4–5 nerve root;
- meralgia paresthetica;
- a "snapping" hip;
- lower spinal neoplasm;
- pelvic tumor;
- hip infection;
- avascular necrosis;
- stress fracture of the femur;
- bone or soft tissue tumor.

There is very little research on physical therapy interventions for trochanteric bursitis.[277] The intervention typically consists of the removal of the causative factors by stretching the lateral thigh tissues, especially the TFL and ITB, and emphasizing flexibility of the external rotators, quadriceps, and hip flexors. Strengthening of the hip abductors and correction of any muscle imbalances between the adductors and abductors is also important. Other interventions include heat and ultrasound. TFM has also been advocated.[278] Orthotics may be prescribed if there is a biomechanical fault in the kinetic chain. A steroid injection at the area of tenderness over the greater trochanter may be useful in particularly intense or recalcitrant cases.

Iliopsoas/Iliopectineal. The IPB is located between the anterior aspect of the hip joint capsule and the musculotendinous junction of the iliopsoas. Iliopsoas bursitis seems to be under-recognized by the medical community despite reports that continue to be published. This may be because the entity often exists for years without being identified. The usual complaint is one of anterior hip or groin pain, which is aggravated by lumbar or hip hyperextension or power walking. In the older populations, psoas bursitis can mimic such conditions as hip joint pathology, an L2–3 nerve root pathology, and meralgia paresthetica.

Objective findings are few, and they include

- pain with passive hip flexion and adduction at the end range;
- pain with passive hip extension and external rotation, which is increased if the hip flexors are resisted in this position;
- palpable tenderness of the involved bursa.

Conservative intervention consists of a stretching and strengthening program of the hip rotators and hip flexors. Johnston and colleagues[279] have published a conservative approach to iliopsoas bursitis, based on a retrospective study of nine patients with the condition. The recommended protocol consists of the following exercises:

- seated hip internal and external elastic resistance exercises;
- side-lying abduction/external rotation elastic resistance exercises;
- mini-squats, weight-bearing on the affected leg;
- stretching of the hip flexor, quadriceps, and lateral hip/piriformis, and hamstring muscles.

Ischial. An ischial bursitis, also referred to as Weaver's bottom, involves two different bursae, one between the ischial tuberosity and the inferior part of the gluteus maximus belly, and the other between the tendons of the biceps femoris and semimembranosus. Inflammation of these bursae usually results from chronic compression or direct trauma.

Subjectively, the patient typically reports pain with sitting in a firm chair, almost as soon as the buttocks touch the chair. Ischial bursitis tends to affect thinner people more than obese individuals and women more than men. It is also common in cyclists.

Differential diagnosis should include lumbar nerve root impingement, hamstring syndrome, piriformis syndrome, and hamstring insertion tendopathy. These can be differentiated between using the history, palpation, and resistive testing, as patients with ischial bursitis generally will not complain of pain in the posterior thigh or demonstrate hamstring flexibility and strength inadequacies.

Conservative intervention is based on the cause, and typically involves relative rest, the use of a padded seat cushion, soft tissue massage, correction of hamstring strength and flexibility deficits, anti-inflammatory measures such as ice massage, and ultrasound.

Gluteal. Inflammation of the gluteal bursa, which is located above and behind the greater trochanter, and underneath the gluteus maximus and medius, is one of the most frequent causes of pseudoradicular pain in the lower extremity. The patient, who is usually in their fourth or fifth decade, typically complains of pain in the gluteal or trochanteric area, which may spread to the outer or posterior thigh, and down to the calf muscles and the malleolus. Unlike the pain caused by a lumbar disk lesion, the symptoms are not related to sitting, but only to walking and going up stairs. A typical pattern is pain on passive internal rotation and abduction, and resisted external rotation or abduction.

Conservative intervention is based on the cause, and usually involves the use of a padded seat cushion, anti-inflammatory measures such as ice massage, and ultrasound.

Integration of Practice Patterns 4C, 4F, and 5F: Impaired Joint Mobility, Motor Function, Muscle Performance, ROM Associated with Spinal Disorders, Sign of the Buttock, Myofascial Pain Dysfunction (Referred Pain Patterns), and Peripheral Nerve Entrapments

If the tests and measures of the hip are negative for a hip disorder or a dysfunction of the lower kinetic chain, the clinician should examine the lumbar spine and sacroiliac joint, both of which can refer pain to this region.

Many internal disorders such as femoral and inguinal hernias, pelvic inflammatory disease, prostatitis, and nephrolithiasis can produce pain in the lower abdomen and groin region (see Chap. 5). These are all out of the scope of practice for the physical therapist, and a proper referral to an internist, urologist, or gynecologist should be sought.

Sign of the buttock

The sign of the buttock is a collection of signs that indicate the presence of serious pathology posterior to the axis of flexion and extension in the hip. Among the causes of the syndrome are osteomyelitis, fracture of the sacrum/pelvis, infections, sacroilitiis, gluteal hematoma, septic bursitis, ischiorectal abscess, tumor, and rheumatic bursitis. Typical findings include gross hip weakness with empty end-feel. The involved buttock looks larger. The seven signs of the buttock are

- a limited straight-leg raise;
- limited hip flexion;
- limited trunk flexion;
- a noncapsular pattern of hip restriction;
- painful and weak hip extension;
- gluteal swelling;
- an empty end-feel on hip flexion.

If the sign of the buttock is present, a medical referral is necessary.

Meralgia paresthetica

Patients with meralgia paresthetica typically describe burning, coldness, lightning-type pain, deep muscle achiness, and tingling or frank anesthesia in the anterolateral thigh (see Chap. 5). There may also be local hair loss in the anterolateral thigh.[280] The symptoms may be exacerbated when the hip is extended, as in prone lying, or when standing erect. Sitting may relieve the symptoms in some patients but exacerbate them in others. Eventually, there may be no position that provides relief.[280]

The initial intervention of meralgia paresthetica is conservative, and patients may benefit from analgesics, NSAIDs, looser clothing, and weight loss.

Piriformis syndrome

Piriformis syndrome is the result of entrapment of the sciatic nerve by the piriformis muscle, as it passes through the sciatic notch (see Chap. 5). Clinical findings include[281]

- restriction in ROM of hip adduction and internal rotation;
- positive FABER test;
- weak gluteus maximus, gluteus medius, and biceps femoris;
- neurologic symptoms in the posterior lower limb if the fibularis (peroneal) nerve is involved;
- ipsilateral short leg.

Conservative intervention for this condition includes gentle, pain-free static stretching of the piriformis muscle, strain–counterstrain techniques, soft tissue therapies (longitudinal gliding combined with passive internal hip rotation, as well as transverse gliding and sustained longitudinal release, with the patient lying on one side), ice massage to the gluteal region, and spray and stretch techniques.[228,282] Local corticosteroid or botox injections may be useful in more acute cases.[283]

Entrapment of the obturator nerve

Compression of the anterior division of the obturator nerve in the thigh has been described recently as one possible cause for adductor region pain, and entrapment of this nerve has been documented by nerve conduction studies.[284] The fascia over the nerve is thought to contribute to compression of the nerve, or perhaps allow for the development of a compartment syndrome.[284]

Myofascial pain dysfunction

Myofascial pain is referred into the hip from the following muscles: quadratus lumborum, piriformis, gluteus minimus, and adductor longus.

Quadratus Lumborum. This muscle is perhaps one of the most overlooked sources of hip pain. The more superficial trigger points of this muscle refer pain to the lateral ilium

and greater trochanter and may also refer pain into the groin in the region of the inguinal ligament. The tenderness in the trochanteric region can be misdiagnosed as trochanteric bursitis.

Clinical findings can include

- restriction of hip joint movements by lumbar spasm;
- trochanteric and buttock tenderness;
- a contralateral short leg;
- an ipsilateral flexed innominate.

Conservative intervention includes gentle, pain-free static stretching of the muscle, soft tissue techniques, and progressive strengthening.

Gluteus Minimus. Trigger points may be located in the posterior and anterior portions of this muscle. The posterior trigger point refers pain to the medial lower buttock and into the posterior thigh and calf. These trigger points have the potential to increase the tone in the hamstring and calf muscles. Stretching the gluteus minimus before hamstring and calf stretching allows these two muscles to lengthen much more readily. The anterior trigger point refers symptoms to the lower buttock, and down the lateral thigh and leg as far as the lateral malleolus, on occasion.

Conservative intervention includes gentle, pain-free static stretching of the muscle, soft tissue techniques, and progressive strengthening.

Adductor Longus. Trigger points in this muscle strongly refer to the anterior hip and anterior knee. Clinical findings include

- pain with resisted strength testing;
- positive FABER test for pain;
- marked restriction of hip abduction.

Conservative intervention includes gentle, pain-free static stretching of the muscle, soft tissue techniques, and progressive strengthening.

Practice Pattern 4G: Impaired Joint Mobility, Motor Function, Muscle Performance, and ROM Associated with Fractures

Avulsions

Apophyseal avulsions of the pelvis and proximal femur occur most commonly to male athletes 10–20 years old, usually as the direct result of vigorous or uncoordinated activities such as kicking, jumping, hurdling, sprinting, and punting, involving the sartorius or TFL.[228,285] The anterior iliac spine is a common site for the injury, especially during the middle-to-late teenage years when the iliac crest unites with the ilium. Clinical findings can include[286]

- point tenderness;
- crepitus;
- hematoma;
- limited hip motion;
- pain with resisted hip flexion and passive hip extension that increase pain at the site.

Conservative intervention includes ice and hip spica compression, followed by bed rest, progressing to crutch ambulation and activity modification. Return to normal activity follows a period of strength, flexibility, and functional training.[228]

Stress fractures of the femoral neck/head

Stress fractures result from accelerated bone remodeling in response to repeated stress. Although stress fractures are a relatively uncommon etiology of hip pain, if not diagnosed in a timely fashion, progression to serious complications can occur.[287] It is estimated that up to 5% of all stress fractures involve the femoral neck, with another 5% involving the femoral head.[288] The fracture typically occurs on the superior side (tension-side fractures) or the inferior side (compression-side fractures) of the femoral neck.[289] These fractures may develop into a complete and displaced fracture if left untreated.

The most frequent symptom is the onset of sudden hip pain, usually associated with a recent change in training (particularly an increase in distance or intensity) or a change in training surface. The earliest and most frequent symptom is pain in the deep thigh, inguinal, or anterior groin area.[289] Pain can also occur in the lateral aspect or anteromedial aspect of the thigh. The pain usually occurs with weight-bearing or at the extremes of hip motion and can radiate into the knee. Less severe cases may only have pain following a long run. Night pain may occur if the fracture progresses. Stress fractures are generally classified as fatigue or insufficiency fractures[145]:

- Fatigue stress fractures are caused by repetitive and abnormally high forces from muscle action and/or weight-bearing torques and are often found in persons with normal bone densities. This type of stress fracture at the hip is most common in athletes involved in intense training, including military personnel.
- Insufficiency stress fractures are associated with individuals who have compromised bone densities. Since insufficiency stress fractures are associated with decreased bone mineral density, they tend to be most common in the elderly, especially postmenopausal women. Other predisposing factors for poor bone density include radiation treatments, rheumatoid arthritis due at least in part to the associated disuse and either corticosteroid or methotrexate treatment, renal failure, coxa vara, metabolic disorders, and Paget's disease.

The physical examination is often negative, although there may be a noncapsular pattern of the hip,[145] an empty end-feel, or pain at the extremes of hip internal or external rotation or pain with resisted hip external rotation.[290] In addition, the auscultatory patellar-pubic percussion test may be positive (see "Special Tests" section).

Differential diagnosis includes OA of the hip, referred symptoms from the spine, trochanteric bursitis, or septic arthritis.

Radiographs taken soon after the symptoms begin have been reported to be positive in only 20% of cases.[289] Diagnosis is best confirmed with bone scintigraphy (scan), although these have been shown to be prone to false negatives.[291] The

intervention varies according to the bone scintigraphy findings.[289]

- If there is a positive scan only, or sclerosis and no fracture line on the radiographs, the intervention ranges from modified bed rest to non–weight-bearing with crutches until symptoms subside. Once pain free, weight-bearing is progressed. When significant PWB is pain free, cycling and swimming may be permitted. Weekly radiographs are obtained until the athlete is full weight-bearing without pain. Water running and water walking are progressed. If these remain pain free, running on land is commenced, with the initial run being no further than one-quarter mile.
- If there is an overt fracture line on the radiographs with no displacement, and provided that only the cortex is involved, an initial period of either bed rest or complete non–weight-bearing is necessary. The patient is progressed to partial and then full weight-bearing on crutches as symptoms permit. Roentgenograms every 2–3 days during the first week are necessary to detect any widening of the fracture line. If healing does not occur, internal fixation with some form of hip pin is indicated.

An overt fracture with radiographic evidence of opening or displacement is significant and requires surgical intervention, usually in the form of a hip screw and plate. Displaced fractures must be treated as an orthopaedic emergency.

HIP FRACTURE

Hip fracture, defined as a fracture of the proximal third of the femur, is the orthopaedic problem with the highest incidence, cost, and risk.[292] The morbidity rates after fracture is 32% to 80%.[293] Hip fractures are associated with substantial morbidity and mortality in the elderly. Approximately 90% of hip fractures result from a simple low energy fall.[294] The most common risk factors for falls (and thus hip fractures) are age, gender, race, institutionalization/hospitalization, medical comorbidities (cardiac disease, stroke, dementia, poor hip fracture, osteoporosis), hip geometry, medication, bone density, diet, smoking, alcohol consumption, fluorinated water, urban versus rural residents, and climate.[295] A number of hip fractures exist:

- Intertrochanteric: occur on the proximal, upper part of the femur or thigh bone between the greater trochanter, where the gluteus medius and minimus muscles attach, and the lesser trochanter, where the iliopsoas muscle attaches.
- Femoral neck: Fractures of the femoral neck are proximal to intertrochanteric fractures, whereas subtrochanteric fractures are distal or below to the trochanters.

Intertrochanteric

The intertrochanteric area of the femur, the area of the lesser and the greater trochanters and where the femur changes from an essentially vertical bone to a bone angling at a 45-degree angle from the near-vertical to the acetabulum or pelvis, is proximal to the femoral shaft and distal to the femoral neck. The etiology of intertrochanteric fractures is typically a combination of increased bone fragility of the intertrochanteric area of the femur associated with decreased muscle tone of the muscles in the area secondary to the aging process.

The current approach for intertrochanteric fractures is surgical intervention. With few exceptions, open reduction and internal fixation (ORIF) is used to treat essentially all intertrochanteric fractures. Following the procedure, a preventive protocol of antiembolism stockings and anticoagulants is followed. Physical therapy involves functional and gait training according to the weight-bearing status, and a progressive exercise program of ROM and strengthening.

CLINICAL PEARL

Hip fractures are associated with a high risk of deep vein thrombosis (DVT). Early mobilization, may reduce the risk of venous thromboembolism.

Subtrochanteric

The subtrochanteric region of the femur is exposed to high stresses during ADL; during normal ADL, up to six times the body weight is transmitted across the subtrochanteric region of the femur.[98] These fractures are most frequently seen in two patient populations; older osteopenic patients after a low-energy fall and younger patients involved in high-energy trauma. This region of the femur consists primarily of cortical bone, so healing in this region is predominantly through a primary cortical healing, which makes fracture consolidation quite slow to occur. Surgical treatment can be divided into three main techniques:

- External fixation: rarely used but is indicated in severe open fractures. External fixation is usually temporary, and conversion to internal fixation can be made if and when the soft tissues have healed sufficiently.
- Open reduction with plates and screws. Following ORIF and plate fixation, minimal protected weight-bearing can begin immediately but is advanced slowly beginning approximately 4 weeks after surgery, with full weight-bearing anticipated at 8–12 weeks.
- Intramedullary fixation. Following intramedullary nailing, if the bone quality and cortical contact is adequate, 50% partial weight-bearing can be allowed immediately. With less stability, patients can perform touchdown weight-bearing.

As most elderly patients may have difficulty complying with the weight-bearing restrictions, they are often permitted to progress to full postoperative weight-bearing status.

Femoral Neck Fracture

Femoral neck fractures are often associated with multiple injuries and high rates of avascular necrosis and nonunion. Hip fractures are common and are often devastating in the geriatric population. A number of factors predispose the elderly population to fractures, including decreased physical activity, osteoporosis, impaired vision, neurologic disease, and poor balance. The decision for operative or nonoperative treatment of femoral neck fractures and the type of surgical intervention are based on many factors. Compression fractures are more stable than tension-type fractures, and they can

be treated nonoperatively. Treatment for nondisplaced fractures is bed rest and/or the use of crutches until passive hip movement is pain free and X-ray films show evidence of callus formation. Tension fractures may require operative stabilization as they are potentially unstable. Nondisplaced femoral neck fractures may need to be stabilized with multiple screws or pins. In the elderly population, premorbid cognitive function, walking ability, and independence in ADL are considered when determining the optimal method of surgical repair.

The prognosis for femoral neck fractures depends on the extent of injury (i.e., amount of displacement, amount of comminution, whether circulation has been disturbed), the adequacy of the reduction, and the adequacy of fixation. Maintaining aerobic conditioning throughout the rehabilitation process is important.

The weight-bearing status following the surgical procedure depends on the stability of reduction, bone, and method of fixation. The exercises performed initially include quadriceps sets, gluteal sets, heel slides, active-assisted hip abduction and adduction, and supine internal and external hip rotation. Once partial weight-bearing ambulation is allowed, aquatic training such as swimming or deep-water running may be used if available. Once full weight-bearing is achieved, exercises begin to address functional strengthening of the gluteus medius, the iliopsoas, gluteus maximus, adductors (magnus, longus, and brevis), quadriceps, and hamstrings.

If protected or non–weight-bearing ambulation is necessary, then upper body exercise, such as an upper body ergometer, can be used.

TOTAL HIP ARTHROPLASTY

The THA is a common procedure performed in cases of severe joint damage resulting from OA, rheumatoid arthritis, displaced femoral neck fractures, and avascular necrosis.[296] Arthroplasty of the hip may be categorized as a THA or a hemiarthroplasty. In a THA, the articular surfaces of both the acetabulum and femur are replaced. This involves either replacement of the femoral head and neck (conventional THA) or replacement of the surface of the femoral head (resurfacing THA); both procedures also replace the acetabulum. In contrast to a THA, a hemiarthroplasty involves replacement of the articular surface of the femoral head without any surgical alteration to the acetabular articular surface. Two main types of hemiarthroplasty exist:

- Unipolar. This involves replacement of the femoral head and the neck and tends to be used with less active and older patients who are unlikely to outlive the hip implant.
- Bipolar. This involves replacement of the femoral head and the neck with an additional acetabular cup that is not attached to the pelvis (bipolar hemiarthroplasty), or replacement of the surface of the femoral head (resurfacing hemiarthroplasty).

More recently, the minimally invasive anterior approach, using one or two small incisions, has become more popular. The rationale for minimally invasive procedures is that the use of small incisions potentially lessens soft tissue trauma during surgery and, therefore, should improve and accelerate a patient's postoperative recovery. Other benefits include reduced blood loss, reduce postoperative pain, shorter length of hospital stay and lower cost of hospitalization, a more rapid recovery of functional mobility and a better cosmetic appearance of the surgical scar.

A review of the literature reveals inconsistent practice patterns in the physical therapy management of THA patients. Most surgeons have designed their own post-surgical protocols, which should be strictly adhered to. Standard precautions are observed with patients who underwent a lateral or posterolateral approach to prevent posterior hip dislocation. These include the following:

- Avoidance of hip adduction. Typically an abduction wedge or pillow is prescribed. A pillow is placed between the legs if the patient wants to lie on the side.
- Avoidance of hip internal rotation. Combinations of hip flexion, internal rotation, and adduction must be avoided for up to 4 months after surgery or until physician clearance.
- Avoidance of hip flexion greater than 90 degrees (bending forward at the hip, reaching for objects or tying shoes). Elevated chairs or toilet seats can be used to increase compliance, as can an assistive device or reacher

Precautions for a patient who underwent an anterior/anterior lateral or direct lateral approach, with or without trochanteric osteotomy include:

- Avoidance of hip flexion greater than 90 degrees
- Avoidance of hip extension, adduction, and external rotation past neutral
- Avoidance of the combined motions of flexion, abduction, and external rotation

If a trochanteric osteotomy was performed, or the gluteus medius was incised and repaired, the patient should not perform active, anti-gravity hip abduction for at least 6–8 weeks or until approved by the surgeon.

THERAPEUTIC TECHNIQUES

Techniques to Increase Joint Mobility

Passive Articular Mobilization Techniques

In a single-blind randomized study[194] investigating interventions for hip OA, 109 subjects were randomly assigned to receive mobilization and manipulation to the hip joint or active exercises designed to improve strength and ROM for nine visits over a period of 5 weeks. Success rates after 5 weeks were 81% in the manual therapy group and 50% in the exercise group. Furthermore, patients in the manual therapy group had significantly better outcomes on pain, stiffness, hip function, and ROM. The effects of manual therapy on the improvement of pain, hip function, and ROM remained after 29 weeks.

Mobilizations of this joint are typically performed using a sustained stretch to decrease a hip joint capsular restriction, with the stretch being governed by the direction of the restriction, rather than by the concave–convex rule. For

example, if hip joint extension is restricted, the distal femur is moved into the direction of hip extension.[209]

The joint is initially positioned in its neutral position and is progressively moved closer to the end of range. A belt can also be used for this technique. Rotations can be combined with any sustained stretch performed in a cardinal plane. Distraction or compression techniques can be used alone or combined with rotations.

Distraction. Joint distraction mobilizations are indicated for pain and any hypomobility at the hip joint, as in the case when pain is reported by the patient before tissue resistance is felt by the clinician. The lateral distraction technique (see Fig. 19-30) can be used to increase hip joint ROM into adduction and internal rotation.

Leg Traction (Inferior Glide). An inferior distraction (Fig. 19-31) can be used for temporary relief of joint pain, to increase ROM into hip joint abduction and for stretching capsular adhesion that is pronounced in the inferior portion of the joint capsule.[63,70]

Quadrant (Scouring) Mobilizations. Quadrant mobilizations involve flexion and adduction of the hip, combined with simultaneous joint compression through the femur.[70,209,297,298] The flexed and adducted thigh is swept through a 90–140-degree arc of flexion, while maintaining joint compression. This arc of motion should feel smooth and should be pain free. In an abnormal joint, pain or an obstruction to the arc occurs during the movement. In selected nonacute cases, the procedure may be used as an effective mobilizing procedure, where grade II to III mobilizations are applied perpendicular to the arc throughout.[70,297]

Posterior Glide. The posterior glide mobilization (Fig. 19-32) is used to increase flexion and to increase internal rotation of the hip.

Anterior Glide. The anterior glide (Fig. 19-33) is used to increase extension and to increase external rotation of the hip.

Inferior Glide. The inferior glide is used to increase abduction of the hip.

Mobilizations with Movement. ***To Restore Internal Rotation of the Hip.***[299–301] This technique is employed when the patient presents with early signs of hip joint degeneration, as indicated by minor capsular signs and slight degenerative changes on radiographs. A belt that can be altered in length is required for the technique.

The patient is positioned in supine with the involved hip and knee flexed and the foot just off the edge of the bed, with the clinician standing on the involved side, facing the patient's head. A belt is placed around the back of the clinician, just below the hip joints, and around the patient's thigh as proximal as possible, so that the belt is approximately horizontal. Using the hand closest to the patient's head, the clinician grasps the lateral iliac crest of the involved side, with the elbow in the crease of the clinician's groin to stabilize the pelvis during the maneuver. The clinician wraps the other hand around the patient's midthigh. From this position, the clinician slowly extends their own hips to apply a distraction force to the patient's hip joint, while maintaining the fixation of the ilium.

If the maneuver produces any pain, it should be discontinued. This should be differentiated from discomfort, which might be caused by inappropriate placement of the belt.

To Restore Flexion of the Hip. The technique to restore flexion of the hip is identical to the one described above, except that during the distraction, the clinician passively flexes the patient's hip into flexion by side bending at the waist.[301]

Techniques to Increase Soft Tissue Extensibility

The efficacy of manual techniques for improving hip ROM has been reported in the literature. Crosman and colleagues[302] studied the effects of hamstring massage (effleurage, petrissage, and friction) on hip flexion range in normal individuals and noted significant range improvements after the soft tissue massage.[70] Godges and colleagues[303] reported improved hip flexion and hip extension ranges in normal individuals after the application of manual stretches to muscle groups opposing each respective motion, combined with exercise of agonistic muscles.

Iliopsoas. The patient is positioned in side lying (Fig. 19-78). The patient is instructed to flex the uninvolved hip and maintain its position by using their arms to help stabilize the lumbopelvic region. While monitoring the lumbopelvic motion with one hand, the clinician passively extends the thigh with the other arm/hand. The advantage of this technique is that varying degrees of hip adduction/abduction and knee flexion/extension can be controlled. The disadvantage is that the technique is more physically demanding for the clinician.

Iliopsoas and Rectus Femoris. Although a number of exercises have been advocated to stretch these muscle groups, because of their potential to increase the anterior shear of the

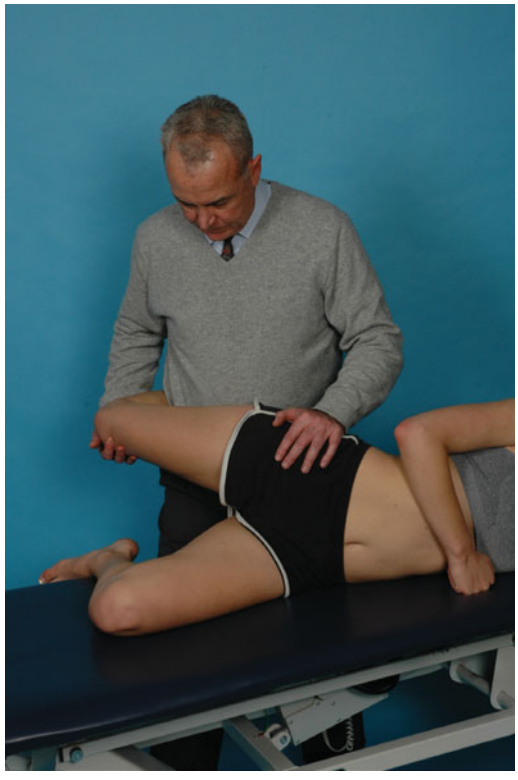

FIGURE 19-78 Sidelying hip flexor stretch.

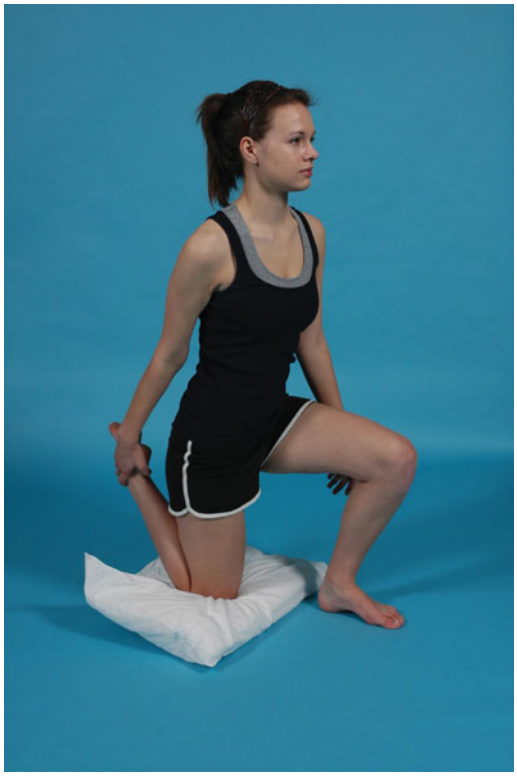

FIGURE 19-79 Iliopsoas and rectus femoris stretch.

lumbar vertebrae either directly or indirectly, the standing/kneeling position is preferred.

A pillow is placed on the floor, and the patient kneels down on the pillow with the other leg placed out in front in the typical lunge position (Fig. 19-79). The patient is asked to perform a posterior pelvic tilt and to maintain an erect position with respect to the trunk. From this starting position, the patient glides the trunk anteriorly, maintaining the trunk in a near vertical position. A stretch on the upper aspect of the anterior thigh of the kneeling leg should be felt. The rectus femoris can be stretched further from this position by grasping the ankle of the kneeling leg and raising the foot toward the buttock (Fig. 19-79).

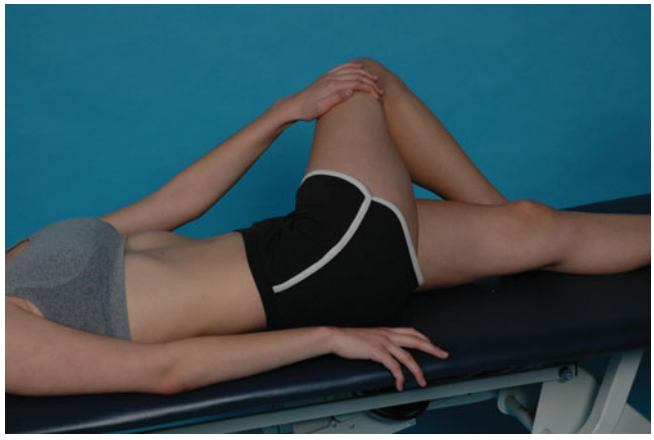

FIGURE 19-80 Tensor fascia latae stretch.

Tensor Fascia Latae. The patient is positioned supine with the legs straight. The foot of the leg to be stretched is placed on the table on the outside of the uninvolved straight leg. The patient reaches and grasps the knee of the involved leg and pulls the knee across and over the straight leg (Fig. 19-80). Both shoulders should be kept flat against the table. At the point the stretch is felt, the position is maintained for approximately 30 seconds. The stretch is repeated 10 times.

CASE STUDY

Right Groin Pain

History

General Demographics

A 62-year-old male.

History of Current Condition

A patient presents with complaints of aching pain in the right groin that varies in severity and extends down the anterior thigh to the knee. The pain began gradually about 3 months before. Initially, the patient felt stiffness whenever he sat for prolonged periods of time or after a night's sleep. The patient reports that he can no longer walk as far as he once did and that negotiating stairs was especially painful.

Past History of Current Condition

A long history of OA of the spine and occasional twinges of pain in the right groin. The patient also has a history of right-sided sciatica.

Past Medical/Surgical History

The patient had a total joint replacement of the right knee approximately 4 months ago.

Medications

Celecoxib.

Other Tests and Measures

Radiographs of right hip are negative for loose bodies, tumors, and fracture. Advanced OA of right hip was noted.

Social Habits (past and present)
Nonsmoker. Drinks occasionally. Active life style.

Social History
Married. Two children, both live close by.

Family History
No relevant history of hip problems in family.

Growth and Development
Normal development; left-handed.

Living Environment
Lives in an apartment. One flight of stairs to negotiate.

Occupational/Employment/School
Retired railroad laborer. High school education.

Functional Status/Activity Level
The patient demonstrates difficulty rising from a chair and transferring from bed to chair.

Health Status (self-report)
In general good health, but pain interferes with tasks at home and with helping his sick wife.

Systems Seview
Unremarkable.

Questions

1. List the possible structure(s) that can produce groin pain.
2. What might the history of pain with early morning stiffness and pain with stair negotiation tell the clinician?
3. What other activities might increase the patient's symptoms? Why?
4. To help rule out the various causes of groin pain, what other questions can you ask?
5. What is your working hypothesis at this stage? List the various diagnoses that could present with these signs and symptoms and the tests you would use to rule out each one.
6. Does this presentation/history warrant a Cyriax lower quarter scanning examination? Why or why not?

CASE-STUDY

Thigh Pain

History

History of Current Condition
A 22-year-old male sustained a kick to the right thigh approximately 2 weeks ago while playing college soccer. He complains of a dull ache on the anterior aspect of his thigh. The pain is worse with activities that involve attempting to squat or kick. The patient also reports feeling a lump on the front of his thigh. The patient saw his physician who diagnosed the condition as a deep quadriceps contusion and prescribed 8 weeks of physical therapy.

Past History of Current Condition
No previous history of thigh pain.

Past Medical/Surgical History

- No history of previous knee or hip injury.
- No back pain/surgery reported.
- No knee surgeries reported.
- History of chronic ankle sprains.

Medications
None.

Other Tests and Measures
Radiograph results pending.

Occupational/Employment/school
Full-time student at local college for the past 2 years.

Functional Status/Activity Level
Very active. In addition to soccer, the patient also plays tennis and racquetball.

Health Status (self-report)
In general, good health.

Questions

1. Given the specific mechanism of injury, list all of the structures you suspect could be injured and will require a specific examination.
2. What condition could be present with the history of pain in a muscle belly following a contusion?
3. What other activities do you suspect would increase the patient's symptoms? Why?
4. In a patient with an insidious onset of pain, what questions would you ask to help rule out the various causes of anterior thigh pain?
5. What is your working hypothesis at this stage?
6. Does this presentation/history warrant a lower quarter scan? Why or why not?

REVIEW QUESTIONS*

1. What is the close-packed position of the hip?
2. In which direction is the acetabulum angled?
3. Which ligament contains the blood supply to the femoral head?
4. The pubofemoral ligament is taut in which three directions?
5. Which muscle is known as the deltoid of the hip?

CHAPTER 20 The Knee

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joint, ligaments, muscles, and blood and nerve supply that comprise the knee joint complex.
2. Describe the biomechanics of the tibiofemoral and patellofemoral joints, including the forces involved with closed-chain and open-chain activities, the open- and close-packed positions, normal and abnormal joint barriers, force couples, and joint stabilizers.
3. Describe the purpose and components of an examination for the knee joint complex.
4. Perform a detailed examination of the knee joint complex, including palpation of the articular and soft tissue structures, specific passive and active mobility tests, stability tests, and special tests.
5. Understand the purpose of muscle function testing and extrapolate information from the findings.
6. Describe the significance of muscle imbalance in terms of functional muscle performance.
7. Outline the significance of the key findings from the history, the tests and measures of the knee complex, and establish a diagnosis.
8. Describe the common pathologies of the knee joint complex and their relationship to impairment.
9. Develop self-reliant intervention strategies based on clinical findings and established goals.
10. Apply active and passive techniques to the knee joint complex and its surrounding structures, using the correct intensity and duration.
11. Evaluate intervention effectiveness to progress or modify the intervention.
12. Plan an effective home program, and instruct the patient in this program.
13. Help the patient to develop self-reliant intervention strategies.

OVERVIEW

The knee joint complex is extremely elaborate and includes three articulating surfaces, which form two distinct joints contained within a single-joint capsule: the patellofemoral and tibiofemoral joints. Anatomically and biomechanically the tibiofemoral joint and the patellofemoral joint can be considered as separate entities, in much the same way as the craniovertebral joints are when compared with the rest of the cervical spine. In 15–20% of the population, an accessory sesamoid bone occurring in the gastrocnemius, the fabella, is present as part of the knee joint complex.[1,2] The fabella, when present, articulates with the lateral femoral condyle and is hence an articular sesamoid.

The knee is one of the most commonly injured joints in the body. The types of knee injuries seen clinically can be generalized into the following categories:

- Unspecified sprains or strains, and other minor injuries, including overuse injuries
- Contusions
- Meniscal or ligamentous injuries

It is important that the clinician be familiar with the diagnostic and therapeutic procedures appropriate for all of the categories of injury. It is also important that the clinician have a good understanding of differential diagnosis as thigh, knee, and calf pain can result from a broad spectrum of conditions.

ANATOMY

TIBIOFEMORAL JOINT

The tibiofemoral joint consists of the distal end of the femur and the proximal end of the tibia (Fig. 20-1). The tibiofemoral joint has great demands placed on it in terms of both stability and mobility. The femur is the largest bone in the body and represents approximately 25% of a person's height.[3] Its distal

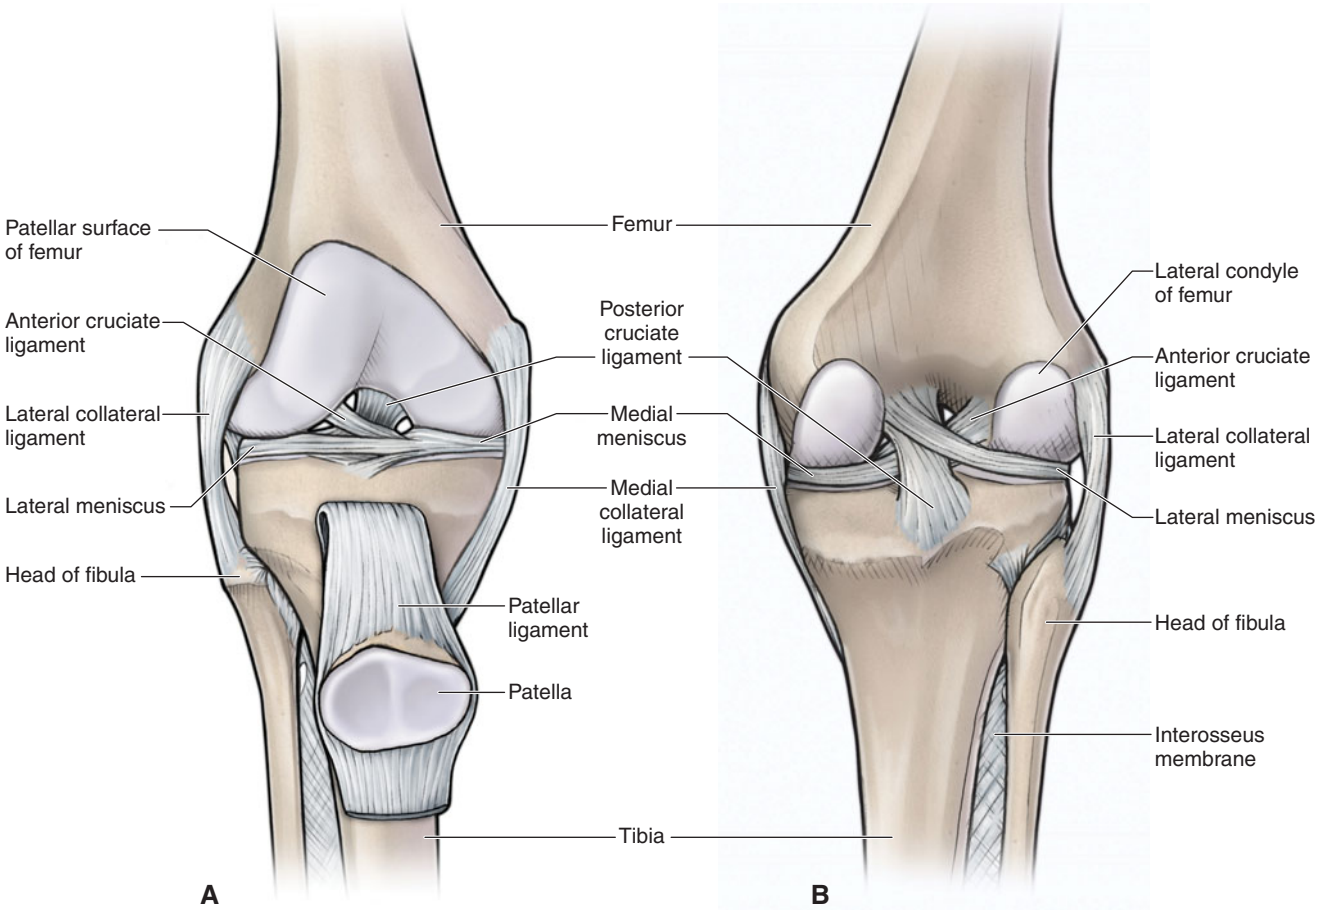

FIGURE 20-1 Anterior and posterior views of the bones of the tibiofemoral joint. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

aspect (Fig. 20-1) is composed of two femoral condyles that are separated by an intercondylar notch or fossa. The intercondylar notch serves to accept the anterior cruciate ligament (ACL) and the posterior cruciate ligament (PCL).

CLINICAL PEARL

A narrow intercondylar notch has been associated with an increase in injuries to the ACL.[4]

The femoral condyles (see Fig. 20-1) project posteriorly from the femoral shaft. The smaller lateral femoral condyle is ball-shaped and faces outward, whereas the elliptical-shaped medial femoral condyle faces inward. The lateral condyle serves as the origin of the popliteus, whereas the lateral epicondyle serves as the origin for the lateral head of the gastrocnemius and the lateral collateral ligament (LCL). The medial epicondyle (see Fig. 20-1) serves as the insertion site for the adductor magnus, the medial head of the gastrocnemius, and the medial collateral ligament (MCL).

The anteroposterior length of the adult medial femoral condyle is on average 1.7 cm greater than that of its lateral counterpart, resulting in an increased length of the articular surface on the medial femoral condyle as compared with that of the lateral femoral condyle.[5] Thus, the articulating surfaces are asymmetric, yet work in unison.[2] The distal and the posterior portion of the femoral condyles articulate with the tibia.

The proximal tibia (see Fig. 20-2) is composed of two plateaus separated by the intercondylar eminence, including the medial and lateral tibial spines.[6] The tibial plateaus are concave in a mediolateral direction. In the anteroposterior direction, the medial tibial plateau is also concave, whereas the lateral is convex, producing more asymmetry and an increase in lateral mobility. The medial plateau has a surface area that is approximately 50% greater than that of the lateral plateau, and its articular surface is three times thicker.[7] The concavity of the tibial plateaus is accentuated by the presence of the menisci (see later).

PATELLOFEMORAL JOINT

The patellofemoral joint is a complex articulation, dependent on both dynamic and static restraints for its function and stability.

The patella (Fig. 20-1), a ubiquitous sesamoid bone found in birds and mammals, plays an important role in the biomechanics of the knee. Its articular anatomy is uncomplicated: it

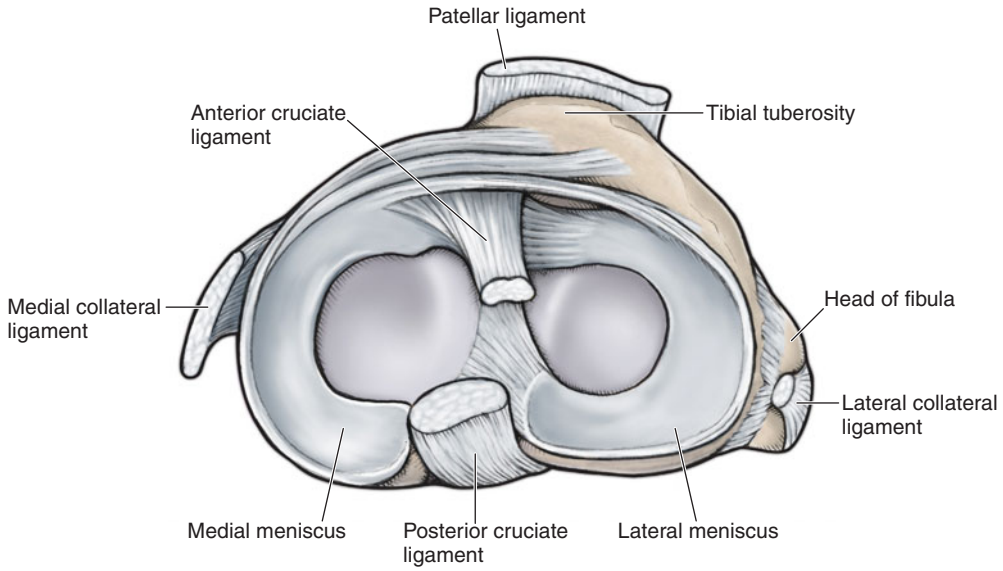

FIGURE 20-2 Articulating surfaces of the tibia. (Reproduced with permission from Morton DA, Foreman KB, Albertine KH: *The Big Picture: Gross Anatomy,* McGraw-Hill, 2011.)

is a very hard, triangular-shaped bone, situated in the intercondylar notch and embedded in the tendon of the quadriceps femoris muscle above and the patellar tendon below. The thickness of the patella varies considerably, attaining a maximum height of 2–2.5 cm (0.77–1 inch) at its central portion.[8] The posterior surface of the patella can include up to seven facets. A smaller facet, known as the odd facet, exists medially and is delineated by a second vertical ridge.[9] These concave medial and lateral facets are separated by a vertical ridge and are covered with aneural hyaline cartilage, the thickest cartilage in the body (up to 7-mm thick).[8] The articular cartilage of the patella is unique because it lacks conformity with the underlying bone.[10] The hyaline cartilage, here as elsewhere, functions to minimize the friction that occurs at the functional contact areas of the joint surfaces.

Radiographic and cadaver studies have classified the patella into four types based on the size and shape of these lateral and medial facets.[11]

The patellar surface of the femur is divided into medial and lateral facets that closely correspond to those on the posterior surface of the patella.[12] The patellofemoral joint functions to[13]

- provide the articulation with low friction;
- protect the distal aspect of the femur from trauma and the quadriceps from attritional wear;
- improve the cosmetic appearance of the knee;
- improve the moment arm (distance between the center of gravity and the center of rotation) of the quadriceps. This is achieved by elevating the quadriceps femoris muscle from the center of knee rotation. This increases the efficiency of the quadriceps muscle and provides it with leverage for extending the leg. The patellar contribution to the knee extensor moment arm increases with increasing amounts of knee extension;
- decrease the amount of anteroposterior tibiofemoral shear stress placed on the joint.

JOINT CAPSULE AND SYNOVIUM

The capsule of the knee joint complex is composed of a thin, strong fibrous membrane and is the largest synovial capsule in the body. The capsule ascends anteriorly approximately 2 finger breadths above the patella to form the suprapatellar pouch. Posteriorly, it ascends to the origins of the gastrocnemius. Inferiorly, the capsule attaches along the edges of the articulating surfaces of the tibial plateaus, with the exception of the intercondylar eminence, and a small portion of the anterior intercondylar region.[14] A synovial membrane lines the inner portion of the knee joint capsule. By lining the joint capsule, the synovial membrane excludes the cruciate ligaments from the interior portion of the knee joint, making them extrasynovial yet intra-articular.

The articularis genu, located superior to the patella, is thought to function to retract the knee capsule during knee extension. Thus, it serves a similar function as the anconeus in the elbow.

PROXIMAL TIBIOFIBULAR JOINT

The proximal, or superior, tibiofibular joint (see Fig. 20-1) is an almost plane joint with a slight convexity on the oval tibial facet and a slight concavity of the fibular head. The joint is located below the tibial plateau on the lateral condyle of the tibia. The tibial articulating facet faces laterally, posteriorly, and inferiorly. Although the joint is often described as a simple, synovial, modified ovoid, it functions as a modified sellar when combined with the distal, or inferior, tibiofibular joint (see Chap. 21).

The joint capsule of the proximal tibiofibular joint complex is thicker anteriorly than posteriorly and, in 10% of the population, the synovium is continuous with that of the knee joint.[15] The joint receives support from anterior and posterior ligaments, and an interosseous membrane. The interosseous membrane attaches between the medial border of the fibula and the lateral border of the tibia, providing attachment to the

deep anterior and posterior muscles of the leg. The majority of its fibers pass obliquely in an inferior and lateral direction.

The proximal tibiofibular joint has more motion than its distal partner. The motion occurring at the proximal joint consists of two glides, one in a superoinferior direction and the other in an anteroposterior direction.[7] These motions are possible because of the orientation of the joint line, which also facilitates an osteokinematic spin of the fibula. The motion at this joint can be decreased by articular fibrosis or by soft tissue restraints; the biceps femoris can pull or hold it posteriorly, whereas the tibialis anterior can pull or hold it anteriorly.

Although the capsular pattern of restriction for this joint is unclear, it is probably indicated by pain during an isometric contraction of the biceps femoris with the knee at 90 degrees of flexion. The close-packed position for this joint, equally debatable, is probably weight-bearing ankle dorsiflexion.

Both the tibia and fibula are vulnerable to fracture at the lower third of their shaft. Anterior joint subluxations occur at this joint as a result of medial knee joint strain or an inversion sprain of the ankle. Posterior joint subluxation can occur as a result of a lateral knee joint strain, but is often missed because of the more serious ligament damage to the knee.

The nerve supply for this joint is provided by the common fibular (peroneal) and recurrent articular nerves. The joint receives its blood supply from a perforating branch of the fibular (peroneal) artery, and the anterior tibial artery.

LIGAMENTS

The static stability of the knee joint complex depends on four major knee ligaments, which provide a primary restraint to abnormal knee motion:

- Anterior cruciate (Fig. 20-1). Provides the primary restraint for anterior translation and medial rotation of the tibia on the femur and is a secondary restraint to valgus and varus rotation of the tibia.
- Posterior cruciate (see Fig. 20-1). Provides the primary restraint for posterior translation and medial rotation of the tibia on the femur and is a secondary restraint to valgus and varus rotation of the tibia.
- Medial (tibial) collateral (see Fig. 20-1). Provides the primary restraint for valgus and lateral rotation of the tibia, and is a secondary restraint to anterior and posterior translation of the tibia on the femur.
- Lateral (fibular) collateral (see Fig. 20-1). Provides the primary restraint for varus and lateral rotation of the tibia, and is a secondary restraint to anterior and posterior translation of the tibia on the femur.

Cruciate Ligaments

The two central intra-articular cruciate ligaments derive their name from the Latin word *crucere* (cross) because they cross each other (Fig. 20-1). Both the ACL and PCL lie in the center of the joint, and each are named according to their attachment sites on the tibia.[15] The cruciate ligaments, which differ from those of other joints in that they restrict normal, rather than abnormal, motion, are the main stabilizing ligaments of the knee and restrain against anterior (ACL) and posterior (PCL) translations of the tibia on the femur. They also restrain against excessive internal and external rotation and varus movement of the tibia.[16]

CLINICAL PEARL

One study[17] analyzed the coupled internal–external rotation of the tibia, finding that when an anterior force was applied to the tibia of a knee with intact ligaments, internal rotation occurred, whereas a posterior force produced external rotation of the tibia. These movements, rotations with coupled anterior and posterior translation, were found to be greater in flexion than near extension.[18] Another study[19] found this increase to be more marked at an angle of 20 degrees of flexion than at full extension or at 90 degrees of flexion.

The blood supply to the cruciate ligaments is largely provided from the middle and inferior geniculate branches of the popliteal artery. The cruciate ligaments are innervated by the posterior articular nerve, a branch of the posterior tibial nerve.[20] The function of this nerve supply is questionable although it may serve as proprioceptive in nature.[21] In addition, the cruciate ligaments contain mechanoreceptors, suggesting that disruption of the ligament structure can produce partial deafferentation of the joint.[22] Evidence of a proprioceptive function of the ACL comes from extensive histologic observations demonstrating that the ACL appears to contain proprioceptive nerve endings.[23,24] Indeed, Krauspe et al.,[20] in single-fiber studies, identified a total of 26 mechanoreceptors of the cruciate ligament among 13 animals.

Although these cruciate ligaments function together, they are described separately.

Anterior Cruciate Ligament

The ACL is a unique structure and one of the most important ligaments to knee stability, serving as a primary restraint to anterior translation of the tibia relative to the femur, and a secondary restraint to both internal and external rotation in the non–weight-bearing knee.[25–28] An injury to this ligament has terminated many a promising sports career.[29,30]

The ACL (see Fig. 20-1) is composed of a vast array of individual fascicles. These, in turn, are composed of numerous interlacing networks of collagen fibrils. The fascicles originate on the inner aspect of the lateral femoral condyle in the intercondylar notch and travel obliquely and distally through the knee joint.[16] They enter the anterior intercondylar surface of the tibial plateau, where they partially blend with the lateral meniscus. As the fascicles of the ACL course through the knee joint and attach to their insertion sites, they fan out and give a slight spiral appearance to the ligament, a phenomenon that is more pronounced during knee flexion.[31,32]

The synovial tissue that enfolds the ACL consists of an intimal layer, facing the joint cavity, and a subsynovial layer.[16] The subsynovial layer is in direct contact with the ACL and contains neurovascular structures. The ACL is considered

TABLE 20-1 Rank Comparison of Peak ACL Strain Values During Commonly Prescribed Rehabilitation Activities

Rehabilitation Activity	Peak Strain (Mean ± ISD)	No. of Subjects
Isometric quads contraction at 15 degrees (30 Newton meters [Nm] of extension torque)	4.4 (0.6)%	8
Squatting with sport cord	4.0 (1.7)%	8
Active flexion–extension of the knee with 45-N weight boot	3.8 (0.5)%	9
Lachman test (150 N of anterior shear load: 30 degrees of flexion)	3.7 (0.8)%	10
Squatting	3.6 (1.3)%	8
Active flexion–extension (no weight boot) of the knee	2.8 (0.8)%	18
Simultaneous quadriceps and hamstring contraction at 15 degrees	2.8 (0.9)%	8
Isometric quadriceps contraction at 30 degrees (30 Nm of extension torque)	2.7 (0.5)%	18
Stair climbing	2.7 (2.9)%	5
Anterior drawer (150 N of anterior shear load: 90 degrees of flexion)	1.8 (0.9)%	10
Stationary bicycling	1.7 (1.9)%	8
Isometric hamstring contraction at 15 degrees (10 Nm of flexion torque)	0.6 (0.9)%	8
Simultaneous quadriceps and hamstring contraction at 30 degrees	0.4 (0.5)%	8
Passive flexion–extension of the knee	0.1 (0.9)%	10
Isometric quads contraction at 60 degrees (30 Nm of extension torque)	0.0%	8
Isometric quadriceps contraction at 90 degrees (30 Nm of extension torque)	0.0%	18
Simultaneous quadriceps and hamstring contraction at 60 degrees	0.0%	8
Simultaneous quadriceps and hamstring contraction at 90 degrees	0.0%	8
Isometric hamstring contraction at 30 degrees, 60 degrees, and 90 degrees to −10 Nm of flexion torque	0.0%	8

ACL, anterior cruciate ligament; ISD, implied standard deviation.
Data from Beynnon BD, Fleming BC: Anterior cruciate ligament strain in-vivo: A review of previous work. *J Biomech* 31:519–525, 1998.

intra-articular yet extrasynovial because of the posterior invagination of the synovial membrane.

Although the posterior articular nerve is the major nerve for the ACL, afferent fibers have also been demonstrated in the medial and lateral articular nerves. [33]

Like all ligaments, the ACL behaves as a viscoelastic structure, allowing it to dissipate energy and to adjust its length and internal load distribution as a function of load history.[34,35] This means that the normal ACL is capable of microscopic adjustments to internal stresses over time, thus influencing the laxity, stresses, and kinematics of the joint in subtle but potentially important ways.[36] One anatomic factor that contributes to selective fiber recruitment during tensile loading is the specific location of the insertions of the ACL on the femur and the tibia. These differing insertion sites allow different fibers of the ACL to be recruited with every subtle three-dimensional change in the position of the joint.[31,36–38]

Butler et al.[39] have shown that whatever the angle of knee flexion, the ACL absorbs nearly 90% of the force causing anterior translation. The anteromedial bundle of the ACL is taut in flexion, whereas in extension, the posterolateral fibers are stretched. These unique properties not only make the ACL the "crucial" ligament of the knee joint, but also increase its potential for injury.[28,40,41]

The tensile strength of the ACL is equal to that of the knee collaterals, but is half that of the PCL.[42] Since its fibers are unyielding, forcing the ACL more than 5% beyond its resting length may result in rupture.[28] Several factors can influence the amount of tension on the ACL.

- Compressive loading of the tibiofemoral joint, such as that occurs during weight-bearing, has been shown to reduce anteroposterior laxity and stiffen the joint when compared with the non–weight-bearing position.[43] These changes appear to reflect the increased strain borne by the ACL during the transition from non–weight-bearing to weight-bearing.[44] Thus, the popular belief in the beneficial effects of early weight-bearing and closed-kinetic chain exercises (CKCEs) following anterior cruciate reconstruction may be open to question (Table 20-1).[44]
- Stair-climbing exercises using exercise equipment such as the Stairmaster 4000PT (Randall Sports Medicine, Kirkland, WA) have been shown to produce moderate strain on the ACL compared with other rehabilitation activities.[45]
- The circumstances that cause the highest loads and strains on the ACL during daily function are[36] quadriceps-powered extension of the knee, moving it from approximately 40 degrees of flexion to full extension; hyperextension of the knee; excessive internal tibial rotation; or excessive varus or valgus stress on the tibia if a collateral ligament is torn.

Both estimates[46,47] and measurements[25,26] have shown that the maximum measured strain differential in the ACL is approximately 5% during any rehabilitation exercise.[36,48] This strain represents only approximately one-quarter of the failure strain of the normal ACL, suggesting that these exercises load the normal ACL to only a small fraction of its failure capacity.[34,36,38]

Posterior Cruciate Ligament

The PCL attaches posteriorly to the insertion of the posterior horns of the lateral and medial menisci on the posterior part of the posterior intercondylar fossa of the tibia.[49] From here, the PCL extends obliquely medially, anteriorly, and superiorly to attach to the lateral surface of the medial femoral condyle (see Fig. 20-1). Overall, the ligament is wider at its femoral origin and narrowest near the tibial insertion.[50] The PCL is covered by synovial lining and is therefore considered to be extra-synovial yet intra-articular.

Information regarding the biomechanical function of the PCL is scant compared with that of the ACL. It is known that the PCL is 50% thicker and has twice the tensile strength of the ACL.[51] The PCL is more vertical in extension and horizontal in flexion.[52] Like the ACL, the PCL consists of two bundles: anterior lateral and posterior medial. Overall, the ligament is most taut with further flexion of the knee.[53] Specifically, the anterior lateral bundle is taut in flexion, while the posterior medial bundle is taut in extension. According to Butler et al.,[39] the PCL provides 90–95% of the total restraint to posterior translation of the tibia on the femur, with the remainder being provided by the collateral ligaments, posterior portion of the medial and lateral capsules, and the popliteus tendon. The contribution percentage resisting posterior translation decreases as the knee extends. The PCL is significantly loaded if a posteriorly directed force is applied to the tibia when the knee is flexed to 90 degrees or greater while in neutral rotation.[54] If the same force is applied to the tibia when the knee is in terminal extension, the load on the PCL is not increased.[54] This is contrary to the popular belief that hyper-extension of the knee is the mechanism of injury of the PCL. The PCL also restrains internal rotation of the tibia on the femur and helps prevent posterior-medial instability at the knee.[55]

Other functions of the PCL include acting as a secondary restraint to external rotation of the tibia on the femur at 90 degrees of flexion,[56] assisting with a rolling/gliding mechanism of the tibiofemoral joint, and resisting varus/valgus forces at the knee after the collateral ligaments have failed.

A significant force is needed to tear the PCL. Thus, tears of the PCL are usually the result of severe contact injuries that often occur in traumatic situations, such as a dashboard injury during a motor vehicle accident.

In concert with the PCL are the anterior and posterior meniscofemoral ligaments, which comprise approximately 22–50% of the cross-sectional area of the PCL.[50,57] Although these ligaments arise from the common PCL origin they are distinct structures having different insertion sites.[58] Both are named with respect to the orientation to the PCL (see "Lateral Meniscus" section). Since the insertion site of the meniscofemoral ligaments are different from that of the PCL, if a midsubstance tear of the PCL occurs, it is possible that one or both of the meniscofemoral ligaments may remain intact.[59]

Medial Collateral Ligament

Both the MCL and the LCL are considered to be extra-articular ligaments.

The MCL, or tibial collateral ligament (see Fig. 20-1), develops as a thickening of the medial joint capsule.[60] It can be subdivided into a superficial band and a deep band.

- The superficial band is a thick, flat band, and has a fan-like attachment proximally on the medial femoral condyle, just distal to the adductor tubercle, from which it extends to the medial surface of the tibia approximately 6 cm below the joint line, covering the medial inferior genicular artery and nerve.[61] The superficial band blends with the posteromedial corner of the capsule and, when combined, is referred to as the posterior oblique ligament.[62] The superficial band is separated from the deep layer of the ligament by a bursa. Since the superficial band is farther from the center of the knee, it is the first ligament injured when a valgus stress is applied.[63]
- The deep band (medial capsular ligament) is a continuation of the capsule. It blends with the medial meniscus and consists of an upper meniscofemoral portion and a lower meniscotibial portion.

The anterior fibers of the MCL are taut in flexion and can be palpated easily in this position. The posterior fibers, which are taut in extension, blend intimately with the capsule and with the medial border of the medial meniscus, making them difficult to palpate.

Information regarding the biomechanical function of the collateral ligaments is quite scarce compared with that of the ACL. It would appear that the MCL is the primary stabilizer of the medial side of the knee against valgus forces, and external rotation of the tibia, especially when the knee is flexed.[64] Grood et al.[65] determined that the MCL was the primary restraint, providing 57% and 78% of the total restraining moment against valgus force at 5 and 25 degrees of flexion.[66]

Lateral Collateral Ligament

The LCL, or fibular collateral ligament (see Fig. 20-1), arises from the lateral femoral condyle and runs distally and posteriorly to insert into the head of the fibula. The LCL forms part of the so-called arcuate-ligamentous complex. This complex also comprises the biceps femoris tendon, iliotibial tract, and the popliteus.

The cord-like LCL develops independently, and remains completely free from the joint capsule and the lateral meniscus. It is separated from these structures by the popliteus tendon, and straddled by the split tendon of the biceps femoris. The LCL can be divided into three parts:

1. ***Anterior.*** This part consists of the joint capsule.
2. ***Middle.*** This part is considered to be part of the iliotibial band (ITB) and covers the capsular ligament.
3. ***Posterior.*** This Y-shaped portion of the ligament is part of the arcuate-ligamentous complex, which supports the posterior capsule.[67,68]

The main function of the LCL is to resist varus forces. It offers the majority of the varus restraint at 25 degrees of knee flexion,[69,70] and in full extension.

OTHER RESTRAINTS

Some structures in the knee clearly augment the functions of the ACL and the PCL. These structures are known as secondary restraints.[36] The secondary restraints include the structures in the posterolateral and posteromedial corners of the knee, which serve to control anterior tibial translation relative to the femur.[36,54,71,72]

Dynamic stability synergistic to the PCL is provided by unopposed contraction of the quadriceps complex, which increases anterior tibial translation. Conversely, an isolated contraction of the hamstrings results in a posterior translation of the tibia, which is synergistic to the ACL. Cocontraction of the hamstrings and the quadriceps has been theorized to minimize tibial translation in either direction.[36] The popliteus muscle–tendon complex (PMTC) contributes to both static and dynamic posterolateral knee joint stabilization.[73] During concentric activation, the popliteus internally rotates the tibia on the femur. During eccentric activation, it serves as a secondary restraint to tibial external rotation on the femur (see "Popliteus" section).[74]

The knee joint is also strengthened externally by the patellar ligament, oblique popliteal ligaments, and the fabella.

- The patellar ligament, or patellar tendon, lies in the thickened portion of the quadriceps femoris tendon between the top of the patella and the tibia (Fig. 20-1). The patellar ligament strengthens the anterior portion of the knee joint and prevents the lower leg from being flexed excessively.
- The oblique popliteal ligament, located on the posterior surface of the knee joint, is a dense thickening in the posterior capsule made up of a continuation of the popliteal tendon and part of the insertion of the semimembranosus.[65] It arises posterior to the medial condyle of the tibia and extends superomedially to attach to the posterior fibrous capsule. The oblique popliteal ligament provides reinforcement to the lateral capsule, limits anteromedial rotation of the tibia, and prevents hyperextension of the knee.[16]
- The fabella is located in the posterolateral corner of the knee and may be osseous or cartilaginous in makeup. When the fabella is present, there is a fabellofibular ligament, which courses superiorly and obliquely from the lateral head of the gastrocnemius to the fibular styloid.[68] The fabellofibular ligament helps prevent excessive internal rotation of the tibia and adds further ligamentous support on the lateral and posterolateral aspects of the knee.[75] Seebacher et al. found through dissection that the arcuate ligament was quite large in the absence of a fabella.[1]

CLINICAL PEARL

Purists classify the patellar tendon as a ligament, because it serves as the connection between two bones (tibia and patella). However, because this structure attaches the quadriceps unit to the tibia, it functions as a tendon.

MENISCI

The crescent-shaped lateral and medial menisci (Fig. 20-2), attached on top of the tibial plateaus, lie between the articular cartilage of the femur and the tibia. The knee menisci, once described as "the functionless remains of leg muscles,"[76] are now recognized as being integral to normal knee function. The blood supply of the meniscus, which is key to successful meniscal repair, comes from the perimeniscal capsular arteries, which are branches of the lateral, medial, and middle genicular arteries.[16] The outer 25% of the lateral meniscus (with the exception of the posterolateral corner of the lateral meniscus adjacent to the popliteus tendon) and the outer 30% of the medial menisci are vascularized, giving these areas the potential for healing.[77] The remaining inner portions of the menisci are considered avascular. Despite the lack of vascularity to the inner portions, tears involving the avascular zone may heal. This healing capacity may be improved with the addition of a fibrin clot or with such techniques as trephination.[78,79]

Medial Meniscus

The semilunar or U-shaped medial meniscus (see Fig. 20-2), with the wider separation of its anterior and posterior horns, is larger and thicker than its lateral counterpart and sits in the concave medial tibial plateau.[80] The medial meniscus is wider posteriorly than anteriorly. It is attached to the anterior and posterior tibial plateau by coronary ligaments. These ligaments connect the outer meniscal borders with the tibial edge and restrict movement of the meniscus. The medial meniscus also has an attachment to the deeper portion of the MCL and the knee joint capsule. The horns of the medial meniscus are further apart than those of the lateral, which makes the former nearly semilunar and the latter almost circular (see Fig. 20-2). The posterior horn of the medial meniscus receives a piece of the semimembranosus tendon.

The transverse genicular ligament serves as a link between the lateral and medial menisci.

Lateral Meniscus

The lateral meniscus, which forms a C-shaped incomplete circle,[80] sits atop the convex lateral tibial plateau (see Fig. 20-2). It is smaller, thinner, and more mobile than its medial counterpart.

The lateral meniscus has an interesting relationship with the popliteus tendon, which supports it during knee extension and separates it from the joint (see later discussion).[73]

The periphery of the lateral meniscus attaches to the tibia, the capsule, and the coronary ligament, but not to the LCL. Two meniscofemoral ligaments, the ligaments of Humphrey and Wrisberg attach to the lateral meniscus.[5]

- The ligament of Humphrey, also known as the anterior meniscofemoral ligament, runs anteriorly to the PCL and inserts on the posterior aspect of the lateral meniscus.[58]
- The ligament of Wrisberg, also known as the posterior meniscofemoral ligament, runs posteriorly to the PCL to insert either into the superior/lateral aspect of the tibia, the

posterior aspect of the lateral meniscus, or the posterior capsule.[81]

The meniscofemoral ligaments become taut with internal rotation of the tibia and help with stabilization of the meniscus.[61]

The lateral meniscus often is associated with the appearance of synovial-filled cysts, which may occur following a minor injury to the meniscus and produce a small internal tear. As fluid begins to congregate within this tear, it is pushed deeper and deeper into the meniscus. The swelling eventually produces a small bulge on the lateral aspect of the meniscus.

Menisci Function

The menisci assist in a number of functions, including load transmission, shock absorption, joint lubrication and nutrition, secondary mechanical stability (particularly the posterior horn of the medial meniscus that blocks anterior translation of the tibia on the femur),[80] and the guiding of movements.[82]

Load Transmission

The meniscus is viscoelastic, with greater stiffness at higher deformation rates. Many studies have confirmed the role of the menisci in load transmission by showing decreased contact area and increased peak articular stresses following partial or total meniscectomy.[83–85] The lateral meniscus carries 70% of the compressive load in the lateral compartment, compared with just 40% by the medial meniscus in its respective compartment.[80,86–88] By converting joint loading forces to radial-directed hoop stresses on their circumferential collagen fibers, and taking advantage of their viscoelastic nature, the menisci transmit 50–60% of the joint load when the knee is in extension, and 85–90% when the knee is in flexion.[86–95]

Shock Absorption

Because of their viscoelastic nature, the menisci are able to assist in shock absorption. During the normal gait pattern, the articular surface of the knee bears up to six times the body weight, with over 70% of that load borne by the medial tibial plateau.[80,96] The medial tibial plateau bears most of this load during stance when the knee is extended, with the lateral tibial plateau bearing more of the much smaller loads imposed during the swing phase.[96] This is compensated for by the fact that the medial tibial plateau has a surface area roughly 50% larger than the lateral plateau, and articular cartilage that is approximately three times thicker than the lateral articular cartilage.[97]

CLINICAL PEARL

A meniscectomy can reduce the shock-absorbing capacity of the knee by 20%.[98] Loss of just 20% of a meniscus can lead to a 350% increase in contact forces.[99]

Joint Lubrication

The menisci assist in joint lubrication by helping to compress synovial fluid into the articular cartilage, which reduces frictional forces during weight-bearing. A meniscectomy increases the coefficient of friction within the knee, thereby increasing the stresses on the articular surfaces.[100]

Joint Stability

The menisci deepen the articulating surfaces of tibial plateaus. This increases the stability of the knee, especially during axial rotation and valgus–varus stresses.[100–104]

If the ACL is intact, the menisci do not significantly contribute to anteroposterior stability.[43,105,106,107] However, in an ACL-deficient knee, the posterior horn of the medial meniscus functions as a secondary restraint to anteroposterior translation by wedging between the femur and the tibia.[106,108] In contrast, the increased mobility of the lateral meniscus prevents it from contributing to anteroposterior stability.[105] This difference helps to explain the higher incidence of medial meniscus tears seen in ACL-deficient knees.[109]

Guiding Movement

During flexion and extension of the knee, the menisci move posteriorly and anteriorly, respectively. The lateral meniscus has greater mobility because it does not attach to the LCL, and, as mentioned previously, its capsular attachment is interrupted by the passage of the popliteus tendon.[73,110] During knee motion, the menisci move on the tibial plateau with the femoral condyles to maintain joint congruence.[110] The femur, accompanied by the menisci, rolls anteriorly on the tibia during extension, and posteriorly during flexion (Fig. 20-3).[100,110,111] Thompson et al.[112] demonstrated that the mean anteroposterior excursion of the menisci during a 120-degree arc of motion was 5.1 mm at the medial meniscus, and 11.2 mm at the lateral. The inner sides of the menisci, which are attached by their horns to the tibial plateau, move with the tibia. As the body of each meniscus is fixed around the femoral condyle, they move with the femur. Therefore, during movements between tibia and femur, distortion of the menisci is inevitable.

- During flexion of the knee, the menisci move posteriorly. The medial meniscus is moved about 5 mm by the pull of the semimembranosus tendon, and the lateral meniscus is pulled about 11 mm by the popliteus, resulting in an external rotation of the tibia.
- During extension, the menisci move anteriorly.
- During external rotation of the tibia, the menisci will follow the displacement of the femoral condyles, which means that the medial meniscus is pushed posteriorly and the lateral meniscus is pulled anteriorly. During internal rotation, the opposite occurs. These rotations are conjunct, integral with flexion and extension, but can also be adjunct and independent, best demonstrated with the knee semiflexed. Conjunct external rotation of the tibia on the femur during the last stages of knee extension is part of a locking mechanism called the "screw home" mechanism, described later.
- The medial coronary ligament is stretched during external rotation of the tibia, whereas the lateral coronary ligament is stretched during internal rotation of the tibia.

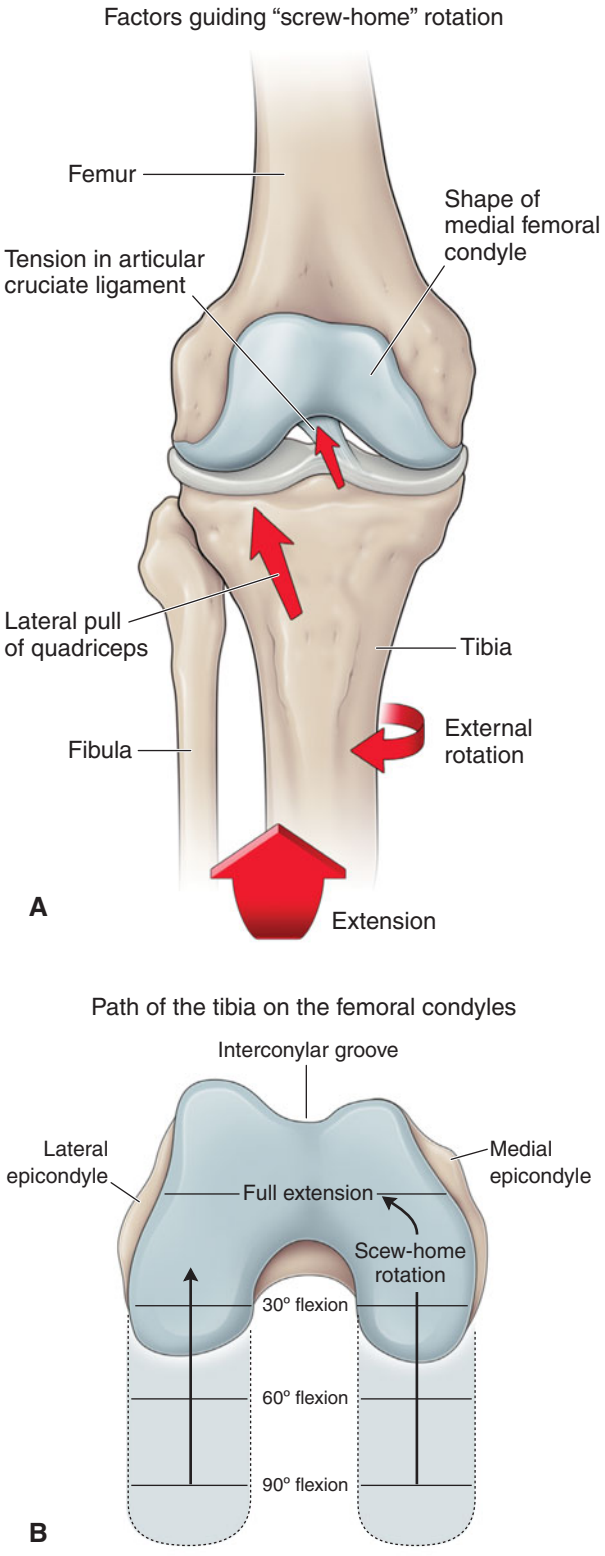

FIGURE 20-3 Tibiofemoral motions.

BURSAE

There are a number of bursae situated in the soft tissues around the knee joint. The bursae serve to reduce friction and to cushion the movement of one body part over another.

Superficial and Deep Infrapatellar Bursae

The superficial infrapatellar bursa is located between the patellar tendon and the skin, whereas the deep infrapatellar bursa is located between the patellar tendon and the tibia.

Prepatellar Bursa

The prepatellar bursa is located between the skin and the anterior aspect of the patella.

Tibiofemoral Bursa

The tibiofemoral bursae consist of a bursa between the head of the gastrocnemius muscle and the joint capsule on both sides, a bursa between the LCL and both the biceps femoris and popliteus, and a bursa between the MCL and the femoral condyle. There are also a number of bursae between the various tendons of the pes anserinus and between the MCL and the superficial pes anserinus.

The bursae around the knee can have contact with each other and with the knee joint capsule.

CLINICAL PEARL

A "Baker's cyst" may occur with fluid accumulation when there is a natural connection between the semimembranosus bursa and the knee joint.

Fat Pads

There are three fat pads located at the anterior knee: the quadriceps fat pad, the prefemoral fat pad, and the infrapatellar (Hoffa's) fat pad. The fat pads of the knee house neurovascular projections. The functions of the fat pads include the following:

- Synovial fluid secretion
- Joint stability
- Neurovascular supply
- Occupiers of dead space

PLICA

Synovial plicae of the knee were first described in the beginning of the last century.[113,114] Postmortem studies have shown plica to be present in 20–50% of knees,[10,115,116] with the highest prevalence in individuals of Japanese descent.[114,117–120]

Synovial plica represents a remnant of the three separate cavities in the synovial mesenchyme of the developing knee. These cavities are supposed to coalesce into one cavity at the 12-week stage of fetal growth.[121,122] The size and extent of this remnant depends on the degree of reabsorption.[123]

The three joints involved in the developing knee from which the remnants evolve are[112]

1. the joint between the fibular and the femur;
2. the joint between the tibia and the femur;
3. the joint between the patella and the femur.

The most common plica in the knee is called the anterior or inferior plica, or mucous ligament.[121,124] This plica is represented by tape-like fold running from the fat pad to the intercondylar notch of the femur and overlying the ACL. The plicae to the medial and lateral sides of the patella, which run in a horizontal plane from the fat pad to the side of the patellar retinaculum, are referred to as the superomedial or superolateral plicae or the suprapatellar membrane, or the medial or lateral synovial shelf. [121]

It has been suggested that symptomatic synovial plicae are one of the causes of anterior pain in the knee in children and adolescents.[125–127]

RETINACULA

The wing-like retinacula of the knee are formed from structures in the first and second layers of the knee joint. The retinacula can be subdivided into the medial and the lateral retinacula for clinical examination and intervention purposes.[128,129] The retinacula serve to connect the patella to a number of structures, including the femur, menisci, and tibia, both medially and laterally.[9]

The lateral retinaculum is the stronger and thicker of the two. It consists of two distinct layers of fibrous connective tissue: the superficial and deep retinacula. These structures are oriented longitudinally with the knee extended.[129]

- The superficial retinaculum consists of fibers from the vastus lateralis (VL) and the ITB.[130]
- The deep retinaculum consists of the lateral patellofemoral ligament, the deep fibers of the ITB, and the lateral patellotibial ligament.[130] These structures connect the patella to the ITB and help prevent medial patellar excursion.[131]

Although partially located deep to the ITB, the lateral retinaculum is blended with the biceps femoris to form a so-called conjoint tendon.[1,129] This relationship may explain why adaptively shortened hamstrings can lead to patellofemoral symptoms.[9] It is also well established that adaptive shortening of the lateral retinaculum is a common finding in patellofemoral dysfunction.[132–136]

Given the fact that the medial retinaculum is thinner than the lateral retinaculum, it is not thought to be as significant to patella position and tracking as its lateral counterpart.

MUSCLES

The major muscles that act on the knee joint complex are the quadriceps, the hamstrings (semimembranosus, semitendinosus, and biceps femoris), the gastrocnemius, the popliteus, and the hip adductors (Table 20-2).

Quadriceps

The four muscles that make up the quadriceps are the rectus femoris, the vastus intermedius, the VL, and the vastus medialis (Fig. 19-7). The quadriceps tendon represents the convergence of all four muscles tendon units, and it inserts

TABLE 20-2 Muscles of the Knee: Actions, Nerve Supply, and Nerve Root Derivation

Action	Primary Muscles	Peripheral Nerve Supply	Nerve Root Derivation
Flexion of knee	Biceps femoris	Sciatic	L5, S1–2
	Semimembranosus	Sciatic	L5, S2–2
	Semitendinosus	Sciatic	L5, S1–2
	Gracilis	Obturator	L2–3
	Sartorius	Femoral	L2–3
	Popliteus	Tibial	L4–5, S1
	Gastrocnemius	Tibial	S1–2
	Tensor fascia latae	Superior gluteal	L4–5
Extension of knee	Rectus femoris	Femoral	L2–4
	Vastus medialis	Femoral	L2–4
	Vastus intermedius	Femoral	L2–4
	Vastus lateralis	Femoral	L2–4
	Tensor fascia latae	Superior gluteal	L4–5
Internal rotation of flexed leg (non–weight-bearing)	Popliteus	Tibial	L4–5
	Semimembranosus	Sciatic	L5, S1–2
	Semitendinosus	Sciatic	L5, S1–2
	Sartorius	Femoral	L2–3
	Gracilis	Obturator	L2–3
External rotation of flexed leg (non–weight-bearing)	Biceps femoris	Sciatic	L5, S1–2

Data from Magee DJ: *Orthopaedic Physical Assessment*, 2nd ed. Philadelphia, PA: WB Saunders, 1992.

into the anterior aspect of the superior pole of the patella. The quadriceps muscle group is innervated by the femoral nerve. The quadriceps muscles can act to extend the knee when the foot is off the ground, although more commonly, they work as decelerators, preventing the knee from buckling when the foot strikes the ground.[137,138]

Rectus Femoris

The rectus femoris (see Fig. 19-7), which originates at the anterior inferior iliac spine (AIIS) is the only quadriceps muscle that crosses the hip joint. The other quadriceps muscles originate on the femoral shaft. This gives the hip joint substantial significance with respect to the knee extensor mechanism in the examination and intervention.[138] The line of pull of the rectus femoris, with respect to the patella, is at an angle of about 5 degrees with the femoral shaft[138] (see Fig. 20-12).

Vastus Intermedius

The vastus intermedius (see Fig. 19-7) has its origin on the proximal part of the femur, and its line of action is directly in line with the femur.

Vastus Lateralis

The VL (Fig. 19-7) is composed of two functional parts: the VL and the vastus lateralis oblique (VLO).[137] The VL has a line of pull of about 12–15 degrees to the long axis of the femur in the frontal plane, whereas the VLO has a pull of 38–48 degrees.[138]

Vastus Medialis

The vastus medialis (Fig. 19-7) is composed of two parts that are anatomically distinct[137]: the vastus medialis obliquus (VMO) and the vastus medialis proper, or longus (VML).[139] The VML appears to have little biomechanical significance unlike its counterpart, the VMO.

Vastus Medialis Obliquus. The VMO arises from the adductor magnus tendon.[140] The insertion site of the normal VMO is the medial border of the patella, approximately one-third to one-half of the way down from the proximal pole. If the VMO remains proximal to the proximal pole of the patella and does not reach the patella, there is an increased potential for malalignment.[11]

The vector of the VMO is medially directed, and it forms an angle of 50–55 degrees with the mechanical axis of the leg.[137,140–142] The VMO is least active in the fully extended position[143–145] and plays little role in extending the knee, acting instead to realign the patella medially during the extension maneuver. It is active in this function throughout the whole range of extension.

According to Fox,[146] the vastus medialis is the weakest of the quadriceps group and appears to be the first muscle of the quadriceps group to atrophy and the last to rehabilitate.[147] The normal VMO/VL ratio of electromyographic (EMG) activity in standing knee extension from 30 to 0 degrees is 1:1,[148] but in patients who have patellofemoral pain, the activity in the VMO decreases significantly; instead of being tonically active, it becomes phasic in action.[149] The presence of swelling also inhibits the VMO, and it requires almost half of the volume of effusion to inhibit the VMO as it does to inhibit the rectus femoris and VL muscles.[150]

The VMO is frequently innervated independently from the rest of the quadriceps by a separate branch from the femoral nerve.[137]

Vastus Medialis Longus. The VML originates from the medial aspect of the upper femur and inserts anteriorly into the quadriceps tendon, giving it a line of action of approximately 15–17 degrees off the long axis of the femur in the frontal plane.[138]

Since the quadriceps group is aligned anatomically with the shaft of the femur and not with the mechanical axis of the lower extremity, any quadriceps muscle contraction (regardless of knee flexion angle) results in compressive forces acting on the patellofemoral joint.[151]

Hamstrings

As a group, the hamstrings primarily function to extend the hip and to flex the knee. The hamstrings are innervated by branches of the sciatic nerve.

Semimembranosus Muscle

The semimembranosus muscle (Fig. 19-8) arises from the lateral facet of the ischial tuberosity and the ischial ramus. This muscle inserts into the posteromedial aspect of the medial tibial condyle and has an key expansion that reinforces the posteromedial corner of the knee capsule. The semimembranosus pulls the meniscus posteriorly, and internally rotates the tibia on the femur, during knee flexion, although its primary function is to extend the hip and flex the knee.

Semitendinosus Muscle

The semitendinosus muscle (see Fig. 19-8) arises from the upper portion of the ischial tuberosity via a shared tendon with the long head of the biceps femoris. From there, it travels distally, becoming cord-like about two-thirds of the way down the posteromedial thigh. Passing over the MCL, it inserts into the medial surface of the tibia and deep fascia of the lower leg, distal to the gracilis attachment, and posterior to the sartorius attachment. These three structures are collectively called the *pes anserinus* ("goose foot") at this point. Like the semimembranosus, the semitendinosus functions to extend the hip, flex the knee, and internally rotate the tibia.

Biceps Femoris

The biceps femoris (see Fig. 19-8) muscle is a two-headed muscle. The longer of the two heads arises from the inferomedial facet of the ischial tuberosity, whereas the shorter head originates from the lateral lip of the linea aspera of the femur. The muscle inserts on the lateral tibial condyle and the fibular head. The biceps femoris functions to extend the hip, flex the knee, and externally rotate the tibia. The superficial layer of the common tendon has been identified as the main force creating external tibial rotation and controlling internal rotation of the femur.[152] The pull of the biceps on the tibia retracts the joint capsule and pulls the iliotibial tract posteriorly, keeping it tight throughout flexion.

Gastrocnemius

The gastrocnemius originates from above the knee by two heads, each head connected to a femoral condyle and to the

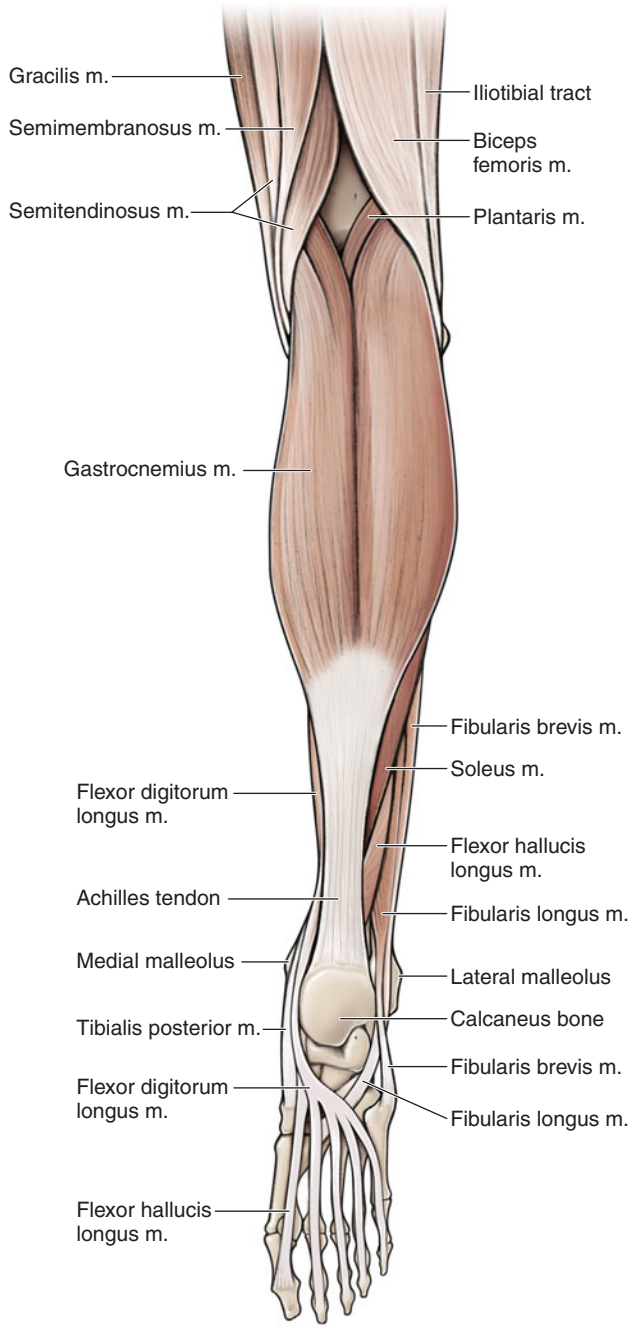

FIGURE 20-4 Gastrocnemius muscle.

joint capsule (Fig. 20-4). Approximately halfway down the leg, the gastrocnemius muscles merge to form an aponeurosis. As the aponeurosis gradually contracts, it accepts the tendon of the soleus, a flat broad muscle deep to the gastrocnemius. The aponeurosis and the soleus tendon end in a flat tendon, called the *Achilles tendon,* which attaches to the posterior aspect of the calcaneus. The two heads of the gastrocnemius and the soleus are collectively known as the *triceps surae* (see Chap. 21).

Although the primary function of the gastrocnemius–soleus complex is to plantar flex the ankle and to supinate the subtalar joint, the gastrocnemius also functions to flex or extend the knee, depending on whether the lower extremity is weight-bearing or not. It has been proposed that weakness of the gastrocnemius may cause knee hyperextension.[153]

In addition, it has been theorized that the gastrocnemius acts as an antagonist to the ACL, exerting an anteriorly directed pull on the tibia throughout the range of knee flexion–extension motion, particularly when the knee is near extension.[154,155]

Popliteus

The popliteus originates from the lateral femoral condyle near the LCL. The muscle has several attachments, including the lateral aspect of the lateral femoral condyle, the posterior-medial aspect of the head of the fibula and the posterior horn of the lateral meniscus.[156] The larger base of this triangular muscle inserts obliquely into the posterosuperior part of the tibia above the soleal line. The muscle has several important functions, including the reinforcement of the posterior third of the lateral capsular ligament[67] and the unlocking of the knee during flexion from terminal knee extension. It performs this latter task by internally rotating the tibia on the femur (a good example of an arcuvial muscle), preventing impingement of the posterior horn of the lateral meniscus by drawing it posteriorly, and, with the PCL, preventing a posterior glide of the tibia.[67,157–159] Since knee joint injury frequently involves some component of transverse-plane rotation and the popliteus muscle has been described as an important, primary, dynamic, transverse-plane, rotatory knee joint stabilizer, an understanding of its function in relation to other posterolateral knee joint structures is important.[160] Attached to the popliteus tendon is the popliteofibular ligament, which forms a strong attachment between the popliteal tendon and the fibula. This ligament adds to posterolateral stability.[161–164] A medial portion of the popliteus penetrates the joint, becoming intracapsular with the lateral meniscus. This part of the popliteus tendon is pain sensitive, and an injury here can often mimic a meniscal injury on the lateral aspect of the joint line.[73] Differentiation between these two lesions can be elucidated with the reproduction of pain with resisted flexion in an extended and externally rotated position of the tibia if the popliteus is involved.

Hip Adductors

The hip adductors, which play an indirect role in the medial stability of the knee (Table 20-3), are described in Chapter 19. The exception to this is the two-joint gracilis muscle, the third member of the pes anserinus group, which in addition to adducting and flexing the hip, assists in flexion of the knee and internal rotation of the lower leg.

Tensor Fascia Latae

The tensor fascia latae (TFL) arises from the outer lip of the iliac crest and the lateral surface of the anterior superior iliac spine (ASIS) (Fig. 19-5). Over the flattened lateral surface of the thigh, the fascia latae thickens to form a strong band, the iliotibial tract.[16] When the hip is flexed, the TFL is anterior to the greater trochanter and helps maintain the hip in flexion. As the hip extends, the TFL moves posteriorly over the greater trochanter to assist with hip extension. The TFL is also a weak extensor of the knee, but only when the knee is already

TABLE 20-3 Hip Adductors Involved in Knee Stability

Muscle	Proximal Attachment	Distal Attachment	Innervation
Adductor longus	Pubic crest and symphysis	By an aponeurosis to middle third of linea aspera of femur	Obturator nerve, L3
Adductor magnus	Inferior ramus of pubis, ramus of ischium, and inferolateral aspect of ischial tuberosity	By an aponeurosis to linea aspera and adductor tubercle of femur	Obturator nerve and tibial portion of sciatic nerve, L2–4
Gracilis	Thin aponeurosis from medial margins of lower half of body of pubis, whole of inferior ramus, and joining part of ramus of ischium	Upper part of medial surface of tibia, below tibial condyle and just proximal to tendon of semitendinosus	Obturator nerve, L2

extended. The muscle is innervated by the superior gluteal nerve, L4–L5.

Iliotibial Band (Tract)

The ITB or tract begins as a wide covering of the superior and lateral aspects of the pelvis and thigh in continuity with the fascia latae (Fig. 20-4 and Fig. 19-5). It inserts distal and lateral to the patella at the tubercle of Gerdy on the lateral condyle of the tibia. Anteriorly, it attaches to the lateral border of the patellar. Posteriorly, it is attached to the tendon of the biceps femoris. Laterally, it blends with an aponeurotic expansion from the VL[165] (see Chap. 19).

Like the patella tendon, the ITB can be viewed as a ligament or a tendon. Its location adjacent to the center of rotation of the knee allows it to function as an anterolateral stabilizer of the knee in the frontal plane[166] and to both flex and extend the knee.[138,167] During stationary standing, the primary function of the ITB is to maintain knee and hip extension, providing the thigh muscles an opportunity to rest. While walking or running, the ITB helps maintain flexion of the hip and is a major support of the knee in squatting from full extension until 30 degrees of flexion. In knee flexion greater than 30 degrees, the iliotibial tract becomes a weak knee flexor, as well as an external rotator of the tibia.

MAJOR NERVES AND BLOOD VESSELS

The posterior structure of the knee joint is a complex of nerves and blood vessels. The major blood supply to this area comes from the femoral, popliteal, and genicular arteries.[16]

Femoral Nerve

The course and distribution of the femoral nerve is described in Chapter 3.

Saphenous Nerve

The saphenous nerve is the largest cutaneous branch of the femoral nerve (L2–L4). It leaves the subsartorial canal approximately 8–10 cm above the medial condyle of the knee and gives off branches to the medial aspect of the knee. Entrapment of the saphenous nerve during its course here can occur because of direct trauma, genu valgus, or knee instability, resulting in saphenous neuritis.

Sciatic Nerve

The sciatic nerve (see Chap. 3) provides motor branches to the hamstrings and all muscles below the knee.[168] It also provides the sensory innervation to the posterior thigh and entire leg and foot below the knee (except the medial aspect, which is innervated by the saphenous nerve).[168] The tibial and fibular (peroneal) divisions of the sciatic nerve serve the posterior aspect of the knee. The common fibular (peroneal) nerve is formed by the upper four posterior divisions (L4, L5, and S1, S2) of the sacral plexus, and the tibial nerve, is formed from all five anterior divisions (L4, L5, and S1–S3).

Common Fibular (Peroneal) Nerve

The common fibular (peroneal) nerve is a component of the sciatic nerve as far as the upper part of the popliteal space. At the apex of the popliteal fossa, the common fibular (peroneal) nerve begins its independent course, descending along the posterior border of the biceps femoris, before traveling diagonally across the posterior aspect of the knee joint to the upper external portion of the leg near the head of the fibula.[16] Sensory branches are given off in the popliteal space. These include the superior and inferior articular branches to the knee joint, and the lateral sural cutaneous nerve.[16] The latter nerve joins the medial calcaneal nerve (from the tibial nerve) to form the sural nerve, supplying the skin of the lower posterior aspect of the leg, the external malleolus, and the lateral side of the foot and fifth toe.[16]

The common fibular (peroneal) nerve curves around the lateral aspect of the fibula toward the anterior aspect of the bone, before passing deep to the two heads of the fibularis (peroneus) longus muscle, where it divides into three terminal branches: the recurrent articular, and the superficial and deep fibular (peroneal) nerves. The recurrent articular nerve accompanies the anterior tibial recurrent artery, supplying branches to the proximal tibiofibular and knee joints, and a twig to the tibialis anterior muscle.

Tibial Nerve

The tibial nerve, the larger of the two branches of the sciatic nerve, begins its own course in the upper part of the popliteal space. It descends vertically through this space, passing between the heads of the gastrocnemius muscle to the posterior aspect of the leg, and to the posteromedial aspect of the

ankle, where its terminal branches serve the foot and ankle (see Chap. 21).

The tibial nerve supplies the gastrocnemius, plantaris, soleus, popliteus, tibialis posterior, flexor digitorum longus pedis, and flexor hallucis longus muscles. Articular branches pass to the knee and ankle joints.

BIOMECHANICS

Tibiofemoral Joint

The tibiofemoral joint, or knee joint, is a ginglymoid, or modified hinge joint, which has six degrees of freedom. The bony configuration of the knee joint complex is geometrically inappropriate and lends little inherent stability to the joint. Joint stability is therefore reliant on the static restraints of the joint capsule, ligaments, and menisci, and the dynamic restraints of the quadriceps, hamstrings, and gastrocnemius.[36,169] Since the ligaments share tensile load-carrying functions with the musculotendinous units, these structures can be considered to complement each other's functions directly.[36] The PCL is located very near the long axis of tibial rotation and has been described as the main stabilizer of the knee.[170]

The motions that occur about the knee consist of flexion and extension, coupled with other motions such as varus and valgus motions, and external and internal rotation. This is because the longitudinal axis of the knee is not perpendicular to the sagittal plane, but lies along a line that connects the origins of the collateral ligaments on the medial and lateral femoral epicondyles.[12,171]

All the motions about the tibiofemoral joint consist of a rolling, gliding, and rotation between the femoral condyles and the tibial plateaus (Fig. 20-5). This rolling, gliding, and rotation occurs almost simultaneously, albeit in different directions, and serves to maintain joint congruency.[5,172]

- Flexion and extension occur with a mediolateral translation around a mediolateral axis. In the relaxed standing position, with the knee straight or slightly flexed, the vector force is behind the knee; therefore there is a tendency for further knee flexion unless the quadriceps contracts.[110]
- A varus–valgus angulation occurs with anteroposterior translation around an anteroposterior axis.
- External and internal rotation of the joint occurs with superior–inferior translation around a superoinferior axis and transverse plane. The available range of motion (ROM) in rotation is dependent on the flexion–extension position of the knee.[173] The amount of rotation progressively increases from no rotation at terminal extension to 70 degrees of rotation (40 degrees of external rotation and 30 degrees of internal rotation) available at 90 degrees of flexion. The amount of available rotation decreases as further flexion occurs.[5,111]

During the initial 30 degrees of knee flexion, the LCL provides a greater contribution to resisting tibial varus and the PMTC provides a greater contribution to resisting tibial external rotation and posterior translation.[160,174] For flexion to be initiated from a position of full extension, the knee joint must first be "unlocked." As mentioned previously, the service of locksmith is provided by the popliteus muscle, which acts to internally rotate the tibia with respect to the femur, enabling flexion to occur.[97]

During flexion of the knee, the femur rolls posteriorly and glides anteriorly, with the opposite motion occurring during extension of the knee. This arrangement resembles a twin wheel, rolling on a central rail. Available knee flexion can vary between 120 and 160 degrees, depending on the position of the

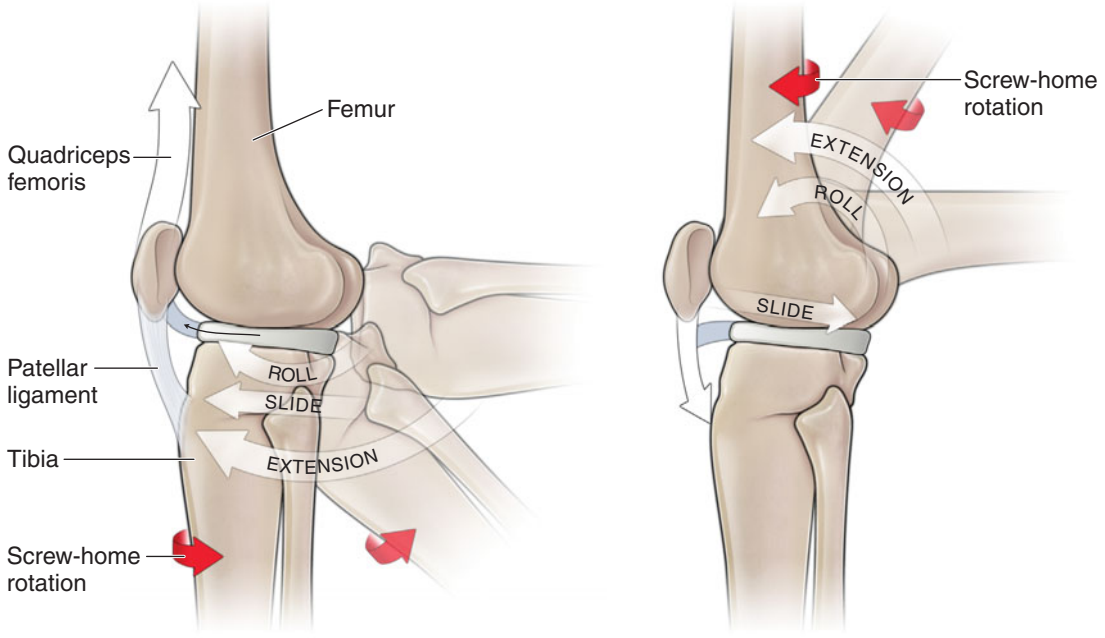

FIGURE 20-5 The arthrokinematics of knee motions.

hip and the girth of the soft tissues around the leg and the thigh.

From 30–5 degrees of weight-bearing knee extension (moving toward full knee extension), the lateral condyle of the femur, together with the lateral meniscus, become congruent, moving the axis of movement more laterally. The tibial glide now becomes much greater on the medial side, which produces internal rotation of the femur, and the ligaments, both extrinsic and intrinsic, start to tighten near terminal extension. At this point, the cruciates become crossed and are tightened.

In the last 5 degrees of extension, rotation is the only movement accompanying extension. This rotation is referred to as the "screw home" mechanism and is a characteristic motion in the normal knee, in which the tibia externally rotates and the femur internally rotates as the knee approaches extension (Fig. 20-3). This motion is known to be a complex function of surface geometry, tension in the ligamentous structures, and the action of muscles,[175,176] and has been described both in vivo[177–180] and in vitro.[181,182]

Knee hyperextension is usually available from 0 to 15 degrees.[183] During knee hyperextension, the femur does not continue to roll anteriorly but instead tilts forward. This creates anterior compression between the femur and the tibia.[153] In the normal knee, bony contact does not limit hyperextension as it does at the elbow. Rather, hyperextension is checked by the soft tissue structures. When the knee hyperextends, the axis of the thigh runs obliquely inferiorly and posteriorly, which tends to place the ground reaction force anterior to the knee. In this position, the posterior structures are placed under tension, which helps to stabilize the knee joint, negating the need for quadriceps muscle activity.[157]

CLINICAL PEARL

The transition from non–weight-bearing to weight-bearing has been found to produce a threefold increase of anterior translation of the tibia relative to the femur in the ACL-deficient knee compared with the contralateral normal knees.[184]

The normal capsular pattern of the knee joint is gross limitation of flexion and slight limitation of extension. The ratio of flexion to extension is roughly 1:10; thus, 5 degrees of limited extension corresponds to a 45–60-degree limitation of flexion. The causes of a capsular pattern in the knee are the same as for any other joint. These include traumatic arthritis, rheumatoid and reactive arthritis, osteoarthrosis, monarticular and steroid-sensitive arthritis, crystal synovitis or gout, hemarthrosis, and septic arthritis.

Open-kinetic chain (OKC) and closed-kinetic chain (CKC) exercises have different effects on tibial translation and ligamentous strain and load:

- During active OKC knee extension, the shear component produced by unopposed contraction of the quadriceps depends on the angle of knee flexion, increasing as the knee flexion angle increases.
- During CKC exercises for the lower extremity, the flexion moment arms of the knee and hip increase as a squat is performed.

Patellofemoral Joint

The patella is an inactive component of the knee extensor mechanism, in which the static and dynamic interactions of the underlying tibia and femur determine the patellar-tracking pattern. As the knee flexes, the compression forces between the patella and the femur increase (see "Patellofemoral Joint Reaction Force" section) as the contact surface area increases, in an attempt to normalize the contact stress unit load. Even though the surface area increases with knee flexion, it cannot keep up with these increased joint reaction forces. To assist in the control of the forces around the patellofemoral joint, there are a number of static and dynamic restraints. The static restraints include the following:

- ***Medial retinaculum.*** Although not as robust as its lateral counterpart, the medial retinaculum is the primary static restraint to lateral patellar displacement at 20 degrees of knee flexion, contributing 60% of the total restraining force.[185]
- ***Bony configuration of the trochlea.*** The patellofemoral joint is intrinsically unstable because the tibial tubercle lies lateral to the long axis of the femur and the quadriceps muscle and the patella is therefore subject to a laterally directed force.[186] If the patella fails to engage securely in the patellar groove at the start of flexion, it slips laterally, and as flexion continues, it can dislocate completely or slip back medially to its correct position.[186] The causes of insufficient engagement include
  - an abnormally high patella,
  - patellar dysplasia,
  - a poorly developed patellar groove (trochlea).
- ***Medial patellomeniscal ligament and lateral retinaculum.*** These structures contribute 13% and 10% of the restraint to translation of the patella, respectively.
- ***Passive restraints.*** The passive restraints to translation of the patella are provided by the structures that form the superficial and deep lateral retinaculum.

The primary dynamic restraints to patellar motion are the quadriceps muscles, particularly the VMO. The activity of the VMO increases as the torque around the knee increases, and it provides the only dynamic medial stability for the patella.[145,150] However, the muscle vector of the VMO is more vertical than normal when a patellar malalignment is present, making it less effective as a dynamic stabilizer.[187,188] The timing of the VMO contractions relative to those of other muscles, especially the VL, also appears to be critical and has been found to be abnormal with patellar malalignment.[137,189–192]

Deficits in the timing of muscle activity have been identified in other musculoskeletal conditions such as lower back pain, in which the EMG activity of transversus abdominus has been shown to be delayed compared with a control group[191,193] (see Chap. 28).

A study by Cowan et al.,[191] which found that on average the onset of EMG activity of the VL occurred before that of VMO in subjects with patellofemoral pain syndrome, appears to lend

support to this theory. Thus, specific retraining of the VMO is believed to improve patellar tracking.[191]

QUADRICEPS ANGLE

The quadriceps (Q) angle can be described as the angle formed by the bisection of two lines, one line drawn from the ASIS to the center of the patella, and the other line drawn from the center of the patella to the tibial tubercle[194] (Fig. 20-6). The angle is a measure of the tendency of the patella to move laterally when the quadriceps muscles are contracted.[195,196]

The Q-angle was originally described by Brattström,[197] although many authors had previously described the importance of genu valgus and its relationship to patellofemoral instability. Brattström described the Q-angle as the angle formed by the resultant vector of the quadriceps force and the patellar tendon with the knee in an "extended, end-rotated" position.

Various normal values for the Q-angle have been reported.[126,194,198–201] The most frequent ranges cited are 8–14 degrees for males and 15–17 degrees for females. The discrepancy between males and females allegedly results from the wider pelvis of the female, although this has yet to be proven. Indeed, it is not even clear that, on average, women have a significantly greater Q-angle.[199,202] Angles of greater than 20 degrees are considered abnormal and may be indicative of potential displacement of the patella.[203–205]

The Q-angle can vary significantly with the degree of foot pronation and supination, and when compared with measurements made in the supine position.[201,206] Confusing this issue is that the Q-angle is increased in patients with a lateralized tibial tuberosity, but it can be falsely normal when the patella is laterally displaced.[11]

The significance of a normal Q-angle was highlighted in a study by Huberti and Hayes[207] who concluded that, with a normal physiologic Q-angle, the pressure distributions on the patella were remarkably uniform at each of the angles of knee flexion tested (20, 30, 60, 90, and 120 degrees) between the medial and lateral facets. In contrast, when the physiologic Q-angle was decreased by 10 degrees, the patellar contact pressure increased by 53% at 20 degrees of knee flexion. However, when the knee flexion angle increased beyond 20 degrees, the contact pressure actually decreased, with the lowest value at 90 degrees.[207]

Although this measurement has been used to evaluate and treat patellofemoral joint pathology, few studies have examined its reliability. Greene et al.[208] evaluated the interobserver and intraobserver reliability of the Q-angle measurement comparing clinically derived Q-angle measurements with radiographically derived measurements. A reliability analysis was performed using intraclass correlation coefficients (ICCs). For interobserver measurements, the ICCs ranged from 0.17 to 0.29 for the four variables evaluated (right and left, extension and flexion). For intraobserver measurements, the ICCs ranged from 0.14 to 0.37. The average ICC between the clinically and radiographically derived measurements ranged from 0.13 to 0.32, which demonstrates poor interobserver and intraobserver reliability of Q-angle measurement and poor correlation between clinically and radiographically derived Q-angles.

CLINICAL PEARL

Although an increased Q-angle is traditionally associated with valgus knees, some of the highest Q-angles are found in patients with a combination of genu varus and proximal tibial torsion.[196,209]

The A angle is another measurement that has been used to evaluate and treat patellofemoral joint pathology and as a quantitative measurement of patellar realignment. The A angle is defined as the relationship between the longitudinal axis of the patellar and the patella tendon, or the patella's orientation to the tibial tubercle. The angle is created by drawing imaginary lines through the patella longitudinally and from the tibial tuberosity to the apex of the inferior pole of the patella. An A angle greater than 35 degrees is often cited as a cause of patellar pathomechanics. Ehrat et al.[210] performed a study to determine intrarater and interrater reliability for the A angle. The results of the study indicated that the A angle was not reproducible and further study is needed before the A angle can be used as a reliable assessment tool for patellar position.

Patella–Femur Contact and Loading

In view of the frequent problems associated with the patellofemoral joint, it is remarkable that, for much of the time, the articulating surfaces of this joint are not even in contact.[211] Indeed, there is no bone-to-bone contact with the femur in full knee extension, or during standing or walking on level ground[11,212,213] (Table 20-4).

The amount of contact between the patella and the femur appears to vary according to a number of factors, including (1) the angle of knee flexion, (2) the location of contact, (3) the

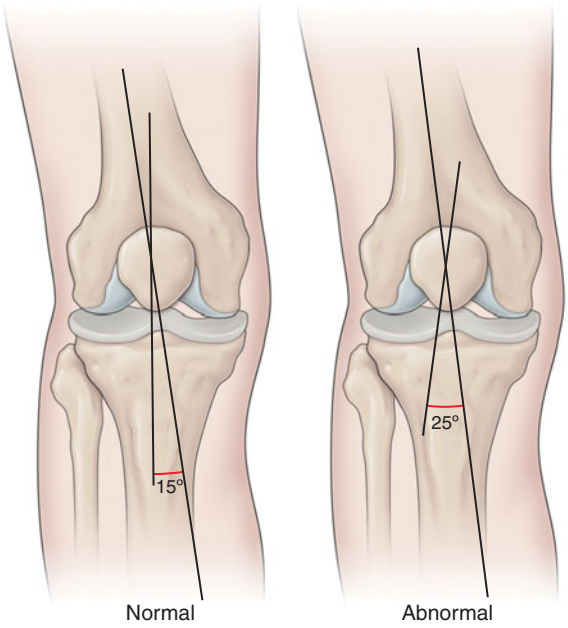

FIGURE 20-6 The Q-angle.

TABLE 20-4 Patella–Femur Contact During Range of Knee Flexion

Knee Range of Flexion (Degrees)	Facet Contact
0	No contact
15–20	Inferior pole
45	Middle pole
90	All facets
Full flexion (135 degrees)	Odd facet and lateral aspect

Data from Goodfellow JW, Hungerford DS, Woods C: Patellofemoral joint mechanics and pathology: I and II. *J Bone Joint Surg* 58B:287–299, 1976; Aglietti P, Insall JN, Walker PS, et al.: A new patella prosthesis. *Clin Orthop* 107:175–187, 1975.

surface area of contact, and (4) the patellofemoral joint reaction force (PJRF).[211] Each of these factors is discussed separately.

Angle of Knee Flexion

As knee flexion proceeds, the quadriceps vector becomes more perpendicular, and the force on the patella gradually increases (Fig. 20-7).[214] This increasing force is somewhat dissipated by the increased patellofemoral contact with increasing flexion (see later discussion).[147] However, because the force increases more rapidly than the surface area, the stress on the patella increases significantly with flexion.[212] Any muscle imbalance between the lateral and medial quadriceps muscles can affect the patellar alignment and distribution of pressure in the lower flexion angles of less than 60 degrees.[211] This can produce a rotation of the patella in the coronal plane.[215] At higher flexion angles, imbalances are likely to produce a tilt of the patella in the sagittal plane.[215]

Location of Contact

In the normal knee, as the knee flexes from 10 to 90 degrees, the contact area shifts gradually from the distal to the proximal pole of the patella.[207,213,216,217] At full extension, the patella is not in contact with the femur, but rests on the supratrochlear fat pad.[215] From full extension to 10 degrees of flexion, the tibia internally rotates, allowing the patella to move into the trochlea.[211] This brings the distal third of the patellar into contact with the femur. From 10 to 20 degrees of flexion, the patella contacts the lateral surface of the femur on the inferior patellar surface.[213,218] The middle surfaces of the inferior aspect of the patellar come into contact with the femur at around 30–60 degrees of flexion, at which point the patella is well seated in the groove.[213,218] As the knee continues to flex to 90 degrees, the patella moves laterally, and the area of patella contact moves proximally.[211] At 90 degrees of knee flexion, the entire articular surface of the patella (except the odd facet) is in contact with the femur.[213,218] Beyond 90 degrees, the patella rides down into the intercondylar notch. At this point, the medial and lateral surfaces of the patella are in contact with the femur, and the quadriceps tendon articulates with the patellar groove of the femur.[211] At approximately 120 degrees of knee flexion, there is no contact between the patella and the medial femoral condyle.[188,219] At 135 degrees of knee flexion, the odd facet of

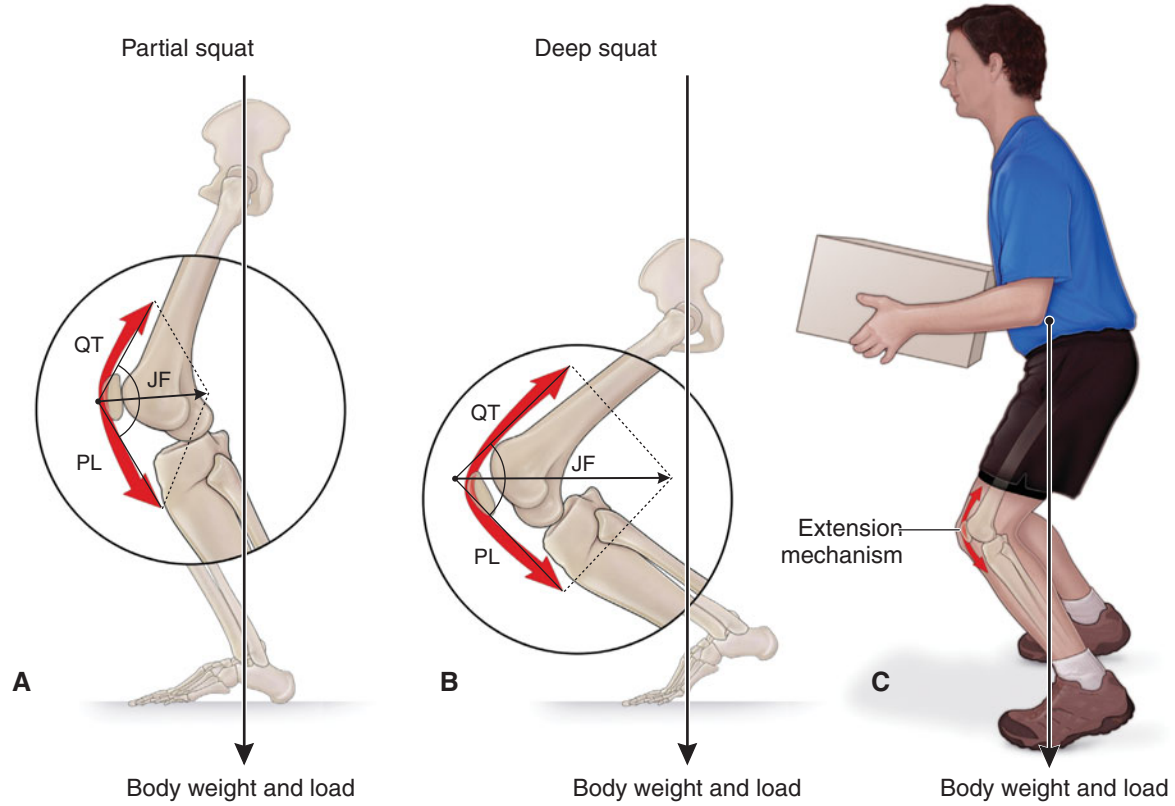

FIGURE 20-7 The relationship between the depth of the squat position and the compression force within the patellofemoral joint.

the patella makes contact with the medial femoral condyle.[213,218]

Surface Area of Contact

Knowledge of the patellofemoral contact pattern is useful for determining the limits of motion when patients with patellofemoral symptoms perform OKC and CKC exercises.[216] Some authors have proposed that the contact area quadruples as the knee flexes from 20 to 90 degrees.[86,192]

Patellofemoral Joint Reaction Force

The PJRF is a function of quadriceps and patellar tendon tension and of the angle formed between the quadriceps and patellar tendon. These forces are caused by the increase in patellar and quadriceps tendon tension and the increase in the acuity of the Q-angle that occurs during knee flexion.[192,217,220,221]

OKC and CKC exercises produce different effects on PJRF and contact stress per unit area:

- During OKC extension, the flexion moment arm for the knee increases as the knee extends from 90 degrees of flexion to full extension (0 degree), resulting in increased quadriceps and patellar tendon tension and increasing PJRFs. Clinicians most often allow OKC exercises at 90–40 degrees of knee flexion as this range provides the lowest PJRF while producing the greatest amount of patellofemoral contact area.
- During CKC exercises, the flexion moment arm of the knee increases as the angle of knee flexion increases (Fig. 20-7). Maximum force in the quadriceps muscle and patellar tendon is generated at 60 degrees of flexion with values approaching 3000 N.[217] CKC, such as the leg press and wall squat, are typically prescribed initially at 0–16 degrees and then progressed to 0–30 degrees where the PJRFs are lower.

Patellar Stability

Once engaged, the patella is held in place as flexion proceeds by two mechanisms:

1. ***Static restraints.*** The primary static restraints for this joint are the medial and lateral retinacula and the contact of the patella with the lateral edge of the patellar groove.
   a. Appropriate tension within the retinacula assures patellar tracking through the groove. Inappropriate tensioning may result in excessive pressure on the lateral patellofemoral joint surfaces (lateral patellofemoral pressure syndrome) or medial subluxation of the patella from the groove.
   b. The trochlea acts as a lateral buffer to the patella. Sometimes the patella engages correctly at the start of the flexion but subluxes or dislocates as flexion proceeds.[186] This disengagement may be the result of a defective lateral trochlear margin, an unusually shallow groove, or malalignment (if excessive genu valgus is present, the laterally directed force applied to the patella is greater).
2. ***Dynamic restraints.*** The dynamic restraints of the patellofemoral joint are the quadriceps muscle and the extensor mechanism in general. The tension provided by these soft tissues can prevent the patella from slipping laterally. However, excessively tight lateral structures or deficient medial structures may increase the laterally directed force. This may result in maltracking of the patella or possible subluxation.[146] The lateral structures (VL, lateral retinaculum, and iliotibial band) may be tight from fibrosis of the VL[222] or adaptively shortened for no obvious reason.[186] The medial structures (medial retinaculum) may be loose after injury to the medial retinaculum, from stretching after repeated dislocations, or from severe wasting of the vastus medialis.[186]

Patellar Tracking

Patellar tracking, specifically patella maltracking, continues to be the subject of much study.[188,192,223–225] In the normal knee, the patella glides in a sinuous path inferiorly and superiorly during flexion and extension, respectively, covering a distance of 5–7 cm with respect to the femur.[226] A concave, lateral, C-shaped curve is produced by the patella as it moves from approximately 120 degrees of knee flexion toward approximately 30 degrees of knee extension. The lateral curve produces a gradual medial glide of the patella from 45 to 15 degrees of knee flexion in the frontal plane and a medial tilt (from 45 to 0 degrees of knee extension) in the sagittal plane.[192,224] Further extension of the knee (between 15 and 0 degrees) produces a lateral glide of the patella in the frontal plane and a lateral tilt in the sagittal plane.[192,224]

One proposed mechanism for abnormal patellar tracking is an imbalance in the activity or tension of the medial and lateral restraints.[190,191,227]

The cause of the imbalance tends to be hypertonus of the VL, or an excessively tight TFL or ITB.[211] Other joints within the lower kinetic chain can also influence the tracking of the patella.

CLINICAL SIGNIFICANCE OF OKC AND CKC ACTIVITIES

As previously discussed, in relation to the lower kinetic chain, which includes the lumbar spine, pelvic joints, hip, knee, foot, and ankle joints, the motions that occur during activities can be described as CKC or OKC motions.

CLINICAL PEARL

A CKC motion at the knee joint complex occurs when the knee bends or straightens while the lower extremity is weight-bearing, or when the foot is in contact with any firm surface. An OKC motion occurs when the knee bends or straightens when the foot is not in contact with any surface.

Since the knee joint complex is an integral part of the lower kinetic chain, movement at any portion of the kinetic chain

will influence knee joint mechanics, necessitating an examination of the entire chain as part of a comprehensive assessment. Kinetic chain exercises need to be monitored carefully to detect the influence of any abnormal motion that occurs in one portion of the segment on the remaining portions of the kinetic chain.[228] For example, normal biomechanics dictate that the tibiofemoral joint extends during midstance as the body traverses the fixed foot. Excessive pronation in either magnitude or duration prevents the knee joint from acquiring the necessary external rotation of the tibia for this extension, which in turn may affect patella tracking.[150,229]

Another example occurs during the descending phase of a squat, which requires simultaneous flexion at the hip and knee, and dorsiflexion at the ankle. If ankle dorsiflexion motion is limited, subtalar joint pronation will increase to compensate for the lack of dorsiflexion.[228,229] This increased pronation, which is coupled with internal rotation of the lower extremity, results in an increase in the functional Q angle and may contribute to persistent patellofemoral pain.[228]

Whether the motion occurring at the knee joint complex occurs as a CKC or OKC has implications on the biomechanics and the joint compressive forces induced. A significant number of studies[42,230–242] have examined the biomechanics of the knee during OKC and CKC activities and have attempted to quantify and compare cruciate ligament tensile forces, tibiofemoral compressive forces, and muscle activity about the knee during these activities.

Closed-Kinetic Chain Motion

Tibiofemoral Joint

During CKC knee flexion, the femoral condyles roll backward and glide forward on the tibia. During CKC knee extension, the femoral condyles roll forward and slide backward. During CKC knee flexion, as the femur rolls posteriorly, the distance between the tibial and femoral insertions of the ACL increases. Since the ACL cannot lengthen, it guides the femoral condyles anteriorly.[183] In contrast, during CKC extension of the knee, the distance between the femoral and tibial insertions of the PCL increases. Since the PCL cannot lengthen, the ligament pulls the femoral condyles posteriorly as the knee extends.[183]

It has been suggested by some studies that the CKCE, with its axial loading of the joint, and resultant joint compressive forces and minimization of shear forces exerted across the knee, may protect the anterior cruciate-graft during quadriceps exercises through use of the contours of the joint, thereby providing greater stabilization to the knee.[243,244] Other studies have shown that CKCEs such as squatting do not necessarily protect the ACL any more than OKC flexion and extension exercises[245] (see Table 20-4). However, increasing the resistance during the CKCEs does not produce a significant increase in ACL strain values, unlike increasing the resistance during OKC flexion–extension exercises.[245]

It would appear that CKCEs are only beneficial if performed in a restricted range, with some studies demonstrating that CKCEs at greater than 30 degrees of knee flexion can exacerbate patellofemoral problems.[232,234]

Thus, a "paradox of exercise"[233] is encountered for the patient recovering after an ACL reconstruction, whereby the patient risks excessive ACL strain if these exercises are performed at less than 30 degrees of knee flexion, but patellofemoral joint complications if the exercises are performed at greater than 30 degrees of knee flexion.[235] Consequently, patients undergoing ACL rehabilitation who are susceptible to patellofemoral pain should be forewarned about potential patellofemoral joint complications when performing these exercises. These patients should also be advised to inform the clinician of any anterior knee pain that develops during their rehabilitative process.

Patellofemoral Joint

During CKCEs, the flexion moment of the arm increases as the angle of knee flexion increases. In addition, the joint-reaction force increases proportionately more during knee flexion than the magnitude of the contact area.[188] Thus, the articular pressure gradually increases as the knee flexes from 0 to 90 degrees,[188] with maximum values occurring at 90 degrees of flexion.[207] However, because this increasing force is distributed over a larger patellofemoral contact area, the contact stress per unit area is minimized. Changes in the Q-angle of 10 degrees can increase patellofemoral contact pressures by 45% at 20 degrees of flexion.[207] As the Q-angle increases, the patella tends to track more laterally.[147] A 50% decrease in tension in the VMO can displace the patella laterally by up to 5 mm.[215]

From 90 to 120 degrees of flexion, the articular pressure remains essentially unchanged because the quadriceps tendon is in contact with the trochlea, which effectively increases the contact area.[246]

Thus, for the patellofemoral joint, CKCEs are performed in the 0–45-degree range of flexion, with caution used when exercising between 90 and 50 degrees of knee flexion, where the PJRFs can be significantly greater.[246]

Open-Chain Motion

Tibiofemoral Joint

During OKC flexion, the tibia rolls and glides posteriorly on the femur, while during extension the opposite occurs. OKC knee extension involves a conjunct external rotation of the tibia, while OKC knee flexion involves a conjunct internal rotation of the tibia.

OKC activities produce shear forces at the tibiofemoral joint in the direction of tibial movement. For example, OKC knee extension produces anterior shear stresses.[247] As the ACL provides 85% of the restraining force to this tibial shear,[39] OKC knee extension may compromise a repaired or reconstructed ACL,[248] especially in the last 45 degrees of knee extension,[247,249,250] although at full extension, the ACL is under no tension.[26,231,248,251–253] However, if resistance is applied to the lower leg during OKCEs, an increase in strain on the ACL is demonstrated,[26] particularly in the last few degrees of extension.[36] OKCE is preferred over CKCE if minimal PCL tensile force is desired. Since PCL tension generally increases with knee flexion, knee ROMs that are less than 60 degrees will minimize PCL tensile force.[235] The higher compressive forces that occur during the beginning and end ranges of knee flexion in OKCE may serve to unload some of the tensile force in these respective cruciate ligaments.[235]

Both OKCEs and CKCEs appear equally effective in minimizing ACL tensile force, except during the final 25 degrees of knee extension in OKCEs.

OKC flexion, resulting from an isolated contraction of the hamstrings, reduces ACL strain throughout the ROM,[26] but increases the strain on the PCL as flexion increases from 30 to 90 degrees.[251]

CLINICAL PEARL

It may be prudent to exclude the final 25 degrees of knee extension range for the patient using OKCE for rehabilitation immediately following an ACL injury.[235]

Patellofemoral Joint

In an OKC activity, the forces across the patella are their lowest at 90 degrees of flexion. As the knee extends from this position, the flexion moment arm (contact stress/unit) for the knee increases, peaking between 35 and 40 degrees of flexion, while the patella contact area decreases.[232,254] This produces an increase in the PJRF at a point when the contact area is very small. At 0 degrees of flexion (full knee extension), the quadriceps force is high, but the contact stress/unit is low.

Thus OKCEs for the patellofemoral joint should be performed from 25 to 90 degrees of flexion (60–90 degrees if there are distal patellar lesions), or at 0 degree of extension (or hyperextension) from a point of view of cartilage stress.[246] OKCEs are not recommended for the patellofemoral joint between 0 and 45 degrees of knee flexion, especially if there are proximal patellar lesions, as the PJRFs are significantly greater.[246]

CLINICAL PEARL

Increased tension in the PCL occurs at greater than 65 degrees of knee flexion in CKCE and at greater than 30 degrees with OKCE.[235] Therefore, it may be prudent to limit knee flexion during both OKCE and CKCE to knee angles of less than 30 degrees following a PCL injury.[235]

EXAMINATION

The common pathologies for the knee joint complex are detailed after this section. An understanding of both is obviously necessary. Since mention of the various pathologies occurs with reference to the examination, and vice versa, the reader is encouraged to switch between the two discussions.

History

With the vast number of specific tests available for the knee joint complex, it is tempting to overlook the important role of the history, which can detail both the chronology and mechanism of events. The diagnosis of most tibiofemoral and patellofemoral joint disorders often can be made on the basis of a thorough history and physical examination alone. The patient's family history, medical history, and history of the present knee problem are necessary for a complete diagnosis. A medical screening questionnaire for the knee, leg, ankle, and foot region is provided in Table 20-5. In addition to those questions outlined in "History" section in Chapter 4, the clinician should determine the following:

Chief Complaint

It is important to elucidate the exact nature and location of the patient's chief complaint. Does the complaint relate to pain or instability, or both? If the chief complaint is pain, is there a history of recent trauma?

Onset of Symptoms

Questions about the onset of symptoms (traumatic versus insidious) are, as with any joint, important. Acute injuries are often traumatic and can be associated with both pain and instability. Reports of immediate pain associated with an inability to weight bear can indicate a muscle, ligament, or fracture injury and should be related to the patient's current complaints to identify the likely cause. As always, an insidious onset of pain should alert the clinician to the possibility of a serious condition. Pain in the knee can be referred from the

TABLE 20-5 Medical-Screening Questionnaire for the Knee, Leg, Ankle, and Foot Region

	Yes	No
Have you recently had a fever?		
Have you recently taken antibiotics or other medicines for an infection?		
Have you had a recent surgery?		
Have you had a recent injection to one or more of your joints?		
Have you recently had a cut, scrape, or open wound?		
Have you been diagnosed as having an immunosuppressive disorder?		
Do you have a history of heart trouble?		
Do you have a history of cancer?		
Have you recently taken a long car ride, bus trip, or plane flight or been bedridden for any reason?		
Have you recently begun a vigorous physical training program?		
Do you have growing, hip, thigh, or calf aching or pain that increases with physical activity, such as walking or running?		
Have you recently sustained a blow to your shins or any other trauma to either of your legs?		

Data from DuVall RE, Godges J: Introduction to physical therapy differential diagnosis: The clinical utility of subjective examination. In: Wilmarth MA, ed. *Medical Screening for the Physical Therapist. Orthopaedic Section Independent Study Course* 14.1.1 La Crosse, WI: Orthopaedic Section, APTA, 2003:1–44.

hip, the back, and the sacroiliac joint. Complaints of shooting pain, burning pain, and pain that travels down the thigh should be carefully investigated using a lumbar screen to rule out radicular symptom production. A gradual, nontraumatic onset of knee pain could also indicate patellofemoral joint dysfunction or symptomatic degenerative joint disease of the knee joint complex. The characteristic clinical features in an uncomplicated osteoarthritis (OA) of the knee joint are a dull and aching pain that occurs at the end of the day or after prolonged periods of standing or walking.[255] As the disease progresses, there is pain and stiffness on rising in the morning, which eases with activity or rest, and a limitation of movement in the capsular pattern.

Mechanism of Injury

The clinician should determine how exactly the injury happened—was it a traumatic blow, a contact injury, a noncontact injury, or did the patient fall? The position of the joint at the time of the traumatic force dictates which anatomic structures are at risk for injury; hence, an important aspect of obtaining the patient's history for acute injuries is to allow him or her to describe the position of the knee and direction of forces at the time it was injured.[256] The direction the patient was turning to and the direction of the blow help to determine the structures likely affected.[257] Twisting injuries can result in injuries to the ligaments or meniscus. Contact injuries can result in deep bone bruising, muscle contusions, and ligamentous or meniscal injury when combined with twisting or hyperextension.

The primary mechanisms of injury in the knee are direct trauma, a varus or valgus force (with or without rotation), hyperextension, flexion with posterior translation, a twisting force, and overuse.[258]

- ***Direct trauma.*** A direct blow to the anterior aspect of the knee may cause a patellar injury. Repetitive microtrauma to the patella may also be a factor. For example, Bloom[259] describes a condition called *airplane knee,* in which the frequent flyer in coach class gets repetitive knee bumps from the passenger in front when the seat is dropped back suddenly.
- ***Valgus force.*** A history of a valgus force to the knee without rotation could indicate damage to the medial meniscus, collateral ligament, epiphyseal plate, or patellar dislocation–subluxation.[256] A history of a valgus force with rotation could indicate damage to the ACL, or the posteromedial capsule (the so-called unholy triad).
- ***Varus force.*** A history of a varus force with rotation can involve the LCL, the posterolateral capsule, and the PCL.[256]
- ***Hyperextension.*** A hyperextension force can result in ACL injuries and associated medial meniscal tears. Complaints of buckling or giving way after the injury can reinforce a suspicion of ligamentous involvement.
- ***Flexion.*** During flexion, as the tibia internally rotates, the posterior horn of the medial meniscus is pulled toward the center of the joint. If excessive, this movement can produce a traction injury of the medial meniscus, tearing it from its peripheral attachment and producing a longitudinal tear of the substance of the meniscus.[257]
- ***Flexion with a posterior translation.*** This mechanism can result in a PCL injury.
- ***Twisting force.*** Meniscal injuries are usually associated with a torsional force that combines compression and rotation, often in activities that require cutting maneuvers.[259] In addition, the ACL often is injured during traumatic twisting injuries in which the tibia moves forward with respect to the femur, often accompanied by valgus stress.[257] No direct blow to the knee or leg is required, but the foot is usually planted and the patient may remember a "popping" sensation at the time of the injury. Similar to the ACL, PCL injuries often occur during twisting with a planted foot in which the force of the injury is directed posteriorly against the tibia with the knee flexed.[257]
- ***Overuse.*** Patellar injury is most often a result of overuse.[259] Typically, there is an associated 4–6-week training program change. These changes can include (1) increasing a training load more than 10% per week; (2) not allowing a 15% decrease for a week off; (3) not using an alternate-day or hard-easy pattern; (4) changing quickly from flat to hill training; (5) running in one direction on a canted road; (6) running in worn-out shoes; or (7) biking in cleated shoes that fix the tibial rotation relative to the pedal.[259]

Location of Symptoms

The location of the symptoms may afford the clinician clues as to the cause. Initially, the clinician should consider the anatomical structures underlying the area of pain to ascertain the cause. Medial knee pain can be caused by a spectrum of possibilities ranging from localized musculoskeletal to nonmusculoskeletal pathology (Table 20-6).[260] For example, medial meniscal lesions frequently result in posterior medial joint line pain and mild medial joint line pain.[256] Medial knee pain also may suggest an MCL injury. MCL injury can produce pain at the medial femoral condyle, medial joint line, or proximal tibia.[256] Lateral joint line pain may be caused by an LCL injury. Localized swelling over specific knee structures, such as the MCL or LCL, also may accompany the pain. Midlateral joint line pain often is caused by a lateral meniscal lesion. Patellofemoral joint pain usually is anterior, radiating medially and laterally, but primarily in, around, or under the patella.[259] Posterior knee pain may be secondary to joint effusion producing distention of the posterior capsule, a mild strain of one of the gastrocnemius muscles or a PCL tear.[256] Posterior knee pain accompanied by snapping could indicate a Baker's cyst.

Behavior of Symptoms

Symptoms that are not alleviated with rest could indicate a nonmechanical source, or a chemically induced source, such as an inflammatory reaction. A hot and swollen joint without a history of trauma should provoke suspicions about hemophilia, rheumatoid arthritis, an infection, or gout.

Quality of the Symptoms

Deep knee pain may indicate damage to one of the cruciate ligaments. Generalized pain in the knee region is characteristic of referred pain, or pain from a contusion or partial tear of a muscle or ligament.[261] Often a patient with a chronic

TABLE 20-6 Differential Diagnosis of Medial Knee Pain

Cause	Condition
Local musculoskeletal	Patellofemoral syndrome
	Medial meniscus tear
	Patellar tendinitis
	Lateral patellar subluxation
	Pes anserine tendinitis
	Pes anserine bursitis
	Vastus medialis strain
	Saphenous neuropathy
	Medial collateral ligament sprain
	Medial tibial plateau fracture
	Medial tibial plateau stress fracture
	Proximal tibia stress fracture

condition has several complaints, and a historical investigation can help identify the original cause. Patients do not always recognize the significance that an old injury may play in their current condition, but these options must be considered if the clinician is unable to make a diagnosis with the information available.

Reports of Swelling

In the presence of trauma, the main thrust of the history should be to establish whether the patient experienced an effusion or hemarthrosis (the assessment of swelling is described in "Observation" section.) An effusion is the method by which the joint reacts to stress and usually takes several hours to accumulate. The effusion can result from blood filling the joint or from an increased production of synovial fluid. The time frame of onset provides the clinician with clues as to the nature of the effusion. Synovial effusion usually takes 6–12 hours to develop and produces a dull, aching pain as the joint capsule is distended. By contrast, an acute hemarthrosis is usually well formed after 1–2 hours, leaving a very tense and inflamed knee. The two diagnoses that represent over 80% of the causes of an acute tense hemarthrosis are an ACL tear and patellar dislocation.[262] Other causes of an intra-articular effusion include MCL rupture and intra-articular fracture. Patients with a meniscal lesion often report repetitive episodes of effusion.[259]

Reports of Joint Noise

Reports of grinding, popping, and clicking in the knee with a particular maneuver are common but may not be related to a pathologic process.[167] However, reports of a "pop" involving sudden rotation of the femur or tibia may indicate damage to the ACL, MCL, coronary ligament, or meniscus, or an osteochondral fracture.[167] Sprains to the ligaments of the knee are often more painful than complete ruptures, because the latter have no intact fibers from which pain of a mechanical origin can occur. Instability of the knee often is described as a sensation of "giving way," sliding, or buckling. Sharp, catching pain usually indicates a mechanical problem.

Aggravating Positions or Activities

Questions should be asked to determine whether certain kinds of activities bring on the symptoms. For example, the pain may be noticed after resting or after certain activities. Morning pain and stiffness that lessens with activity or movement may indicate a degenerative joint complaint. Complaints of locking or pseudolocking during active or passive flexion and extension can highlight a dysfunctional structure. True locking of the knee is rare; however, loose bodies can cause recurrent locking or the sensation of something catching or getting in the way of movement. "Locking" that occurs with extension could indicate a lesion of the meniscus, a hamstring muscle spasm or an entrapment of the cruciate ligament. "Locking" that occurs with flexion could indicate a lesion to the posterior horn of the medial meniscus. With patellar irritability, there is no true mechanical blocking, although there may be stiffness, grating, or rapid movement inhibition.[259]

Impact on Function

The clinician should determine which functional activities reproduce the pain or exacerbate the symptoms. The following statements should be viewed as generalizations, as there are always exceptions.

- Weight-bearing activities involving a twisting weight-bearing load (e.g., getting in and out of a car with low seats) tend to aggravate a meniscal lesion.
- Patellofemoral joint pain often develops as a result of extended activity, such as in the middle of a long run or bike ride, continues into the evening or night, and can disturb sleep.[259]

- Walking upstairs or downstairs is usually difficult for patients with knee pathology. Usually, patients with a meniscal lesion complain of increased pain with stair climbing, whereas patients with a patellofemoral joint lesion complain of increased pain when descending stairs.
- Patients with a meniscal lesion or patellofemoral pain rarely can do a full squat without pain.
- Complaints of pain with kneeling activities are more likely to indicate a patellofemoral lesion than a meniscal lesion.
- Sitting tends to provoke more symptoms in patients with patellofemoral dysfunction than it does in those with meniscal or ligamentous lesions.

Anterior Knee Pain

Due to the prevalence of patellofemoral related disorders, there is a significant temptation to cut corners with a patient who presents with anterior knee pain, and to proceed directly to the diagnosis of patellofemoral pain.[147] However, this should be avoided, especially in light of the fact that the literature is replete with descriptions of physical examination techniques for the evaluation of the patellofemoral joint.[133,226,263–268]

CLINICAL PEARL

The differential diagnosis of anterior knee pain (see Chap. 5) should include tears of the menisci, medial synovial plica syndrome, inflammatory or degenerative arthritis, tumors of the joint, ligament injuries that mimic patellar instability, osteochondritis dissecans of the medial femoral condyle, prepatellar bursitis, patellar tendinitis, inflammation of the patellar fat pad, and Sindig–Larsen–Johansson syndrome.[8,147,269–271]

Classically, the pain from patellofemoral joint dysfunction is anterior, but it also can be medial,[196,272] lateral,[196,272] or popliteal (posterior).[194] Particular activities can help with differential diagnosis. Pain from rotational malalignment of the patella is typically exacerbated by activity and relieved by rest. Complaints of pain that occur when a patient arises from a seated position, negotiates stairs, or squats are associated with patellofemoral dysfunction. The so-called movie-theater sign[196]—pain with prolonged sitting—traditionally has been associated with patellar pain from any source. Venous congestion and stretching of painful tissues are potential explanations for this symptom.[246] Activities that involve eccentric loading of the knee, and increased hill work with running, tend to provoke patellar tendinitis, whereas inferior patellar pain following vigorous kicking, flip turns in swimming, or delivery of a fast ball in cricket would tend to implicate the fat pad.[273] The fat pad also may be irritated with the straight leg raise exercise.[266]

If a patellofemoral disorder is suspected, the clinician should look for evidence of an anatomical variant and/or a biomechanical dysfunction involving the lower quadrant. These anatomical variants can occur in any of the following joints: hip, patellofemoral, tibiofemoral, subtalar, intertarsal, or any combination of these joints. Examples of biomechanical dysfunctions that can cause patellofemoral disorders include excessive femoral anteversion, excessive genu valgum, excessive tibial external rotation, excessive pronation, and VMO dysplasia.

Edema rarely is reported with insidious onset overuse injuries, except in the case of plical irritation, ITB friction syndrome (ITBFS), irritation of the pes anserine or Osgood–Schlatter's disease.[167] Following the history, a hypothesis is made and this hypothesis is then tested with the physical examination. Ideally, the clinician is able to process and identify responsible structures for the patient's complaints and the history of injury to aid in the differential diagnosis.

Systems Review

Knee pain and dysfunction can arise from multiple sources. Knee pain that has gradually worsened over time should lead to an evaluation of systemic illness and overuse complications such as tendinitis. A subjective complaint of stiffness may imply swelling, and the joint mobility and effusion should be assessed. Complaints of weakness should be followed by an examination of the patient's strength and gait pattern.

The clinician needs to consider the likelihood of a specific diagnosis based on age. For example, a slipped capital femoral epiphysis (SCFE) is less likely to be the cause of a recent onset of pain in a 40-year-old fully developed man that it would be in an adolescent. Knee pain can be referred to the knee from the lumbosacral region (L3–S2 segments) or from the hip. For example, anteromedial pain can be referred from the L2 and L3 spinal levels, whereas posterolateral knee pain can be referred from the L4, L5, and S1 to S2 levels. The peripheral nerves are also capable of referring pain to this area. Medial knee pain having a burning quality could indicate saphenous nerve neuritis. A family history of knee problems, rheumatoid arthritis, or OA may need further investigation with a laboratory work-up or X-ray films. Pain that is constant and burning in nature should alert the clinician to the possibility of complex regional pain syndrome (CRPS), gout, or radicular pain. Intermittent pain usually indicates a mechanical problem (meniscus). The health intake questionnaire should be designed to provide evidence of undiagnosed systemic problems that relate to the knee dysfunction (e.g., Lyme disease). Chapter 5 describes some of the more common causes of referred knee pain, and causes of a more serious nature.

TESTS AND MEASURES

Observation

The observation component of the examination begins as the clinician meets the patient and ends as the patient is leaving. This informal observation should occur at every visit.

Swelling or Effusion

The amount of swelling present may provide the clinician with valuable information regarding the internal damage that may have resulted. Diffuse swelling indicates fluid in the joint or synovial swelling, or both. An effusion can be detected by noticing the loss of the peripatellar groove and by palpation of

FIGURE 20-8 Patellar ballottement test.

the fluid. A perceptible bulge on the medial aspect suggests a small effusion; this sign may not be present with larger effusions. The swelling is examined with the patient positioned in supine, in the following manner[274]:
